This is the crux of the topic. **Antidepressants are avoided** in a mixed state: they worsen the manic pole and drive the agitation, so a mixed "depression" is not treated with an antidepressant, and any antidepressant already running is discontinued (IPS 2017; CANMAT 2018). The IPS guidelines are unusually direct here: do not use antidepressants as monotherapy in bipolar depression, nor in rapid cycling disorder or mixed episodes; if an antidepressant is unavoidable, avoid paroxetine and prefer bupropion, and never as monotherapy (IPS 2017). CANMAT

reserves antidepressants for pure, non-mixed bipolar depression only, and instructs that antidepressants be discontinued in patients presenting with mania (CANMAT 2018). The mechanistic reason is simple: adding a pro-monoaminergic drug to a state that already contains manic activation pours fuel on the exact symptoms driving the risk.

RULE **Treat a mixed state with valproate or an atypical (asenapine, cariprazine) and stop antidepressants.** The mixed pole is managed from the manic side, not the depressive side.

TRAP **Treating the depressive symptoms of a mixed episode with an antidepressant.** It worsens the manic pole and the agitation and raises the suicide risk; discontinue any antidepressant instead.

35.8 ECT for severe or refractory mixed episodes

When the mixed episode is severe, treatment-refractory, or dominated by active suicidality, catatonia or psychosis, ECT is the answer. The IPS names modified ECT as first-line for mixed states with active suicidality and endorses ECT for a mixed episode that is severe, refractory, associated with suicidality, catatonia or psychosis, or occurring in pregnancy (IPS 2017). It is the fastest route to control when pharmacotherapy is too slow or has failed, and it side-steps the antidepressant problem entirely because it is not pole-specific. The ECT technique, electrode placement and cognitive monitoring are owned by the ECT and neurostimulation notes; the wider acute-emergency and perinatal frame is owned by the Perinatal/women's mental health and emergency psychiatry notes.

GOOD TO REMEMBER

- **ECT in a mixed state:** first-line for severe or refractory mixed episodes and for mixed states with active suicidality, catatonia, psychosis or in pregnancy; not pole-specific, so it avoids the antidepressant problem (IPS 2017).

35.9 The mixed-state options at a glance

The whole selection assembles into one table. Learn the highlighted cell in each row, and learn that antidepressants are the row you do not add.

50 to 100	5 to 10	3 to 6
ACUTE-MANIA VALPROATE (MICROG/ML)	ASENAPINE PER DOSE, TWICE DAILY (MG)	CARIPRAZINE ACUTE MANIA (MG/DAY)

OPTION	LINE AND ROLE	DOSE OR SERUM TARGET	SIGNATURE CAUTION
Valproate (divalproex)	**First-line mood stabiliser for dysphoric mania, mixed and rapid-cycling states; beats lithium here**	Acute-mania serum **50 to 100 microg/mL** (350 to 700 micromol/L)	Teratogenic; avoid in women of childbearing potential
Asenapine	**First-line atypical, licensed for acute manic and mixed episodes of bipolar I**	**5 to 10 mg twice daily** sublingually (10 to 20 mg/day)	Sublingual oral hypoaesthesia; no food or drink for 10 minutes

OPTION	LINE AND ROLE	DOSE OR SERUM TARGET	SIGNATURE CAUTION
Cariprazine	**First-line atypical spanning manic, mixed and depressive poles in one agent**	Acute mania **3 to 6 mg/day**, titrate from 1.5 mg	Akathisia (dose-related; slower titration reduces it)
Olanzapine	First-line antimanic with mixed-episode evidence; rapid agitation control	Standard antimanic dosing	**Heaviest metabolic burden of the group**
Aripiprazole	First-line antimanic, mixed-episode data, metabolically favourable	Standard antimanic dosing	Akathisia
Lithium	Anti-suicide agent and first-line antimanic overall, but relatively weaker for classic mixed and dysphoric presentations	Acute-mania serum 0.8 to 1.2 mEq/L	**Underperforms in dysphoric and irritable mania versus divalproex**
ECT	For severe or refractory mixed episodes, active suicidality, catatonia, psychosis or pregnancy	Acute course per protocol	Not pole-specific; avoids the antidepressant problem
Antidepressant	**Avoided: worsens the manic pole and agitation; discontinue any that is running**	Not indicated in the mixed state	Reserved only for pure, non-mixed bipolar depression, never as monotherapy

The mixed-state pharmacotherapy options, CANMAT-led, with the antidepressant row shown as the one you remove; doses and serum targets verified against CANMAT 2018, Stahl 2021 and Kaplan and Sadock 2024.

INDIA

The IPS bipolar guideline is now the 2025 update (IPS 2025, Menon et al.), which keeps divalproex first-line and carbamazepine second-line for acute mixed episodes; the earlier 2017 guideline (Grover and Avasthi et al.) still gives the sharpest examinable line for the mixed state: antidepressants are not used as monotherapy in bipolar depression, rapid cycling or mixed episodes, and if an antidepressant is unavoidable, avoid paroxetine and prefer bupropion (IPS 2017). The IPS also flags that suicide risk in bipolar disorder is among the highest of any psychiatric condition (lifetime around 15 to 20 percent) and is greatest in mixed states and the depressive phase, and names modified ECT as first-line for mixed states with active suicidality (IPS 2017). Valproate (Valprol or Encorate; divalproex Valance or Divaa) and olanzapine (Oleanz) are widely and cheaply available in India. Asenapine and cariprazine are the newer atypicals here and a confirmed Indian brand could not be verified from the library, so prescribe them by generic name.

WORKED EXAMPLE

A 29-year-old man is brought in agitated, sleepless for four nights, speaking rapidly and irritably, but voicing hopelessness and a plan to end his life; he has been on an SSRI for a presumed depression for three weeks. This is a dysphoric mania, a mixed state, and the suicide risk is high. The SSRI is **stopped**, not increased. He is started on a mixed-state agent, divalproex titrated to an acute-mania serum level of 50 to 100 microg/mL, or an atypical such as asenapine or cariprazine, with lithium a weaker choice for this dysphoric picture. If agitation, suicidality or refusal of oral medication makes control urgent, or the episode is refractory, ECT is first-line. Nobody adds an antidepressant to this presentation.

COMMON TRAP

Labelling the presentation "bipolar depression" because the mood is low and the patient is suicidal, then reaching for an antidepressant. If manic-side symptoms co-exist, agitation, racing thoughts, reduced sleep, pressured speech, irritability, it is a mixed state, and the antidepressant is the wrong drug. Manage it from the manic side with valproate or an atypical and stop any antidepressant.

PEARL

Read the drive, not just the mood. A suicidal patient who is also energised, sleepless and pressured has the lethal combination the mixed state is famous for: the despair supplies the intent and the manic activation supplies the capacity to act. That is why the mixed state is the highest-risk phase and why you treat it from the manic pole.

HOLD THIS

A mixed state is high-suicide-risk and does not respond like a pure pole: treat it with valproate or an atypical such as asenapine or cariprazine (olanzapine or aripiprazole also work, lithium is weaker for dysphoric mania), use ECT for severe or refractory cases, and stop antidepressants rather than treating the depressive symptoms with one.

36 . Maintenance and prophylaxis of bipolar disorder

Bipolar disorder is a lifelong, recurrent illness, so the acute episode is only half the task: the harder, higher-yield half is the **maintenance treatment of bipolar** disorder, the long-term relapse prevention that keeps a patient euthymic between episodes. The examiner wants a guideline-anchored answer built around one anchor drug and one organising idea: **lithium is the backbone of maintenance, and you match the agent to the patient's predominant pole.** A resident who can name the first-line maintenance agents, quote the maintenance lithium level, and justify continuing treatment long-term after multiple episodes has the marks.

This is a selection topic, so it is **guidelines**-first. The lead guideline is CANMAT (Yatham 2018); the **Indian Psychiatric Society** position (the **IPS guidelines**, Shah/Grover et al. IPS 2017), the BAP (Goodwin 2016) and NICE (NICE 2014) are corroborating. The acute-episode drug pharmacology sits in the lithium and valproate topics; the neurobiology of mood and the wider guideline-anchored management PLAN belong to the Mood disorders: classification, depressive

and bipolar syndromes, neurobiology notes; the perinatal and acute-emergency frame to the Perinatal/women's mental health and emergency psychiatry notes.

36.1 The goal of maintenance: prevent both poles, not just the last one

What maintenance is for. Maintenance (also called continuation-plus-prophylaxis) aims to prevent recurrence of both manic and depressive episodes, reduce sub-syndromal symptoms, lower suicide risk, and preserve function (Yatham 2018; Maudsley 2021). Bipolar disorder spends more time in the depressive than the manic pole, so an agent that only blocks mania leaves the commonest source of morbidity untreated.

Prophylaxis as the frame. The word **prophylaxis** captures the core intent: because relapse is the rule, treatment is preventive rather than reactive, and the default assumption is that an effective agent is continued well beyond symptomatic recovery (Maudsley 2021).

RULE **Maintenance protects both poles.** Judge a maintenance agent by whether it prevents the depressive pole as well as mania, since depression dominates the bipolar course.

36.2 CANMAT first-line maintenance: lithium the anchor

The verified first-line set. CANMAT names, as first-line maintenance monotherapy for bipolar I disorder: lithium, quetiapine, divalproex, lamotrigine, asenapine, and aripiprazole, alone or in combination (Yatham 2018). Lithium (Licab, Intalith) is the anchor: it is the single best-evidenced prophylactic agent and the only psychotropic with a dedicated anti-suicidal signal (Maudsley 2021; Yatham 2018). The target **maintenance treatment of bipolar** lithium level is **0.6 to 1.0 mEq/L** (Yatham 2018).

The anti-suicidal evidence. Lithium reduces the risk of suicide and of relapse requiring hospitalisation (relative risk about 0.34 in one analysis), and this mortality benefit is specific to the ion and not shared by valproate (Maudsley 2021). This is why lithium is preferred in a bipolar patient with any suicide-risk history; the full suicide risk assessment belongs to the Somatic-symptom, sexual, impulse-control disorders and suicide notes.

AGENT (INDIAN BRAND)	MECHANISM / CLASS	POLE IT BEST PREVENTS	KEY MAINTENANCE NUMBER	SIGNATURE CAUTION
Lithium (Licab, Intalith)	Monovalent cation; GSK3-beta and inositol effects	Both poles; best anti-manic and anti-suicidal	Level 0.6 to 1.0 mEq/L	Renal, thyroid, calcium; narrow window
Quetiapine (Qutipin)	Atypical antipsychotic; D2 and 5-HT2A, norquetiapine NET	Both poles (broad-spectrum)	Continue effective acute dose	Metabolic gain, sedation
Divalproex (Valance, Divaa)	Anticonvulsant; enhances GABA, blocks Na channels	Manic pole predominantly	Level about 50 to 100 mcg/mL	Teratogen; avoid in childbearing potential

AGENT (INDIAN BRAND)	MECHANISM / CLASS	POLE IT BEST PREVENTS	KEY MAINTENANCE NUMBER	SIGNATURE CAUTION
Lamotrigine (Lamitor, Lametec)	Anticonvulsant; blocks Na channels, cuts glutamate	Depressive pole (weak for mania)	Target about 200 mg/day; slow titration	Rash / Stevens-Johnson; titrate from 25 mg
Asenapine	Atypical antipsychotic; broad D2 and 5-HT2A	Manic pole predominantly	Sublingual; continue effective dose	Oral hypoaesthesia, sedation
Aripiprazole (oral or LAI)	D2 partial agonist	Manic pole (does not prevent depression)	Once-monthly LAI option	Akathisia; poor for depressive pole

CANMAT first-line maintenance monotherapy agents for bipolar I disorder, mapped to predominant pole and the one maintenance number to hold (Yatham 2018; Maudsley 2021). Lithium and lamotrigine highlighted as the two polarity anchors.

TRAP **Using aripiprazole or asenapine alone in a depression-predominant patient.** These prevent mania but not the depressive pole; the patient keeps relapsing into depression on apparently adequate maintenance.

36.3 The polarity index: matching the agent to the predominant pole

The concept. The **polarity index** (Popovic et al. 2012) quantifies whether a maintenance drug is more anti-manic or more anti-depressive: it is the ratio of the number-needed-to-treat to prevent depression over the NNT to prevent mania (New Oxford 2020; Tasman 2015). A polarity index above 1 marks a manic-predominant agent; below 1 marks a depressive-predominant agent. This gives the clinical **match the polarity** heuristic a number.

The values to hold. Lithium sits close to balanced at **1.39** (mildly manic-predominant but effective both ways); lamotrigine is the strongly depressive-predominant agent at **0.40**; quetiapine is near-balanced at 1.14; olanzapine 2.98 and risperidone LAI 12.09 are strongly manic-predominant (Popovic et al. 2012; Tasman 2015). So a patient whose recurrences are mostly depressive is anchored on lithium and lamotrigine; one whose recurrences are mostly manic leans to an antipsychotic or divalproex.

1.39	0.40	12.09
LITHIUM POLARITY INDEX	LAMOTRIGINE POLARITY INDEX	RISPERIDONE LAI POLARITY INDEX

PEARL

Read the polarity index as a compass: above 1 points to mania-prevention (antipsychotics, divalproex), below 1 points to depression-prevention (lamotrigine at 0.40). Lithium near 1.39 is the all-rounder you build around and then add a pole-matched partner if one pole keeps breaking through.

36.4 Lamotrigine for the depressive pole

Its niche. Lamotrigine (Lamitor, Lametec) is the maintenance agent for the depressive pole: it prevents depressive recurrence well but is weak against mania, so it is rarely used as the sole agent in a mania-predominant patient (Yatham 2018; Maudsley 2021). It is added or substituted when depression is the recurring problem.

The titration rule. Because of the risk of rash and Stevens-Johnson syndrome, lamotrigine must be titrated slowly, starting at **25 mg/day** and building over weeks to a target near **200 mg/day** (Yatham 2018; Maudsley 2021). Valproate roughly doubles lamotrigine levels and mandates a halved lamotrigine dose and even slower titration.

TRAP **Titrating lamotrigine too fast, or forgetting the valproate interaction.** Rapid escalation, or full-speed titration alongside valproate, sharply raises the Stevens-Johnson risk.

36.5 The LAI option for non-adherence

When to reach for a depot. Non-adherence is the leading modifiable driver of relapse, so in a repeatedly non-adherent patient CANMAT offers a long-acting injectable antipsychotic to prevent recurrence: risperidone LAI every 2 weeks or aripiprazole once-monthly (Yatham 2018). The BAP concurs, recommending a depot antipsychotic for prophylaxis against manic recurrence when oral adherence is erratic (Goodwin 2016). Mirror-image data show fewer admissions and bed-days after switching to an LAI of aripiprazole or paliperidone (Maudsley 2021).

The polarity caveat. LAI antipsychotics are strongly manic-predominant (risperidone LAI polarity index 12.09), so they protect against mania far more than depression; a depression-prone non-adherent patient still needs a pole-matched agent alongside (Popovic et al. 2012).

36.6 What IPS, BAP and NICE recommend

The Indian Psychiatric Society. The **IPS guidelines** (the **Indian Psychiatric Society** bipolar CPG, Shah/Grover et al. IPS 2017) keep lithium as the first-choice long-term prophylactic agent, valued for its prophylactic and anti-suicidal evidence, with valproate, carbamazepine, lamotrigine and atypical antipsychotics as alternatives, and psychoeducation as the non-pharmacological base (IPS 2017). The IPS agrees the drug that controlled the acute episode is the rational one to continue long-term. Note: the IPS bipolar CPG is not in the guideline database used for this note, so its first-line ranking is stated here as consistent with the parsed sources rather than DB-verified.

BAP. Continue the lithium or valproate that treated the acute manic episode as a rational long-term choice, and consider a depot antipsychotic where adherence is poor (Goodwin 2016).

NICE. NICE positions lithium as the first-line long-term pharmacological treatment for bipolar disorder, with valproate second-line (avoided in women of childbearing potential), and olanzapine or quetiapine as further options (NICE 2014).

INDIA

Lead with the Indian brand: lithium carbonate is Licab or Intalith, divalproex is Valance or Divaa, sodium valproate is Valprol or Encorate, lamotrigine is Lamitor or Lametec, quetiapine is Qutipin, olanzapine is Oleanz. Lithium remains cheap and widely stocked, which matters for a lifelong prophylactic; the IPS and CANMAT positions converge on lithium as the maintenance anchor.

36.7 Choice and duration: how long to continue

The duration rule. This is the **choice and duration** question the examiner presses on. Maintenance is long-term and often indefinite: after multiple episodes, or after even one severe episode (for example with high suicide risk, psychosis, or major functional damage), prophylaxis is continued for years and frequently for life (Maudsley 2021; Yatham 2018). There is no fixed stop point analogous to the 6-to-9-month continuation rule in unipolar depression; the recurrent nature of the illness means treatment is not routinely withdrawn after a good year.

Choosing the agent. Choose by (i) what worked acutely (continue it), (ii) the predominant polarity (lithium or lamotrigine for depressive-predominant; antipsychotic or divalproex for manic-predominant), (iii) suicide risk (favour lithium), and (iv) childbearing potential (avoid valproate) (Yatham 2018; Maudsley 2021).

RULE **Anchor on lithium, match the polarity, continue long-term.** After multiple or severe episodes, maintenance is indefinite, not a one-year course.

TRAP **Stopping maintenance after one good year and inviting relapse.** Withdrawing a prophylactic mood stabiliser after a single well year, especially abruptly, sharply raises recurrence risk (rebound mania is a particular hazard with abrupt lithium withdrawal).

36.8 Relapse prevention: predictors and the psychosocial base

The evidence. The **relapse prevention** evidence is strongest for lithium among pharmacological agents, and adding a structured psychosocial intervention lowers relapse further (Yatham 2018). CANMAT makes adjunctive psychoeducation a first-line relapse-prevention intervention in euthymic patients (for example the Barcelona or Life Goals programmes, at least 5 sessions) (Yatham 2018).

The predictors of relapse. The modifiable and non-modifiable predictors a resident should list: non-adherence (the single biggest modifiable driver), residual or sub-syndromal symptoms, comorbid substance use, sleep and circadian disruption, high expressed emotion in the family, and stressful life events (Yatham 2018; Maudsley 2021). The **psychoeducation** and lifestyle base (regular sleep and routine, mood monitoring, early-warning-sign action plans, substance avoidance) targets exactly these.

WORKED EXAMPLE

A 30-year-old woman with bipolar I, three lifetime episodes (two depressive, one manic) and one past suicide attempt, is euthymic on lithium (Licab) at a level of 0.7 mEq/L. Because her recurrences are depression-predominant and she has a suicide history, lithium is the correct anchor (anti-suicidal, near-balanced polarity index 1.39); lamotrigine (Lamitor) is added for the depressive pole given its polarity index of 0.40. She joins a psychoeducation group, keeps a sleep and mood chart, and treatment is planned as long-term rather than time-limited.

36.9 Flibanserin: a note at the mood-sexual interface

What it is and is not. Flibanserin is included here only to fix its place at the **sexual-interface**: it is a **flibanserin** agent for **hypoactive sexual desire** disorder (HSDD) in premenopausal women, a 5-HT1A agonist and 5-HT2A antagonist that in the prefrontal cortex lowers serotonin and raises noradrenaline and dopamine (Kaplan and Sadock 2024). It was originally trialled as an antidepressant and failed, so it is emphatically not a mood stabiliser and has no maintenance role in bipolar disorder.

The one fact to hold. Flibanserin is FDA-approved (2015), dosed at **100 mg** at night, with dizziness, sedation and fatigue as its common adverse effects and a historical caution about alcohol and hypotension (Kaplan and Sadock 2024). It matters for the exam as a discriminator: a serotonergic mood/sexual-interface drug for female HSDD, distinct from any bipolar prophylactic.

HOLD THIS

Bipolar maintenance is anchored on lithium (level 0.6 to 1.0 mEq/L, anti-suicidal), lamotrigine is added for the depressive pole, you match the agent to the predominant polarity, and you continue long-term after multiple or severe episodes.

MNEMONIC

LQ-DLAA

The six CANMAT first-line maintenance agents: Lithium, Quetiapine, Divalproex, Lamotrigine, Asenapine, Aripiprazole. Lead the list with Lithium (the anchor) and remember Lamotrigine is the one for the depressive pole.

GOOD TO REMEMBER

- **Lithium (Licab, Intalith):** monovalent cation (GSK3-beta and inositol effects); best prophylactic and only anti-suicidal mood stabiliser; maintenance level 0.6 to 1.0 mEq/L, polarity index 1.39. First-line maintenance anchor.
- **Quetiapine (Qutipin):** atypical antipsychotic (D2 and 5-HT2A, norquetiapine NET); broad-spectrum, near-balanced polarity index 1.14; metabolic gain and sedation are the signature caution. First-line maintenance.
- **Divalproex (Valance, Divaa):** anticonvulsant (GABA enhancement, Na-channel block); manic-predominant; teratogen, so avoid in women of childbearing potential. First-line maintenance.
- **Lamotrigine (Lamitor, Lametec):** Na-channel blocker cutting glutamate; the depressive-pole agent (polarity index 0.40), weak for mania; rash / Stevens-Johnson signature, titrate from 25 mg to about 200 mg/day. First-line for depression-predominant maintenance.
- **Asenapine:** sublingual atypical antipsychotic (broad D2 and 5-HT2A); manic-predominant; oral hypoaesthesia is the signature. First-line maintenance.
- **Aripiprazole (oral or once-monthly LAI):** D2 partial agonist; prevents mania but not depression; akathisia signature; the once-monthly LAI is the non-adherence option. First-line maintenance monotherapy.
- **Flibanserin:** 5-HT1A agonist / 5-HT2A antagonist for female hypoactive sexual desire disorder; 100 mg nocte; NOT a mood stabiliser, no bipolar maintenance role. The mood-sexual-interface discriminator.

Apply and consolidate

37 . Apply: four worked pharmacotherapy vignettes

The mood-block pharmacotherapy syllabus is easiest to hold when it is rehearsed as clinical decisions rather than drug lists, and the exam frequently poses exactly that: a short case, a demand for the next drug, and an implied demand for the reasoning behind it. This closing topic runs **four** short worked vignettes that each fuse a scenario, the reasoning and the resolution, so that the antidepressant-selection, lithium-initiation, emergency and treatment-resistance chapters are exercised together as they will be at the bedside.

How to read each vignette. Every vignette below is presented as a worked example: it starts with the case (each opens with the literal marker "case:"), states the reasoning against a named guideline or a verified dose, and ends with the resolution and the trade-off. The class detail behind each is developed in the parent topics; here the skill is **application**. Doses, serum levels and first-line agents are verified against the Maudsley Prescribing Guidelines, Stahl, CANMAT, the BAP and the Indian Psychiatric Society CPGs (Maudsley 2021; Stahl 2021; CANMAT 2016; Malhi 2015; Gautam 2017). Where a brand is named it leads with the Indian brand.

37.1 Vignette 1: an antidepressant choice in comorbid depression with chronic pain and prior SSRI sexual dysfunction

The decision. This vignette is a **selection** problem: two patient-specific factors, a comorbid pain syndrome and an intolerable adverse effect on the previous drug, should steer the choice off the default SSRI. The reasoning turns on matching the drug's secondary pharmacology to the comorbidity, and its adverse-effect profile to what the patient could not tolerate before. Both

candidates below are CANMAT first-line agents, so the choice is a trade-off, not a hierarchy (CANMAT 2016).

WORKED EXAMPLE

Case: a 46-year-old man with a moderate depressive episode and long-standing diabetic neuropathic pain. A prior trial of an SSRI (escitalopram) helped his mood but caused marked sexual dysfunction that he found intolerable, and he stopped it. Reasoning: the SSRI class as a whole causes sexual dysfunction through serotonin-transporter blockade, so simply swapping to another SSRI is likely to reproduce the problem; the comorbid neuropathic pain is a positive reason to choose a drug that treats both targets. The two rational off-SSRI choices are an SNRI, duloxetine (Duzela), which is CANMAT first-line for major depression at 60 mg/day and separately licensed for diabetic neuropathic pain and fibromyalgia because of its noradrenergic action on descending spinal pathways; or bupropion (Bupron), a noradrenaline-dopamine reuptake inhibitor that is CANMAT first-line at 150 to 300 mg/day and carries the lowest sexual-dysfunction rate of the common antidepressants. Resolution: duloxetine is the sharper choice here because it treats the depression and the neuropathic pain with one drug, and it does not aggravate the previous problem the way another SSRI would; the trade-off is that duloxetine, like the SSRIs, can itself cause some sexual dysfunction, whereas bupropion would spare sexual function most fully but does nothing for the pain. If the sexual adverse effect were the single dominant concern and there were no pain, bupropion would be the first pick.

The trade-off stated cleanly. Duloxetine (Duzela) 60 mg/day wins on the pain comorbidity; bupropion (Bupron) 150 to 300 mg/day wins on sexual tolerability. A third option, mirtazapine (Mirtaz) 15 to 45 mg/day, also spares sexual function and aids sleep and appetite but does not treat pain (Stahl 2021; CANMAT 2016). Both duloxetine and bupropion require the standard adequate-trial window before they can be judged: response is assessed at 4 weeks and again at 6 to 8 weeks (BAP 2015; CANMAT 2016). The SSRI-versus-SNRI class detail and the full antidepressant-selection algorithm are set out in the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes.

RULE **Let the comorbidity and the prior intolerance pick the antidepressant.** Comorbid pain points to duloxetine; prior sexual dysfunction points to bupropion or mirtazapine, never to a second SSRI.

TRAP **Swapping one SSRI for another after SSRI-induced sexual dysfunction.** The adverse effect is a serotonin-transporter class effect, so a second SSRI usually reproduces it; switch class, not molecule.

37.2 Vignette 2: lithium initiation, target level, the twelve-hour trough and the no-NSAID counselling

The decision. This vignette is an **initiation and monitoring** problem: the baseline work-up, the target serum level for the phase being treated, the sampling rule, and the interaction counselling that keeps the patient out of toxicity. Every figure below is verified (Maudsley 2021; Yatham 2018; Shah 2017).

WORKED EXAMPLE

Case: a 30-year-old woman with bipolar I disorder, recovering from an acute manic episode, for whom lithium is chosen for maintenance. Reasoning: before the first tablet, establish the two organs lithium threatens and the cardiac baseline. The baseline work-up is renal function (eGFR, creatinine, urea and electrolytes), thyroid function (TSH), serum calcium, weight or BMI, an ECG where there are cardiovascular risk factors, and, because lithium is a human teratogen (Ebstein anomaly), a pregnancy test with contraception counselling in a woman of child-bearing potential (Maudsley 2021; Yatham 2018). Start lithium carbonate (Licab, or the controlled-release Intalith CR) and titrate to a maintenance target of 0.6 to 1.0 mmol/L, drawing the level as a twelve-hour trough: the blood is taken 12 hours (ideally 10 to 14 hours) after the last dose, which for a bedtime dose means the next morning before the day's tablet. Recheck the trough 5 to 7 days after each dose change, then roughly 3-monthly once stable, with renal and thyroid function about 6-monthly. Resolution: counsel the patient that anything reducing renal lithium clearance raises the level and can cause toxicity, so she must avoid NSAIDs (ibuprofen, diclofenac) for pain and tell any doctor she is on lithium before starting a thiazide diuretic or an ACE inhibitor; she should keep well hydrated, and report tremor, ataxia, slurred speech, vomiting or diarrhoea at once as toxicity signs.

The phase sets the target. In acute mania the target trough is higher, 0.8 to 1.2 mmol/L, and it steps down to 0.6 to 1.0 mmol/L for maintenance; toxicity appears reliably above 1.5 mmol/L (Yatham 2018; Maudsley 2021). The twelve-hour trough and the 5-to-7-day recheck after a dose change are the two most-tested sampling facts, developed in full in the lithium-monitoring topic of these mood-block notes.

0.6 to 1.0	0.8 to 1.2	12	1.5
MAINTENANCE LITHIUM (MMOL/L)	ACUTE MANIA TARGET (MMOL/L)	TROUGH SAMPLING (HOURS POST-DOSE)	TOXICITY THRESHOLD (MMOL/L)

RULE **Draw lithium as a twelve-hour trough and counsel against NSAIDs.** The **12-hour** post-dose sample is the only interpretable level; NSAIDs, thiazides and ACE inhibitors raise the level toward toxicity.

TRAP **Checking a lithium level at the wrong time.** A non-trough sample drawn a few hours post-dose reads falsely high and invites a wrong dose cut; standardise to 12 hours every time.

INDIA

Lithium carbonate is cheap and heavily prescribed in India as Licab and the controlled-release Intalith CR, and the serum assay is inexpensive and widely available. The practical failure point is the twelve-hour trough discipline in a busy outpatient department, so counsel the patient to attend fasting in the morning before the day's dose and to note the time of the last tablet. Over-the-counter NSAID use for musculoskeletal pain is common and unsupervised, which makes the no-NSAID counselling a genuine safety instruction, not a formality.

37.3 Vignette 3: suspected serotonin syndrome on an SSRI plus tramadol, reasoned through the Hunter criteria

The decision. This vignette is a **recognition and emergency-management** problem: identify the syndrome from a combination of a serotonergic antidepressant and a serotonergic analgesic, apply the diagnostic rule, take the first management step, and separate it from its dopamine-blocker mimic. The management sequence and the discriminator are verified (Maudsley 2021; Kaplan and Sadock 2024).

WORKED EXAMPLE

Case: a 52-year-old man on sertraline (Serta) for depression is given tramadol for acute back pain and within hours becomes agitated, sweaty and febrile at 39 degrees Celsius, with dilated pupils, a tachycardia of 130, brisk lower-limb reflexes and sustained ankle clonus. Reasoning: sertraline plus tramadol is a two-drug serotonergic combination, and tramadol is itself weakly serotonergic, so this is the classic precipitant of serotonin syndrome. Apply the Hunter Serotonin Toxicity Criteria: in a patient on a serotonergic agent, the diagnosis is met by any one of spontaneous clonus; inducible clonus with agitation or diaphoresis; ocular clonus with agitation or diaphoresis; tremor plus hyperreflexia; or hypertonia plus temperature above 38 degrees Celsius plus ocular or inducible clonus. This patient has spontaneous clonus, which alone satisfies the Hunter criteria. Resolution: the first and most important step is to stop all serotonergic agents at once (both the sertraline and the tramadol); then give supportive care with intravenous fluids and active cooling for the hyperthermia, sedate with a benzodiazepine for agitation and neuromuscular hyperactivity, and in this moderate-to-severe case give cyproheptadine (Ciplactin, or Practin), a 5-HT2A antagonist, orally as the serotonin-antagonist antidote, a common regimen being an initial 12 mg then 2 mg every two hours if symptoms persist, to a ceiling around 32 mg in 24 hours. Most cases resolve within about 24 hours of stopping the trigger.

The NMS differential is the point. Serotonin syndrome and neuroleptic malignant syndrome share hyperthermia, rigidity, autonomic instability and altered consciousness, so the examiner rewards the one discriminator: serotonin syndrome follows a serotonergic drug, comes on rapidly over hours, and shows clonus with hyperreflexia; neuroleptic malignant syndrome follows a dopamine-blocker, comes on slowly over days, and shows lead-pipe rigidity with hyporeflexia and a markedly raised creatine kinase, often above 1000 units per litre (Maudsley 2021). The wider acute-emergency management frame is set out in the Perinatal/women's mental health and emergency psychiatry notes.

clonus	hours	12 then 2
THE HUNTER ANCHOR AND NMS DISCRIMINATOR	SEROTONIN-SYNDROME ONSET AFTER TRIGGER	CYPROHEPTADINE (MG, INITIAL THEN Q2H)

RULE **Stop the serotonergic drugs first, then support, sedate and give cyproheptadine.** Clonus with hyperreflexia in a patient on a serotonergic agent is serotonin syndrome until proven otherwise.

TRAP **Missing serotonin syndrome when an SSRI meets tramadol, or mislabelling it as NMS.** Tramadol is serotonergic; clonus and hyperreflexia (not lead-pipe rigidity) separate serotonin syndrome from its dopamine-blocker mimic.

INDIA

Tramadol is casually co-prescribed for musculoskeletal pain across Indian practice, so the highest-risk everyday scenario is a patient already on an antidepressant who is given tramadol. Cyproheptadine is freely available in India as an oral antihistamine (commonly stocked as Ciplactin or Practin), which makes the specific antidote easy to obtain once moderate-to-severe serotonin syndrome is recognised.

37.4 Vignette 4: treatment-resistant depression up the augmentation ladder

The decision. This vignette is an **escalation-discipline** problem: before augmenting, prove the depression is genuinely resistant and not merely under-treated, then climb the augmentation ladder in the guideline order. Every guideline opens the treatment-resistant depression pathway with a mandatory review of adequacy and diagnosis before any escalation (CANMAT 2016; BAP 2015; Gautam 2017).

WORKED EXAMPLE

Case: a 40-year-old woman with a major depressive episode that has not remitted despite an SSRI (escitalopram) followed by an SNRI (venlafaxine). Reasoning: first confirm this is true resistance, defined as failure of at least two adequate antidepressant trials in the current episode, each at an adequate dose for an adequate duration (response judged at 4 weeks and again at 6 to 8 weeks). Confirm each trial actually reached a therapeutic dose and was taken long enough, and confirm adherence, because most apparent resistance is pseudoresistance from an inadequate dose, an inadequate duration, poor adherence or a wrong diagnosis; review the diagnosis for a missed bipolar disorder, psychotic depression, or an organic or substance cause. Resolution: with two genuinely adequate failures confirmed, augment rather than endlessly switch. The first-line augmentation moves are to add lithium (Licab) 600 to 1200 mg/day titrated to a therapeutic serum level, or to add an atypical antipsychotic such as aripiprazole 2 to 15 mg/day or quetiapine (Qutipin) 150 to 300 mg/day (CANMAT 2016; BAP 2015). If augmentation fails, the next tier is the glutamatergic and neurostimulation options: add intranasal esketamine (Spravato) to an SSRI or SNRI for patients who have failed at least two adequate antidepressant trials, monitoring blood pressure and dissociation, or refer for electroconvulsive therapy, which is considered for patients who have not responded to other treatments and is the treatment of choice in severe, psychotic or high-suicide-risk depression.

The ladder in order. Optimise and confirm adequacy and adherence, review the diagnosis, then augment with lithium or an atypical (first-line augmentation), then move to esketamine or ECT. Lithium augmentation has the best evidence in older people, and CANMAT places aripiprazole, brexpiprazole, quetiapine and lithium among the first-line adjuncts, with esketamine reserved for at least two failed trials (BAP 2015; CANMAT 2016). The staging systems (Thase-Rush, Maudsley staging method) and the full ladder are developed in the treatment-resistant depression topic; the ECT technique itself is in the ECT and neurostimulation notes.

STEP	ACTION	AGENT / DOSE (VERIFIED)
1	**Confirm adequacy and adherence, review diagnosis**	Two adequate trials at therapeutic dose, judged at 4 and 6 to 8 weeks; exclude bipolar, psychotic, organic and substance causes
2	Optimise the current antidepressant	Raise a low or marginal dose to a recommended therapeutic dose first
3	**First-line augmentation: lithium or an atypical**	Lithium 600 to 1200 mg/day (to therapeutic serum level); aripiprazole 2 to 15 mg/day; quetiapine 150 to 300 mg daily
4	Glutamatergic or neurostimulation	Intranasal esketamine added to an SSRI/SNRI after 2 failed adequate trials; or ECT

The treatment-resistant depression ladder as applied in the vignette: confirm resistance and adherence, optimise, augment with lithium or an atypical, then esketamine or ECT (CANMAT 2016; BAP 2015). Highlighted steps are the board-critical moves.

RULE **Prove adequacy and adherence before you augment.** Two adequate trials must fail in the current episode; then augment with lithium or an atypical before moving to esketamine or ECT.

TRAP **Stopping at response instead of remission, or escalating over pseudoresistance.** Response without remission relapses; an inadequate dose, an inadequate duration or a missed bipolar diagnosis is under-treatment, not resistance.

GOOD TO REMEMBER

- **Vignette 1, antidepressant choice:** comorbid pain plus prior SSRI sexual dysfunction reasons to duloxetine (Duzela) 60 mg/day (treats pain and mood, CANMAT first-line SNRI) or bupropion (Bupron) 150 to 300 mg/day (lowest sexual-dysfunction rate); never a second SSRI for a class-effect adverse event.
- **Vignette 2, lithium initiation:** baseline renal (eGFR/creatinine), thyroid (TSH), calcium, weight, ECG where indicated, and pregnancy test; maintenance target 0.6 to 1.0 mmol/L (acute mania 0.8 to 1.2); draw a twelve-hour trough; counsel no NSAIDs, and caution with thiazides and ACE inhibitors.
- **Vignette 3, serotonin syndrome:** SSRI plus tramadol, Hunter criteria met by spontaneous clonus; stop all serotonergic agents first, then support and cool, benzodiazepine, then cyproheptadine (Ciplactin/Practin) 12 mg then 2 mg every 2 hours; clonus and hyperreflexia (not lead-pipe rigidity) distinguish it from NMS.
- **Vignette 4, treatment-resistant depression:** confirm two adequate failed trials and adherence, review the diagnosis, then augment with lithium 600 to 1200 mg/day or an atypical (aripiprazole 2 to 15 mg/day, quetiapine 150 to 300 mg/day), then esketamine (Spravato) or ECT.

HOLD THIS

The four clinical moves: match the antidepressant to the comorbidity and the prior intolerance (duloxetine for pain, bupropion for sexual sparing); start lithium on a full baseline work-up with a twelve-hour trough and no-NSAID counselling; in serotonin syndrome stop the serotonergic drugs first and give cyproheptadine; and in resistant depression prove adequacy and adherence before augmenting with lithium or an atypical and then esketamine or ECT.

38 . Consolidate: mnemonic, retrieval and synthesis

This is the closing topic of the mood pharmacotherapy block, and its job is not to add new drug facts but to **consolidate** the ones already taught into a form you can retrieve cold in an examination. Two evidence-based study moves do the heavy lifting: a single master **mnemonic** that chains the whole chapter into four movements so nothing is dropped, and **active recall** against a map you can redraw from memory. The pharmacology and the algorithms are all upstream; here they are re-indexed for retrieval.

The board does not reward a resident who can recognise a fact when prompted; it rewards one who can **generate** it under time pressure. That is why this topic is built around retrieval, not re-reading: the mnemonic is the retrieval cue, the recall prompts are the practice, and the synthesis map is the whole chapter compressed to one page you rebuild without looking. Everything below points back to a topic taught in full elsewhere in these notes.

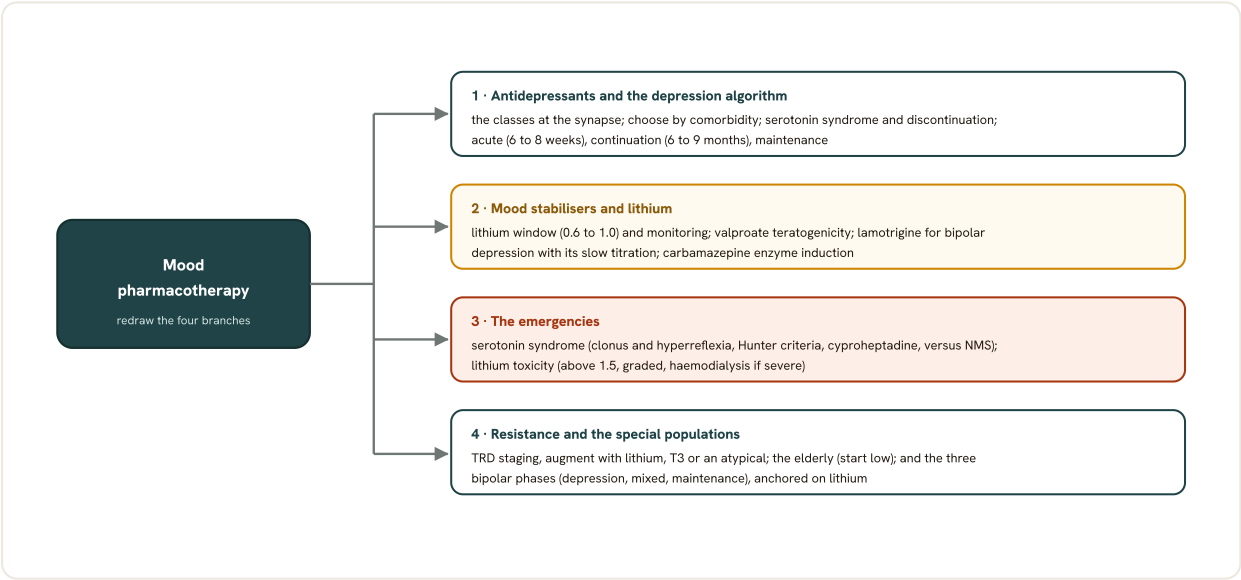

Fig 12.17 The whole chapter at a glance, framed for retrieval: cover the branches and redraw them from memory. The four branches are the antidepressants and the depression algorithm; the mood stabilisers and lithium with their monitoring and teratogenicity; the emergencies (serotonin syndrome and lithium toxicity); and treatment resistance with the special populations and the three bipolar-management phases.

38.1 The master mnemonic: chaining the whole chapter

One handle, four movements. The entire pharmacotherapy block hangs on the Step-2 seed you planted at the outset, and this is its payoff. Hold the whole chapter as **"A SNoM LiVeS, then CALM the STORM, then climb the LADDER"**. The first beat is the antidepressant classes and the depression algorithm; the second is lithium and the mood stabilisers with their monitoring and teratogenicity; the third is the two pharmacological emergencies; the fourth is treatment

resistance, augmentation and the bipolar-phase management. Each capitalised letter is a slot that expands into a full topic, and every fact chained below is verified against the source that owns it (Maudsley 2021; Stahl 2021; CANMAT 2016; CANMAT 2018; Yatham 2018).

MNEMONIC

A SNoM LiVeS, then CALM the STORM, then climb the LADDER

A SNoM is the antidepressant classes and the depression algorithm. **A**ntidepressants classify by synaptic action: SSRIs (SERT block, first-line, escitalopram **10 to 20 mg/day**), **S**NRIs (SERT plus NET, venlafaxine **75 to 225 mg/day** with dose-related blood-pressure rise), **N**aSSA/**N**DRI (mirtazapine, an alpha-2 antagonist that sedates; bupropion, a noradrenaline-dopamine reuptake inhibitor that spares sexual function and lowers the seizure threshold), the **o**lder tricyclics and **M**AOIs (reserved, dangerous, the tyramine and serotonergic hazards), and the **M**ultimodal and glutamatergic agents (vortioxetine, ketamine/esketamine). The depression algorithm is treat by phase to **remission**: acute review every **1 to 2 weeks**, judge by **2 to 4 weeks**, continuation at the same acute dose for **6 to 9 months**, maintenance **2 years or longer** if recurrent (CANMAT 2016). **LiVeS** is the mood stabilisers: **Li**thium (maintenance level **0.6 to 1.0 mmol/L**, twelve-hour trough, specific anti-suicide effect, first-trimester Ebstein signal), **V**alproate (serum **50 to 100 microg/mL**, the highest-risk teratogen: neural-tube defects, major-malformation rate around **10 percent**, dose-related IQ and autism harm, avoided in women of childbearing potential), lamotrigine (the depression pole, titrate **25 to 200 mg/day** slowly for the rash), the Stabiliser antipsychotics and carbamazepine (serum **4 to 12 mg/L**, enzyme induction, HLA-B*1502). **CALM the STORM** is the two emergencies: serotonin syndrome (clonus, hyperreflexia, autonomic instability, altered mental state, rapid over hours; stop the drug and give cyproheptadine) and lithium toxicity (coarse tremor and ataxia, toxic above **1.5 mmol/L**; stop, rehydrate with saline, dialyse if severe). **The LADDER** is treatment resistance and the bipolar phases: prove adequacy first (dose, duration, adherence, diagnosis), then switch, augment (lithium to **0.6 to 1.0 mmol/L**, or an atypical), combine, neuromodulate (ECT); and treat bipolar by phase (mania: lithium/valproate/an atypical, stop the antidepressant; bipolar depression: quetiapine, lurasidone, lithium, lamotrigine, never an antidepressant alone; maintenance: continue what worked, lithium level **0.6 to 1.0 mmol/L**).

RULE **Classify first, then treat by phase and polarity.** A SNoM LiVeS names the drug; CALM the STORM and the LADDER name what to do when it goes wrong or fails.

TRAP **Reciting the mnemonic without the numbers.** The letters are a scaffold; the exam marks fall on the doses, the serum levels and the monitoring intervals hung on each letter, so rehearse the figures, not just the acronym.

38.2 Retrieval practice, cover the answers

Practise generating, not recognising. The single most efficient consolidation move is **active recall**: close the notes and force the fact out, then check. What follows is a set of answer-free prompts spanning the four bands of the chapter. Use them as **retrieval practice**: read a prompt, say or write the full answer aloud from memory, and only then reveal the source topic to mark yourself. The prompts print no answers by design; that is the point of **cover the answers** practice. Space the repetitions across sittings rather than massing them.

RETRIEVAL PRACTICE, COVER THE ANSWERS

1. Name the primary synaptic action of each antidepressant class (SSRI, SNRI, TCA, MAOI, NaSSA, NDRI, multimodal, glutamatergic), and the one signature adverse effect or interaction that belongs to each.
2. State the four phases of the unipolar depression algorithm with the review interval, the response-judging point, the continuation duration and the maintenance duration, and say what defines the end of the acute phase.
3. Give the first-line agents for bipolar depression and state the one thing you never do with an antidepressant in bipolar disorder.
4. Recite the tyramine (cheese-reaction) food list for a patient on an irreversible MAOI, and the two washout intervals when switching to and from an MAOI or fluoxetine.
5. State lithium's molecular target and mechanism, its maintenance and acute serum ranges, the sampling rule (when the level is drawn), and the two anti-suicide claims attached to it.
6. List the lithium monitoring schedule: the trough timing, the recheck interval after a dose change, the ongoing level interval once stable, and the thyroid and renal monitoring intervals.
7. Give the drugs that raise and the drugs that lower the lithium level, and name the teratogenic signal and the trimester it belongs to.
8. State valproate's serum range, its full adverse-effect set, and the complete teratogenicity picture (structural, neurodevelopmental and its dose-dependence) with the prescribing rule that follows.
9. Give the lamotrigine titration and the one drug interaction that forces you to halve the schedule, and name the pole and phase lamotrigine is best for.
10. State carbamazepine's serum range, its three signature hazards, and the effect of its autoinduction on the level.
11. Recite the serotonin syndrome triad, the one sign that discriminates it from neuroleptic malignant syndrome, and the four-step management sequence.
12. Give the lithium toxicity level bands (mild, moderate, severe), the matching clinical features, the classic precipitants, and the four-step management including the dialysis indication.
13. State the definition of treatment-resistant depression, the four adequacy checks you clear before escalating, and the order of the switch-augment-combine-neuromodulate ladder.
14. Name the best-evidenced augmentation agents and the target lithium level for lithium augmentation.
15. Lay out the three bipolar phases (mania, depression, maintenance) with the first-line agents for each and the maintenance lithium level.

TRAP **Re-reading the notes and mistaking familiarity for mastery.** Recognising a fact on the page is not the same as retrieving it under a stem; only cover-the-answers recall trains the generation the board tests.

38.3 The synthesis map: redraw from memory

Rebuild the chapter on one page. The final consolidation move is to draw the whole-chapter **synthesis map** and then **redraw from memory** until it comes out clean. The map is a single

node, the mood pharmacotherapy block, with four branches, each a movement of the master mnemonic. Branch one is the antidepressants and the depression algorithm (the class map keyed to synaptic action, and the acute-continuation-maintenance phases). Branch two is the mood stabilisers and lithium (lithium initiation, monitoring, toxicity and teratogenicity, then valproate, carbamazepine, lamotrigine and the stabiliser antipsychotics). Branch three is the emergencies (serotonin syndrome and lithium toxicity, each with its discriminator and first management step). Branch four is treatment resistance and the special populations (the adequacy work-up and the augmentation ladder, the three bipolar phases, and prescribing in pregnancy and old age). Draw the four branches from the central node, hang the two or three load-bearing numbers on each leaf, and repeat the exercise cold until nothing is missing; the leaves you cannot fill are exactly the topics to revisit.

HOLD THIS

A SNoM LiVeS, then CALM the STORM, then climb the LADDER: four movements, four branches, one page you can redraw from memory.

GOOD TO REMEMBER

- **Branch 1 (antidepressants and the algorithm):** classify by synaptic action, then treat by phase to remission, continuation **6 to 9 months**, maintenance **2 years or longer** if recurrent (CANMAT 2016).
- **Branch 2 (stabilisers and lithium):** lithium maintenance **0.6 to 1.0 mmol/L** at a twelve-hour trough; valproate **50 to 100 microg/mL**, the highest-risk teratogen; lamotrigine for the depressive pole, titrated slowly (CANMAT 2018; Maudsley 2021).
- **Branch 3 (emergencies):** serotonin syndrome is clonus plus hyperreflexia (stop the drug, cyproheptadine); lithium toxicity is coarse tremor and ataxia above **1.5 mmol/L** (stop, saline, dialyse if severe) (Maudsley 2021).
- **Branch 4 (resistance and special populations):** prove adequacy (dose, duration, adherence, diagnosis) before you switch, augment, combine or neuromodulate; treat bipolar by phase and never give an antidepressant alone in bipolar depression (CANMAT 2016; Yatham 2018).
- **The retrieval rule:** generate the fact from a cue and space the repetitions; recognition on re-reading is not the skill the examination tests.

INDIA

For the Indian postgraduate examination, lead every management answer with CANMAT (CANMAT 2016 for depression, CANMAT 2018 and Yatham 2018 for bipolar disorder), then name the Indian Psychiatric Society position (Gautam et al. 2017 for depression, Grover and Avasthi 2017 for bipolar disorder), then note BAP and NICE where they converge (BAP 2015; NICE 2014). The Indian brands are learnt one drug at a time in the individual topics, Indian brand first: for example escitalopram (Nexito or S-Citadep), sertraline (Serta or Daxid), lithium carbonate (Licab or Intalith), sodium valproate (Valprol or Encorate), lamotrigine (Lamitor or Lametec) and quetiapine (Qutipin). Lithium remains a mainstream first-line stabiliser in Indian practice.

Previously asked

Mood pharmacotherapy is examined heavily and at the level of the individual drug: the SSRIs, the SNRIs, lithium, ketamine and the newer antidepressants have each come as standalone short notes, and the management of resistant depression and of refractory bipolar illness recurs as both a short note and the tail of a long essay. The reliable pattern is that every long mood question ends in a guideline-anchored drug plan, and a drug-specific note (a class, an agent, a monitoring rule, an adverse effect) can be asked on its own. The genuine questions on record are grouped by band below. The classification, the clinical syndromes and the neurobiology that these drugs treat are developed in the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes.

HOW THIS TERRITORY IS ACTUALLY TESTED

- **Antidepressant classes and agents.** "SSRI antidepressants", "SNRI antidepressants" and "newer antidepressants" have each been asked as 10-mark notes, and "the recent advances in depression and development of antidepressants" as a longer question, so each class must be ready with its mechanism, its representative agents, its adverse-effect signature and its place. "Antidepressants in epilepsy with depression" tests the drug choice in a comorbidity. Prepare the class map, the individual agents and the comorbidity-driven selection. short note and essay, recurring

- **Serotonin syndrome and drug-induced states.** A case of a patient on an antidepressant and an antipsychotic who develops involuntary movements has been asked as a diagnose-investigate-manage question, and serotonin syndrome sits behind any antidepressant-combination scenario. Prepare serotonin syndrome (the Hunter criteria, the discrimination from NMS, the management) and the drug-induced movement disorders by cross-reference. case question, recurring

- **Rapid-acting and novel agents.** "The use of ketamine in depression" has come as a standalone note, so the NMDA mechanism, the rapid effect, the esketamine indication and the monitoring must be exam-ready, and the glutamatergic and other novel agents are worth a line. short note

- **Lithium and the mood stabilisers.** "Lithium" is a classic 10-mark note (mechanism, indications, the therapeutic range, monitoring, toxicity and the organ effects), and "carbamazepine" recurs across the papers. Prepare lithium in full, and valproate, carbamazepine and lamotrigine with their monitoring and their signature risks (valproate teratogenicity, lamotrigine and Stevens-Johnson). short note, recurring

- **Treatment resistance and bipolar management.** "The management of resistant depression" and "the management of treatment-resistant depression" have both come as standalone questions, and "the conceptual overview of bipolar spectrum disorder with the management of treatment-refractory bipolar II" and "the clinical features, differential diagnosis and management of bipolar depression" as essays. Prepare the TRD staging and augmentation ladder, and the three dedicated bipolar-management topics (bipolar depression, mixed episodes and maintenance), guideline-first. essay and short note, recurring

Prepare this material to be prescribed and monitored, not just recited: the class map, the dose-anchored good-to-remember boxes, the lithium monitoring and toxicity figures, the serotonin-syndrome differential and the guideline-anchored selection and management topics in these notes are built to the way the block is examined. The mood classification, the clinical syndromes and the neurobiology live in the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes; the ECT and neurostimulation technique lives in the ECT and neurostimulation notes; the full clinical suicide risk assessment lives in the Somatic-symptom, sexual, impulse-control disorders and suicide notes; and the wider perinatal and emergency frames live in the Perinatal/women's mental health and emergency psychiatry notes.

Quick review

The whole subject in one table	
ANTIDEPRESSANT CLASSES	Classify by the primary synaptic action: reuptake inhibitors (SSRI at SERT, SNRI at SERT and NET, TCA at both plus H1/M1/alpha-1 blockade), enzyme inhibitors (irreversible MAOI, reversible moclobemide), receptor-acting (mirtazapine NaSSA, bupropion NDRI), multimodal (vortioxetine, agomelatine, trazodone) and glutamatergic (ketamine, esketamine). The site predicts the tolerability and the dangerous interactions.
SSRIS	First-line, broadly equal in efficacy; differ in half-life, interactions and adverse-effect emphasis. Fluoxetine (long half-life, activating), sertraline (broadest), escitalopram and citalopram (cleanest, dose-dependent QTc, citalopram capped at 40 mg/day), paroxetine (short half-life, anticholinergic, worst discontinuation, avoid in pregnancy), fluvoxamine (OCD, CYP1A2). Class effects: GI upset, sexual dysfunction, hyponatraemia/SIADH in the elderly, bleeding with NSAIDs, early activation.
SNRIS AND TCAS	SNRIs: venlafaxine (dose-dependent noradrenergic effect and blood-pressure rise, marked discontinuation), desvenlafaxine, duloxetine (neuropathic pain). TCAs: reuptake blockade plus off-target H1/M1/alpha-1 (the adverse effects); dangerous in overdose (quinidine-like cardiotoxicity, QRS widening, seizures), so weigh the suicide risk; amitriptyline, imipramine, clomipramine (OCD), nortriptyline (best tolerated).
MAOIS	Irreversible non-selective (phenelzine, tranylcypromine) or reversible RIMA (moclobemide, safer). Tyramine (cheese) reaction gives a hypertensive crisis; never combine with a serotonergic drug (serotonin syndrome). Washout: at least two weeks off an MAOI before a serotonergic drug; about one week off most SSRIs/SNRIs (two off a TCA) before an MAOI; five weeks off fluoxetine before an MAOI.
MIRTAZAPINE, BUPROPION, NEWER	Mirtazapine (NaSSA): sedation and weight gain (more at low dose), minimal sexual dysfunction, for depression with insomnia and poor appetite. Bupropion (NDRI): activating, low sexual dysfunction, smoking cessation, lowers the seizure threshold (avoid in seizure and eating disorders). Newer: vortioxetine and vilazodone (multimodal), agomelatine (melatonergic, needs LFT monitoring), trazodone (SARI, priapism), tianeptine.

The whole subject in one table	
SEROTONIN SYNDROME VS NMS	Serotonin syndrome: rapid onset from a serotonergic combination; clonus, hyperreflexia, tremor, hyperthermia, hyperactive bowel sounds, mydriasis; Hunter criteria; stop the agent, supportive care, cyproheptadine. NMS: slow onset from a dopamine blocker; lead-pipe rigidity, hyporeflexia, marked CK rise; dantrolene, bromocriptine. The pivot is clonus and hyperreflexia (serotonin) versus lead-pipe rigidity (NMS).
KETAMINE, DISCONTINUATION	Ketamine and esketamine (NMDA antagonists): rapid effect within hours via AMPA and synaptogenesis; esketamine (intranasal) for treatment-resistant depression and MDD with acute suicidality, given under observation for dissociation and blood pressure; effect is transient. Discontinuation syndrome (FINISH: flu-like, insomnia, nausea, imbalance, sensory zaps, hyperarousal): worst with paroxetine and venlafaxine, least with fluoxetine; taper slowly, it is not addiction.
CHOOSING AND THE PHASES	First-line agents are equal in efficacy, so choose by comorbidity, adverse-effect profile, past response, safety and cost (CANMAT lead; IPS and NICE agree). Acute phase: treat to remission over 6 to 8 weeks, review by 2 to 4 weeks. Continuation: the SAME acute dose for 6 to 9 months. Maintenance: 2 years or longer for recurrent or high-risk depression. Psychotic depression needs an antidepressant plus an antipsychotic, or ECT.
LITHIUM: DOSE AND MONITORING	Mechanism: inositol depletion and GSK-3 inhibition; renally excreted, sodium-linked, narrow therapeutic index. Range: acute mania 0.8 to 1.0 (up to 1.2), maintenance 0.6 to 0.8 (up to 1.0), elderly 0.4 to 0.6 mmol/L. Sample as a 12-hour trough; recheck 5 to 7 days after a dose change; renal and thyroid function 6-monthly. Baseline: renal, thyroid, calcium, ECG, pregnancy, weight.
LITHIUM: TOXICITY AND ORGANS	Toxicity (dehydration, NSAIDs, thiazides, ACE inhibitors precipitate): mild 1.5 to 2.0 (coarse tremor, GI, lethargy), moderate 2.0 to 2.5 (confusion, ataxia, dysarthria), severe above 2.5 (seizures, coma, renal failure); stop, saline, haemodialysis for severe. Organs: nephrogenic DI and long-term CKD (watch eGFR trend), hypothyroidism and goitre (thyroxine, keep lithium), hypercalcaemia, benign T-wave changes, acne and psoriasis, fine tremor. Ebstein anomaly first-trimester (small but raised). Interactions that RAISE the level: NSAIDs, thiazides, ACE inhibitors and ARBs.
VALPROATE, CARBAMAZEPINE, LAMOTRIGINE	Valproate: anti-manic and maintenance (not bipolar depression alone); hepatotoxicity and PCOS; CRITICAL teratogenicity (neural-tube and neurodevelopmental risk), so avoid in women of childbearing potential without a pregnancy-prevention programme. Carbamazepine: potent CYP3A4 autoinducer (oral-contraceptive failure), hyponatraemia, blood dyscrasias, HLA-B*1502 SJS screen. Lamotrigine: for bipolar depression and

The whole subject in one table	
	maintenance (weak for mania); slow titration, HALVED with valproate; stop for a serious or mucosal rash (Stevens-Johnson).
TRD AND AUGMENTATION	TRD: failure of at least two adequate antidepressant trials, but exclude pseudoresistance first (dose, duration, adherence, missed bipolarity); Thase-Rush and Maudsley staging; STAR-D showed remission falls with each step. Ladder: optimise, switch, augment (lithium the classic and anti-suicidal, T3, an atypical, the best evidence), combine, then ECT, esketamine or neuromodulation.
BIPOLAR MANAGEMENT BY PHASE	Acute mania: stop any antidepressant; first-line lithium, quetiapine, valproate, or an atypical (aripiprazole, asenapine, risperidone, cariprazine), combination for severe. Bipolar depression: quetiapine, lurasidone, lithium, lamotrigine, olanzapine-fluoxetine, cariprazine; never an antidepressant alone (manic switch). Mixed episodes: valproate, asenapine, cariprazine, olanzapine, ECT; antidepressants avoided; lithium relatively weaker. Maintenance: lithium anchors (anti-suicidal), quetiapine, valproate, lamotrigine for the depressive pole, LAI for non-adherence.
ECT, NEUROMODULATION, PSYCHOTHERAPY	ECT: first-line in the emergencies (severe, psychotic or treatment-resistant depression, high suicide risk, food refusal, catatonia, pregnancy), rapid and effective; technique elsewhere. rTMS: non-invasive, for treatment-resistant depression. VNS: later-line, slow. DBS: experimental. Psychotherapy: CBT, IPT and behavioural activation are first-line in mild-to-moderate depression alone and combined with medication in severe depression.
SPECIAL POPULATIONS AND SUICIDE	Elderly: somatic and cognitive presentation, vascular depression; start low and go slow but still reach an adequate dose; prefer an SSRI (watch hyponatraemia, falls, the QTc cap), avoid TCAs; ECT works well in severe late-life depression. Suicide: mood disorders carry the highest risk (severe, mixed, early illness, early recovery); lithium is anti-suicidal; avoid a large TCA supply; counsel early antidepressant activation.

References

The pharmacology is grounded in the standard prescribing and psychopharmacology sources (the source hierarchy below), with the Maudsley Prescribing Guidelines and Stahl as the depth bar for the mechanisms, doses, serum levels and monitoring, and the management is guideline-first (CANMAT leading, with the Indian Psychiatric Society, the British Association for Psychopharmacology and NICE). Every dose, serum level, therapeutic range, monitoring interval, teratogenicity fact, drug interaction and first-line recommendation has been checked against these sources; anything that could not be confirmed was omitted and flagged rather than guessed. Each journal PMID here was verified against PubMed this build, matched on title, first author

and year; identifiers that resolved to the wrong paper were corrected or dropped. The classic sources seeding the field (Cade's 1949 report of lithium in mania, Schou's lithium work) are named in the prose by author and year.

PAPER II

Substance use disorders

Six sections . one complete notes document

This material gathers the substance use disorders into one document, by substance and by treatment. The first band is **general concepts and assessment**: the dependence syndrome and harmful use, the neurobiology of addiction and the reward pathway, tolerance and withdrawal, the screening instruments and their cut-offs, dual diagnosis and harm reduction. The second band is **alcohol use disorder**: the pharmacology, the withdrawal spectrum with the CIWA-Ar and the benzodiazepine protocol, delirium tremens, Wernicke encephalopathy and Korsakoff syndrome, alcoholic hallucinosis, the medical complications and the laboratory markers. The third band is **opioid use disorder**: overdose and naloxone, withdrawal and the COWS, opioid substitution with buprenorphine and methadone, antagonist relapse prevention and detoxification. The fourth band is **the other substances of misuse**: cannabis, the stimulants, tobacco, the sedative-hypnotics, the inhalants, hallucinogens and caffeine, the behavioural addictions, and the special populations. The fifth band is **psychosocial treatment and relapse prevention**: motivational interviewing, the stages of change, the Marlatt relapse-prevention model, brief interventions, the twelve-step groups and contingency management. The sixth band is **anti-craving and aversive pharmacotherapy**: disulfiram, naltrexone, acamprosate and the guideline-anchored choice between them. The examinable skill is the safe, guideline-anchored assessment and treatment of each substance: which scale and which cut-off, which withdrawal regimen at what dose, which emergency behind which sign, and which treatment for which patient and stage.

HOW TO USE THESE NOTES

Read the six bands as one continuous account of how substance use disorder is assessed and treated. The **general** band builds the frame: the dependence syndrome, the reward-pathway neurobiology and the screening scales with their verified cut-offs. The **alcohol** and **opioid** bands teach each substance by its intoxication, its withdrawal and its complications, and carry the core emergencies, the alcohol-withdrawal and Wernicke management on one side and opioid overdose and substitution on the other. The **other substances** band covers cannabis, the stimulants, tobacco and the sedative-hypnotics in working depth and the rest compactly. The **psychosocial** band teaches motivational interviewing, the stages of change and the Marlatt model as the SUD-core skills, and the **anti-craving** band teaches disulfiram, naltrexone and acamprosate and how to choose between them. Every management recommendation is guideline-anchored, led by the BAP guidelines with the Indian Psychiatric Society, NICE and WHO positions stated, on the where-to-treat, target-by-phase, modes-of-treatment spine; every named drug ends with a **Good to remember** box giving the mechanism, the signature caution and the one dose, and every named emergency ends with one giving the feature, the discriminator and the first step. Figures declare one axis and code it in colour: **petrol** marks structure and the neutral case, **coral** marks the trap or the danger, and **marigold** highlights the number to hold; the screening and withdrawal scales are reproduced as the actual instruments, credited to their sources. Several boundaries are stated up front: the reward-pathway anatomy is taught in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and cross-referenced here; the wider psychosis boundary in the Other psychotic disorders, delusional syndromes and catatonia notes; the wider delirium and emergency frame and substance use in pregnancy in the Perinatal and emergency psychiatry notes; the NDPS Act and the medico-legal frame in the Mental health legislation and forensic psychiatry notes; the wider psychotherapy technique in the Psychotherapies notes; and the wider amnestic frame in the Dementias and the Neuropsychiatry of systemic disease notes. This is doctor-facing revision, so the full technical vocabulary is used, brand names lead with the Indian brand, and every dose, scale cut-off, thiamine regimen and first-line recommendation is verified against a source or omitted and flagged.

General concepts and assessment

1 · Dependence syndrome and harmful use

The whole of the substance-use chapter turns on one distinction, and this is where it is drawn: the difference between a pattern of use that is *damaging* a person (**harmful use**) and a pattern that has captured them (the **dependence syndrome**). Get this pair right and every downstream question, from which scale to reach for to whether a person needs assisted withdrawal, follows. Examiners love it because it is a criterion-count item: they will ask what the criteria are, how many are needed, over what period, and how the old ICD-10 list maps onto the newer ICD-11 concept. The construct is not arbitrary. The dependence syndrome descends directly from Edwards and Gross's 1976 description of the alcohol dependence syndrome, which is why the same clustering of features reappears across every substance class.

Why it matters clinically. Naming dependence rather than harmful use changes the plan: dependence implies a physiological withdrawal risk, a need to consider assisted withdrawal and relapse-prevention pharmacotherapy, and a much higher chance of relapse, whereas harmful use is often addressed with brief, motivation-based intervention alone. The reward-pathway biology that underlies the **salience** and **compulsion** at the heart of the syndrome is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and is not re-derived here.

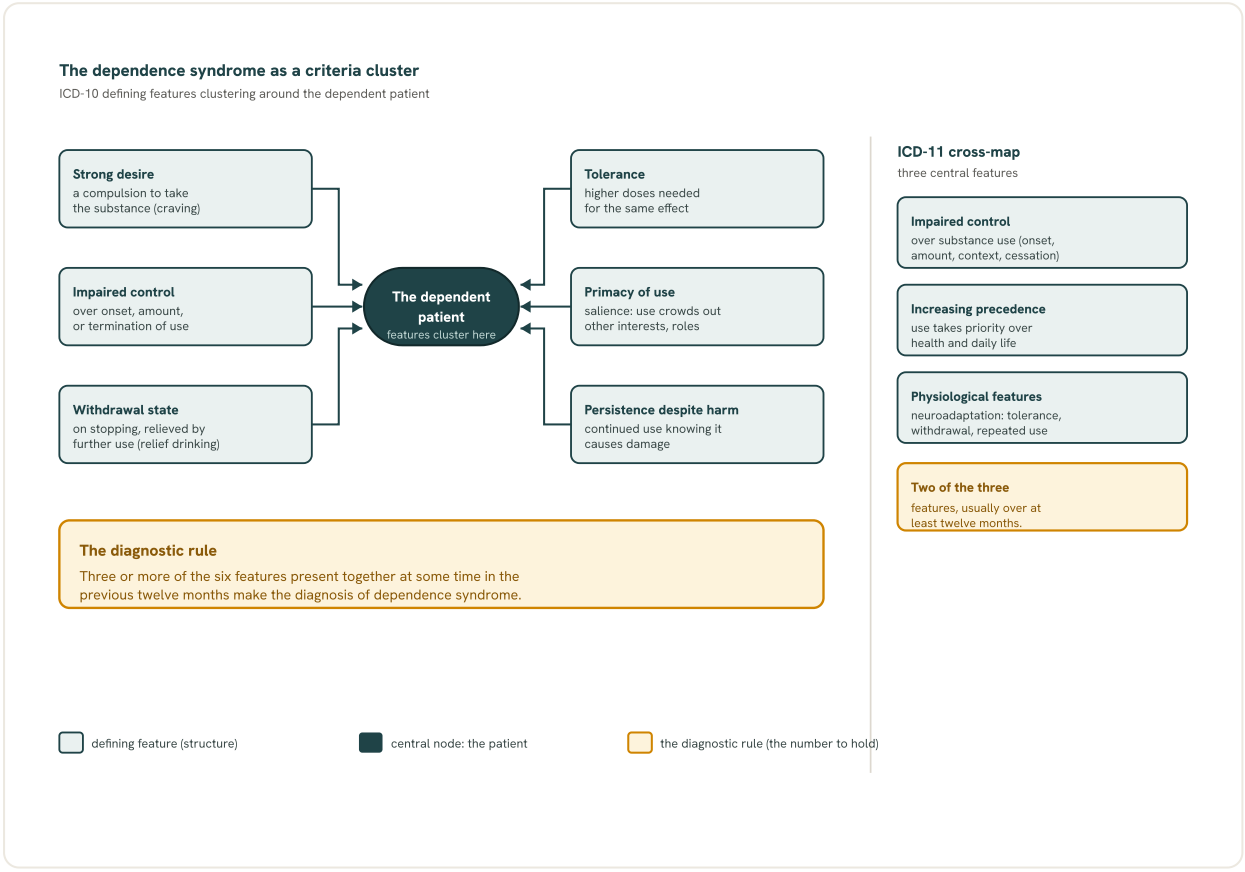

Fig 13.1 The dependence syndrome: the criteria cluster and the ICD-11 cross-map. In ICD-10 the dependent patient sits at the centre of six defining features: a strong desire or compulsion to use, impaired control, a physiological withdrawal state, tolerance, primacy or salience of use over other interests, and persistence despite clear harm. The rule to hold, in the marigold chip, is that three or more of these clustering together at some time in the previous twelve months make the diagnosis. ICD-11 reduces this to three central features, requiring two of three: impaired control, increasing precedence of use, and physiological features of neuroadaptation (tolerance, withdrawal, or repeated use to relieve or avoid withdrawal).

1.1 The two ICD-10 categories: harmful use is damage, dependence is capture

Harmful use (F1x.1). Harmful use is a pattern of psychoactive substance use that is actually causing damage to health, where the damage may be to **physical health** (for example alcoholic hepatitis, or a bloodborne infection from injecting) or to **mental health** (for example a substance-induced depressive episode) (WHO 1992; Shorter Oxford 2018). The harm must be real and demonstrable, not merely disapproved of by others: social or legal consequences alone do not make the diagnosis. Critically, in ICD-10 harmful use and dependence are mutually exclusive at any one time; if dependence is present, that is the diagnosis and harmful use is not coded alongside it.

Dependence syndrome (F1x.2). The dependence syndrome is a cluster of behavioural, cognitive and physiological phenomena that develop after repeated use, in which the substance takes on a far higher priority for the person than behaviours that once had greater value (WHO 1992). It is the more severe, self-perpetuating end of the spectrum, and it is defined by counting criteria, not by quantity consumed. A person can drink heavily and be harmful-use only; another can drink less but meet dependence.

RULE **Count the criteria, not the units.** Dependence is diagnosed by the clustering of the defining features, never by how much a person drinks or uses; a modest intake with three clustering features is dependence, a large intake without them is not.

1.2 The icd-10 dependence definition: three or more of six, clustering within a 12-month period

The counting rule. A diagnosis of the **icd-10 dependence** syndrome is made if **three or more** of six defining features have been experienced or exhibited together at some time during the previous **12 months** (WHO 1992; Shorter Oxford 2018). Three is the threshold and twelve months is the window; both are examinable and both are frequently mis-stated. The features must cluster, meaning present together within that year, not scattered across a lifetime.

The six features. They are: a strong desire or sense of **compulsion** to take the substance; impaired control over its use (onset, termination or level of use); a physiological withdrawal state on cessation or reduction; evidence of tolerance; the **primacy** of use, that is progressive neglect of alternative pleasures or interests plus increasing time spent obtaining, using or recovering from the substance; and persistence despite clear evidence of overtly harmful consequences. This is the criterion set to hold cold, and the concept figure lays out all six as a cluster (Fig 13.1).

ICD-10 DEPENDENCE CRITERION (THREE OR MORE WITHIN 12 MONTHS)	WHAT IT MEANS CLINICALLY
1. Strong desire or sense of compulsion	Craving; a felt drive to use, often triggered by cues.
2. Impaired control	Difficulty controlling onset, termination or level of use; using more or longer than intended.
3. Physiological withdrawal state	Characteristic withdrawal on stopping or reducing, or using the substance (or a related one) to relieve or avoid it.
4. Tolerance	Increased doses needed to achieve the effect once produced by lower doses.
5. Primacy / salience	Progressive neglect of alternative pleasures and interests; more time to obtain, use or recover from the substance.
6. Persistence despite harm	Continued use despite clear evidence of overtly harmful physical or mental consequences.

The six ICD-10 (F1x.2) dependence features; any three clustering within a 12-month period make the diagnosis (WHO 1992).

MNEMONIC

WITHDRAWAL → but memorise as the "3 C's + 3": Compulsion, impaired Control, and Continued use despite harm, plus the physiological trio of tolerance, withdrawal, and salience.

The three cognitive-behavioural features (compulsion, impaired control, persistence despite harm) sit alongside the physiological and priority features (tolerance, withdrawal, primacy/salience). Any three of the six, clustering in a year, suffice.

HOLD THIS

ICD-10 dependence syndrome = three or more of six features (compulsion, impaired control, physiological withdrawal, tolerance, primacy/salience, persistence despite harm) clustering together at some time in the previous 12 months; count criteria, never units.

1.3 The seven criteria question: why the count is six, not seven, and where "seven" comes from

Six, not seven. A recurring trap is the "**seven criteria**" phrasing. ICD-10 dependence has **six** defining features; the answer to "how many dependence criteria in ICD-10?" is six, with a threshold of three. The number seven belongs to a different classification: the older DSM-IV substance *dependence* also listed seven criteria, and DSM-5 substance use disorder collapsed abuse and dependence into a single list of eleven criteria (with two or more needed, and a severity gradient of two to three mild, four to five moderate, six or more severe). If a stem says "seven criteria" it is testing whether you can keep the systems apart.

Keep the systems distinct. ICD-10 keeps harmful use and dependence as two separate categories; DSM-5 merged them into one dimensional disorder. This is the single most common point of confusion, so anchor to it: ICD-10 = harmful use plus a six-feature dependence syndrome; DSM-5 = one substance use disorder with eleven criteria; the phrase "seven criteria" is the DSM-IV dependence relic.

TRAP **Reciting seven criteria for ICD-10 dependence.** ICD-10 dependence has six features (threshold three); "seven criteria" is DSM-IV dependence, and DSM-5 has eleven for a single substance use disorder.

1.4 Tolerance and the physiological withdrawal state: neuroadaptation, not addiction by itself

Tolerance. Tolerance is the need for increasing doses to achieve the effect once produced by lower doses, reflecting neuroadaptation of receptor systems. It is one of the two physiological features and, on its own, does not equal dependence: a patient on chronic opioid analgesia or a benzodiazepine may show tolerance and a withdrawal state (physical dependence) without the compulsion, impaired control and salience that define the syndrome (DSM-5-TR 2022, which is explicit that prescribed-drug tolerance and withdrawal are normal responses and do not by themselves indicate addiction).

The physiological withdrawal state. This is the characteristic, substance-specific syndrome appearing on cessation or reduction, or the use of the same or a closely related substance to

relieve or avoid it (the "relief use" clause). The quality and severity of withdrawal are set by the substance class, and avoidance of withdrawal becomes a powerful driver of continued use. The detailed time-courses and management of alcohol, opioid and sedative withdrawal are developed in the withdrawal and management topics; here the point is only that physiological features are one arm of the syndrome, not the whole of it.

PEARL

Physical dependence (tolerance plus a withdrawal state) is not the same as the dependence syndrome. A person can be physically dependent on a legitimately prescribed drug without addiction; the syndrome needs the behavioural core, compulsion, impaired control and salience, as well.

1.5 Primacy and salience: the behavioural heart of the syndrome

Salience of drug use. Salience, also called primacy, is the feature in which the substance takes priority over behaviours that once mattered more: work, relationships, health and other pleasures are progressively neglected, and more and more of the day is given to obtaining, using and recovering from the substance. In Edwards and Gross's original description this "narrowing of the repertoire" and salience of drink-seeking was the signature of the syndrome, and it remains the feature that most distinguishes dependence from heavy but still-controlled use.

Compulsion and impaired control. The two other behavioural features are the strong desire or compulsion to use (craving) and impaired control over onset, termination and level of use. Together, compulsion, impaired control and salience form the psychological core of the syndrome; tolerance, withdrawal and persistence-despite-harm form the reinforcing shell around it. This is exactly the split that carries into ICD-11.

RULE **Salience is the discriminator.** When the substance has climbed above health, work and relationships in a person's priorities, you are looking at dependence, not harmful use, however modest the reported quantity.

1.6 The cross-map to ICD-11: three central features, two of three needed

The ICD-11 dependence concept. ICD-11 keeps dependence but streamlines the six ICD-10 features into three central features, requiring **two or more** of them (WHO ICD-11 CDDR 2024). The **icd-11 criteria** for dependence are: impaired control over substance use (onset, frequency, intensity, duration, termination, context); increasing precedence of substance use over other aspects of life, that is salience, such that use continues or escalates despite harm; and physiological features indicative of neuroadaptation, namely tolerance, withdrawal, or repeated use to relieve or prevent withdrawal (note that physiological features apply only to certain substances).

The time frame. ICD-11 features are usually evident over at least 12 months, but the diagnosis may be made if use is continuous (daily or almost daily) for at least 3 months. So the six ICD-10 criteria collapse cleanly: compulsion folds into impaired control, primacy/salience becomes

"increasing precedence", and tolerance plus withdrawal become the single "physiological features" arm. Two of these three make ICD-11 dependence.

ICD-10 DEPENDENCE (SIX; NEED THREE)	ICD-11 DEPENDENCE (THREE CENTRAL; NEED TWO)
Strong desire / compulsion	**Impaired control over substance use**
Impaired control	
Physiological withdrawal state	**Physiological features of neuroadaptation (tolerance or withdrawal)**
Tolerance	
Primacy / progressive neglect (salience)	**Increasing precedence of use over life (salience)**
Persistence despite overtly harmful consequences	Subsumed within the above features and their harm clause

How the six ICD-10 dependence features map onto the three central ICD-11 features; ICD-11 needs two of three (WHO 1992; ICD-11 CDDR 2024).

1.7 ICD-11 harmful pattern of use: harm to others is now explicit

The renamed category. ICD-10 "harmful use" becomes ICD-11 harmful pattern of use. Its essential feature is a pattern of continuous, recurrent or sporadic use that has caused clinically significant damage to a person's physical or mental health *or has resulted in behaviour leading to harm to the health of others* (ICD-11 CDDR 2024). The explicit inclusion of harm to others (for example harm from drink-driving or violence during intoxication) is the key ICD-11 change from ICD-10, which framed harm as being to the user's own health only.

The time frame. The harmful pattern must be evident over at least 12 months if use is episodic, or at least 1 month if use is continuous (daily or almost daily). ICD-11 also adds an intermediate risk category, a "single episode of harmful use", below the harmful-pattern threshold, which has no ICD-10 equivalent.

COMMON TRAP

Do not confuse ICD-11 "harmful pattern of use" (a diagnosis requiring demonstrable harm to health) with "hazardous use", which is a risk-level term for a pattern that increases the risk of harm but has not yet caused it. Hazardous use sits in the ICD-11 risk factors chapter, not among the substance-use disorders.

1.8 Screening at the harmful-use end: AUDIT, CAGE and where the cut-offs sit

Why screen here. Harmful and hazardous use are precisely where brief intervention works and where screening instruments earn their place, because these patterns are common, often unrecognised, and reversible before dependence is entrenched. Two instruments dominate the exam. The full instrument forms are reproduced in the scales gallery, so only what they are and their cut-offs are given here.

The two to hold. The AUDIT (Alcohol Use Disorders Identification Test) is a 10-item WHO screen; a score of **8 or more** indicates hazardous or harmful drinking, and NICE advises a comprehensive assessment for anyone scoring above 15. The CAGE is a four-item bedside screen

(Cut down, Annoyed, Guilty, Eye-opener) taking one to two minutes; a score of **2 or more** positive answers is clinically significant and warrants fuller assessment (NICE 2011). Dependence-severity and withdrawal-severity scales (SADQ, CIWA-Ar) belong to the withdrawal topics, not to screening.

3 of 6 ICD-10 DEPENDENCE THRESHOLD, WITHIN 12 MONTHS	**2 of 3** ICD-11 DEPENDENCE CENTRAL FEATURES	**8** AUDIT HAZARDOUS OR HARMFUL-USE CUT-OFF	**2** CAGE POSITIVE-ANSWER CUT-OFF

INDIA

India carries a very large substance-use treatment gap: most people meeting dependence criteria never reach formal care, and services concentrate in the government de-addiction centres and a handful of Drug De-addiction Programme (DDAP) units rather than in general practice. The legal frame is the Narcotic Drugs and Psychotropic Substances Act, 1985 (Act 61 of 1985, in force 16 September 1985; the medico-legal detail is developed in the Mental health legislation and forensic psychiatry notes), which lists cannabis, cocaine, opium, poppy straw and 76 scheduled psychotropics including diazepam, pentazocine and phenobarbital. The practical consequence for diagnosis is that the harmful-use category matters greatly here: brief, motivation-based intervention delivered by trained non-specialist workers, closing the gap at the point where use is damaging but dependence is not yet fixed, is the strategic priority the IPS substance-use guidelines emphasise (IPS 2014). Buprenorphine is the workhorse of Indian opioid-agonist treatment precisely because methadone access is limited, and its induction detail belongs to the substitution topics.

WORKED EXAMPLE

A 34-year-old lorry driver reports drinking most evenings. He describes a strong pull to drink after work (compulsion), repeatedly drinking more than he plans (impaired control), morning shakes relieved by an early drink (a physiological withdrawal state with relief use), needing far more than before to feel the effect (tolerance), and having given up cricket and family evenings for drinking (salience). That is five of the six ICD-10 features clustering within the year, well past the threshold of three: this is the dependence syndrome, not harmful use, and the plan must consider assisted withdrawal and relapse prevention, not brief advice alone. Map it to ICD-11 and he meets all three central features; two would have sufficed.

GOOD TO REMEMBER

- **Dependence syndrome (ICD-10 F1x.2):** three or more of six features (compulsion, impaired control, withdrawal, tolerance, primacy/salience, persistence despite harm) clustering within 12 months; the discriminator from harmful use is salience, the substance climbing above health, work and relationships; first step on recognising it is to assess withdrawal risk and the need for assisted withdrawal.
- **Harmful use (ICD-10 F1x.1) / harmful pattern (ICD-11):** a pattern actually causing demonstrable damage to physical or mental health; the ICD-11 change is that harm to the health of others now counts too; the discriminator from dependence is the absence of the dependence cluster; first step is brief, motivation-based intervention.
- **ICD-11 dependence:** two or more of three central features (impaired control, increasing precedence/salience, physiological features of neuroadaptation); evident over 12 months, or 3 months if continuous daily use; the one number to hold is two of three.
- **The "seven" trap:** ICD-10 dependence has six criteria (threshold three); "seven criteria" is DSM-IV dependence; DSM-5 merged abuse and dependence into one substance use disorder with eleven criteria (threshold two, graded mild/moderate/severe).

2 · ICD-11 changes in substance use disorders

The **icd-11 changes** to the substance use disorders are the single most exam-friendly restructuring in the whole chapter, because they turn the old two-box ICD-10 scheme (harmful use versus dependence) into a graded ladder that begins *before* any harm has occurred and rises through a discrete harm event to an entrenched pattern to full dependence. The examiner tests this as a discrimination task: given a vignette, can you place the drinker or the drug user in the right **icd-11 substance** category, and can you say why it is not the neighbouring one. The two genuinely new pieces are the **single episode of harmful use** (a one-off harm event, not a settled pattern) and **hazardous use** (increased risk but no harm yet, and deliberately *not* a mental disorder at all). This is a nosology topic, so the payload is criteria and boundaries; the reward-pathway mechanics behind why the ladder exists sit in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes, the substance-induced psychotic boundary in the Other psychotic disorders, delusional syndromes and catatonia notes, and the NDPS medico-legal frame in the Mental health legislation and forensic psychiatry notes.

How to use this page. Fix the four rungs of the ladder first, in order (hazardous use, episode of harmful use, harmful pattern, dependence), then the discriminators that separate each rung from the one above and below it, then the ICD-10-to-ICD-11 crosswalk, then how ICD-11 lines up against the DSM-5-TR single dimensional use disorder. The one clause that carries most of the marks is the boundary between an **episode of harmful use** and a harmful *pattern*: a single discrete harm event versus harm from a use pattern running over roughly twelve months.

2.1 The old ICD-10 dichotomy this replaces

Two boxes: harmful use and dependence. ICD-10 gave each substance class a small fixed set of clinical conditions, of which the two the examiner cares about were **harmful use** (F1x.1) and the dependence syndrome (F1x.2), alongside acute intoxication, withdrawal, withdrawal with delirium, psychotic disorder and the amnesic syndrome (Companion to Psychiatric Studies). Harmful use required actual damage to physical or mental health from the substance; below that

threshold ICD-10 offered nothing to code, so the person who was drinking dangerously but had not yet come to harm fell through the classification entirely. Dependence was operationalised from Edwards and Gross's **alcohol dependence syndrome** (1976) as a cluster requiring three or more of six features over the past year. The whole scheme was therefore a two-step: harm, or the syndrome, and nothing in between or before.

GOOD TO REMEMBER

- **ICD-10 dependence syndrome (the discriminator against harmful use):** three or more of six features (compulsion/craving, impaired control, physiological withdrawal, tolerance, salience/neglect of alternatives, persistence despite harm) for at least one month or repeatedly within twelve months; the feature to hold is that dependence needs the *cluster*, whereas harmful use needs only demonstrated *harm*; the source is Edwards & Gross (1976).

2.2 The ICD-11 restructuring: a graded ladder

Four rungs instead of two boxes. The core of the **icd-11 changes** is that each substance class (6C40 alcohol, 6C43 opioids, 6C41 cannabis, and so on) now carries a graded set of disorders due to substance use, and the WHO in ICD-11 identifies acute intoxication, harmful use, dependence syndrome, withdrawal state (with or without delirium), substance-induced psychotic disorder, substance-induced amnesic disorder and the residual categories (Maudsley Prescribing Guidelines, ICD-11 CDDR). What is new is that "harmful use" itself has been *split* into two levels, a discrete **episode of harmful use** and a settled **harmful pattern of use**, and a pre-harm category, hazardous use, has been added outside the mental-disorders chapter entirely. Read as a ladder, an icd-11 substance presentation climbs: hazardous use (risk, no harm, not a disorder) then episode of harmful use (one harm event) then harmful pattern of use (harm from a pattern) then dependence (the neuroadaptive syndrome).

RUNG	ICD-11 CATEGORY (ALCOHOL CODE)	THE ONE-LINE DISCRIMINATOR
1. Hazardous use	QE10 (Chapter 24, not a disorder)	**Risk of harm appreciably raised, but no harm has yet occurred; a health-behaviour problem, not a mental disorder**
2. Episode of harmful use	6C40.0	**A single discrete episode of use has caused clinically significant harm to the user's health or, via intoxicated behaviour, to others**
3. Harmful pattern of use	6C40.1 (episodic/continuous)	**Harm arises from a recurrent or continuous pattern of use, generally over at least 12 months**
4. Dependence	6C40.2 (with course specifiers)	**Two of three core features (impaired control, increasing precedence, neuroadaptation); the internal driven syndrome, not merely its harms**

The ICD-11 ladder for each substance class, alcohol codes shown; the reward-circuit basis for the climb is in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes (ICD-11 CDDR).

RULE **Grade by harm and pattern, not by drug alone.** The ICD-11 category is fixed by whether harm has occurred (none = hazardous; some = harmful) and whether it comes from a single episode or a sustained pattern, then by whether the dependence features are present, in that order.

2.3 The single episode of harmful use (new)

A one-off harm event, coded before a pattern is established. The **single episode of harmful use** (6C40.0 for alcohol) is diagnosed when a *single* episode of use of a psychoactive substance has caused clinically significant damage to the person's physical health (for example a bloodborne infection from one instance of intravenous self-administration), or mental health (a substance-induced mood disturbance), or has led, through intoxicated behaviour, to harm to the health of others (an assault, or a road traffic accident from impaired driving) (ICD-11 CDDR). There must be a clear causal link between the harm and that episode, and the harm must not be better explained by another condition. Crucially, this category exists precisely so that a clinician can code a first, discrete harmful event *without* having to assert a pattern that the history does not yet support; if no information about the pattern of use is available, an **episode of harmful use** may be coded until evidence of a pattern emerges, at which point the diagnosis is revised upward to harmful pattern or dependence. It is a deliberate hook for early, low-intensity intervention.

TRAP **Coding a single harm event as a harmful pattern.** One discrete harmful episode is 6C40.0 (episode of harmful use); "harmful pattern" needs a recurrent or continuous pattern over roughly twelve months. Reserve the pattern code for when the history actually shows one.

GOOD TO REMEMBER

- **Episode of harmful use (the diagnosis):** a single episode of substance use causing clinically significant harm to the user's physical or mental health, or to others via intoxicated behaviour; the discriminator from harmful pattern is *single/discrete versus recurrent-or-continuous*; the first-management step is a brief low-intensity intervention, and the code is revised upward once a pattern is shown.

2.4 Harmful pattern of use, and the 12-month boundary

Harm from a pattern, not from one occasion. The harmful pattern of use (6C40.1, specified as episodic or continuous) is assigned when the harm to physical or mental health results from a *known episodic or continuous pattern* of substance use and all other requirements are met. ICD-11 sets the operational threshold explicitly: substance use is generally considered to follow a pattern if there has been at least episodic or intermittent use over a period of **at least 12 months** (ICD-11 CDDR). This is the boundary the examiner probes. Below the pattern threshold but with a single demonstrable harm you are at "episode of harmful use"; above it, with harm attributable to the ongoing pattern, you are at "harmful pattern"; and if the neuroadaptive dependence features are present you climb again to dependence regardless of how the harm is distributed.

GOOD TO REMEMBER

- **Harmful pattern of use (the diagnosis):** clinically significant harm arising from a recurrent (episodic) or continuous pattern of use, the pattern generally running over at least twelve months; the discriminator downward is the single-episode category, upward is the presence of dependence features; specify episodic or continuous.

2.5 Hazardous use: risk without harm, and not a disorder

The pre-harm rung, deliberately outside the mental-disorders chapter. Hazardous use (QE10 hazardous alcohol use, QE11 hazardous drug use) is the genuinely conceptual novelty: a pattern of use that appreciably increases the risk of harmful physical or mental health consequences, to the user or to others, to a degree warranting attention and advice from health professionals, but where *no overt harm has yet occurred* (ICD-11 CDDR). Because there is as yet no harm and no syndrome, ICD-11 does *not* classify it as a mental or behavioural disorder at all; it is placed in Chapter 24, among "problems associated with health behaviours" (factors influencing health status or contact with health services). The raised risk may come from the frequency of use, the amount per occasion, a risky route of administration, or the context of use, and the pattern often persists despite the person's awareness of it. Its clinical point is to license a coded screening-and-brief-advice contact before any damage is done, exactly the population that an AUDIT score in the hazardous band identifies.

TRAP **Treating hazardous use as a mild substance use disorder.** Hazardous use is *not* a mental disorder in ICD-11; it lives in Chapter 24. The moment demonstrable harm appears, the person moves out of QE10/QE11 and into the 6C4x harmful-use categories.

PEARL

The cleanest way to hold the split: hazardous use is *risk, no harm, not a disorder*; episode of harmful use is *harm from one occasion*; harmful pattern is *harm from a pattern*; dependence is *the syndrome, whatever the harm*. The single question that sorts the first two from the last two is simply: has harm actually occurred yet?

2.6 The ICD-11 dependence syndrome: two of three

Streamlined to three core features, and the harms stripped out. ICD-11 dependence is defined by three core features, of which *two or more* must usually be present together over at least twelve months, or if use is continuous (daily or almost daily) for at least three months (ICD-11 CDDR). The three are: (a) *impaired control* over substance use (onset, frequency, intensity, duration, termination, context); (b) *increasing precedence* of substance use over other aspects of life, so that use continues or escalates despite harm; and (c) *physiological features of neuroadaptation*, that is tolerance, withdrawal on cessation, or repeated use to relieve or prevent withdrawal. Two structural moves distinguish this from ICD-10's six-item, three-required list: the criterion count is smaller and tighter, and the old "persistence despite harmful consequences" and craving are folded into precedence rather than standing as separate boxes. ICD-11 also warns explicitly that physiological features alone (tolerance and withdrawal from appropriately prescribed opioids for

cancer pain, say) do *not* make a dependence diagnosis; either impaired control or increasing precedence must also be present.

MNEMONIC

CPN: Control, Precedence, Neuroadaptation

Control impaired, substance takes **P**recedence over life, and **N**euroadaptation (tolerance/withdrawal): any *two* of these three, over roughly twelve months (or three months if near-daily), is ICD-11 dependence. Neuroadaptation on its own is never enough.

GOOD TO REMEMBER

- **ICD-11 dependence syndrome (the diagnosis):** two of three core features (impaired control; increasing precedence; physiological neuroadaptation = tolerance/withdrawal) present together, usually over twelve months or over three months if use is continuous; the discriminator from ICD-10 is the tighter three-feature/two-required structure; the trap-guard is that neuroadaptation alone does not qualify.

2.7 Course specifiers and the intoxication/withdrawal categories

Remission and pattern are now coded, not just noted. Beyond the four rungs, ICD-11 attaches structured specifiers that ICD-10 lacked. Dependence carries pattern-and-remission specifiers: current use (for alcohol, distinguished as continuous or episodic), early full remission (abstinent 1 to 12 months after a diagnosis), sustained partial remission and sustained full remission (more than 12 months) (ICD-11 CDDR). The acute states are retained and sharpened: substance intoxication and substance withdrawal each have their own codes, and withdrawal may be specified with perceptual disturbances or with delirium, which keeps the withdrawal-delirium (delirium tremens) presentation visible within the coding. The amnesic and psychotic sequelae become *substance-induced* amnesic disorder and substance-induced psychotic disorder. The effect is a scheme that records not just "which disorder" but "at what stage and in what state," which is what the graded ladder was designed to support.

2.8 ICD-11 versus DSM-5-TR: two philosophies

ICD-11 keeps categories; DSM-5 went dimensional. The two systems diverged deliberately. DSM-5 (and DSM-5-TR) *eliminated* the DSM-IV split of abuse and dependence and replaced it with a single overarching **substance use disorder** per drug, rated on a continuum from mild to severe by counting how many of eleven criteria are met, with two or more required for the diagnosis (DSM-5-TR 2022; Shorter Oxford Textbook of Psychiatry). ICD-11 kept a *categorical* structure but graded it into the ladder above, so that the two classifications no longer map one-to-one: a DSM-5 mild use disorder (two to three criteria) corresponds roughly to the ICD-11 harmful-pattern band, while moderate-to-severe DSM-5 disorder maps toward ICD-11 dependence (Kaplan & Sadock 2024). DSM-5 also folded craving in as a new criterion and dropped the old legal-problems criterion. The exam-usable summary: DSM-5 answers "how severe, on one scale," while ICD-11 answers "which category on the harm-and-dependence ladder."

FEATURE	ICD-11	DSM-5-TR
Overall structure	Categorical, graded ladder	**Single dimensional use disorder per drug**
Sub-harm risk category	Hazardous use (Chapter 24, not a disorder)	**None (no pre-harm category)**
Harm level	Episode of harmful use / harmful pattern of use	**Captured within mild/moderate use disorder**
Dependence / severe end	Dependence: 2 of 3 core features	**Severity by count of 11 criteria (2+ = disorder)**
Craving	Within "increasing precedence"	**A separate, explicitly added criterion**

The two classifications answer different questions; the crosswalk is approximate, not one-to-one (DSM-5-TR 2022, Kaplan & Sadock 2024, ICD-11 CDDR).

2.9 Screening scales that map onto the ICD-11 rungs

The instruments sort people onto the ladder. The graded structure is clinically usable because the standard screens read out roughly where a person sits. The AUDIT (10 items, each 0 to 4, maximum 40) flags **a score of 8 or more** as hazardous or harmful alcohol use, exactly the QE10-to-6C40.1 zone (Maudsley Prescribing Guidelines). The CAGE (four items) takes **2 or more** positive answers as identifying a problem drinker, quick enough for a busy clinic at one to two minutes. The SADQ (Severity of Alcohol Dependence Questionnaire, 20 items scored 0 to 3, maximum 60) grades dependence severity itself and informs the size of the withdrawal benzodiazepine regimen. The instrument forms are reproduced centrally in the scales gallery; here only the verified cut-offs matter.

8	2	12 months
AUDIT HAZARDOUS/HARMFUL CUT-OFF (MAX 40)	CAGE POSITIVE-SCREEN THRESHOLD (OF 4)	USE-PERIOD DEFINING A HARMFUL PATTERN

GOOD TO REMEMBER

- **AUDIT (scale):** 10 items, 0 to 4 each, maximum 40; the discriminator is a score of 8 or more, suggesting hazardous or harmful use; the cut-off to hold is 8.
- **CAGE (scale):** 4 items; the discriminator is 2 or more positive answers identifying a problem drinker; the number to hold is 2, in a 1 to 2 minute screen.

2.10 Anti-craving pharmacotherapy as the ladder's treatment end

The dependence rung is where relapse-prevention drugs are anchored. The classification is not just descriptive: the dependence category is the one that indicates maintenance anti-craving pharmacotherapy after medically assisted withdrawal, so the highest rung and the drug decision are linked. The three long-established agents for alcohol dependence are acamprosate (Acamprol), naltrexone (Nodict or Naltima) and disulfiram (Esperal or Dizone), all used with psychosocial support (BAP 2026, NICE 2011, Maudsley Prescribing Guidelines). Naltrexone reduces craving and heavy drinking but must not be started within a week of any opioid use, because it precipitates opioid withdrawal in an opioid-dependent person; disulfiram is an

aversive agent reserved for motivated, abstinence-goal, supervised patients and started at least 24 hours after the last drink; acamprosate maintains abstinence and is safe in liver disease but needs renal caution. The full withdrawal and opioid-substitution detail is owned by the other Day-13 treatment topics; here the point is only that the ICD-11 dependence category is the gate to these drugs.

GOOD TO REMEMBER

- **Naltrexone (Nodict/Naltima):** opioid-receptor antagonist reducing craving and heavy drinking; the signature caution is precipitated opioid withdrawal, so start only after at least one opioid-free week; oral maintenance **50 mg/day**.
- **Acamprosate (Acamprol):** glutamatergic NMDA-modulating anti-craving agent to maintain abstinence; the caution is renal impairment; dose **1998 mg/day** (666 mg three times daily) if over 60 kg, 1332 mg/day if under.
- **Disulfiram (Esperal/Dizone):** aldehyde-dehydrogenase inhibitor giving an aversive reaction with alcohol; reserve for motivated, supervised, abstinence-goal patients and start at least 24 hours after the last drink; dose **250 to 500 mg/day**.

INDIA

The ICD-11 ladder matters more in India than in most settings because of the sheer **treatment gap**: the large majority of people with alcohol and drug use disorders never reach care, and the graded scheme is built to catch them earlier, at the hazardous-use and single-episode rungs, through brief interventions in general and primary care rather than only at the dependence end. Indian de-addiction practice has long run on the ICD tradition (the F1x harmful-use and dependence codes are what the standard Indian teaching texts use), so the shift is evolutionary: the familiar harmful-use/dependence pair simply gains a pre-harm rung (hazardous use) and a split of harmful use into episode and pattern. The de-addiction centre and the Drug De-addiction Programme model, and the IPS substance-use clinical practice guidelines, are the service context; the NDPS Act frame that governs who can hold and dispense controlled drugs (and constrains buprenorphine and opioid-substitution access) is cross-referenced to the Mental health legislation and forensic psychiatry notes. Anti-craving generics are affordable and widely stocked; lead with the Indian brand and verify it locally before naming one.

HOLD THIS

ICD-11 replaces the ICD-10 harmful-use/dependence dichotomy with a graded ladder: hazardous use (risk, no harm, a Chapter-24 health-behaviour problem, not a mental disorder), then a single episode of harmful use (one discrete harm event, 6C40.0), then harmful pattern of use (harm from a pattern over about 12 months, 6C40.1), then dependence (two of three core features, impaired control / increasing precedence / neuroadaptation, over 12 months or 3 months if near-daily, 6C40.2 with remission specifiers); DSM-5-TR instead uses one dimensional use disorder graded mild-to-severe by counting 2 or more of 11 criteria.

3 . The neurobiology of addiction

Why this leads the substance block. The **neurobiology of addiction** is the mechanistic spine that makes every later topic legible: it explains why tolerance escalates use, why abstinence hurts, why craving outlives detoxification, and why a relapse-prevention agent has anything to aim at.

Addiction is best understood not as a failure of will but as a learned **reward pathway** disorder in which a normal survival circuit is hijacked by drugs that flood it with **dopamine** more explosively than any natural reward can (Stahl's Substance Use 2020). The examiner reward is a small, high-yield set: the **mesolimbic** circuit from the **ventral tegmental** area to the **nucleus accumbens**, the dopamine surge that all drugs of abuse share, the **incentive-sensitisation** account of **craving**, and Koob and Volkow's three-stage cycle. Get this frame right and intoxication, withdrawal, negative affect and relapse all fall out of one diagram.

This fragment teaches the anatomy of reward, then the dopamine signal that unifies all drugs of abuse, then the incentive-sensitisation model that separates wanting from liking, and finally the three-stage addiction cycle that maps the whole disorder onto three brain networks. The deep monoamine and second-messenger anatomy of the reward-pathway circuit sits in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; here we teach the addiction application. This topic carries Fig 13.2, the reward-circuit and three-stage-cycle schematic.

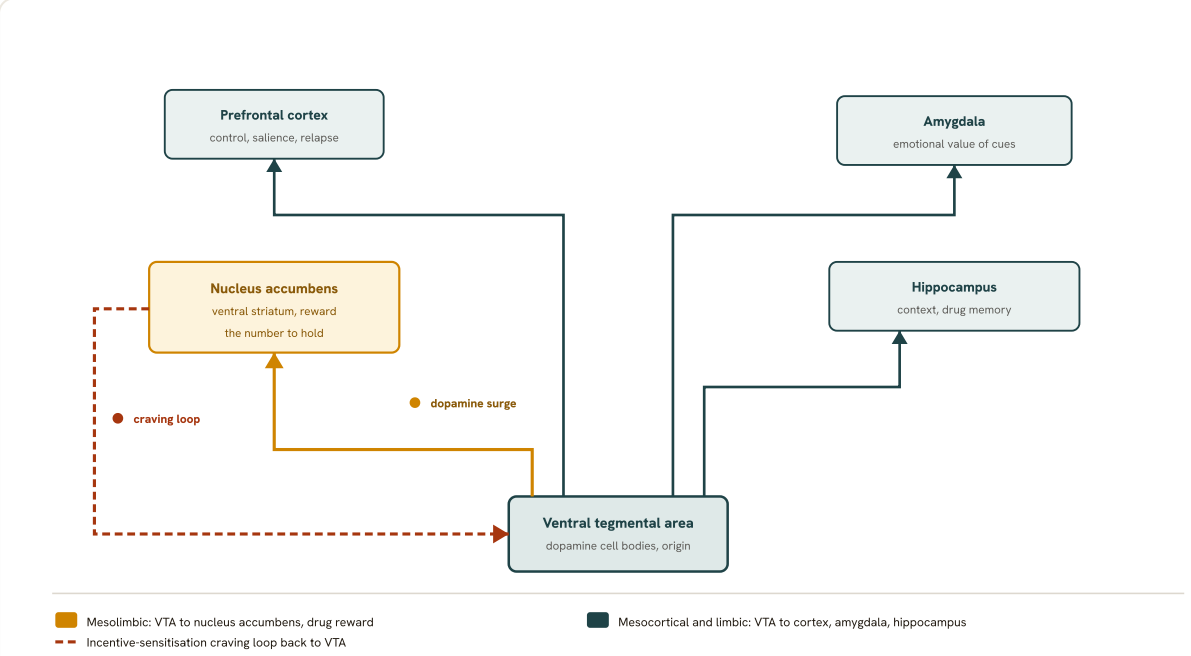

Fig 13.2 The mesolimbic reward circuit and the neurobiology of addiction. Dopamine cell bodies in the ventral tegmental area project along the mesolimbic tract to the nucleus accumbens, where drug reward drives a dopamine surge far larger than any natural reinforcer. Parallel projections reach the prefrontal cortex (control and salience), the amygdala (emotional value of drug cues) and the hippocampus (drug-associated context and memory). With repeated use the accumbens-driven incentive-sensitisation loop feeds back to the ventral tegmental area, so cues alone come to trigger craving even after the drug is stopped.

3.1 The mesolimbic reward pathway: the anatomy to hold

VTA to nucleus accumbens. The core of the reward system is the mesolimbic dopamine pathway, which runs from dopamine cell bodies in the ventral tegmental area (VTA) of the midbrain to the nucleus accumbens (NAc) in the ventral striatum (Stahl's Substance Use 2020; Kaplan and Sadock 2024). This projection is "central to reward": naturally rewarding activities such as a good meal or a major accomplishment cause fast, large increases in dopamine here, and drugs of abuse hijack the same wire (Stahl's Substance Use 2020). Two neighbouring dopamine

pathways round out the picture without being the reward core: the nigrostriatal pathway (substantia nigra to dorsal striatum), which the transition to compulsive, habit-like use recruits, and the mesocortical pathway (VTA to prefrontal cortex), which supplies the top-down control that addiction erodes (Stahl's Substance Use 2020). The VTA-NAc line is the phrase to reproduce; the amygdala links reward learning to it, and the prefrontal cortex regulates it from above.

RULE **One wire, hijacked.** The reward pathway is the mesolimbic dopamine projection from the ventral tegmental area to the nucleus accumbens; drugs of abuse do not build a new circuit, they seize the survival circuit that already exists.

3.2 The dopamine surge: the final common pathway of drug reward

All drugs of abuse raise accumbens dopamine. Whatever their molecular target, every major drug of abuse increases dopamine in the nucleus accumbens, either directly or indirectly (Stahl's Substance Use 2020). This shared endpoint is why chemically unrelated substances produce a common syndrome. The routes differ: stimulants block the dopamine transporter or release dopamine directly; opioids disinhibit VTA dopamine neurons by inhibiting the GABA interneurons that restrain them; nicotine directly stimulates nicotinic receptors on VTA dopamine neurons; alcohol and cannabinoids act more indirectly through GABA, glutamate and endocannabinoid modulation (Stahl's Substance Use 2020). Crucially, drugs raise dopamine "in a manner that is more explosive and pleasurable than that which occurs naturally," and it is the abrupt, large, phasic rise, not the mere presence of dopamine, that carries the reward and saliency signal (Stahl's Substance Use 2020).

DRUG CLASS	MOLECULAR TARGET	HOW ACCUMBENS DOPAMINE RISES
Stimulants (cocaine, amphetamines)	**Dopamine transporter (DAT)**	Blocks reuptake (cocaine) or drives release (amphetamine) at VTA-to-NAc terminals
Opioids	Mu-opioid receptor	**Disinhibits VTA dopamine neurons by inhibiting GABA interneurons**
Nicotine	Nicotinic receptor (alpha4 beta2)	Directly stimulates VTA dopamine neurons
Alcohol	Multiple (GABA, glutamate, opioid)	Facilitates GABAergic transmission and disinhibits dopamine indirectly
Cannabinoids	Cannabinoid CB1 receptor	Modulates dopamine signalling via CB1 in NAc and on GABA/glutamate terminals

Every drug of abuse converges on a dopamine rise in the nucleus accumbens by a different molecular route (Stahl's Substance Use 2020).

COMMON TRAP

Thinking dopamine equals pleasure. Dopamine encodes reward prediction and incentive salience ("wanting"), not the hedonic hit ("liking") itself, which is carried more by opioid and endocannabinoid signalling in accumbens hedonic hotspots. This distinction is the whole point of the incentive-sensitisation model below, and it is why craving can be intense while the drug no longer feels good.

3.3 Route and rate: why speed of onset drives addictiveness

Fast in, fast reward. The reinforcing effect of a drug is determined not only by how much dopamine it releases but by how fast the level rises, which is set by how quickly the drug enters the brain (Stahl's Substance Use 2020). Abrupt, large dopamine increases mimic the phasic firing that normally signals reward, so faster uptake means stronger reinforcement. This is why route of administration is a core addictiveness variable: intravenous injection and inhalation (smoking) give the fastest uptake, followed by snorting, then oral use (Stahl's Substance Use 2020). The same molecule is far more addictive smoked or injected than swallowed, which is the pharmacological logic behind harm-reduction shifts in route and behind the danger of smokable and injectable preparations.

3.4 Incentive sensitisation: wanting divorced from liking

The Robinson and Berridge model. The incentive-sensitisation theory (Robinson and Berridge) separates two dissociable psychological components that the folk model fuses: "liking," the hedonic pleasure a reward gives, and "wanting," the motivational pull toward it, technically termed **incentive salience** (Tasman 2015). Repeated drug exposure produces long-lasting sensitisation of the mesolimbic dopamine system, so the neural "wanting" signal grows and becomes attached to drug cues, while "liking" does not sensitise and often fades with tolerance. The result is the clinical paradox of addiction: the pull toward the drug becomes progressively more intense and cue-triggered even as the drug delivers less and less pleasure. This is the mechanistic account of pathological **craving**, especially the cue-evoked craving that survives detoxification and drives relapse long after withdrawal has passed.

Why cues matter clinically. Because incentive salience is stamped onto conditioned cues (people, places, paraphernalia, mood states), the sensitised "wanting" is reactivated by those cues rather than by an internal decision, which is why cue-exposure, environment change and stimulus control are built into relapse-prevention work (Tasman 2015). Incentive sensitisation is the bridge from the acute dopamine surge of first use to the durable, relapse-driving craving of established addiction.

MNEMONIC

WANT > LIKE

Incentive sensitisation = "wanting" (incentive salience, dopamine-driven, sensitises and attaches to cues) grows and outlasts "liking" (hedonic pleasure, opioid-driven, does not sensitise and fades with tolerance). Craving is sensitised wanting, not remembered liking.

3.5 The three-stage addiction cycle: the master framework

Binge, withdrawal, preoccupation. Koob and Volkow's cycle divides addiction into three recurring stages, each mapped to its own network and its own neurotransmitter shift (Kaplan and Sadock 2024). *Binge and intoxication* is the reward stage, driven by the basal ganglia, the nucleus accumbens and dorsal striatum, and dominated by the dopamine surge and positive reinforcement. *Withdrawal and negative affect* engages the extended amygdala (central amygdala, bed nucleus of the stria terminalis and the shell of the accumbens), where the brain stress systems, notably corticotropin-releasing factor and dynorphin, are recruited and reward is blunted, so the drug is now taken to relieve dysphoria (negative reinforcement). *Preoccupation and anticipation* is the craving stage, driven by the prefrontal cortex, orbitofrontal cortex, hippocampus and insula, where executive control fails and cue-triggered craving takes over (Kaplan and Sadock 2024).

Four neuroadaptations, one transition. The cycle summarises the transition to addiction as four combined changes: increased incentive salience, decreased reward, increased stress, and decreased executive function (Kaplan and Sadock 2024). Behaviourally, this is a progression from impulsive, positively reinforced use toward compulsive, negatively reinforced use driven by escape from a negative affective state (Stahl's Substance Use 2020).

STAGE	DOMINANT CIRCUIT	DRIVER / NEUROCHEMISTRY	REINFORCEMENT
Binge and intoxication	Basal ganglia (NAc, dorsal striatum)	**Dopamine surge; incentive salience**	Positive (pleasure/reward)
Withdrawal and negative affect	Extended amygdala (CeA, BNST, NAc shell)	**CRF and dynorphin up; reward down**	Negative (relief of dysphoria)
Preoccupation and anticipation	Prefrontal cortex, OFC, hippocampus, insula	**Executive dyscontrol; cue-driven craving**	Anticipatory (craving, relapse)

The three-stage addiction cycle, its networks, its neurochemistry and its reinforcement logic (Koob and Volkow, in Kaplan and Sadock 2024).

3.6 Opponent process: why abstinence turns painful

The b-process grows. The withdrawal stage is best explained by the opponent-process theory of motivation (Solomon and Corbit; Koob). Every hedonic state is automatically opposed by a counter-regulatory process: the positive drug response (the a-process) is fast, correlates with dose, and shows tolerance, while the opposing negative-affect response (the b-process) is slow to develop, slow to decay, and grows in magnitude with repeated exposure (Kaplan and Sadock 2024). With escalating use the b-process comes to dominate, so the baseline mood between doses drifts downward and the drug is increasingly taken not for euphoria but to cancel the withdrawal dysphoria the drug itself created. This "allostatic" resetting of the reward set-point is the neurobiology behind negative reinforcement and the persistence of use despite loss of pleasure.

3.7 Reactive versus reflective: the loss of top-down control

Bottom-up drive, top-down brake. A useful clinical shorthand splits the reward system into a reactive "bottom-up" component (VTA, nucleus accumbens and amygdala) that generates the

immediate pull toward pleasure or away from pain, and a reflective "top-down" component (prefrontal projections from the orbitofrontal, dorsolateral and ventromedial cortex, with the insula) that decides whether to act on that pull (Stahl's Substance Use 2020). In addiction the reactive system is sensitised and the reflective system is weakened, so cue-triggered drug-seeking is amplified at exactly the moment the brake is failing. This maps directly onto the preoccupation-anticipation stage and explains why insight and good intentions do not, on their own, prevent relapse.

HOLD THIS

All drugs of abuse converge on a dopamine surge in the nucleus accumbens via the mesolimbic pathway from the ventral tegmental area; repetition sensitises "wanting" (incentive salience) and recruits brain stress systems, moving the person through binge and intoxication, then withdrawal and negative affect, then preoccupation and anticipation, from positive to negative reinforcement.

3.8 Risk and the natural-reward comparison

Why not everyone who uses becomes addicted. The same cycle operates in all people, but the risk of moving from controlled, impulsive use to compulsive addiction is shaped by drug factors (the substance itself and its route and rate of uptake), genetics (many small-effect and epigenetic contributions, no single "addiction gene") and environment (early exposure, stress, deprivation, comorbid mental illness) (Stahl's Substance Use 2020). A useful examiner line: risk of *initiating* use is driven more by psychosocial factors, whereas risk of *progression* to addiction is driven more by neurobiological factors (Stahl's Substance Use 2020). The drug reward is pathological precisely because it is larger, faster and more reliable than natural rewards, so over time it out-competes food, work and relationships for the same circuit.

3	4	2
STAGES OF THE ADDICTION CYCLE	NEUROADAPTATIONS OF THE TRANSITION TO ADDICTION	DISSOCIABLE COMPONENTS: WANTING VS LIKING

3.9 The India frame: why the neurobiology is a treatment argument

From mechanism to access. In India the neurobiology of addiction is not an academic aside; it is the argument against moralising a disorder and for building services. The substance-use treatment gap is very large, with the great majority of people who are dependent never reaching any structured care, and the response is organised around a de-addiction and drug-de-addiction programme (DDAP) network of centres, the Indian Psychiatric Society substance-use clinical practice guidelines, and community and home-based delivery by trained non-specialist workers to reach the gap (IPS_CPG). The legal frame is the Narcotic Drugs and Psychotropic Substances Act (NDPS Act, Act 61 of 1985, in force 16 September 1985), which criminalises trafficking yet also provides for court-ordered detoxification, and whose access provisions govern how buprenorphine and methadone can be dispensed for opioid substitution. The full medico-legal detail of the NDPS Act sits in the Mental health legislation and forensic psychiatry notes; the point here is that the dopamine-hijack model reframes dependence as a brain disorder with

pharmacological targets rather than a vice, which is exactly what closing the treatment gap requires.

INDIA

The neurobiology carries directly into Indian practice on two fronts. First, buprenorphine (Indian brand Tidigesic; buprenorphine-naloxone as Suboxone or Bunorph) is the workhorse of opioid substitution precisely because it acts on the same mu-opioid step that disinhibits VTA dopamine, and its access is structured by the NDPS Act. Second, the incentive-sensitisation and opponent-process models are the teaching that lets a clinician explain to a family why relapse after months of abstinence is a cue-driven, sensitised-wanting phenomenon and not a moral failure, which is central to the non-confrontational, family-supported style the IPS guidelines recommend.

GOOD TO REMEMBER

- **Reward pathway (anatomy):** mesolimbic dopamine projection from the ventral tegmental area to the nucleus accumbens; amygdala adds reward learning, prefrontal cortex adds top-down control.
- **Dopamine surge (the discriminator):** all drugs of abuse raise accumbens dopamine by different molecular routes; the fast, phasic rise (set by route and rate of uptake) carries the reinforcement.
- **Incentive sensitisation (craving):** repeated use sensitises "wanting" (incentive salience, dopamine, cue-attached) which grows and outlasts "liking" (hedonic pleasure, opioid, fades); craving is sensitised wanting.
- **Three-stage cycle (the framework):** binge and intoxication (basal ganglia, dopamine, positive reinforcement); withdrawal and negative affect (extended amygdala, CRF and dynorphin, negative reinforcement); preoccupation and anticipation (prefrontal cortex, executive failure and cue-driven craving); the four neuroadaptations are increased incentive salience, decreased reward, increased stress and decreased executive function.

4 · Tolerance, withdrawal and neuroadaptation

Underneath every substance-use diagnosis sits a single physiology: the brain, exposed repeatedly to a drug, changes itself to oppose that drug, and those opposing changes are what a clinician meets as **tolerance** and, on cessation, as **withdrawal**. This topic is the mechanism chapter for the whole substance-use block. Examiners test it because it is where definitions, biology and clinical prediction meet: they will ask you to define the kinds of tolerance, to separate physical dependence from the dependence syndrome, to explain why the first fit of a drinker is rarely their worst, and to name the theory (allostasis) that ties reward loss to compulsive use. Get the vocabulary exact and the rest of the day, from why a benzodiazepine treats alcohol withdrawal to why successive detoxifications get more dangerous, follows without memorising each fact separately.

Why it matters clinically. The **neuroadaptation** that produces tolerance and withdrawal is also what makes withdrawal dangerous, predicts its time-course, and explains relapse long after the drug has cleared. Tolerance and a withdrawal state on their own are a normal, expected response to a chronically administered central nervous system drug and do *not* by themselves equal addiction (DSM-5-TR 2022). The reward-pathway and mesolimbic-dopamine anatomy on which all of this is built is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and

Basic Psychopharmacology notes and is not re-derived here; the amnestic mechanism behind repeated-withdrawal brain injury is developed in the Dementias and neurocognitive disorders notes and the Neuropsychiatry of systemic and neurological disease notes.

4.1 Tolerance defined: the same dose does less, so more is needed

The core definition. Tolerance is the state in which, after repeated administration, a larger dose of a substance is required to produce the effect once achieved by a lower dose, or, equivalently, a given dose produces a progressively smaller effect (Kaplan and Sadock 2024; WHO ICD-11 CDDR 2024). It is a shift of the whole dose-response curve to the right. Tolerance is one of the physiological features of the dependence syndrome, but it is neither necessary nor sufficient for the syndrome on its own: a surgical patient on a stable opioid can be fully tolerant with no compulsion, salience or impaired control.

What it is not. Do not equate tolerance with the dependence syndrome or with addiction. Tolerance is a pharmacological adaptation; the syndrome adds a behavioural core (compulsion, impaired control, salience) on top of it. This distinction is the one DSM-5-TR is at pains to make, precisely so that prescribed-drug tolerance is not mislabelled as addiction.

4.2 The three mechanisms of tolerance: pharmacokinetic, pharmacodynamic and behavioural

The classification to hold. Kaplan and Sadock describe tolerance as arising through at least three distinct processes, and this taxonomy is a favourite short-answer item (Kaplan and Sadock 2024). **Pharmacokinetic (dispositional) tolerance** is adaptation of the drug-metabolising systems so the body clears the substance faster; for alcohol this is induction of hepatic and microsomal enzymes, so the same intake yields lower blood levels over time. **Pharmacodynamic (cellular) tolerance** is the most important: an adaptation of the nervous system itself so it can function despite high drug concentrations by resisting the drug's action at the cell, through receptor down-regulation, altered coupling and opposing changes in the balance of excitation and inhibition. **Behavioural (learned) tolerance** is where a person learns, through practice, to perform tasks effectively while under the drug's influence, so the observable impairment shrinks without the pharmacology changing.

Why the split matters. Pharmacodynamic tolerance is the one that generates the withdrawal state: because the cell has adapted *against* the drug, removing the drug leaves the adaptation unopposed, and the withdrawal syndrome is the adaptation showing through. Behavioural and pharmacokinetic tolerance do not, by themselves, produce a withdrawal state.

TYPE OF TOLERANCE	MECHANISM	WORKED ALCOHOL EXAMPLE
Pharmacokinetic (dispositional)	Faster metabolism / clearance of the drug (enzyme induction).	Hepatic and microsomal enzyme induction lowers blood alcohol for the same intake.
Pharmacodynamic (cellular)	Nervous system adapts to resist the drug's action at the cell.	GABA-A down-regulation and NMDA up-regulation let the brain function at high blood alcohol; this is what withdrawal unmasks.
Behavioural (learned)	Learned skill at performing while intoxicated; pharmacology unchanged.	The experienced drinker who walks a line at a level that would floor a novice.

The three mechanisms of tolerance; only pharmacodynamic (cellular) tolerance generates a physiological withdrawal state (Kaplan and Sadock 2024).

RULE **Pharmacodynamic tolerance is the one that bites.** Withdrawal is unopposed cellular (pharmacodynamic) adaptation; the more of it a substance produces, the more dangerous its withdrawal, which is why alcohol and sedatives, not opioids, kill in withdrawal.

GOOD TO REMEMBER

- **Tolerance:** more drug needed for the same effect (dose-response curve shifts right); three mechanisms, pharmacokinetic (faster clearance), pharmacodynamic/cellular (nervous-system resistance, the one that produces withdrawal), and behavioural (learned performance); it is one physiological feature of dependence, not the syndrome itself.

4.3 Cross-tolerance: tolerance to one drug carries to another in the same class

The definition. Cross-tolerance is the phenomenon whereby tolerance developed to one substance confers tolerance to a second, pharmacologically related substance the person may never have taken (Kaplan and Sadock 2024). It arises because the two drugs share a final common mechanism; once the cell has adapted against that mechanism, both drugs are resisted. Alcohol, benzodiazepines and barbiturates are all central nervous system depressants acting on the GABA-A system, so they show mutual cross-tolerance.

The two clinical consequences. First, cross-tolerance is exactly why a benzodiazepine treats alcohol withdrawal: the benzodiazepine substitutes at the same GABA-A system the brain has adapted around, and is then tapered. Second, a heavy drinker who stops will, in the short run, need a *higher* dose of another depressant such as a benzodiazepine for sedation. A separate danger is that two depressants taken together do not merely add but **potentiate**, so their combined depressant effect can be lethal even at individually modest doses. Note that cross-tolerance can be incomplete: between different opioids it is only partial, which is why equianalgesic switching lowers the dose.

COMMON TRAP

Do not assume tolerance to a drug's wanted effect means tolerance to its lethal effect. Tolerance to opioid euphoria and analgesia outruns tolerance to respiratory depression, so a person chasing the same high can reach a respiratory-arrest dose; and after a period of abstinence (for example release from custody or completed detoxification) tolerance falls fast, so a previously routine dose becomes fatal. This mismatch is the mechanism behind most opioid overdose deaths.

4.4 Physical dependence versus the dependence syndrome: two different things

Physical dependence. **Physical dependence** is the physiological state of adaptation in which a characteristic withdrawal syndrome appears on stopping, reducing or antagonising the drug; operationally it is tolerance plus a withdrawal state. It is a normal consequence of chronic administration of many central nervous system drugs and can exist without any addictive behaviour at all.

The dependence syndrome. The dependence syndrome (developed in the dependence-syndrome topic) is a behavioural-cognitive-physiological cluster in which the substance acquires abnormally high priority: compulsion, impaired control and salience sit alongside the physiological features. DSM-5-TR states plainly that the tolerance and withdrawal that once defined "dependence" are normal responses to prescribed centrally acting drugs and do not by themselves indicate the presence of an addiction (DSM-5-TR 2022). A patient stabilised on a long-term benzodiazepine or opioid analgesic is physically dependent but is not, on that ground alone, addicted.

TRAP **Calling a stable prescribed patient "addicted".** Tolerance and a withdrawal state are physical dependence, a normal drug adaptation; addiction needs the behavioural core (compulsion, impaired control, salience). Labelling the compliant chronic-pain or panic patient as addicted is a criterion error, not a clinical finding.

4.5 Withdrawal as neuroadaptation unmasked: mirror-image and relief use

The mirror-image principle. The withdrawal state is the substance-specific syndrome that appears on cessation or reduction. For many substances the withdrawal features are the mirror image of the drug's acute pharmacological effects (WHO ICD-11 CDDR 2024): a central nervous system depressant such as alcohol calms and sedates, so its withdrawal is hyperexcitable, with tremor, tachycardia, seizures and, at the extreme, delirium tremens; an opioid produces analgesia, pupillary constriction, constipation and euphoria, so its withdrawal produces pain, mydriasis, diarrhoea and dysphoria. This is the neuroadaptation showing through once the drug is removed: the opposing cellular changes that produced tolerance now have nothing to oppose.

Relief use. A key clinical rider is the "relief-use" clause: taking the same or a closely related substance to relieve or avoid withdrawal is itself a marker of the physiological arm of dependence, and avoidance of withdrawal becomes a powerful driver of continued use. The full time-courses and drug-specific management of alcohol, opioid and sedative withdrawal are developed in the withdrawal-management topics; here the point is only mechanistic.

PEARL

Read a withdrawal syndrome by inverting the intoxication. If you can recall what the drug does acutely, you can predict its withdrawal: the depressant's withdrawal is excitation (seizures, delirium), the stimulant's is a "crash" (hypersomnia, hyperphagia, dysphoria), and the opioid's is a flu-like autonomic storm that is distressing but, in the physically healthy adult, rarely life-threatening.

4.6 The molecular substrate: what actually adapts

Alcohol and sedatives. The prototype is the GABA-glutamate axis. Chronic alcohol enhances inhibitory GABA-A transmission and inhibits excitatory NMDA-glutamate transmission acutely; the brain compensates by down-regulating GABA-A receptors and up-regulating NMDA receptors. When alcohol is withdrawn, this leaves reduced inhibition and unopposed glutamatergic excitation, a hyperexcitable state that manifests as tremor, autonomic arousal and, if severe, seizures and delirium (Kaplan and Sadock 2024). Benzodiazepines and barbiturates share the GABA-A target, hence the cross-tolerance and the clinical use of benzodiazepines to cover alcohol withdrawal.

Opioids. Chronic mu-opioid receptor agonism drives receptor uncoupling and desensitisation and a compensatory up-regulation of the cyclic-AMP and locus-coeruleus noradrenergic systems; on withdrawal, the noradrenergic overshoot produces much of the autonomic storm, which is why the alpha-2 agonists clonidine and lofexidine, and the mixed benefit of an alpha-2A agonist added to substitution, blunt opioid-withdrawal severity. The receptor-level detail belongs to the substitution and withdrawal-management topics.

4.7 Allostasis and the anti-reward system: why the setpoint moves

From homeostasis to allostasis. The dominant modern framework, from Koob and Le Moal, reframes addiction as a failure not of homeostasis (return to a fixed setpoint) but of allostasis: the brain achieves stability through change, and repeated drug use shifts the hedonic setpoint itself to a new, lower baseline that can only be maintained by continued use (Tasman 2015, Koob; Kaplan and Sadock 2024). The "allostatic load" is the accumulating cost of these repeated adaptations. Addiction, in this model, is a spiral driven as much by the loss of a normal reward baseline as by the pursuit of a high.

The anti-reward / opponent-process arm. Reward systems are opposed by **anti-reward** systems whose job is to limit reward (an opponent-process concept). As tolerance and withdrawal develop, brain-stress systems are recruited: corticotropin-releasing factor and noradrenaline in the extended amygdala, and the dynorphin-kappa-opioid system in the ventral striatum, which reduces accumbal dopamine release. The result is a dual hit: a within-system dampening of dopaminergic reward (blunted, so more drug is needed) and a between-system recruitment of stress/anti-reward circuitry (so abstinence feels actively bad). This is the negative-reinforcement engine of the withdrawal/negative-affect stage of the three-stage cycle (binge/intoxication, withdrawal/negative affect, preoccupation/anticipation).

WORKED EXAMPLE

A person with severe alcohol use disorder says drinking no longer makes them feel good; it only stops them feeling terrible. That single sentence is the allostasis model in the room: the hedonic setpoint has dropped (within-system reward loss) and the CRF/noradrenaline/dynorphin anti-reward systems are recruited (between-system stress), so the drink now works by negative reinforcement, relieving a manufactured distress rather than producing pleasure. It also explains why anti-craving pharmacotherapy and relapse prevention, not just detoxification, are needed: clearing the drug does not restore the setpoint.

4.8 Kindling: why each successive withdrawal is worse

The definition. Kindling is the phenomenon whereby substance-withdrawal symptoms become progressively more severe with each repeated episode of withdrawal, so that a person who has withdrawn many times faces worse and more dangerous withdrawals than a first-timer, independent of how much they drink (WHO ICD-11 CDDR 2024; Becker 1998). It is best characterised for alcohol. Repeated cycles of intoxication and abrupt withdrawal sensitise the central nervous system, borrowing the term from the electrophysiological kindling in which repeated sub-threshold stimulation eventually triggers seizures. Each detoxification is not a clean reset; it lays down a sensitised substrate for the next.

The clinical corollaries. Kindling is why a history of multiple prior withdrawals or prior withdrawal seizures is a red flag that predicts a more complicated course, why "just letting them dry out at home again" is dangerous in the multiply-detoxified drinker, and part of why aggressive, adequate benzodiazepine cover of each withdrawal matters, since under-treated withdrawals may worsen the next. The same repeated-cycle sensitisation is invoked for the paradoxical worsening seen in some benzodiazepine re-instatements (Maudsley Deprescribing Guidelines).

RULE **Count the prior withdrawals.** A history of repeated detoxifications or any prior withdrawal seizure predicts a more severe next withdrawal (kindling); treat such a patient's withdrawal as high-risk and cover it adequately, do not send them home to detox unassisted again.

2 of 3	8 to 10	3
ICD-11 DEPENDENCE CENTRAL FEATURES (IMPAIRED CONTROL, SALIENCE, NEUROADAPTATION)	CIWA-AR SCORE AT OR ABOVE WHICH TO MEDICATE ALCOHOL WITHDRAWAL	MECHANISMS OF TOLERANCE (PHARMACOKINETIC, PHARMACODYNAMIC, BEHAVIOURAL)

4.9 Where tolerance and withdrawal enter diagnosis and screening

The neuroadaptation arm of the criteria. In ICD-11, tolerance, withdrawal and relief use are collapsed into a single "physiological features indicative of neuroadaptation" criterion, one of the three central features of dependence, of which two are needed (WHO ICD-11 CDDR 2024). So on their own, tolerance and withdrawal contribute one of three; the behavioural features (impaired control, increasing precedence/salience) supply the rest. A crucial rider is that the physiological features apply only to certain substances, so their absence (as in some stimulant or hallucinogen use) does not exclude dependence.

Scales that touch this. Withdrawal severity is quantified for management, not diagnosis: the **CIWA-Ar** for alcohol withdrawal and the **COWS** for opioid withdrawal, both taught with their cut-offs in the withdrawal-management topics and reproduced in the scales gallery. At the screening end, the AUDIT (a score of 8 or more flags hazardous or harmful drinking) and CAGE identify problem use before dependence is entrenched. The severity-of-dependence instruments (for example the SADQ for alcohol) index the physiological adaptation this topic describes; their cut-offs belong to the withdrawal topics.

MNEMONIC

"PK-PD-B" for the three tolerances, and "mirror, relief, kindle" for withdrawal

Tolerance splits into PharmacoKinetic (faster clearance), PharmacoDynamic (cellular resistance, the withdrawal-maker), and Behavioural (learned). Withdrawal is the Mirror image of intoxication, drives Relief use, and Kindles (worsens) with each repeated episode.

INDIA

The mechanistic picture has a sharp Indian edge. India carries a very large substance-use treatment gap, with most people meeting dependence criteria never reaching formal care, and services concentrated in government de-addiction centres and Drug De-addiction Programme (DDAP) units rather than general practice (IPS 2014). Kindling is the reason this matters clinically here: the multiply-detoxified drinker who has cycled through unassisted or under-resourced withdrawals repeatedly arrives with a sensitised, higher-risk withdrawal, so adequate benzodiazepine cover and parenteral thiamine before any glucose load are not optional. The legal frame is the Narcotic Drugs and Psychotropic Substances (NDPS) Act, 1985, whose scheduling shapes access to controlled agents; the medico-legal detail is developed in the Mental health legislation and forensic psychiatry notes. On the neuroadaptation-reversal side, buprenorphine (Indian brand Tidigesic; buprenorphine-naloxone as Suboxone) is the workhorse of Indian opioid-agonist treatment because it substitutes at the adapted mu-opioid receptor while capping respiratory risk, and its induction detail belongs to the substitution topics.

GOOD TO REMEMBER

- **Cross-tolerance:** tolerance to one drug carries to a related drug sharing the mechanism (alcohol / benzodiazepines / barbiturates via GABA-A); it is why a benzodiazepine treats alcohol withdrawal; combined depressants potentiate and can be lethal; between opioids it is only partial (lower the dose when switching).
- **Physical dependence:** tolerance plus a withdrawal state; a normal adaptation to chronic centrally acting drugs; not the same as addiction, which needs the behavioural core; the first management step on stopping is to assess and cover withdrawal risk.
- **Kindling:** withdrawal severity rises with each repeated withdrawal episode, best characterised for alcohol; the discriminator of a high-risk withdrawal is the count of prior detoxifications or a prior withdrawal seizure; the first step is to treat the next withdrawal as high-risk with adequate cover.
- **Allostasis / anti-reward:** repeated use lowers the hedonic setpoint (within-system reward loss) and recruits CRF, noradrenaline and dynorphin-kappa stress systems (between-system anti-reward), driving use by negative reinforcement; the corollary is that detoxification alone does not restore the setpoint, so relapse-prevention pharmacotherapy is needed.

GOOD TO REMEMBER

- **Naltrexone (Indian brands Naltima, Nodict):** a mu-opioid receptor antagonist; oral 50 mg/day is a first-line anti-craving agent in alcohol use disorder (blunting alcohol's reward, an allostasis-relevant target); the signature caution is that giving it to a current opioid user precipitates an acute withdrawal, so an opioid-free window (about 7 to 10 days) is mandatory before starting; not itself a treatment for the physiological withdrawal state.

HOLD THIS

Withdrawal is pharmacodynamic (cellular) neuroadaptation unmasked, so it mirrors intoxication and worsens with each repeated episode (kindling); tolerance and a withdrawal state are physical dependence, a normal drug adaptation, and are not addiction until the behavioural core (compulsion, impaired control, salience) is present.

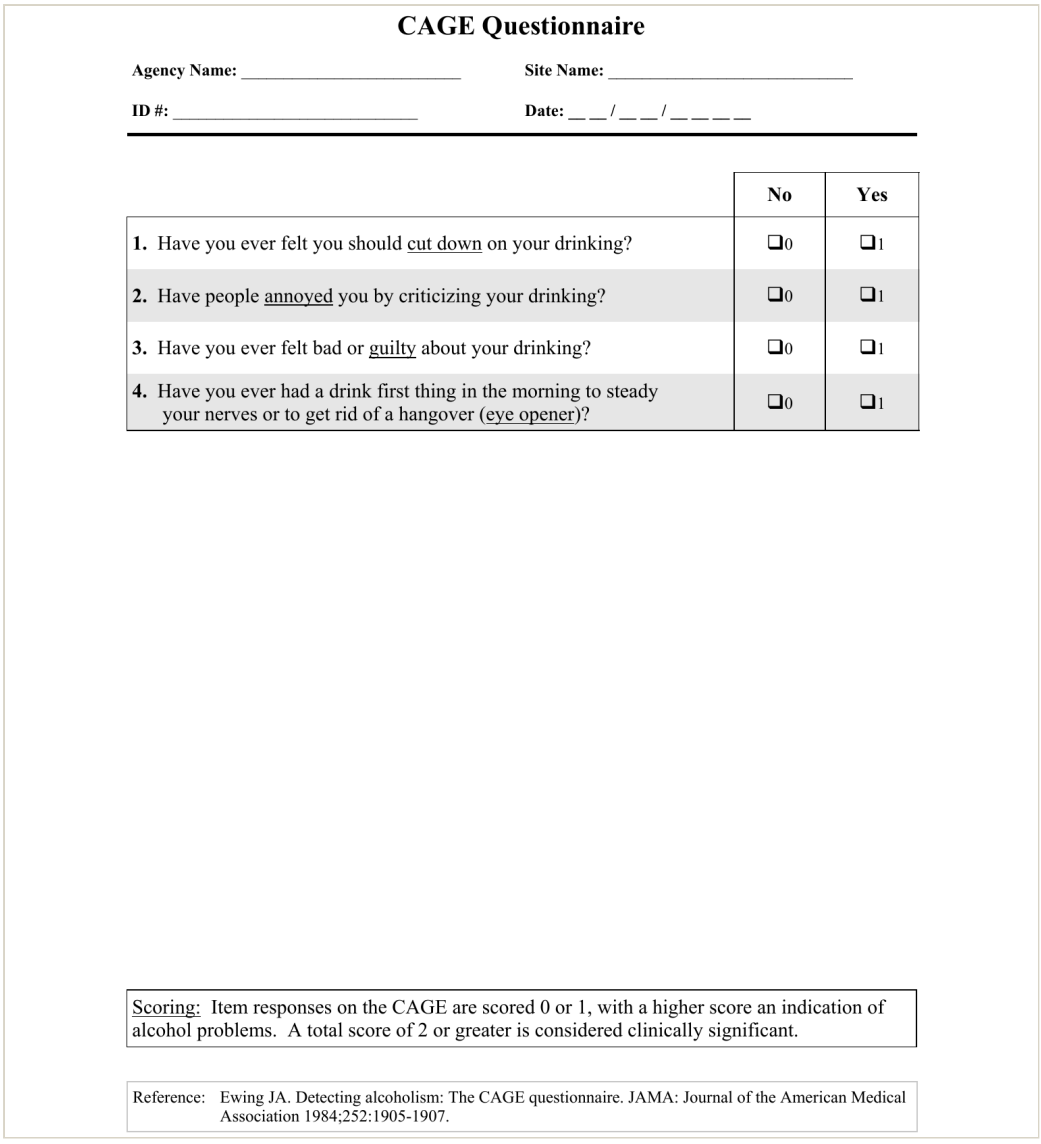
5 · Screening instruments for substance use

Most people with a substance problem never volunteer it, and most present for something else entirely, so the substance-use disorders are found by *asking in a structured way*, not by waiting for a confession. That is the whole logic of screening: short, validated **questionnaire**s that a clinician (or the patient) can complete in a couple of minutes to flag the person who needs a fuller assessment. Examiners love this topic because it is pure recall of numbers: they will ask how many items an instrument has, what it screens for, and above all its **cut-off** score. A wrong cut-off is the classic dropped mark, so the whole of this topic is built around getting four numbers cold: AUDIT 8, CAGE 2, DAST-10 3, and the ASSIST risk bands.

Why it matters clinically. Screening earns its place precisely at the hazardous-and-harmful end, where the problem is common, under-recognised and still reversible by brief, motivation-based intervention before dependence is entrenched. A positive screen is never a diagnosis; it is a trigger for assessment. This is where India's substance-use treatment gap is most tractable, because a validated instrument in a non-specialist's hands catches the drinker or user long before they would ever reach a de-addiction centre. The full instrument forms are reproduced in the

scales gallery figure (Fig 13.3), so this topic teaches what each instrument is and how it is scored, not the item wording.

Box 10



The Alcohol Use Disorders Identification Test: Self-Report Version

PATIENT: Because alcohol use can affect your health and can interfere with certain medications and treatments, it is important that we ask some questions about your use of alcohol. Your answers will remain confidential so please be honest.
Place an X in one box that best describes your answer to each question.

Questions	0	1	2	3	4	
1. How often do you have a drink containing alcohol?	Never	Monthly or less	2-4 times a month	2-3 times a week	4 or more times a week	
2. How many drinks containing alcohol do you have on a typical day when you are drinking?	1 or 2	3 or 4	5 or 6	7 to 9	10 or more	
3. How often do you have six or more drinks on one occasion?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
4. How often during the last year have you found that you were not able to stop drinking once you had started?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
5. How often during the last year have you failed to do what was normally expected of you because of drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
7. How often during the last year have you had a feeling of guilt or remorse after drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
8. How often during the last year have you been unable to remember what happened the night before because of your drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
9. Have you or someone else been injured because of your drinking?	No		Yes, but not in the last year		Yes, during the last year	
10. Has a relative, friend, doctor, or other health care worker been concerned about your drinking or suggested you cut down?	No		Yes, but not in the last year		Yes, during the last year	
					Total	

The AUDIT, self-report version: 10 items, each scored 0 to 4 (total 0 to 40); the examinable cut-off is 8 or more for hazardous or harmful use.

Reproduced from WHO AUDIT manual (WHO/MSD/MSB/01.6a, 2001); free for non-commercial reproduction per the WHO copyright grant.

CAGE Questionnaire

Agency Name: _____ **Site Name:** _____

ID #: _____ **Date:** __ __ / __ __ / __ __ __ __

	No	Yes
1. Have you ever felt you should cut down on your drinking?	❑0	❑1
2. Have people annoyed you by criticizing your drinking?	❑0	❑1
3. Have you ever felt bad or guilty about your drinking?	❑0	❑1
4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (eye opener)?	❑0	❑1

Scoring: Item responses on the CAGE are scored 0 or 1, with a higher score an indication of alcohol problems. A total score of 2 or greater is considered clinically significant.

Reference: Ewing JA. Detecting alcoholism: The CAGE questionnaire. JAMA: Journal of the American Medical Association 1984;252:1905-1907.

The CAGE questionnaire: four yes/no items (Cut down, Annoyed, Guilty, Eye-opener), each 0 or 1; a total of 2 or more is clinically significant.

CAGE questionnaire (Ewing JA, JAMA 1984); reproduced with acknowledgement, non-commercial use, per the Bowles Center permission.

DAST-10 (TYPESET, NOT REPRODUCED)	VERIFIED STRUCTURE AND CUT-OFF
Instrument	Drug Abuse Screening Test, 10-item version (Skinner 1982)
Items	10 yes/no items; drug use excluding alcohol and tobacco, past 12 months; item 3 is reverse-scored; total range 0 to 10
Cut-off / bands	**3 or more warrants assessment; 0 none, 1 to 2 low, 3 to 5 moderate, 6 to 8 substantial, 9 to 10 severe (Skinner)**

DAST-10: typeset structure and verified cut-off only; the form is permission-required and is not reproduced (Skinner HA. The Drug Abuse Screening Test. Addict Behav. 1982;7(4):363-71; © 1982 Harvey A. Skinner / CAMH).

WHO ASSIST V3.1 (TYPESET, NOT REPRODUCED)	VERIFIED STRUCTURE AND RISK BANDS
Instrument	Alcohol, Smoking and Substance Involvement Screening Test, interviewer-administered, 10 substance classes (Humeniuk et al., WHO 2010)
Items	8 questions per substance; a Substance Involvement (SI) score is summed from questions 2 to 7
Risk bands	**Most substances: 0 to 3 lower, 4 to 26 moderate, 27 or more high. Alcohol: 0 to 10 lower, 11 to 26 moderate, 27 or more high**

WHO ASSIST: typeset structure and verified bands only; verbatim reproduction requires WHO Press permission (Humeniuk R, et al. The ASSIST: manual for use in primary care. Geneva: WHO; 2010. ISBN 978 92 4 159938 2).

Fig 13.3 The substance-use screening instruments: AUDIT, CAGE, DAST and ASSIST. The AUDIT and CAGE are shown as their actual open, freely reproducible forms: the AUDIT is the 10-item WHO alcohol screen (each item 0 to 4, total 0 to 40, cut-off 8 or more), and the CAGE is the four-item bedside screen (Cut down, Annoyed, Guilty, Eye-opener, cut-off 2 or more). The DAST-10 and the WHO ASSIST are permission-required instruments and so are given as typeset structure and verified cut-offs only, not reproduced: the DAST-10 is the 10-item non-alcohol drug screen with a cut-off of 3 or more, and the ASSIST is the WHO all-substance screen whose per-substance Substance Involvement score sorts the person into lower, moderate or high risk (0 to 3, 4 to 26, 27 or more for most substances; 0 to 10, 11 to 26, 27 or more for alcohol) and directs the matched intervention.

5.1 What a screening instrument is (and is not): screen, do not diagnose

The purpose. A **screening instrument** is a brief, standardised tool designed to identify people who are likely to have a problem and who therefore warrant fuller assessment; it trades depth for speed and reach (Clinical Methods in Psychiatry 2024). Screening instruments such as the AUDIT, DAST and CAGE are deliberately over-inclusive: they favour sensitivity so as not to miss cases, accepting some false positives that the follow-up assessment will sort out.

The contrast with diagnostic instruments. A screen only sorts people into "assess further" versus "reassure"; the diagnosis is made afterwards against ICD-11 or DSM-5-TR criteria (the criterion sets are developed in the dependence-syndrome topic). Reading a positive screen as a diagnosis is the single commonest misuse of these tools.

RULE **A screen triggers assessment, never a diagnosis.** A score over the cut-off means "ask more", not "this person has a substance use disorder"; the diagnosis is always made against the criterion set, not the questionnaire.

5.2 The AUDIT: the 10-item WHO alcohol screen and its cut-off of eight

What it is. The AUDIT (Alcohol Use Disorders Identification Test) is the standard alcohol screen, developed by the WHO in the late 1980s for the early detection of **hazardous** and **harmful** drinking across settings (Kaplan & Sadock 2024; Maudsley 2021). It is a **10-item** self-report **questionnaire**, each item scored 0 to 4, giving a total of 0 to 40, and takes under five minutes with no professional training. Its three domains are structured: items 1 to 3 cover the quantity and frequency of alcohol consumed, items 4 to 6 the signs and symptoms of dependence, and items 7 to 10 the behaviours and problems of harmful use (Maudsley 2021).

The cut-off. A score of **8 or more** is the standard threshold, suggestive of hazardous or harmful drinking (Kaplan & Sadock 2024; Maudsley 2021). It is quite sensitive, at least in men; lower cut-offs (7 in women, adolescents and older adults) improve detection in those groups, and a threshold of 10 buys more specificity. NICE advises a comprehensive specialist assessment for anyone scoring more than 15 (NICE 2011). The abbreviated **audit**-C uses only the first three consumption items (score 0 to 12) for rapid consumption screening.

AUDIT BAND (TOTAL SCORE)	INTERPRETATION	ACTION
0 to 7	Low risk	Reinforce; no intervention needed
8 to 15	Hazardous / increasing risk	Brief advice / simple brief intervention
16 to 19	Harmful / higher risk	Brief intervention plus monitoring / referral
20 to 40	Possible dependence	Refer for specialist / diagnostic assessment

The AUDIT score bands; the single examinable number is the cut-off of 8 for hazardous or harmful use (Kaplan & Sadock 2024; Maudsley 2021; NICE 2011).

GOOD TO REMEMBER

- **AUDIT:** 10-item WHO alcohol screen, each item 0 to 4, total 0 to 40; cut-off **8 or more** = hazardous or harmful drinking; NICE refers >15 for comprehensive assessment; domains are consumption (Q1-3), dependence (Q4-6), harm (Q7-10); AUDIT-C = the first 3 consumption items.

5.3 The CAGE: the four-item bedside screen and its cut-off of two

What it is. The CAGE (Ewing 1984) is the classic ultra-brief bedside alcohol screen, four yes/no questions taking one minute or less (Kaplan & Sadock 2024; Tasman). The acronym is the whole instrument: **C**ut down (have you ever felt you should cut down?), **A**nnoyed (have people annoyed you by criticising your drinking?), **G**uilty (have you ever felt bad or guilty about your drinking?), and **E**ye-opener (have you ever had a drink first thing in the morning to steady your nerves or cure a hangover?). Each "yes" scores 1, for a total of 0 to 4.

The cut-off. A score of **2 or more** is clinically significant and strongly suggests an alcohol problem warranting fuller assessment; a score of 1 or more warrants follow-up (Kaplan & Sadock 2024). The trade-off is deliberate: a threshold of 2 is more specific, a threshold of 1 more sensitive. CAGE's weakness is that it detects established problem drinking well but is poor at picking up the early, hazardous drinking that brief intervention most helps, which is exactly where the AUDIT is stronger. The **cage**-AID variant extends the four questions to cover other drugs.

MNEMONIC

CAGE = Cut down · Annoyed · Guilty · Eye-opener

Four questions, one point each; two or more positive answers is the cut-off that flags a likely alcohol problem. The Eye-opener item (a morning drink) is the one most specific for dependence.

GOOD TO REMEMBER

- **CAGE:** 4-item bedside alcohol screen (Cut down, Annoyed, Guilty, Eye-opener), each 1 point; cut-off **2 or more** positive answers is clinically significant; good for established problem drinking, weak for early hazardous use; CAGE-AID extends it to other drugs.

5.4 The DAST-10: the drug-abuse counterpart and its cut-off of three

What it is. The DAST (Drug Abuse Screening Test, Skinner 1982) is the drug-use analogue of the AUDIT, screening for problems related to *non-alcohol* psychoactive drugs (illicit and prescription misuse) over the past 12 months (Clinical Methods in Psychiatry 2024). The widely used short form, the DAST-10, is a **10-item** yes/no **questionnaire** where most items score 1 for "yes" (one reverse-scored item scores 1 for "no"), giving a total of 0 to 10; longer 20-item and 28-item versions also exist.

The cut-off. On the DAST-10 a score of **3 or more** is the usual threshold prompting further assessment, with higher scores grading the problem (1 to 2 low, 3 to 5 moderate, 6 to 8 substantial, 9 to 10 severe). Because it deliberately excludes alcohol and tobacco, the DAST is paired with the AUDIT for a full picture, or replaced by the ASSIST where a single all-substance tool is wanted.

GOOD TO REMEMBER

- **DAST-10:** 10-item yes/no drug-use screen (non-alcohol drugs, past year), total 0 to 10; cut-off **3 or more** = warrants assessment (3-5 moderate, 6-8 substantial, 9-10 severe); the drug counterpart of the AUDIT.

5.5 The WHO ASSIST: the all-substance screen with its per-substance risk bands

What it is. The ASSIST (Alcohol, Smoking and Substance Involvement Screening Test) is the WHO's single instrument covering *all* substance classes at once, developed for use in primary and general health care (Kaplan & Sadock 2024). It is an eight-question interviewer-administered **questionnaire** asking, for each substance (tobacco, alcohol, cannabis, cocaine, amphetamine-type stimulants, inhalants, sedatives, hallucinogens, opioids and "other"), about lifetime and recent use, urge, problems, failed control, and concern from others. It generates a **Specific Substance Involvement Score** (SSIS) for each substance, which sorts the person into a risk band that maps directly onto the intervention needed.

The bands. For most substances the SSIS bands are **0 to 3** lower risk (no intervention), **4 to 26** moderate risk (brief intervention), and **27 or more** high risk (more intensive treatment / referral). Alcohol is the one exception, where the lower-risk band runs 0 to 10 and the moderate band 11 to 26 (WHO ASSIST manual). The tiered structure is the point: the ASSIST does not just

detect, it directs the person straight to brief intervention or specialist referral. Shorter variants (ASSIST-Lite, the NIDA-Modified ASSIST) exist for rapid use.

ASSIST SSIS BAND	OTHER SUBSTANCES (SCORE)	ALCOHOL (SCORE)	LINKED ACTION
Lower risk	0 to 3	0 to 10	No intervention; feedback only
Moderate risk	4 to 26	11 to 26	Brief intervention
High risk	27 or more	27 or more	More intensive treatment / referral

The WHO ASSIST per-substance risk bands; note the alcohol lower-risk band runs to 10 whereas other substances cut at 3 (WHO ASSIST manual).

GOOD TO REMEMBER

- **ASSIST:** 8-question WHO all-substance screen giving a per-substance SSIS; bands **0-3 lower / 4-26 moderate / 27+ high** for most drugs, but **0-10 / 11-26 / 27+** for alcohol; the moderate band triggers brief intervention, the high band triggers referral.

5.6 Choosing the instrument: matching the screen to the question

The decision. The four instruments are not interchangeable, and the exam tests whether you know which to reach for. Reach for the *AUDIT* when the question is specifically about alcohol and you want to catch it early; the *CAGE* when you need a one-minute bedside screen and lifetime problem drinking is the concern; the *DAST* when the question is non-alcohol drug use; and the *ASSIST* when you want one tool across every substance class with a built-in link to the intervention.

The common thread. Every one is a screen, so every positive result routes to the same next step: a fuller, criterion-based assessment. The value added by the ASSIST and the AUDIT bands is that they also tell you *how intensively* to respond, which is why they suit stepped-care systems and the Indian treatment-gap context better than a bare yes/no screen.

INSTRUMENT	ITEMS	SCREENS FOR	CUT-OFF / BANDS
AUDIT	10	Hazardous / harmful alcohol use	**8 or more (NICE >15 refer)**
CAGE	4	Established problem drinking	**2 or more positive**
DAST-10	10	Non-alcohol drug problems	**3 or more**
ASSIST	8 (per substance)	All substance classes	**4-26 moderate / 27+ high (alcohol 11-26 / 27+)**

The four screens at a glance; the cut-off column is the one that earns or loses the mark (Kaplan & Sadock 2024; Maudsley 2021; WHO ASSIST manual).

8	2	3	27
AUDIT HAZARDOUS OR HARMFUL-USE CUT-OFF	CAGE POSITIVE-ANSWER CUT-OFF	DAST-10 CUT-OFF FOR FURTHER ASSESSMENT	ASSIST HIGH-RISK SSIS THRESHOLD

TRAP **Blurring the cut-offs.** The numbers are not the same: AUDIT is 8, CAGE is 2, DAST-10 is 3, and the ASSIST high-risk band is 27 (with alcohol's moderate band uniquely starting at 11, not 4). Swapping one cut-off for another is the classic dropped mark.

INDIA

Screening is the sharpest tool against India's substance-use treatment gap, where the large majority meeting dependence criteria never reach the government de-addiction centres or the Drug De-addiction Programme (DDAP) units that hold most formal services. The IPS substance-use guidelines therefore emphasise brief, motivation-based intervention delivered by trained non-specialist health workers, with a strategic shift toward community and home-based delivery (IPS 2014); a validated screen in a general-practice or primary-care hand is the entry point to that pathway. The AUDIT and ASSIST have been widely used in Indian primary-care and epidemiological work, and the WHO ASSIST's built-in brief-intervention link fits the non-specialist model well. The wider legal frame is the Narcotic Drugs and Psychotropic Substances Act, 1985, which shapes how opioid problems (buprenorphine being the workhorse of Indian opioid-agonist treatment) are managed once a screen has flagged them; that medico-legal detail is developed in the Mental health legislation and forensic psychiatry notes.

WORKED EXAMPLE

A 40-year-old man attends a general clinic for dyspepsia. The clinician administers the AUDIT: he scores 17, in the harmful band, so brief intervention plus monitoring is indicated rather than reassurance. Because he also mentions occasional sleeping-tablet use, the clinician adds the DAST-10, on which he scores 4 (moderate), prompting a fuller drug history. Neither score is a diagnosis; both are triggers. Had a single all-substance tool been wanted, the ASSIST alone would have covered both the alcohol and the sedative use and sorted each into its own risk band, pointing directly to brief intervention for the alcohol and assessment of the sedatives.

COMMON TRAP

Do not confuse a *screening* instrument with a *severity* scale. The AUDIT, CAGE, DAST and ASSIST answer "is there a problem worth assessing?"; the SADQ (dependence severity), CIWA-Ar (alcohol withdrawal severity), COWS (opioid withdrawal severity) and Fagerstrom (nicotine dependence) answer a different question and belong to the withdrawal and dependence-management topics, not to screening.

HOLD THIS

Four screens, four numbers: AUDIT 8 (10 items, alcohol), CAGE 2 (4 items, alcohol), DAST-10 3 (10 items, drugs), ASSIST 27 for high risk (8 questions per substance, alcohol moderate band uniquely 11-26); every positive screen triggers assessment, never a diagnosis.

6 · Dual diagnosis

Some patients do not fit into one clinic. A person can have both a substance use disorder *and* another mental disorder at the same time, and when they do, treating one and ignoring the other tends to fail both. This is the topic that names that situation, teaches how services have historically tried (and mostly failed) to handle it, and states the one management principle the exam wants: treat both together. The construct sits at the seam between the substance-use chapter and the rest of psychiatry, which is exactly why it is a favourite. The reward-pathway biology that makes psychiatric illness and substance use so intertwined is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and is not re-derived here.

Why it matters clinically. Comorbidity is not the exception; among people with alcohol dependence roughly a third carry a second psychiatric diagnosis, and among those with drug dependence nearly half do (Farrell et al 2001, in the Companion). Miss it and you mis-diagnose, under-treat, and watch the person cycle through crisis presentations. The examinable spine is a triad: the **concept, models** of service delivery, and the integrated-treatment principle. Learn those three and the topic is yours.

6.1 The concept: a co-occurring substance use disorder plus another mental disorder

Definition. Dual diagnosis is the co-occurrence, in the same person, of a substance use disorder and at least one other mental disorder (WHO; Companion to Psychiatric Studies 2010). The term is used loosely and many textbooks prefer **comorbidity**: the Companion states explicitly that for its chapter the word comorbidity, rather than dual diagnosis, is used when one diagnosis is psychoactive substance use and the second a mental and behavioural disorder. The Shorter Oxford treats the two as synonyms and notes the modern move away from diagnostic hierarchies (which forced one label) toward recognising comorbidity, because comorbidity is very common (Kessler 2004). Hold both words; an examiner may use either.

What it is not. Dual diagnosis in current psychiatric usage means a mental disorder plus a substance use disorder. It no longer means, as it once did, a mental disorder co-occurring with intellectual disability; that older, stigmatising usage has been retired (Tasman). Keep the modern meaning.

RULE **Screen everyone, both ways.** Ask every psychiatric patient about substances and every substance-use patient about mental illness; comorbidity is the rule, not the exception, and it is routinely missed when only one door is opened.

GOOD TO REMEMBER

- **Dual diagnosis / comorbidity:** a substance use disorder plus a second mental disorder in the same person; the discriminator from a single diagnosis is that both independently need treatment; the first step on recognising it is to establish which came first and whether the second is truly independent or substance-induced.

6.2 How common, and which pairings: the numbers to hold

Base rates. Against a general-population psychiatric-diagnosis rate near 12%, comorbidity rises to **30%** in alcohol dependence and to **45%** in drug dependence (Farrell et al 2001; Companion). On inpatient psychiatric units, substance misuse is found in roughly 20% before drug screening and 35% after, reaching 65% in young, male, urban, lower-income groups. These are the figures examiners quote.

The classic pairings. Substance misuse is the single most prevalent comorbid condition in schizophrenia (cannabis and stimulants predominate); bipolar disorder carries a comorbidity rate around 35% (stimulants most common); antisocial personality disorder rises from a 5% population rate to 18% in substance users and up to 44% in injectors; and mood disorders before age 20 carry a four-fold increased risk of later substance misuse (Companion). ADHD, PTSD and anxiety disorders complete the common list.

COMORBID DISORDER	COMORBIDITY SIGNAL (FROM THE COMPANION)
Schizophrenia	The most prevalent comorbidity in schizophrenia; cannabis and amphetamines predominate; worse compliance, more violence, more relapse, poorer prognosis.
Bipolar disorder	Comorbidity rate around 35%; stimulants (cocaine, amphetamine) most common; mood stabilisers (lithium, valproate, carbamazepine) supported.
Antisocial personality disorder	5% population rate rises to 18% in substance users, up to 44% in IV drug users.
Mood disorders	Onset before age 20 gives a four-fold increased risk of later substance misuse.
PTSD	Substance misuse parallels PTSD development (self-medication of hyperarousal); sedative preference; a present-focused coping-skills model is best-tested.
ADHD	Adult ADHD drives comorbid misuse (usually stimulants); medication alone is inadequate for both.

The high-yield comorbid pairings and their signals; substance misuse is the commonest comorbidity in schizophrenia (Companion 2010).

6.3 Which came first: primary, secondary, and the self-medication question

The temporal question. In any comorbid case, ask which condition came first, because it changes both the label and the plan. An initial substance problem (through intoxication, withdrawal or chronic toxic effects) can produce a **substance-induced** psychiatric state; the Companion is firm that these drug-induced states are not true comorbidity and should be seen as secondary phenomena. Conversely, a primary psychiatric illness may be unmasked or precipitated by substances in a vulnerable person, or the two may share common risk factors. The substance-induced psychotic-disorder boundary is drawn in detail in the Other psychotic disorders, delusional syndromes and catatonia notes.

The self-medication hypothesis. One influential account holds that some patients use particular drugs for symptomatic relief, for example smoking to ease negative symptoms or cognitive deficits in schizophrenia, or sedatives to blunt PTSD hyperarousal (New Oxford; Kaplan & Sadock). The evidence is mixed: formal tests measuring the temporal sequence often fail to support pure self-medication, and shared vulnerability (a common pathophysiology or genetic risk) is at least as plausible (Kaplan & Sadock). Treat self-medication as a hypothesis to hold lightly, not a rule.

TRAP **Calling a substance-induced state a comorbidity.** A depressive or psychotic picture arising only during intoxication, withdrawal or chronic use is a secondary, substance-induced state, not independent comorbidity; re-assess after a period of abstinence before fixing the second diagnosis.

6.4 The three service models: sequential, parallel, integrated

The taxonomy. Historically, services for dual diagnosis have been organised in one of three ways (El-Mallakh 1998, the canonical treatment-models paper; Companion). In the sequential (or serial) model the two disorders are treated one after the other, in separate services, usually demanding abstinence before the mental illness is addressed. In the parallel model both are treated at the same time but by two different teams in two different services. In the integrated model both are treated together, in one setting, ideally by the same clinical team (El-Mallakh 1998). The three form a natural progression, and the exam wants you to name all three and to know which one wins.

Why sequential and parallel fail. Sequential treatment (the "get sober first, then we will treat the depression" stance) is associated with worse outcomes and higher attrition, because the untreated disorder undermines treatment of the other and the patient falls through the gap between services (IPS 2014). Parallel treatment is better but fragments care: two teams, two care plans, poor communication, and the patient ping-ponging between them with each service disowning the other's problem, exactly the confidence-and-training gap Johnson described, with psychiatric staff seeing substance users only in crisis and addiction staff lacking psychiatric experience (Companion).

MODEL	STRUCTURE	PROBLEM
Sequential / serial	One disorder treated, then the other; separate services; often abstinence-first.	Worse outcomes, high attrition; the untreated disorder sabotages the treated one.
Parallel	Both treated at once, but by two teams in two services.	Fragmented care; poor communication; each service disowns the other's problem.
Integrated	Both treated together, one setting, same team, one care plan.	The recommended model; the resource and training demand is the main barrier.

The three service-delivery models for dual diagnosis; integrated treatment is the recommended standard (El-Mallakh 1998; IPS 2014).

MNEMONIC

SPI: Sequential, Parallel, Integrated → "Same Place, one clinician In charge"

Three models, in order of increasing togetherness: Sequential = one then the other; Parallel = both at once but two teams; Integrated = both at once, one team, one plan. Integrated is the answer.

6.5 Integrated treatment: the recommended standard and its principles

The principle. Co-occurring substance use and mental illness require **integrated treatment** rather than serial treatment: address both conditions concurrently, in the same setting, with the same clinical team wherever possible (IPS 2014). This is the single most examinable line in the topic. It is the reason sequential and parallel models exist mainly as foils; the whole point of the taxonomy is to arrive at integration.

What integration contains. Drake and colleagues distilled nine key principles for this group: assertiveness (assertive outreach), close monitoring, integration, comprehensiveness, a stable living environment, flexibility, staged treatment, a longitudinal perspective, and optimism (Companion). Modern integrated programmes are staged and long-term, blend motivational interviewing with relapse prevention and psychosocial support, use a single care plan, and treat family work as a core component, not an add-on (IPS 2014). Pharmacotherapy for the mental disorder is used alongside substance-use pharmacotherapy within the same plan rather than being withheld until abstinence. The general motivational-interviewing frame is developed in the Psychotherapies, clinical assessment, MSE and nosology notes.

PEARL

Integrated does not mean abstinence-first. Withholding antidepressant or antipsychotic treatment until a patient stops using is a sequential-model reflex; in integrated care you start the psychiatric treatment and the substance-use work together, because each makes the other more achievable.

6.6 Pharmacology in the comorbid patient: pick agents that treat both, avoid ones that clash

Choose dual-purpose agents. Where one drug can serve both conditions, prefer it. In comorbid alcohol dependence with bipolar disorder, prefer naltrexone (Naltima or Nodict; oral opioid antagonist, **50 mg/day** for alcohol, titrated from 25 mg) as the anti-craving agent (BAP). Where alcohol-related liver disease limits hepatic metabolism, prefer acamprosate (Acamprol; **666 mg** three times daily) instead (BAP). In comorbid nicotine dependence, varenicline (Champix) helps both. Where comorbid depression coexists with nicotine dependence, bupropion (Bupron; 150 mg once daily for 3 days, then 150 mg twice daily) carries a dual indication (BAP; NICE). In comorbid ADHD with amphetamine use, prescription stimulants may improve ADHD and reduce use (NICE).

Watch the clashes. In comorbid depression after starting opioid agonist treatment, adopt watchful waiting: depression often remits within a month as the person stabilises, so do not rush an antidepressant; and avoid combining tricyclic antidepressants with methadone because of safety risks (WHO mhGAP 2016). The most dangerous single error is giving naltrexone to a

current opioid user (it precipitates acute withdrawal), so the opioid-free window and the substitution-versus-antagonist decision, developed in the opioid substitution topics, matter as much in the comorbid patient as in the pure one.

COMORBID PAIRING	PREFERRED AGENT	DOSE / LINE	SOURCE
AUD + bipolar disorder	**Naltrexone (Naltima / Nodict)**	50 mg/day PO, from 25 mg; first-line here	BAP
AUD + liver disease	**Acamprosate (Acamprol)**	666 mg three times daily	BAP
AUD + nicotine dependence	Varenicline (Champix)	Standard course; treats both	BAP
Nicotine + depression	Bupropion (Bupron)	150 mg OD x3 days then 150 mg BD	BAP / NICE
Opioid + depression on OST	**Watchful waiting**	Often remits within a month; avoid TCA + methadone	WHO mhGAP
Amphetamine + ADHD	Prescription stimulant	May improve ADHD and cut use	NICE

Pharmacological choices that treat both conditions or avoid a clash in the comorbid patient (verified against the day guideline supplement).

GOOD TO REMEMBER

- **Naltrexone (Naltima / Nodict):** oral opioid antagonist, 50 mg/day (from 25 mg) for alcohol craving and first-line where alcohol coexists with bipolar disorder; the signature caution is precipitated withdrawal if given to a current opioid user, so an opioid-free window is mandatory before starting.
- **Acamprosate (Acamprol):** 666 mg three times daily anti-craving agent acting on NMDA-glutamatergic transmission; preferred in comorbid alcohol-related liver disease because it is not hepatically metabolised.
- **Bupropion (Bupron):** 150 mg OD for 3 days then 150 mg BD for smoking cessation; dual indication when depression coexists; avoid where there is a seizure history or an eating disorder.

6.7 The India frame: the treatment gap, de-addiction services, NDPS and buprenorphine access

The gap and where care sits. India carries a very large substance-use treatment gap: most people meeting dependence criteria never reach formal care, and services concentrate in government de-addiction centres and Drug De-addiction Programme (DDAP) units rather than in general or psychiatric practice. For the dual-diagnosis patient this fragmentation is acute, because the addiction service and the psychiatric service are often physically and administratively separate, defaulting the system into a parallel or even sequential model when integrated care is what the patient needs. The IPS substance-use guidelines therefore push integrated, concurrent management with family work as a core component (IPS 2014).

The legal and access frame. The controlling statute is the Narcotic Drugs and Psychotropic Substances Act, 1985 (the medico-legal detail is developed in the Mental health legislation and forensic psychiatry notes). For opioid-agonist treatment the practical reality is that methadone

was not recommended by the Indian expert committee for de-addiction services, so buprenorphine (Tidigesic; buprenorphine-naloxone as Suboxone) is the workhorse of Indian OST, and its induction detail belongs to the substitution topics. Disulfiram (Esperal or Dizone; 250 to 500 mg/day) remains widely used for alcohol relapse prevention but must never be started in a still-drinking or cardiac patient.

INDIA

The Indian dual-diagnosis patient is where the treatment gap bites hardest: a person with, say, cannabis use and a first-episode psychosis may pass between a de-addiction centre and a psychiatry OPD with neither owning the whole picture, which is the parallel or sequential trap the IPS guidelines warn against. Because methadone is not part of the Indian de-addiction formulary, buprenorphine (Tidigesic) carries opioid-agonist maintenance; because de-addiction services are few, integrated care often has to be built inside a single general-hospital psychiatry unit rather than assumed across services. The strategic priority the IPS emphasises is integrated, family-inclusive, non-specialist-deliverable care that closes the gap at the point of first contact (IPS 2014).

6.8 Putting it together: assessment to plan in the comorbid patient

The clinical sequence. Detect (a low threshold, screening both ways), establish the temporal relationship and whether the second diagnosis is independent or substance-induced (re-assessing after abstinence where possible), then build a single integrated plan that treats both concurrently. Where a drug can serve both conditions, choose it; where an agent clashes, avoid it. Family work and psychosocial rehabilitation are part of the plan, not appendices to it. The wider delirium, emergency and pregnancy considerations for the intoxicated or withdrawing comorbid patient are developed in the Perinatal/women's mental health and emergency psychiatry notes.

30%	45%	3	50
COMORBIDITY RATE IN ALCOHOL DEPENDENCE	COMORBIDITY RATE IN DRUG DEPENDENCE	SERVICE MODELS: SEQUENTIAL, PARALLEL, INTEGRATED	NALTREXONE ANTI-CRAVING DOSE, MG PER DAY

WORKED EXAMPLE

A 26-year-old man is referred with paranoid delusions and near-daily cannabis use. The addiction centre wants him "clean first"; the psychiatry team wants him admitted for the psychosis. That split is the sequential-versus-parallel failure in miniature. The integrated answer: admit to one setting, treat the psychosis with an antipsychotic now (do not wait for abstinence), run motivational and relapse-prevention work for the cannabis in the same plan, involve the family, and re-assess whether the psychosis is independent or substance-related once he is stable. One team, one plan, both problems, from the outset.

COMMON TRAP

Do not let the two services each treat "their half" and disown the other; that is the parallel-model failure. And do not demand abstinence before starting psychiatric medication; that is the sequential-model failure. Both are the classic errors the integrated model was designed to correct.

HOLD THIS

Dual diagnosis = a substance use disorder plus another mental disorder; the three service models are sequential, parallel and integrated; integrated treatment (both disorders, concurrently, same setting, same team, one care plan) is the recommended standard, and sequential "get sober first" care is associated with the worst outcomes.

GOOD TO REMEMBER

- **Integrated treatment (the principle):** treat the substance use disorder and the comorbid mental disorder concurrently, in the same setting, with the same clinical team and a single care plan; the discriminator from parallel care is one team and one plan rather than two; the first step is to start both treatments together rather than sequencing them.
- **The three models:** sequential (one then the other, separate services, abstinence-first, worst outcomes), parallel (both at once but two teams, fragmented), integrated (both together, one team, recommended); the answer to "which model?" is integrated.

7 · Harm reduction

Not everyone who uses drugs can, or will, stop today, and **harm reduction** is the pragmatic clinical and public-health response to that reality: a set of policies and interventions that aim to reduce the *harms* of continued substance use for the individual, their family and society, without insisting on abstinence as the precondition for help (Companion to Psychiatric Studies; Tasman Psychiatry). It is not the opposite of abstinence-oriented treatment but the lowest, most inclusive tier of a **hierarchy of goals** that still runs all the way up to abstinence; **the whole point** is to keep a person alive and infection-free long enough to reach the higher rungs later. Synonyms you may meet are harm minimisation, risk reduction and risk minimisation (Tasman Psychiatry).

Why it matters clinically and in exams. Injecting drug use kills through two routes that harm reduction directly targets: blood-borne viral infection (HIV, hepatitis B and C) from shared injecting equipment, and fatal opioid overdose. Examiners test whether you can name the four flagship interventions (needle and syringe programmes, take-home naloxone, opioid substitution as harm reduction, and supervised consumption facilities), place opioid substitution treatment correctly as *both* a treatment and a harm-reduction measure, and state the naloxone rescue dose. The India device is genuine and heavy here: with a very large substance-use treatment gap, the NDPS legal frame, and buprenorphine as the OST workhorse, harm reduction is where Indian policy (through the National AIDS Control Organisation) has done its most concrete work.

7.1 The philosophy: reduce harm, do not require abstinence first

The core idea. Harm reduction accepts that abstinence is not achievable for every person at every moment and asks a different question: given that this person is using, how do we cut the damage? It reduces harm not only to the user but to family, friends and society generally (Tasman Psychiatry). Crucially it is *not* a rival to abstinence; the best models integrate a harm-reduction component with a use-reduction and an abstinence component in one framework, so that reducing either the quantity of use or the harm per use lowers total harm (Tasman Psychiatry).

The controversy. Harm reduction has been resisted where it is misread as condoning or legalising drug use. The counter-argument, and the exam-safe framing, is that it is a clinically salient goal of good medicine that keeps people alive and connected to services, and that it acts as a conduit into more comprehensive treatment rather than an alternative to it (Tasman Psychiatry; Kaplan & Sadock 2024).

RULE **Meet the patient where they are.** Offer harm-reduction measures to anyone who is still using; keeping a person alive and infection-free is the precondition for every later goal, not a reward for stopping.

7.2 The hierarchy of goals: harm reduction is the bottom rung, not a dead end

The ladder. The Companion sets out an explicit **hierarchy of therapeutic goals** for injecting drug users (Box 14.6): (1) reduce sharing of injecting equipment, (2) reduce injecting, (3) reduce street-drug use, (4) stabilise on substitute prescribing, (5) manage the features of the dependence syndrome, (6) reduce substitute prescribing, and finally (7) maintain abstinence from psychoactive drugs (Companion to Psychiatric Studies). The clinician works with whichever rung the patient can reach now, and the lower rungs are legitimate goals in their own right.

Why the order matters. The first and most urgent target is stopping needle-sharing, because that is the step that prevents the irreversible harm of HIV or hepatitis seroconversion; abstinence sits at the top precisely because it is the hardest and last-reached goal, not the entry requirement.

RUNG	GOAL	HARM TARGETED
1	**Reduce sharing of injecting equipment**	Blood-borne virus transmission
2	Reduce injecting (route shift)	Injecting-related infection, overdose
3	Reduce street-drug use	Unknown purity, overdose, crime
4	**Stabilise on substitute prescribing**	Illicit use, overdose, mortality
5	Manage dependence-syndrome features	Morbidity of dependence
6	Reduce substitute prescribing	Ongoing medication burden
7	Maintain abstinence	All substance-related harm

The Companion Box 14.6 hierarchy of therapeutic goals for injecting drug users; harm reduction occupies the lower, most urgent rungs, abstinence the top (Companion to Psychiatric Studies).

7.3 Needle and syringe programmes: clean needles as the first-line harm-reduction intervention

What it is. A needle and syringe programme (also called **needle exchange**) supplies sterile injecting equipment, and safe disposal for used equipment, to people who inject drugs, so that each injection can be done with **clean needles** rather than shared ones. Providing clean needles directly attacks the top rung of the hierarchy: the sharing of injecting equipment that transmits blood-borne viruses (Companion to Psychiatric Studies).

The evidence. Needle exchange has been one of the most controversial strategies, yet the research is broadly favourable: participation is associated with a reduction in the spread of blood-borne infections such as hepatitis and HIV, with cessation of syringe-sharing, and it acts as a conduit into more comprehensive treatment, drawing users into medical withdrawal and other services (Tasman Psychiatry; Companion to Psychiatric Studies). A prospective cohort found no evidence that needle-exchange participation causally transmits HIV, countering the early fear that it might concentrate high-risk users (Tasman Psychiatry). Strategies to cut HIV transmission in people who inject drugs therefore pair needle exchange with pre-exposure prophylaxis, medication-assisted treatment for opioid use disorder, and linkage to HIV care (Kaplan & Sadock 2024).

TRAP **Reading needle exchange as "enabling" drug use.** The evidence is that a needle exchange reduces viral transmission and pulls users into treatment; it does not increase drug use, and treating it as condoning addiction is the classic policy error.

GOOD TO REMEMBER

- **Needle and syringe programme:** supplies sterile equipment so injections use clean needles, not shared ones; targets the top rung (equipment-sharing); reduces HIV and hepatitis transmission and acts as a conduit into treatment; first management step to prevent irreversible blood-borne-virus harm.

7.4 Take-home naloxone: overdose prevention put in the community's hands

What it is. Naloxone is a short-acting mu-opioid antagonist that reverses opioid-induced respiratory depression. **Take-home naloxone** distribution is the harm-reduction strategy of supplying naloxone, with rescue-breathing and recovery-position training, to people who use opioids and to their significant others, so a bystander can reverse an overdose before an ambulance arrives (Maudsley 2021; BAP 2026). Because overdose is the most common cause of death in opioid use disorder, this is the single most life-saving harm-reduction measure for opioid users (Kaplan & Sadock 2024).

The rescue dose. The verified rescue regimen is intramuscular naloxone **0.4 to 2 mg**, repeated every 2 to 3 minutes up to a total of **10 mg**, or intranasal **4 mg** per spray repeated after 2 to 3 minutes (BAP 2026); take-home kits are commonly the **0.4 mg in 1 mL** ampoule or a prefilled device (WHO). The critical caution is that naloxone is short-acting: if the opioid taken is long-acting (methadone, sustained-release preparations) the antagonist can wear off before the agonist does, so **re-narcotisation** can recur and a further dose or infusion and continued observation are needed (Companion to Psychiatric Studies). Overdose risk is highest after any period of forced abstinence (post-detox, post-incarceration, after disengaging from OST) when tolerance has fallen, which is exactly when take-home naloxone should be provided (BAP 2026).

WORKED EXAMPLE

A man who injects heroin is found unresponsive with pinpoint pupils and a respiratory rate of 4. A trained family member gives intramuscular naloxone 0.4 mg, starts rescue breathing and places him in the recovery position; the breathing improves within a couple of minutes. Because the effect is short-lived, they call emergency services and keep him under observation, ready to repeat the dose, since the opioid outlasts the naloxone. The trained bystander and the take-home kit are the intervention that bought the time.

GOOD TO REMEMBER

- **Naloxone (take-home):** short-acting mu-opioid antagonist reversing opioid respiratory depression; rescue dose IM 0.4 to 2 mg, repeat every 2 to 3 min up to 10 mg, or intranasal 4 mg/spray; take-home kit typically 0.4 mg in 1 mL; short half-life means re-narcotisation with long-acting opioids, so observe and repeat; give to any current or recent opioid user, especially after detox or release from custody.

7.5 Opioid substitution as harm reduction: OST is a treatment and a harm-reduction measure at once

The dual identity. Opioid substitution treatment (OST) with methadone or buprenorphine is the pivot where treatment and harm reduction meet. Replacement pharmacotherapy on methadone or buprenorphine is explicitly considered a harm-reduction measure because it reduces the morbidity, mortality and crime of the injecting lifestyle, much as antihypertensives control but do not cure hypertension (Companion to Psychiatric Studies; Tasman Psychiatry). By substituting a prescribed oral or sublingual agonist for injected street opioid it moves the patient up rungs 3 and 4 of the hierarchy at once: off unknown-purity street drugs and off injecting.

The harm-reduction pay-off. OST is the most extensively evaluated treatment in the field; adequate-dose maintenance improves treatment retention, reduces illicit opioid use, and lowers the risk of HIV and hepatitis seroconversion and of overdose death, provided the person stays in treatment (Companion to Psychiatric Studies; Maudsley 2021). Buprenorphine adds a harm-reduction advantage of its own: as a partial agonist it has a ceiling on respiratory depression, making overdose less likely than with full-agonist methadone. Maintenance doses that actually suppress illicit use are needed: buprenorphine typically **16 mg/day** or more, methadone typically **60 to 120 mg/day** after slow induction (Maudsley 2021; NICE 2011).

GOOD TO REMEMBER

- **Buprenorphine (OST as harm reduction):** partial mu-agonist with a respiratory-depression ceiling; substitutes for injected street opioid, reducing injecting, overdose and blood-borne-virus risk; maintenance typically 16 mg/day or more; the Indian OST workhorse; the signature caution is precipitated withdrawal if started before objective withdrawal appears (COWS about 8 to 12).

GOOD TO REMEMBER

- **Methadone (OST as harm reduction):** full mu-agonist; reduces illicit use, mortality and crime as a harm-reduction measure; maintenance typically 60 to 120 mg/day after slow induction (start 20 to 30 mg/day, not more than 30 mg initially); the first two weeks of induction are the high-risk overdose window because of accumulation, so observe closely.

7.6 Supervised consumption facilities and other measures: the higher-threshold end of harm reduction

Supervised consumption. A **supervised consumption facility** (drug consumption room, supervised injection facility) provides a clean, monitored space where people inject or use their own drugs under staff observation, so an overdose can be reversed on the spot and equipment stays sterile. Modelling of Vancouver's supervised injection facility estimated it prevents HIV infections, and such facilities extend **overdose prevention** and blood-borne-virus prevention to the highest-risk users while acting as a further conduit into treatment (Tasman Psychiatry). Related higher-threshold approaches include supervised or daily-observed heroin-assisted treatment for people who fail standard OST, trialled positively in Switzerland, the Netherlands, Germany and Canada (Tasman Psychiatry).

Other harm-reduction measures. The continuum also includes education on safer injecting technique, HIV pre-exposure prophylaxis, testing and linkage to HIV and hepatitis care, and, for tobacco, nicotine harm reduction via safer nicotine delivery (Maudsley 2021; Kaplan & Sadock 2024). The common thread is that every measure keeps the person alive, uninfected and in contact with services.

PEARL

The four flagship harm-reduction interventions map neatly onto the two ways injecting kills: needle and syringe programmes and supervised consumption facilities attack blood-borne infection and unsafe injecting, while take-home naloxone and opioid substitution attack overdose death. Naming this two-axis structure is the clean way to answer an "outline harm reduction" question.

7.7 The Indian harm-reduction and policy context: NACO OST, NDPS and the treatment gap

The frame. India carries a very large substance-use **treatment gap**, with most people meeting dependence criteria never reaching formal care, which is concentrated in government de-addiction centres and Drug De-addiction Programme (DDAP) units rather than in general practice (IPS 2014). The controlling statute is the Narcotic Drugs and Psychotropic Substances (NDPS) Act, 1985, which schedules controlled drugs and shapes access to opioid agonists; its Section 64A allows diversion of an addict into treatment in lieu of conviction, a harm-reduction-flavoured legal provision (the medico-legal detail is developed in the Mental health legislation and forensic psychiatry notes).

Indian harm reduction in practice. The concrete national harm-reduction machinery sits with the National AIDS Control Organisation (NACO), whose targeted interventions for people who inject drugs deliver needle and syringe programmes and opioid substitution treatment as HIV-

prevention. Methadone in India is restricted to government OST clinics run under NACO and select institutional programmes (for example AIIMS NDDTC and NIMHANS), so it is referred to a licensed OST centre rather than prescribed in private practice (IPS 2014). Buprenorphine, usually the sublingual buprenorphine-naloxone 4:1 combination (Indian brands include Tidigesic; the combination as Suboxone or Bunorph), is the accessible workhorse of Indian opioid-agonist maintenance, inducted at 4 mg/1 mg once objective withdrawal appears and maintained at about 8 to 16 mg/day. The IPS emphasis on brief, motivation-based, non-specialist-deliverable care is itself a treatment-gap-closing strategy that complements the harm-reduction pathway (IPS 2014).

INDIA

Harm reduction in India is largely an HIV-prevention story routed through NACO's targeted interventions: needle and syringe programmes and opioid substitution treatment for people who inject drugs sit inside the national AIDS-control machinery rather than mainstream psychiatry, which is why buprenorphine (Tidigesic; buprenorphine-naloxone as Suboxone or Bunorph) rather than tightly restricted methadone is the accessible agent. Take-home naloxone is recommended for opioid-dependent people and their families (BAP 2026) but is not yet widely distributed here; the intranasal naloxone spray marketed for lay overdose reversal is where policy is moving. The NDPS Act, 1985 both restricts access and, through Section 64A treatment-in-lieu-of-conviction, offers a harm-reduction-adjacent diversion route.

0.4 to 2	4	16
IM NALOXONE RESCUE DOSE IN MG (REPEAT EVERY 2 TO 3 MIN, UP TO 10 MG)	BUPRENORPHINE-NALOXONE INDUCTION IN MG (4 MG/1 MG) AT OBJECTIVE WITHDRAWAL	BUPRENORPHINE MAINTENANCE TARGET IN MG/DAY OR MORE

RULE **OST is treatment and harm reduction.** Methadone or buprenorphine maintenance is the single measure that reduces injecting, overdose death and blood-borne-virus transmission at once, and it is the most evidence-based treatment in opioid use disorder.

COMMON TRAP

Do not treat harm reduction and abstinence as mutually exclusive. They are rungs of one hierarchy: harm reduction (clean needles, naloxone, substitution) keeps the person alive and in contact with services so that the higher goals, including abstinence, remain reachable. Insisting on abstinence as the entry ticket loses the very patients harm reduction is designed to save.

HOLD THIS

Four flagship harm-reduction interventions: needle and syringe programmes (clean needles, cut blood-borne-virus transmission), take-home naloxone (IM 0.4 to 2 mg for overdose prevention), opioid substitution treatment (methadone or buprenorphine, both treatment and harm reduction), and supervised consumption facilities; abstinence sits at the top of the hierarchy of goals, not at its entrance.

Alcohol use disorder

8 · The pharmacology of alcohol

Almost everything a psychiatrist does with a drinking patient rests on one small molecule and how the body handles it. **Alcohol pharmacology** is the grammar behind intoxication, the breathalyser reading, why the blood level falls at a fixed pace no matter how drunk the person is, why the chronic drinker metabolises faster, and why a "standard drink" is a fixed dose rather than a glass of any size. Examiners like this topic because it is clean and quantitative: they can ask you to name the two enzymes of the primary pathway, to state that **metabolism** is zero-order, to explain the microsomal route that appears on chronic use, and to convert a drink into units. Get the numbers cold and the clinical topics later in this block, the withdrawal time-course, the disulfiram reaction, the safe-drinking advice, follow from the same physiology.

Why it matters clinically. The reward and mesolimbic-dopamine anatomy on which alcohol's addictive pull is built is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and is not re-derived here; this topic is the pharmacokinetics and molecular pharmacodynamics that every downstream management decision assumes. Zero-order kinetics is why you cannot "sober someone up" faster and why the level drops predictably in a collapsed drinker; the GABA and glutamate story is why alcohol is a central nervous system depressant and why its withdrawal, covered in the withdrawal-management topics, is a hyperexcitable mirror image; the units concept is the currency of every brief intervention and safe-drinking conversation.

8.1 Absorption: a small, fully miscible molecule the gut takes up fast

Where and how fast. Ethanol is a small, water-soluble molecule with no need for a transporter; it is taken up by simple diffusion, a little from the stomach but mostly and rapidly from the proximal small intestine, so gastric emptying is the main rate-limiter of **absorption** (Kaplan and Sadock 2024). An empty stomach speeds absorption and food, especially fat and protein, slows it by delaying emptying, which is why the same drink taken on an empty stomach produces a higher peak. Absorption from the skin is minimal in adults but can be significant in infants sponged with alcohol.

First-pass and the gastric enzyme. A fraction of a drink is oxidised before it ever reaches the systemic circulation, a first-pass effect occurring in the gastric mucosa and liver via gastric alcohol dehydrogenase. This gastric first-pass metabolism is lower in women (contributing, with a smaller volume of distribution, to higher blood levels for the same intake) and is reduced by some drugs, which is one reason a given amount of alcohol hits harder in certain patients.

8.2 Distribution: into total body water, straight across the barriers

Volume of distribution. Once absorbed, ethanol distributes widely and evenly into body water, with a volume of distribution of about **0.7 L/kg**, essentially the volume of total body water (KDT 2019). It crosses the blood-brain barrier efficiently, so brain concentration tracks blood concentration closely, and it crosses the placenta freely, the pharmacological basis of the fetal

alcohol effects developed in the Perinatal/women's mental health and emergency psychiatry notes.

Why body composition changes the level. Because alcohol sits in body water and not in fat, a person with less body water, women on average, and older or leaner patients, reaches a higher blood alcohol concentration for the same dose. The blood-to-breath partition is consistent enough (about 2100:1) that the breathalyser can read blood level from exhaled air, the medico-legal basis of the roadside test.

8.3 The primary metabolic pathway: two enzymes, alcohol to acetaldehyde to acetate

The sequence to memorise. Around 98% of ingested alcohol is oxidised in the liver, and the primary pathway is a two-step oxidation (KDT 2019; Kaplan and Sadock 2024). Step one: alcohol dehydrogenase (ADH), a cytosolic enzyme, oxidises ethanol to **acetaldehyde**, using NAD as cofactor. Step two: aldehyde dehydrogenase (ALDH), a mitochondrial enzyme, oxidises the toxic acetaldehyde to harmless acetate, again NAD-dependent. Acetate is then used peripherally. The whole of alcohol's therapeutics, from the disulfiram reaction to the East-Asian flushing response, turns on this single intermediate, acetaldehyde.

Why acetaldehyde is the pivot. Acetaldehyde is the noxious metabolite; when it accumulates, the person feels flushed, nauseated and unwell. Genetic variation in these enzymes explains population differences: an inactive ALDH variant common in East-Asian people lets acetaldehyde build up after a small drink, producing an aversive flush that lowers dependence risk. Blocking ALDH pharmacologically reproduces this on purpose, which is exactly how disulfiram (Indian brands Esperal, Dizone) works, detailed in the anti-craving and aversion topics.

GOOD TO REMEMBER

- **The primary pathway:** ethanol goes alcohol dehydrogenase (cytosolic, NAD-dependent) to acetaldehyde (the toxic intermediate), then aldehyde dehydrogenase (mitochondrial, NAD-dependent) to acetate; about 98% of a dose is metabolised in the liver; acetaldehyde accumulation is the feature behind both the disulfiram reaction and the East-Asian flush; disulfiram acts by inhibiting aldehyde dehydrogenase.

8.4 Zero-order kinetics: a fixed amount cleared per hour, whatever the level

The defining fact. Because the metabolising enzymes are saturated at ordinary drinking concentrations, alcohol is eliminated by zero-order kinetics: a constant *amount*, not a constant fraction, is cleared per unit time regardless of how high the blood level is (KDT 2019; Kaplan and Sadock 2024). The figure to hold is roughly **8 to 12 mL of absolute alcohol per hour**, which corresponds to falling by about one unit an hour and a blood-alcohol decline on the order of 15 to 20 mg/dL per hour. Contrast this with the first-order elimination of most drugs, where a constant proportion is removed and a half-life can be quoted; ethanol has no meaningful single half-life at intoxicating levels.

The clinical consequences. Three things fall straight out of zero-order handling. You cannot accelerate sobering-up (coffee, fresh air and fructose drips do not meaningfully change the fixed rate); the time to clear a large load is long and roughly predictable, which lets you estimate when a

level will reach zero; and small increases in intake produce disproportionately large and prolonged rises in level once the enzymes are saturated. Methanol is handled the same way (zero-order, but with a far longer effective clearance), which is why its toxicity is delayed and severe.

RULE **You cannot rush a zero-order drug.** Alcohol clears at a fixed amount per hour irrespective of the blood level, so nothing "sobers a person up" faster; management of the intoxicated patient is time, airway and supportive care, not stimulants.

COMMON TRAP

Do not quote a half-life for alcohol at intoxicating levels or reach for a first-order calculation. At ordinary drinking concentrations the pathway is saturated, so elimination is zero-order (a fixed amount per hour), and a half-life is not defined. Only at very low, sub-saturating concentrations does elimination start to look first-order.

8.5 The microsomal route: CYP2E1 and why the chronic drinker clears faster

The second pathway. Alongside alcohol dehydrogenase, a smaller share of alcohol is oxidised by the hepatic microsomal ethanol-oxidising system, chiefly the cytochrome CYP2E1 (KDT 2019). At low intake this route is minor, but it is *inducible*: regular heavy drinking up-regulates CYP2E1, so a chronic drinker metabolises alcohol faster than a naive person. This is the pharmacokinetic (dispositional) arm of tolerance developed in the Tolerance, withdrawal and neuroadaptation topic.

Why induction matters beyond alcohol. An induced CYP2E1 does not only clear alcohol; it changes the handling of other CYP2E1 substrates. The clinically dangerous example is paracetamol: in the chronic drinker, more paracetamol is shunted to its toxic metabolite (NAPQI), so hepatotoxicity occurs at lower doses and the "safe" paracetamol ceiling is reduced. Induction also alters the metabolism of drugs such as phenytoin and tolbutamide, and smoking further induces CYP2E1, adding to the interaction.

PEARL

Acute versus chronic alcohol have opposite effects on drug metabolism. Taken acutely, alcohol competes for and inhibits hepatic enzymes, so it can raise the level of a co-ingested drug; taken chronically, it induces them (notably CYP2E1), so it lowers steady-state levels and clears faster. The same patient can therefore be an inhibitor when drinking and an inducer when sober, which is why timing matters when you read an interaction.

8.6 Pharmacodynamics: a central nervous system depressant on GABA and glutamate

The dual molecular action. Alcohol is a central nervous system depressant, and its acute action has two arms on the brain's main fast-signalling systems (Kaplan and Sadock 2024). It *enhances* inhibitory transmission at the GABA-A receptor (the same target as benzodiazepines and barbiturates, hence their cross-tolerance and the use of a benzodiazepine to cover alcohol withdrawal), and it *inhibits* excitatory transmission at the NMDA subtype of glutamate receptor. The net effect is global central nervous system depression: anxiolysis and disinhibition at low

doses, sedation, ataxia and dysarthria as the level rises, and respiratory depression and coma at high levels.

Where withdrawal comes from. Chronic exposure drives the brain to compensate: it down-regulates GABA-A receptors and up-regulates NMDA receptors to keep functioning against the depressant load. When alcohol is removed, this leaves reduced inhibition and unopposed glutamatergic excitation, the hyperexcitable state that manifests as tremor, autonomic arousal, seizures and, at the extreme, delirium tremens. The dose-response and management of that state are developed in the withdrawal-management topics; here the point is only that intoxication and withdrawal are two faces of the GABA-glutamate adaptation.

GOOD TO REMEMBER

- **Alcohol pharmacodynamics:** a central nervous system depressant that enhances GABA-A (inhibitory) and inhibits NMDA-glutamate (excitatory) transmission; chronic use down-regulates GABA-A and up-regulates NMDA, and withdrawal is that adaptation unmasked (hyperexcitability, seizures, delirium tremens); the shared GABA-A target is why benzodiazepines show cross-tolerance and are first-line to cover alcohol withdrawal.

8.7 The unit and the standard drink: alcohol as a fixed dose

The definitions to hold. To count alcohol as a dose rather than a volume of liquid, two conventions are used. In the UK, one of the units of alcohol is 10 mL of pure ethanol (equivalently 8 g), so a 250 mL glass of 10% wine is 2.5 units (Companion to Psychiatric Studies). In the US, one standard drink contains 14 g of ethanol (about 17.7 mL, so 1.77 UK units); by design a 355 mL beer, a 150 mL glass of wine and a 44 mL shot of spirits each deliver about one US standard drink. Spain and Australia use a 10 g "drink". The point is that beverage strength, not glass size, sets the dose: spirits at 40% pack far more alcohol per millilitre than beer at 4 to 6%.

Where the number is used. Units are the working currency of every safe-drinking conversation, brief intervention and screening tool. They let you quantify weekly intake against low-risk guidance, convert a patient's self-report into a comparable figure, and score the consumption items of the AUDIT (developed with its cut-offs in the screening topics). Knowing that one unit is metabolised in roughly an hour ties the units concept back to the zero-order clearance in 8.4.

CONVENTION	DEFINITION OF ONE DRINK/UNIT	WORKED CONVERSION
UK unit	10 mL (8 g) of pure ethanol	250 mL of 10% wine = 2.5 units
US standard drink	14 g (17.7 mL) of ethanol = 1.77 UK units	355 mL beer = 150 mL wine = 44 mL spirit shot
Spain / Australia "drink"	10 g of ethanol	slightly larger than a UK unit, smaller than a US drink
Clearance anchor	about 1 unit per hour (zero-order)	lets you estimate time for a level to fall

Standard-drink and units conventions; beverage strength (not glass size) sets the dose, and clearance is about one unit per hour (Companion to Psychiatric Studies; KDT 2019).

8 to 12 mL	10 mL	14 g	0.7 L/kg
ABSOLUTE ALCOHOL CLEARED PER HOUR, ZERO-ORDER (ROUGHLY ONE UNIT)	PURE ETHANOL IN ONE UK UNIT (8 G)	ETHANOL IN ONE US STANDARD DRINK	VOLUME OF DISTRIBUTION (TOTAL BODY WATER)

8.8 The India lens: a large treatment gap, the NDPS frame and the de-addiction setting

The epidemiology and the gap. Alcohol is the dominant substance of concern in Indian psychiatric practice, and most people who meet dependence criteria never reach formal care, a very large substance-use treatment gap (IPS 2014). Services are concentrated in government de-addiction centres and Drug De-addiction Programme (DDAP) units rather than general practice, so a strategic shift toward community and home-based delivery using trained non-specialist workers is part of the Indian clinical-practice-guideline response. This is where the pharmacology becomes practical: brief interventions counted in units, safe-drinking advice keyed to the zero-order clearance, and screening keyed to the AUDIT are the front-line tools that scale.

The legal and prescribing frame. The controlling statute is the Narcotic Drugs and Psychotropic Substances (NDPS) Act, 1985, whose scheduling shapes access to controlled agents; the medico-legal detail is developed in the Mental health legislation and forensic psychiatry notes. On the drug side, the anti-craving and aversion agents used in Indian practice are available as familiar brands, disulfiram as Esperal or Dizone, naltrexone as Naltima or Nodict, acamprosate as Acamprol, with the buprenorphine story (Indian brand Tidigesic) belonging to the opioid-substitution topics.

INDIA

The metabolic facts have a direct Indian bedside payoff. Because clearance is fixed and slow (about one unit an hour), the intoxicated patient in a busy Indian emergency setting is managed by time and supportive care, not by any agent that claims to "sober up". Because chronic drinking induces CYP2E1, the malnourished chronic drinker who also takes paracetamol is at hepatotoxic risk at lower doses, a real hazard given over-the-counter availability. And because acetaldehyde is the pivot, disulfiram (Esperal, Dizone) is offered only to a motivated, abstinence-goal patient with a reliable family supervisor and started at least 24 hours after the last drink, a caution that fits the family-supervised model common in Indian de-addiction care (IPS 2014).

MNEMONIC

"ADH makes the poison, ALDH clears it"

Alcohol Dehydrogenase (ADH) makes acetaldehyde, the toxic intermediate; ALdehyde Dehydrogenase (ALDH) clears it to acetate. Disulfiram blocks the second enzyme, so the poison piles up, which is the whole reaction. Chronically, the microsomal CYP2E1 route is induced, so the seasoned drinker clears faster.

GOOD TO REMEMBER

- **Disulfiram (Indian brands Esperal, Dizone):** an aldehyde-dehydrogenase inhibitor that causes acetaldehyde to accumulate on drinking, producing an aversive flush-nausea-hypotension reaction lasting 1 to 4 hours; a maintenance option (250 to 500 mg/day) only in a motivated, abstinence-goal patient with a reliable supervisor, started at least 24 hours after the last drink; the signature caution is that it is dangerous in a still-drinking or cardiac patient and is never a withdrawal treatment.

HOLD THIS

Alcohol distributes into total body water (about 0.7 L/kg), is oxidised in the liver by alcohol dehydrogenase then aldehyde dehydrogenase (acetaldehyde is the toxic pivot), clears by zero-order kinetics at a fixed 8 to 12 mL of absolute alcohol per hour (about one unit), and induces CYP2E1 on chronic use; pharmacodynamically it is a central nervous system depressant that enhances GABA-A and inhibits NMDA-glutamate transmission.

9 · Alcohol withdrawal, CIWA-Ar and SADQ

Stopping alcohol in a physically dependent drinker unmasks a brain that has spent months opposing a depressant, and the result is a time-ordered, potentially lethal **withdrawal spectrum** that a psychiatrist must recognise, stage and treat. This is the first clinical management topic of the substance-use block and one of the highest-yield: examiners want the withdrawal time-course by the clock, the two severity instruments (the **CIWA-Ar** for the withdrawal state and the **SADQ** for dependence severity) with their exact action thresholds and bands, the choice between a symptom-triggered and a fixed-dose benzodiazepine schedule, the choice of agent, and the parenteral-thiamine-before-glucose rule. Get the numbers exact here and most of the day's viva follows.

Why it matters clinically. **Alcohol withdrawal** is the one substance withdrawal that routinely kills: untreated **delirium tremens** carries a mortality of the order of 10 to 20 per cent, and a withdrawal seizure or unrecognised Wernicke encephalopathy converts a routine detoxification into an emergency. The underlying neuroadaptation (down-regulated GABA-A, up-regulated NMDA-glutamate) is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and is not re-derived here; the amnestic mechanism of Korsakoff sits in the Dementias and neurocognitive disorders notes and the Neuropsychiatry of systemic and neurological disease notes. Here the task is to read the syndrome off the clock and manage it by the number.

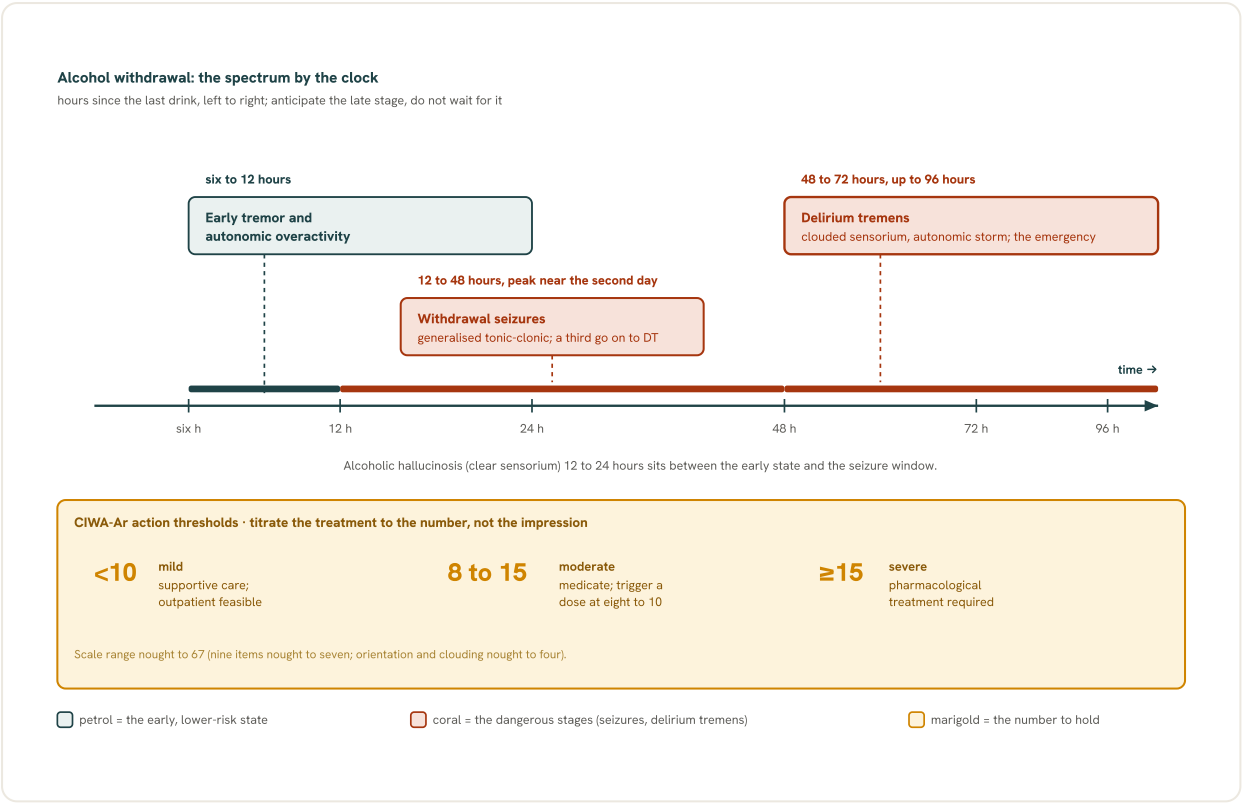


Fig 13.4 The alcohol-withdrawal spectrum read off the clock. Early tremor and autonomic overactivity begin at six to 12 hours, generalised withdrawal seizures cluster at 12 to 48 hours (peaking near day two, and about a third go on to delirium tremens), and delirium tremens, the high-mortality emergency, characteristically emerges at 48 to 72 hours and can extend to 96 hours; alcoholic hallucinosis in a clear sensorium sits at 12 to 24 hours in between. Stage the patient on the axis and treat forwards, titrating a long-acting benzodiazepine to the CIWA-Ar: under 10 is mild (supportive care), 8 to 15 moderate (medicate, with a symptom-triggered dose around a score of eight to 10), and 15 or more severe (pharmacological treatment required), on a scale that runs from nought to 67.

Clinical Institute Withdrawal Assessment of Alcohol Scale, Revised (CIWA-Ar)

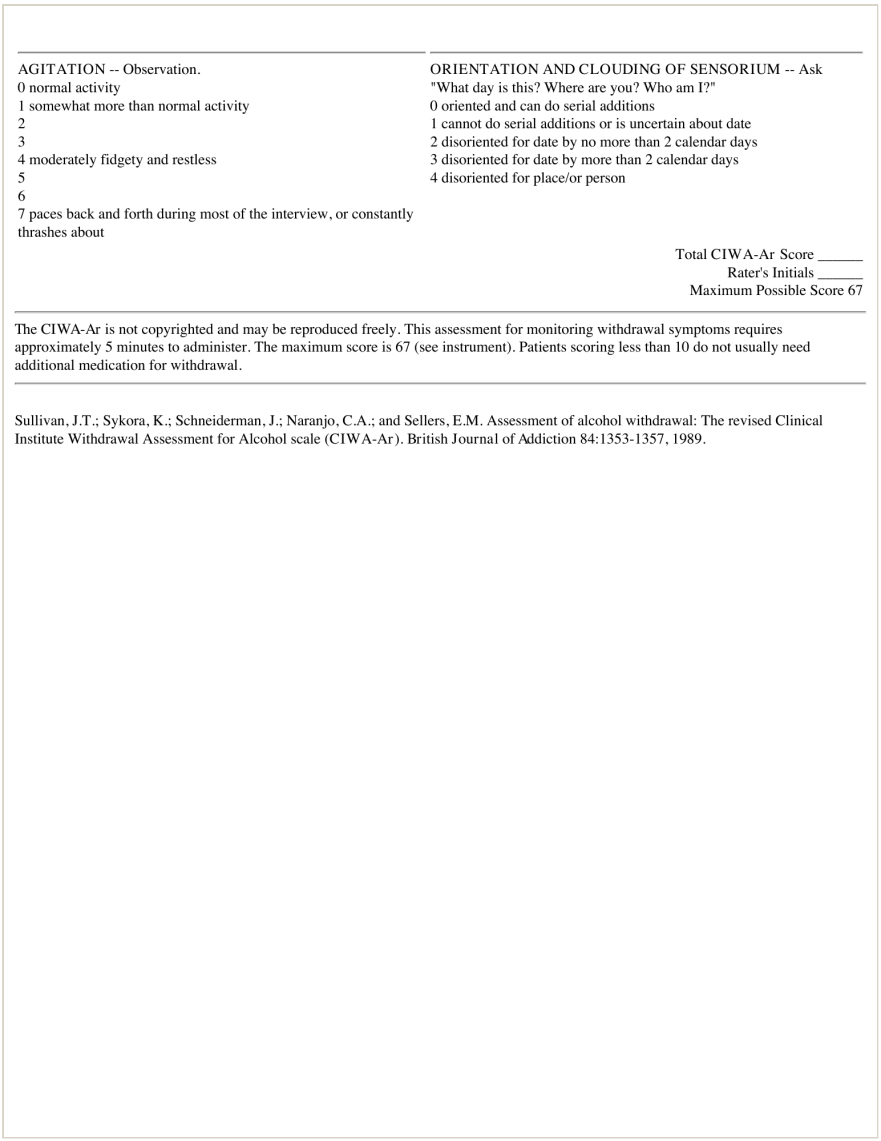
Patient:_____ Date: _____ Time: _____ (24 hour clock, midnight = 00:00)

Pulse or heart rate, taken for one minute:_____ Blood pressure:_____

NAUSEA AND VOMITING -- Ask "Do you feel sick to your stomach? Have you vomited?" Observation.
0 no nausea and no vomiting
1 mild nausea with no vomiting
2
3
4 intermittent nausea with dry heaves
5
6
7 constant nausea, frequent dry heaves and vomiting

TACTILE DISTURBANCES -- Ask "Have you any itching, pins and needles sensations, any burning, any numbness, or do you feel bugs crawling on or under your skin?" Observation.
0 none
1 very mild itching, pins and needles, burning or numbness
2 mild itching, pins and needles, burning or numbness
3 moderate itching, pins and needles, burning or numbness
4 moderately severe hallucinations
5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

TREMOR -- Arms extended and fingers spread apart. Observation.
0 no tremor
1 not visible, but can be felt fingertip to fingertip
2
3
4 moderate, with patient's arms extended
5
6
7 severe, even with arms not extended



AUDITORY DISTURBANCES -- Ask "Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?" Observation.
0 not present
1 very mild harshness or ability to frighten
2 mild harshness or ability to frighten
3 moderate harshness or ability to frighten
4 moderately severe hallucinations
5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

PAROXYSMAL SWEATS -- Observation.
0 no sweat visible
1 barely perceptible sweating, palms moist
2
3
4 beads of sweat obvious on forehead
5
6
7 drenching sweats

VISUAL DISTURBANCES -- Ask "Does the light appear to be too bright? Is its color different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?" Observation.
0 not present
1 very mild sensitivity
2 mild sensitivity
3 moderate sensitivity
4 moderately severe hallucinations
5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

ANXIETY -- Ask "Do you feel nervous?" Observation.
0 no anxiety, at ease
1 mild anxious
2
3
4 moderately anxious, or guarded, so anxiety is inferred
5
6
7 equivalent to acute panic states as seen in severe delirium or acute schizophrenic reactions

HEADACHE, FULLNESS IN HEAD -- Ask "Does your head feel different? Does it feel like there is a band around your head?" Do not rate for dizziness or lightheadedness. Otherwise, rate severity.
0 not present
1 very mild
2 mild
3 moderate
4 moderately severe
5 severe
6 very severe
7 extremely severe

AGITATION -- Observation.
0 normal activity
1 somewhat more than normal activity
2
3
4 moderately fidgety and restless
5
6
7 paces back and forth during most of the interview, or constantly thrashes about

ORIENTATION AND CLOUDING OF SENSORIUM -- Ask "What day is this? Where are you? Who am I?"
0 oriented and can do serial additions
1 cannot do serial additions or is uncertain about date
2 disoriented for date by no more than 2 calendar days
3 disoriented for date by more than 2 calendar days
4 disoriented for place/or person

Total CIWA-Ar Score _____
Rater's Initials _____
Maximum Possible Score 67

The CIWA-Ar is not copyrighted and may be reproduced freely. This assessment for monitoring withdrawal symptoms requires approximately 5 minutes to administer. The maximum score is 67 (see instrument). Patients scoring less than 10 do not usually need additional medication for withdrawal.

Sullivan, J.T.; Sykora, K.; Schneiderman, J.; Naranjo, C.A.; and Sellers, E.M. Assessment of alcohol withdrawal: The revised Clinical Institute Withdrawal Assessment for Alcohol scale (CIWA-Ar). British Journal of Addiction 84:1353-1357, 1989.

CIWA-Ar (Sullivan et al., 1989); public domain.

Fig 13.5 The CIWA-Ar (Clinical Institute Withdrawal Assessment for Alcohol, revised) as the actual clinician-rated form. Nine items are scored nought to seven and the tenth, orientation and clouding of sensorium, nought to four, for a maximum of 67; this is the observer-rated instrument that drives a symptom-triggered benzodiazepine regimen.

SEVERITY OF ALCOHOL DEPENDENCE QUESTIONAIRE (SADQ-C)[1]

NAME_____AGE_____No._____

DATE:

Please recall a typical period of heavy drinking in the last 6 months.

When was this? Month:…… Year……..

Please answer all the following questions about your drinking by circling your most appropriate response.

During that period of heavy drinking

1. The day after drinking alcohol, I woke up feeling sweaty.
ALMOST NEVER SOMETIMES OFTEN NEARLY ALWAYS

2. The day after drinking alcohol, my hands shook first thing in the morning.
ALMOST NEVER SOMETIMES OFTEN NEARLY ALWAYS

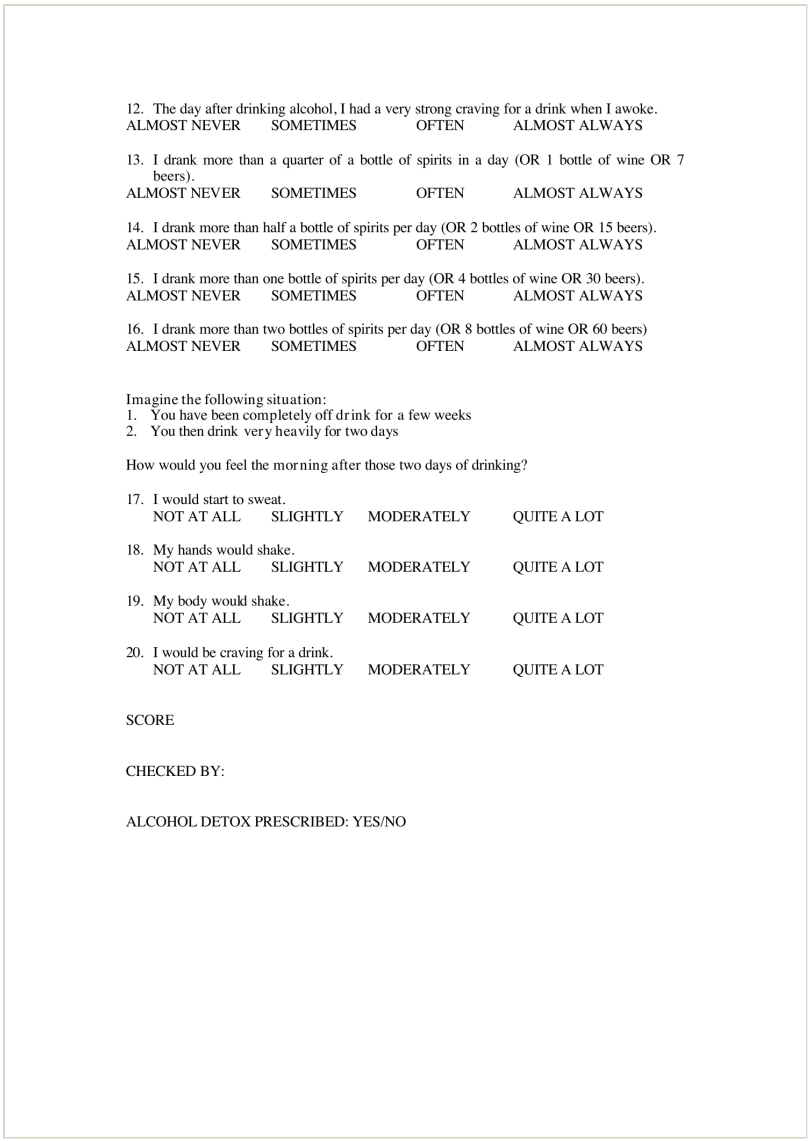
3. The day after drinking alcohol, my whole body shook violently first thing in the morning if I didn't have a drink.
ALMOST NEVER SOMETIMES OFTEN NEARLY ALWAYS

4. The day after drinking alcohol, I woke up absolutely drenched in sweat.
ALMOST NEVER SOMETIMES OFTEN NEARLY ALWAYS

5. The day after drinking alcohol, I dread waking up in the morning.
ALMOST NEVER SOMETIMES OFTEN NEARLY ALWAYS

6. The day after drinking alcohol, I was frightened of meeting people first thing in the morning.
ALMOST NEVER SOMETIMES OFTEN NEARLY ALWAYS

7. The day after drinking alcohol, I felt at the edge of despair when I awoke.
ALMOST NEVER SOMETIMES OFTEN NEARLY ALWAYS



8. The day after drinking alcohol, I felt very frightened when I awoke.
ALMOST NEVER SOMETIMES OFTEN NEARLY ALWAYS

9. The day after drinking alcohol, I liked to have an alcoholic drink in the morning.
ALMOST NEVER SOMETIMES OFTEN NEARLY ALWAYS

10. The day after drinking alcohol, I always gulped my first few alcoholic drinks down as quickly as possible.
ALMOST NEVER SOMETIMES OFTEN NEARLY ALWAYS

11. The day after drinking alcohol, I drank more alcohol to get rid of the shakes.
ALMOST NEVER SOMETIMES OFTEN NEARLY ALWAYS

[1] Stockwell, T., Sitharan, T., McGrath, D.& Lang, . (1994). The measurement of alcohol dependence and impaired control in community samples. Addiction, 89, 167-174.

12. The day after drinking alcohol, I had a very strong craving for a drink when I awoke.
ALMOST NEVER SOMETIMES OFTEN ALMOST ALWAYS

13. I drank more than a quarter of a bottle of spirits in a day (OR 1 bottle of wine OR 7 beers).
ALMOST NEVER SOMETIMES OFTEN ALMOST ALWAYS

14. I drank more than half a bottle of spirits per day (OR 2 bottles of wine OR 15 beers).
ALMOST NEVER SOMETIMES OFTEN ALMOST ALWAYS

15. I drank more than one bottle of spirits per day (OR 4 bottles of wine OR 30 beers).
ALMOST NEVER SOMETIMES OFTEN ALMOST ALWAYS

16. I drank more than two bottles of spirits per day (OR 8 bottles of wine OR 60 beers)
ALMOST NEVER SOMETIMES OFTEN ALMOST ALWAYS

Imagine the following situation:
1. You have been completely off drink for a few weeks
2. You then drink very heavily for two days

How would you feel the morning after those two days of drinking?

17. I would start to sweat.
NOT AT ALL SLIGHTLY MODERATELY QUITE A LOT

18. My hands would shake.
NOT AT ALL SLIGHTLY MODERATELY QUITE A LOT

19. My body would shake.
NOT AT ALL SLIGHTLY MODERATELY QUITE A LOT

20. I would be craving for a drink.
NOT AT ALL SLIGHTLY MODERATELY QUITE A LOT

SCORE

CHECKED BY:

ALCOHOL DETOX PRESCRIBED: YES/NO

SADQ (Stockwell et al.); reproduced with acknowledgement, non-commercial use.

Fig 13.6 The SADQ (Severity of Alcohol Dependence Questionnaire) as the actual self-report form. Twenty items are each scored nought to three, for a maximum of 60; the SADQ indexes dependence severity before withdrawal (15 or less mild, 16 to 30 moderate, above 30 severe and an indication for inpatient detoxification), the complement to the CIWA-Ar, which measures the withdrawal state as it happens.

9.1 The withdrawal spectrum by the clock: a time-ordered emergency

The core sequence. The **withdrawal spectrum** unfolds in a predictable temporal order after the last drink, and the single most examinable fact is that order. Early autonomic overactivity and tremor begin at roughly **6 to 12 hours**; alcoholic hallucinosis (typically visual or tactile, in a clear sensorium) appears around 12 to 24 hours; generalised tonic-clonic withdrawal seizures (the classic "rum fits") cluster at roughly **12 to 48 hours**, peaking near the second day; and delirium tremens, the most dangerous stage, characteristically emerges at **48 to 72 hours** and can extend to 96 hours (Kaplan and Sadock 2024; Maudsley Prescribing Guidelines). Symptoms can begin before the blood alcohol level reaches zero.

Why the order matters. The sequence is not trivia: it lets you place a patient on the curve, anticipate what is coming, and decide setting and intensity. A tremulous, sweating patient at hour

eight is early; the danger window for seizures and delirium is still ahead, so this is precisely the patient in whom to start adequate benzodiazepine cover rather than to reassure and discharge.

STAGE	ONSET AFTER LAST DRINK	KEY FEATURES
Early / minor withdrawal	**6 to 12 hours**	Tremor of hands, tongue, eyelids; anxiety, agitation, insomnia; sweating, nausea, tachycardia, systolic hypertension, low-grade fever (autonomic overactivity).
Alcoholic hallucinosis	12 to 24 hours	Transient visual, tactile or auditory hallucinations in a *clear* sensorium (distinguishes it from delirium tremens); usually settles within 24 to 48 hours.
Withdrawal seizures ("rum fits")	**12 to 48 hours (peak near day two)**	Generalised tonic-clonic; often 2 to 6 in a cluster; about a third go on to develop delirium tremens; a first or focal fit needs investigation for another cause.
Delirium tremens	**48 to 72 hours (up to 96 hours)**	Clouding of consciousness and disorientation, vivid visual and tactile hallucinations, coarse tremor, gross autonomic storm (tachycardia, hypertension, fever, sweating); a medical emergency, 10 to 20 per cent mortality if untreated.

The alcohol withdrawal spectrum in temporal order; delirium tremens is the late, high-mortality stage and is the one to anticipate, not to wait for (Kaplan and Sadock 2024; Maudsley Prescribing Guidelines).

RULE **Place the patient on the clock, then treat forwards.** Read the hours since the last drink; adequate benzodiazepine cover started early prevents the seizures and delirium that come later, so you medicate the trajectory, not just the current score.

GOOD TO REMEMBER

- **Delirium tremens:** the criterion picture is clouding of consciousness plus disorientation, vivid visual and tactile hallucinations and a gross autonomic storm, onset 48 to 72 hours (up to 96 hours) after the last drink; the discriminator from alcoholic hallucinosis is the *clouded* sensorium; the first management step is to treat it as a medical emergency with generously titrated benzodiazepine (an antipsychotic only as adjunct, never alone) and to exclude infection and electrolyte derangement.
- **Alcohol withdrawal seizures:** the criterion feature is a generalised tonic-clonic fit 12 to 48 hours after the last drink, peaking near day two; the first step is a long-acting benzodiazepine (which both treats and prevents further fits) rather than a standard anticonvulsant; a focal or very late fit demands a search for another cause.

9.2 The CIWA-Ar: what it measures and why it is objective

What it is. The CIWA-Ar (Clinical Institute Withdrawal Assessment for Alcohol, revised) is a validated 10-item clinician-rated scale, completed in about five minutes, that quantifies

withdrawal severity so that treatment can be titrated to a number rather than to impression (Sullivan 1989; Tasman; Maudsley Prescribing Guidelines). Nine items (nausea and vomiting, tremor, paroxysmal sweats, anxiety, agitation, tactile disturbances, auditory disturbances, visual disturbances, headache) are each scored **0 to 7**, and the tenth item, orientation and clouding of sensorium, is scored **0 to 4**, giving a maximum total of **67**. The full instrument is reproduced in the scales gallery.

Why it is preferred. The CIWA-Ar is an *objective*, observer-rated scale (contrast the self-completed Short Alcohol Withdrawal Scale, SAWS), which is what makes it the standard tool for driving a symptom-triggered regimen: the same score means the same thing across raters and across time, so repeated scoring tracks the withdrawal and the effect of each dose.

9.3 CIWA-Ar action thresholds: the numbers that drive treatment

The thresholds to memorise. A score under **10** is mild withdrawal that usually needs supportive care only, and is the cut-off below which outpatient detoxification can reasonably be attempted with adequate support; scores of **8 to 15** are moderate and benefit from medication; a score of **15 or more** requires pharmacological treatment (Sullivan 1989; Foy 1988; Tasman). In a symptom-triggered regimen the operational trigger most guidelines use is to medicate when the CIWA-Ar reaches about **8 to 10** and to dose until it falls below 10 (IPS guidelines; BAP 2026). The higher the score, the more the risk: mortality in delirium tremens climbs sharply where the CIWA-Ar exceeds 25 with fever, marked tachycardia or seizures.

CIWA-AR SCORE	SEVERITY	ACTION
under 10	Mild	Supportive care usually sufficient; outpatient detoxification feasible with good support; medication optional.
8 to 15	Moderate	Symptomatic benefit from benzodiazepine; symptom-triggered dosing begins around a trigger of 8 to 10.
15 or more	Severe	Pharmacological treatment required; high-level supportive care and medical monitoring; consider inpatient setting.

CIWA-Ar action thresholds; the operative symptom-triggered trigger is a score of about 8 to 10, and 15 or more mandates medication (Sullivan 1989; Foy 1988; Tasman; IPS guidelines).

COMMON TRAP

Do not use the CIWA-Ar in a delirious, unco-operative or non-communicative patient, or in one with a language barrier or a co-existing head injury. The scale depends on the patient reliably reporting nausea, anxiety and perceptual disturbance and on assessable orientation; in established delirium tremens the score is unreliable and management shifts to clinical titration of benzodiazepine to light sedation, not to a CIWA-Ar number.

9.4 The SADQ: dependence severity, not withdrawal severity

What it is and what it is for. The SADQ (the **Severity of Alcohol Dependence Questionnaire**) is a 20-item self-report questionnaire, each item scored 0 to 3, giving a maximum total of **60**, that indexes the *severity of dependence* and thereby predicts how difficult a withdrawal is likely to be and how much medication it will need (Maudsley Prescribing Guidelines; Shorter Oxford Textbook of Psychiatry). The key conceptual point, and a favourite discriminator, is that the SADQ (also written **SAD-Q**) measures dependence severity *before* withdrawal, whereas the CIWA-Ar measures the withdrawal state as it happens: one sets the starting dose and setting, the other titrates the taper.

The bands. A SADQ score of **15 or less** is mild dependence, **16 to 30** is moderate, and a score **above 30** is severe dependence and is itself an indication for inpatient or residential detoxification (Maudsley Prescribing Guidelines; NICE 2011). The instrument is reproduced in the scales gallery.

SADQ SCORE	DEPENDENCE BAND	PRACTICAL IMPLICATION
15 or less	Mild	Often needs only small benzodiazepine doses or none; community detoxification usually feasible.
16 to 30	Moderate	Fixed-dose reducing benzodiazepine regimen, community or non-specialist inpatient setting.
above 30	Severe	An indication for inpatient / residential detoxification; higher starting doses; anticipate complications.

SADQ dependence-severity bands; a score above 30 flags severe dependence and points to inpatient detoxification (Maudsley Prescribing Guidelines; NICE 2011; Shorter Oxford Textbook of Psychiatry).

PEARL

Keep two questions separate. "How dependent is this person?" is answered before you start, by the SADQ (and by units per day and history of complications), and it sets the starting dose and the setting. "How bad is the withdrawal right now?" is answered repeatedly during detoxification by the CIWA-Ar, and it drives each dose. Mixing them up (using a SADQ to titrate, or a CIWA-Ar to decide inpatient versus outpatient in a currently sober patient) is a classic conceptual error.

9.5 Benzodiazepines: the first-line agent and why

The rule. A benzodiazepine is the first-line, gold-standard treatment for alcohol withdrawal (BAP 2026; IPS guidelines; NICE 2011; WHO mhGAP 2016). The reason is mechanistic: benzodiazepines show cross-tolerance with alcohol at the GABA-A receptor, so they substitute for the missing depressant at exactly the adapted target and are then tapered, and they are anticonvulsant, so they both relieve the withdrawal and prevent withdrawal seizures. Long-acting agents are preferred because their slow elimination self-tapers and gives a smoother course. WHO

mhGAP calls benzodiazepines the front-line medication and states plainly that antipsychotics must not be used as stand-alone treatment for alcohol withdrawal.

The guideline positions, in order. BAP names benzodiazepines the gold standard, preferring longer-acting agents (diazepam, chlordiazepoxide) except where hepatic metabolism is impaired (BAP 2026). The **Indian Psychiatric Society** offers a benzodiazepine (chlordiazepoxide or diazepam) as first-line, with chlordiazepoxide 25 to 50 mg orally every four to six hours as needed for uncomplicated withdrawal and a switch to lorazepam in hepatic compromise (IPS guidelines). NICE names chlordiazepoxide or diazepam as the preferred medication, reduced over 7 to 10 days (NICE 2011). WHO mhGAP recommends long-acting benzodiazepines limited to the first 3 to 7 days (WHO mhGAP 2016). None of these is contradicted here; benzodiazepine-first is verified across all four.

GOOD TO REMEMBER

- **Benzodiazepine (class):** first-line, gold-standard treatment for alcohol withdrawal; works by cross-tolerance at GABA-A and is anticonvulsant, so it treats symptoms and prevents seizures; prefer long-acting agents (diazepam, chlordiazepoxide) for a smoother, self-tapering course; the dose is titrated to the CIWA-Ar and reduced to zero over about 5 to 10 days.

9.6 Choice of agent: chlordiazepoxide and diazepam, and the hepatic switch

The default long-acting agents. For most patients the agent is chlordiazepoxide (the UK and Indian community workhorse) or diazepam; both are long-acting, cross-tolerant and anticonvulsant (BAP 2026; NICE 2011; IPS guidelines). Chlordiazepoxide is favoured for community detoxification because its lower euphoria and slower onset give it lower misuse potential than diazepam.

The hepatic-impairment switch. The one signature exception every candidate must know: in significant liver disease (and in the elderly, or where the oral route is unreliable) switch to lorazepam or oxazepam. These are metabolised by glucuronidation and have no active metabolites (unlike chlordiazepoxide and diazepam, whose long-lived active metabolites accumulate in hepatic failure and can cause oversedation and encephalopathy). Lorazepam 1 to 2 mg every four to six hours is the standard hepatic-compromise substitute (IPS guidelines); oxazepam is BAP's preferred agent in pregnancy for the same reason, an intermediate half-life with no active metabolite (BAP 2026). In severe liver impairment, avoid benzodiazepines with extensive hepatic metabolism altogether and monitor closely.

AGENT	WHEN TO USE	NOTE
Chlordiazepoxide (community default)	**Most uncomplicated withdrawal**	Long-acting, low misuse potential; UK and Indian first choice; reduce over 5 to 10 days.
Diazepam	Alternative long-acting; front-loading in severe risk	Long-acting active metabolites; smoothest course; used in front-loading regimens under close monitoring.
Lorazepam	**Hepatic impairment, elderly, unreliable oral route**	Glucuronidated, no active metabolite; does not accumulate in liver failure; 1 to 2 mg q4 to 6h.
Oxazepam	Hepatic impairment; BAP-preferred in pregnancy	Intermediate half-life, no active metabolite; hospitalise pregnant women for withdrawal.

Choice of benzodiazepine; the mnemonic exception is the LOT of glucuronidated agents (lorazepam, oxazepam, temazepam) in hepatic impairment (BAP 2026; IPS guidelines; NICE 2011).

MNEMONIC

LOT for the liver

Lorazepam, **O**xazepam, **T**emazepam are the glucuronidated benzodiazepines with no active metabolite, so they are the ones to reach for in hepatic impairment; the long-acting agents (chlordiazepoxide, diazepam) accumulate and oversedate the failing liver.

GOOD TO REMEMBER

- **Chlordiazepoxide (Librium):** the default long-acting benzodiazepine for alcohol withdrawal; a moderate-dependence fixed-dose schedule is about 20 mg four times daily on day one tapering to zero over roughly 5 days; low misuse potential makes it the community first choice; switch to lorazepam or oxazepam if the liver is compromised.
- **Lorazepam:** the hepatic-impairment substitute; glucuronidated with no active metabolite so it does not accumulate in liver failure; about 1 to 2 mg orally every four to six hours; also the practical choice when the oral route is unreliable (it can be given IM or IV).

9.7 Symptom-triggered versus fixed-dose: choosing the regimen

The two regimens. A **symptom-triggered** regimen gives a benzodiazepine only when the CIWA-Ar crosses a trigger (about 8 to 10), re-scoring every one to two hours and dosing until the score settles; a **fixed-dose** regimen gives a pre-set, tapering schedule regardless of moment-to-moment symptoms, with as-needed top-ups. Two randomised trials showed that symptom-triggered dosing shortens treatment duration and reduces the total benzodiazepine given compared with fixed dosing (Saitz 1994; Daeppen 2002; Tasman), but it depends on trained staff able to score reliably and frequently.

How to choose. The dividing line is monitoring capacity, not preference. NICE and the IPS position both direct that *community* and non-specialist settings use a *fixed-dose* reducing regimen (because reliable frequent scoring is not available and unsupervised as-needed dosing is unsafe), while symptom-triggered dosing is reserved for inpatient or specialist settings with adequate

monitoring and for patients without a history of complications (NICE 2011; IPS guidelines; BAP 2026). In practice symptom-triggered treatment often lasts only 24 to 48 hours before switching to an individualised fixed-dose taper.

FEATURE	SYMPTOM-TRIGGERED	FIXED-DOSE REDUCING
How dosed	Only when CIWA-Ar reaches trigger (about 8 to 10)	Pre-set tapering schedule, with PRN top-ups
Setting	**Inpatient / specialist, adequate monitoring**	**Community and non-specialist settings**
Requires	Trained staff, frequent reliable CIWA-Ar scoring	No moment-to-moment scoring; safer where monitoring is limited
Evidence signal	Shorter treatment, less total benzodiazepine (Saitz 1994; Daeppen 2002)	Predictable, standardised; preferred for outpatient safety

Symptom-triggered versus fixed-dose benzodiazepine regimens; the choice is decided by monitoring capacity, not clinician preference (NICE 2011; IPS guidelines; Tasman).

9.8 A worked fixed-dose chlordiazepoxide schedule

The rule of thumb. For a fixed-dose regimen the starting dose is estimated from the severity of dependence, using SADQ, units per drinking day and history: a rough guide is that consuming about 20 units a day suggests a starting dose near 20 mg four times daily, tapered to zero over 5 to 10 days (Maudsley Prescribing Guidelines). Mild dependence often needs very little or nothing; severe dependence usually needs inpatient care and a longer taper.

DAY	MODERATE DEPENDENCE (MG, CHLORDIAZEPOXIDE)	TOTAL (MG/DAY)
Day one	20 four times daily	**80**
Day two	15 four times daily	60
Day three	10 four times daily	40
Day four	5 four times daily	20
Day five	5 twice daily	10

A typical fixed-dose reducing chlordiazepoxide regimen for moderate alcohol dependence; severe dependence uses higher starting doses (for example a 200 mg first-day total) over a 7 to 10 day taper (Maudsley Prescribing Guidelines).

TRAP **Do not start the benzodiazepine while the patient is still intoxicated,** and do not taper faster than the schedule. Prescribing on top of alcohol risks respiratory depression; an over-rapid taper in a severely dependent or multiply-detoxified drinker re-opens the seizure and delirium window.

9.9 Parenteral thiamine before glucose: the non-negotiable

The rule. Every withdrawing or malnourished drinker at risk of Wernicke encephalopathy must receive parenteral thiamine before any intravenous glucose. Thiamine is the cofactor needed to metabolise glucose; giving a glucose load to a thiamine-deplete patient consumes the last of their

thiamine and can precipitate acute Wernicke encephalopathy (Maudsley Prescribing Guidelines; IPS guidelines). This is the single most tested management error on the topic.

The regimens. BAP recommends parenteral thiamine 300 to 1500 mg/day for 3 to 5 days for anyone with risk factors for Wernicke-Korsakoff, followed by an oral course, and treating established Wernicke encephalopathy as an emergency (BAP 2026). The IPS position gives parenteral thiamine 100 mg IM or IV daily for at least 3 to 5 days for prophylaxis, escalating to about 500 mg IV three times daily for 2 to 3 days if any Wernicke feature is present, then oral thiamine 100 mg/day for the duration of detoxification and at least 3 months (IPS guidelines). Wernicke encephalopathy is a thiamine-deficiency emergency in which the classical triad (confusion, ophthalmoplegia, ataxia) is complete in only about 10 per cent, so treat empirically on any single new neurological sign in a withdrawing patient; the amnestic Korsakoff endpoint is developed in the Dementias and neurocognitive disorders notes.

WORKED EXAMPLE

A malnourished man is brought in confused and unsteady 40 hours after his last drink; the intern sets up intravenous 5 per cent dextrose for presumed hypoglycaemia. The correct order is to give parenteral thiamine *first* (a Wernicke feature, ataxia, is already present, so an escalated regimen, for example 500 mg IV three times daily, is indicated), and only then the glucose. Reversing the order, glucose before thiamine, is the classic examination trap and can convert a treatable state into irreversible Korsakoff amnesia.

GOOD TO REMEMBER

- **Thiamine (parenteral, vitamin B1):** give it *before* any glucose in a malnourished or withdrawing drinker; prophylaxis is roughly 100 mg IM/IV daily (BAP: 300 to 1500 mg/day) for 3 to 5 days, escalated to about 500 mg IV three times daily for 2 to 3 days if any Wernicke feature appears, then a long oral course; the criterion trigger to treat empirically is a single new neurological sign, since the full triad is present in only about 10 per cent.

9.10 When benzodiazepines are not enough: seizures, delirium tremens and adjuncts

Seizures. After an alcohol withdrawal seizure, use a benzodiazepine (not a standard anticonvulsant) to prevent further fits; phenytoin does not prevent alcohol withdrawal seizures, and long-acting benzodiazepines are the meta-analytic winner for seizure prevention (WHO mhGAP 2016; Maudsley Prescribing Guidelines). A history of prior withdrawal seizures is an indication for long-acting benzodiazepine prophylaxis and for treating the withdrawal as high-risk.

Delirium tremens. Delirium tremens is a medical emergency needing generous, titrated benzodiazepine (often high doses, sometimes intravenous lorazepam or diazepam to light sedation) plus correction of electrolytes (magnesium, potassium, phosphate) and a search for infection; where agitation and hallucinations are not controlled by adequate benzodiazepine, add a dopamine antagonist (haloperidol) as an *adjunct*, never as monotherapy, watching for the lowered seizure threshold (IPS guidelines; BAP 2026). Carbamazepine or gabapentin can be

added or substituted where benzodiazepines are contraindicated or where past withdrawal seizures or benzodiazepine-misuse concerns apply (IPS guidelines; BAP 2026).

15	above 30	48 to 72 h
CIWA-AR SCORE AT OR ABOVE WHICH BENZODIAZEPINE TREATMENT IS REQUIRED	SADQ SCORE DEFINING SEVERE DEPENDENCE (INDICATION FOR INPATIENT DETOXIFICATION)	CHARACTERISTIC ONSET WINDOW FOR DELIRIUM TREMENS AFTER THE LAST DRINK

9.11 The India frame: treatment gap, NDPS and the de-addiction context

The clinical reality. India carries a very large substance-use treatment gap, with most people meeting dependence criteria never reaching formal care, and alcohol the commonest substance in de-addiction services (IPS guidelines). Care is concentrated in government de-addiction centres and Drug De-addiction Programme (DDAP) units and in the day care centre model rather than in general practice, so the psychiatrist is often the first and only clinician to stage a withdrawal correctly. The IPS position deliberately shifts brief, motivation-based interventions toward community and home-based delivery by trained non-specialist workers precisely to close that gap.

Access and law. The controlled status of benzodiazepines and of opioid agents sits under the Narcotic Drugs and Psychotropic Substances (NDPS) Act, 1985, whose scheduling shapes access; the medico-legal detail is developed in the Mental health legislation and forensic psychiatry notes. Indian brands the candidate should recognise for the relapse-prevention agents that follow detoxification are disulfiram (Indian brands Esperal, Dizone), naltrexone (Naltima, Nodict) and acamprosate (Acamprol); the withdrawal-management agents themselves are the generic benzodiazepines and parenteral thiamine above. A verified caution to carry forward: naltrexone must never be started in a current opioid user (it precipitates acute withdrawal) and needs an opioid-free window of about 7 to 10 days, a point developed in the opioid-substitution topics.

INDIA

Two India-specific management points recur in the viva. First, the parenteral-thiamine-before-glucose rule is not academic here: malnourished, multiply-detoxified drinkers presenting late to under-resourced services are exactly the Wernicke-risk population, and the IPS position specifies escalated parenteral thiamine on any Wernicke feature. Second, the fixed-dose chlordiazepoxide regimen is the default for community and non-specialist Indian settings because reliable frequent CIWA-Ar scoring for a symptom-triggered regimen is often unavailable; symptom-triggered dosing belongs to the inpatient de-addiction ward. Disulfiram (Esperal, Dizone) remains widely used in supervised, family-monitored abstinence programmes but is a relapse-prevention, not a withdrawal, agent and is started only after withdrawal is complete and at least 24 hours after the last drink.

HOLD THIS

Alcohol withdrawal runs on a clock (tremor and autonomic overactivity at 6 to 12 hours, seizures at 12 to 48 hours, delirium tremens at 48 to 72 hours); stage it with the CIWA-Ar (medicate at 8 to 10, treat at 15 or more) and the SADQ (severe above 30), cover it with a long-acting benzodiazepine (chlordiazepoxide or diazepam, or lorazepam/oxazepam if the liver is compromised) symptom-triggered inpatient or fixed-dose in the community, and give parenteral thiamine before any glucose.

10 · Delirium tremens and the substance-emergency differential

A patient stops drinking, and two or three days later becomes floridly confused, terrified, drenched in sweat, tachycardic and hallucinating. Recognising that picture as **delirium tremens** rather than a psychiatric decompensation, and separating it in a single beat from the other substance emergencies it mimics, is one of the highest-yield decisions on this block: get it right and you treat a reversible, high-mortality state; get it wrong and a treatable emergency is missed. Examiners want the onset window by the clock, the core clinical picture, the mortality figure, the parenteral-benzodiazepine-and-supportive plan, and the one discriminator that peels delirium tremens apart from Wernicke encephalopathy, alcoholic hallucinosis, opioid overdose and sedative-hypnotic withdrawal.

Why it matters clinically. **Delirium tremens** is the most severe form of alcohol withdrawal and the one that routinely kills. It is a clouded, fluctuating **confusion**al state with a gross **autonomic** storm, and its danger is that it is often missed early, dismissed as "simple withdrawal" until the patient is delirious and unstable. The underlying neuroadaptation (down-regulated GABA-A, up-regulated NMDA-glutamate) is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and is not re-derived here; the amnestic mechanism of Korsakoff sits in the Dementias and neurocognitive disorders notes and the Neuropsychiatry of systemic and neurological disease notes; the wider delirium and restraint frame is in the Perinatal/women's mental health and emergency psychiatry notes. Here the task is to recognise the syndrome, treat it by the number, and run the emergency differential.

Discriminator the row you read across	Delirium tremens alcohol withdrawal	Wernicke encephalopathy thiamine deficiency	Alcoholic hallucinosis the clear-mind case	Opioid overdose the killable one	Sedative withdrawal benzo/barbiturate
Substance and timing	alcohol; 48 to 96 h after the last drink	thiamine lack; any time in a malnourished drinker	alcohol; 12 to 24 h, on continued use	opioid; acute, at the point of overdose	**timed to half-life:** short 12 to 24 h, long peaks at 5 to 8 days
Conscious-ness	clouded, fluctuating, disoriented (a delirium)	confused, but the eye and gait signs dominate	**clear and oriented, no clouding**	reduced, to coma	clouded if it reaches a delirium
Pupils	normal to dilated	normal	normal	**pinpoint (miotic), survive tolerance**	normal
Autonomic state	**gross storm: tachycardia, fever, sweating, hypertension**	no autonomic storm	minimal, if any	respiratory depression, not a sympathetic storm	overactivity, like alcohol withdrawal
The key sign what settles it in one look	clouded mind and autonomic storm together	**ophthalmoplegia or nystagmus with ataxia, no autonomic storm**	hallucinations in a clear sensorium	pinpoint pupils with failing respiration	delirium keyed to the agent's half-life
First management step	**parenteral benzodiazepine,** plus thiamine and supportive care	**IV thiamine at once, 500 mg three times daily**	reassure and observe; antipsychotic if it persists or distresses	**naloxone, with airway and ventilation support**	long-acting benzodiazepine or phenobarbital taper

shaded cell = the single best discriminator for that column

coral = opioid overdose, the reversible-in-minutes emergency

Fig 13.7 The substance emergencies discriminated. Read down the column, but the shaded cell is the one that settles each: delirium tremens is the clouded mind plus autonomic storm, Wernicke the eye signs and ataxia without a storm, alcoholic hallucinosis the clear sensorium, opioid overdose the pinpoint pupils with failing respiration, and sedative-hypnotic withdrawal the delirium timed to the agent's half-life. The first move follows straight from the discriminator: benzodiazepine, thiamine, reassurance, naloxone, or a long-acting taper.

10.1 What delirium tremens is: the criterion picture

The core state. Delirium tremens (DT, plural **DTs**) is an acute organic brain syndrome (a delirium) precipitated by cessation or a sharp reduction of heavy alcohol intake in a physically dependent drinker (Kaplan and Sadock 2024; Maudsley Prescribing Guidelines). The defining triad, and the thing to say first in a viva, is *clouded fluctuating consciousness*, *disorientation*, and a *gross autonomic storm*, on which vivid hallucinations are superimposed. It is not a functional psychosis: the sensorium is impaired, and that single fact drives most of the differential below.

The full clinical picture. The features cluster into four groups (Maudsley Prescribing Guidelines): clouding of consciousness with disorientation in time and place, poor attention span and distractibility; vivid, frightening visual and tactile hallucinations (the classic tactile hallucination of insects or small animals crawling over the skin, formication) with illusions; marked **autonomic** hyperactivity (tachycardia, hypertension, sweating, fever); and psychomotor agitation, coarse tremor, ataxia, insomnia with sleep-wake reversal, and dehydration with electrolyte imbalance. Prodromal night-time insomnia, restlessness and fear often precede the full state.

FEATURE CLUSTER	WHAT YOU SEE
Clouded consciousness	**Disorientation in time and place, fluctuating attention, distractibility (the delirium itself)**
Perceptual disturbance	Vivid, frightening visual and tactile hallucinations; formication (insects crawling on skin); illusions
Autonomic storm	**Tachycardia, hypertension, profuse sweating, fever (sympathetic overactivity)**
Psychomotor / other	Coarse tremor, agitation, ataxia, insomnia with sleep-wake reversal, dehydration and electrolyte derangement

The four feature-clusters of delirium tremens; the clouded sensorium plus autonomic storm is the criterion picture and separates it from alcoholic hallucinosis (Maudsley Prescribing Guidelines; Kaplan and Sadock 2024).

RULE **Clouded consciousness makes it delirium tremens.** Hallucinations in a clear sensorium are alcoholic hallucinosis; the moment consciousness clouds and the patient is disoriented with an autonomic storm, it is delirium tremens and a medical emergency.

10.2 The onset window and course: the 48-to-96-hour rule

Onset by the clock. Delirium tremens characteristically begins **48 to 96 hours** (2 to 4 days) after the last drink, later than the early tremor (6 to 12 hours), the hallucinosis (12 to 24 hours) and the withdrawal seizures (12 to 48 hours) that may precede it (Maudsley Prescribing Guidelines; Kaplan and Sadock 2024). The window is 2 to 4 days; the Maudsley Prescribing Guidelines give the peak at 3 to 4 days (72 to 96 hours). It is the *late* stage of the withdrawal spectrum, which is exactly why it must be anticipated in a tremulous patient at hour eight rather than waited for.

Course and who gets it. Delirium tremens develops in roughly **5 per cent** of patients admitted for alcohol withdrawal (the Maudsley Prescribing Guidelines 3 to 5%), compared with acute tremulousness in about a third; and in about **30 per cent** of alcohol-withdrawal seizure cases, delirium tremens follows the fit. The **course** once established is short, typically resolving over 3 to 7 days with treatment. Risk factors that should raise your guard: severe dependence, self-detoxification without medical cover, multiple previous withdrawal admissions, a past history of delirium tremens or withdrawal seizures, concurrent medical illness, and low potassium, low magnesium or thiamine deficiency (Maudsley Prescribing Guidelines).

GOOD TO REMEMBER

- **Delirium tremens (syndrome):** the criterion picture is clouded fluctuating consciousness plus disorientation plus a gross autonomic storm, with vivid visual and tactile hallucinations on top; onset 48 to 96 hours (2 to 4 days) after the last drink; develops in about 5 per cent of alcohol-withdrawal admissions; the discriminator from alcoholic hallucinosis is the *clouded* sensorium; the first management step is to treat it as a medical emergency with generously titrated parenteral benzodiazepine plus supportive care, and to give parenteral thiamine before any glucose.

10.3 Mortality: why untreated delirium tremens kills

The number to hold. Untreated delirium tremens carries a mortality of the order of **10 to 20 per cent** (Maudsley Prescribing Guidelines; Kaplan and Sadock give a range of 4 to 20%); with

prompt treatment this falls to roughly 5 per cent or less. Death is from cardiovascular collapse, hyperthermia, aspiration, infection, self-injury, or the complications of an untreated autonomic storm and its electrolyte derangement. Mortality rises sharply where the withdrawal is severe: a CIWA-Ar over **25** with concurrent fever, marked tachycardia (over 120) or seizures flags a patient who needs care escalated immediately.

48 to 96 h	5	10 to 20	25
ONSET OF DELIRIUM TREMENS AFTER LAST DRINK	PER CENT OF WITHDRAWAL ADMISSIONS WHO DEVELOP IT	PER CENT MORTALITY UNTREATED (MAUDSLEY)	CIWA-AR ABOVE WHICH MORTALITY CLIMBS WITH FEVER OR FITS

COMMON TRAP

The classic error is missing delirium tremens behind "simple withdrawal". A patient two to three days into an unsupervised detoxification who becomes agitated, confused and febrile is not decompensating psychiatrically and is not merely anxious: this is the late, lethal stage of the withdrawal spectrum. Treating it as agitation with an antipsychotic alone, without adequate benzodiazepine cover and without excluding infection and electrolyte derangement, is dangerous and misses the diagnosis.

10.4 Management of delirium tremens: the parenteral-benzodiazepine and supportive plan

The first step. The **management of delirium tremens** begins by treating it as a medical emergency: admit, ideally to a high-dependency or monitored setting, and consider intensive care (Maudsley Prescribing Guidelines; IPS guidelines). The mainstay is a benzodiazepine, given *parenterally* and titrated generously to light sedation, because the delirious patient cannot reliably take or absorb oral medication and needs rapid control of the autonomic storm. Escalate to intravenous lorazepam or intravenous diazepam, titrated to a lightly sedated, arousable state; established delirium tremens needs larger benzodiazepine doses than uncomplicated withdrawal (IPS guidelines; Maudsley Prescribing Guidelines). In the delirious patient the CIWA-Ar is unreliable (it depends on the patient reporting symptoms and being orientable), so dosing is by clinical titration, not by a score.

The supportive package. Alongside the benzodiazepine: give parenteral thiamine before any glucose load (see 10.5); actively correct fluid and electrolyte derangement (potassium, magnesium, phosphate); monitor pulse, blood pressure and temperature closely; and exclude the mimics and precipitants, particularly infection, head injury, hepatic encephalopathy and metabolic derangement, which can both cause and complicate the delirium. An antipsychotic (haloperidol or olanzapine) is added only as an adjunct for severe agitation or hallucinations that persist despite adequate benzodiazepine, never as monotherapy, and with care because antipsychotics lower the seizure threshold (BAP 2026; WHO: do not use antipsychotics as stand-alone treatment for alcohol withdrawal).

STEP	ACTION
Setting	**Medical emergency: admit to high-dependency/monitored bed; consider ICU**
Mainstay	**Parenteral benzodiazepine (IV lorazepam or diazepam) titrated to light sedation**
Vitamin	Parenteral thiamine BEFORE any glucose (Wernicke prophylaxis and treatment)
Supportive	Correct fluids and electrolytes (K, Mg, phosphate); monitor pulse, BP, temperature
Exclude	Infection, head injury, hepatic encephalopathy, metabolic causes
Antipsychotic	Adjunct only (haloperidol/olanzapine) for refractory agitation, never as monotherapy

The management of delirium tremens: parenteral benzodiazepine plus a supportive, exclusionary package; the antipsychotic is an adjunct, never the mainstay (Maudsley Prescribing Guidelines; IPS guidelines; BAP 2026).

GOOD TO REMEMBER

- **Lorazepam (in delirium tremens):** the parenteral benzodiazepine of choice when the oral route is unreliable or the liver is compromised; glucuronidated with no active metabolite so it does not accumulate; give IV/IM, titrated to light arousable sedation (about 1 to 2 mg per dose repeated to effect); it controls the autonomic storm and prevents seizures.
- **Diazepam (in delirium tremens):** long-acting benzodiazepine used IV, titrated to light sedation; its long half-life self-tapers and smooths the course; front-loading (repeated doses until symptoms settle) is used under close inpatient monitoring; avoid where hepatic metabolism is significantly impaired (active metabolites accumulate).

10.5 Thiamine before glucose: the one supportive rule that cannot be skipped

The rule. Give parenteral thiamine *before* any intravenous glucose in a malnourished or actively withdrawing drinker (NICE; WHO mhGAP 2016; IPS guidelines). A carbohydrate load consumes the last of a depleted thiamine store and can precipitate acute Wernicke encephalopathy; the sequence is thiamine first, glucose second. For prophylaxis in withdrawal, parenteral thiamine 100 mg IM/IV daily for at least 3 to 5 days is standard; where any Wernicke feature is present, escalate to **500 mg IV three times daily** for 2 to 3 days (the emergency regimen; see 10.7).

TRAP **Never give IV glucose before thiamine in a drinker.** A glucose load in a thiamine-depleted patient can precipitate acute Wernicke encephalopathy; the order is thiamine first, always, and parenterally.

GOOD TO REMEMBER

- **Thiamine (vitamin B1):** give parenterally BEFORE any glucose in a malnourished or withdrawing drinker; withdrawal prophylaxis is 100 mg IM/IV daily for at least 3 to 5 days (then oral); suspected Wernicke encephalopathy is treated as an emergency with 500 mg IV three times daily for 2 to 3 days; oral thiamine has poor, saturable absorption, so the acute treatment must be parenteral.

10.6 The substance-emergency differential, one discriminator each

The five-way split. This is arc Step 5a: when a patient with a substance history is acutely disturbed, the emergency differential is delirium tremens against Wernicke encephalopathy, alcoholic hallucinosis, opioid overdose and sedative-hypnotic withdrawal. Each pair separates on a single high-yield discriminator, and holding those five discriminators is what lets you decide the treatment in one beat (Kaplan and Sadock 2024; New Oxford Textbook of Psychiatry; the substance-induced psychotic boundary sits in the Other psychotic disorders, delusional syndromes and catatonia notes).

EMERGENCY	CORE PICTURE	THE ONE DISCRIMINATOR	FIRST MOVE
Delirium tremens	Clouded consciousness, disorientation, autonomic storm, vivid visual/tactile hallucinations, 48 to 96 h after last drink	**Clouded sensorium PLUS autonomic storm (a delirium)**	Parenteral benzodiazepine, supportive care, thiamine
Wernicke encephalopathy	Confusion, ophthalmoplegia/nystagmus, ataxia (classic triad in only ~10%)	**Eye signs (ophthalmoplegia/nystagmus) and ataxia, no autonomic storm**	High-dose IV thiamine (500 mg TID) immediately
Alcoholic hallucinosis	Hallucinations (usually auditory) after regular use, ~2% of drinkers	**CLEAR consciousness, no disorientation**	Reassurance, observation; antipsychotic if distressing/persistent
Opioid overdose	Coma, respiratory depression, cyanosis	**PINPOINT (miotic) pupils + respiratory depression**	Naloxone plus airway/ventilation support
Sedative-hypnotic withdrawal	Tremor, autonomic overactivity, seizures, delirium; resembles alcohol withdrawal	**Timing keyed to the agent's half-life (short-acting 12 to 24 h; long-acting peaks at 5 to 8 days)**	Long-acting benzodiazepine or phenobarbital taper

The substance-emergency differential, keyed on one discriminator each; delirium tremens is the clouded-plus-autonomic delirium, Wernicke the eye-signs-and-ataxia state, hallucinosis the clear-sensorium exception, opioid overdose the pinpoint-pupil respiratory failure, sedative-hypnotic withdrawal the half-life-timed mimic (Kaplan and Sadock 2024; New Oxford Textbook of Psychiatry).

MNEMONIC

PUPILS tell the story

In the collapsed or confused substance patient, look at the **pupils** first: *pinpoint* pupils with slow respiration point to opioid overdose (give naloxone); ophthalmoplegia or nystagmus with ataxia point to Wernicke (give IV thiamine); a clouded, autonomically stormy delirium with normal-to-dilated pupils points to delirium tremens (give benzodiazepine). The eyes and the sensorium do most of the triage.

10.7 Delirium tremens versus Wernicke encephalopathy: the discriminator that changes the drug

The split that matters most. Both arise in the malnourished drinker and both can present with confusion, so they are the pair most often confused, yet the first drug differs. Wernicke encephalopathy is a thiamine-deficiency emergency whose classic triad is *confusion, ophthalmoplegia (or nystagmus) and ataxia*, and the exam trap is that the full triad appears in only about **10 per cent** of cases, so any one of the three in a malnourished or withdrawing patient should trigger empirical treatment (Kaplan and Sadock 2024; NICE). The discriminator from delirium tremens is the presence of *eye signs and ataxia without a florid autonomic storm*; delirium tremens clouds consciousness and drives the autonomic system, Wernicke gives ocular and cerebellar signs. Treat suspected Wernicke immediately with high-dose IV thiamine (500 mg three times daily for 2 to 3 days, then 250 mg daily for 5 days) before it progresses to the irreversible amnesia of Korsakoff syndrome (anterograde amnesia with confabulation).

GOOD TO REMEMBER

- **Wernicke encephalopathy (syndrome):** the criterion is the triad of confusion, ophthalmoplegia/nystagmus and ataxia, but the full triad is present in only about 10 per cent, so treat on any one feature; the discriminator from delirium tremens is eye signs and ataxia without the autonomic storm; the first step is high-dose IV thiamine (500 mg TID) at once, before it becomes irreversible Korsakoff.

10.8 Opioid overdose and naloxone: the emergency that is not withdrawal

The picture and the antidote. The far more urgent opioid emergency is *overdose*, not withdrawal. Opioid overdose is a triad of *coma, respiratory depression and pinpoint (miotic) pupils*, with cyanosis in severe cases (Kaplan and Sadock 2024). The antidote is naloxone, a competitive opioid antagonist: intramuscular 0.4 to 2 mg, repeated every 2 to 3 minutes up to about 10 mg, or intranasal 4 mg per spray repeated after 2 to 3 minutes, alongside airway and ventilatory support (BAP 2026; WHO). Because naloxone's half-life is shorter than that of many opioids, watch for re-narcotisation and re-dose as needed. Take-home naloxone (in India, the 0.4 mg/1 mL ampoule; the branded intranasal spray Nexnal where available) with family training in rescue breathing is recommended for anyone with current or recent opioid use, especially after a period of forced abstinence (post-detoxification, post-release from custody) when tolerance has fallen, the leading cause of death in opioid use disorder.

TRAP **Opioid withdrawal is not a medical emergency; opioid overdose is.** Opioid withdrawal is intensely unpleasant but rarely life-threatening; do not treat it as an emergency, and do not confuse it with overdose, which is the pinpoint-pupil respiratory failure that naloxone reverses.

GOOD TO REMEMBER

- **Naloxone:** competitive opioid antagonist and the antidote to opioid overdose (coma + respiratory depression + pinpoint pupils); give IM 0.4 to 2 mg, repeat every 2 to 3 minutes up to about 10 mg, or intranasal 4 mg per spray; short half-life means watch for re-narcotisation and re-dose; take-home naloxone is recommended for anyone with current or recent opioid use, especially in the fallen-tolerance windows after detoxification or custody.

10.9 Sedative-hypnotic withdrawal: the half-life-timed mimic

Why it hides. Withdrawal from benzodiazepines, barbiturates and other sedative-hypnotics closely resembles alcohol withdrawal, tremor, autonomic overactivity, seizures and its own delirium, and is genuinely life-threatening (Kaplan and Sadock 2024). The discriminator is *timing keyed to the agent's half-life*: short-acting agents (for example alprazolam, lorazepam) begin 12 to 24 hours after the last dose and peak at 24 to 72 hours, whereas long-acting agents (diazepam, clonazepam, phenobarbital) may not peak until **5 to 8 days** after the last dose. A patient who looks well for four days and then develops a withdrawal delirium is far more likely to be withdrawing from a long-acting sedative than from alcohol. Management is a controlled taper: substitute a long-acting benzodiazepine (or use a phenobarbital taper for mixed sedative dependence) and reduce slowly; abrupt cessation is the danger, and a too-fast benzodiazepine taper is itself a classic error.

INDIA

India carries a very large substance-use treatment gap: most people with alcohol or opioid dependence never reach formal care, and delirium tremens frequently presents to general and emergency wards after an unsupervised, abrupt stop rather than through a planned detoxification. Services concentrate in the government de-addiction centres and the Drug De-addiction Programme (DDAP) units, not in general practice, and the legal frame for the opioid emergencies here is the Narcotic Drugs and Psychotropic Substances (NDPS) Act, 1985 (the medico-legal detail is developed in the Mental health legislation and forensic psychiatry notes). Naloxone for overdose reversal is available as the 0.4 mg/1 mL ampoule and, increasingly, as take-home kits, and buprenorphine is the workhorse of Indian opioid-agonist treatment precisely because methadone is restricted to licensed OST clinics. The practical exam point: recognise delirium tremens early, because the Indian patient who self-detoxifies at home to save cost or avoid stigma is exactly the one who arrives at hour 60 in a full autonomic storm.

HOLD THIS

Delirium tremens is clouded consciousness plus disorientation plus an autonomic storm, 48 to 96 hours after the last drink, ~10 to 20 per cent mortality untreated; treat it as a medical emergency with parenteral benzodiazepine and supportive care, and give thiamine before glucose.

11 · Wernicke encephalopathy and Korsakoff syndrome

Chronic heavy drinking starves the brain of **thiamine** (vitamin B1), and thiamine is the cofactor two glucose-handling enzymes cannot work without. When it runs out, the diencephalon and brainstem fail acutely, producing **Wernicke encephalopathy**; if that acute failure is not reversed fast, the mammillary bodies and thalamus are permanently damaged and the patient is left with the chronic amnestic state called **Korsakoff syndrome**. Examiners treat this pair as a package because they are two ends of one thiamine-deficiency continuum, and because it carries the single most testable emergency rule in the whole substance-use block: **parenteral thiamine goes in before any glucose.**

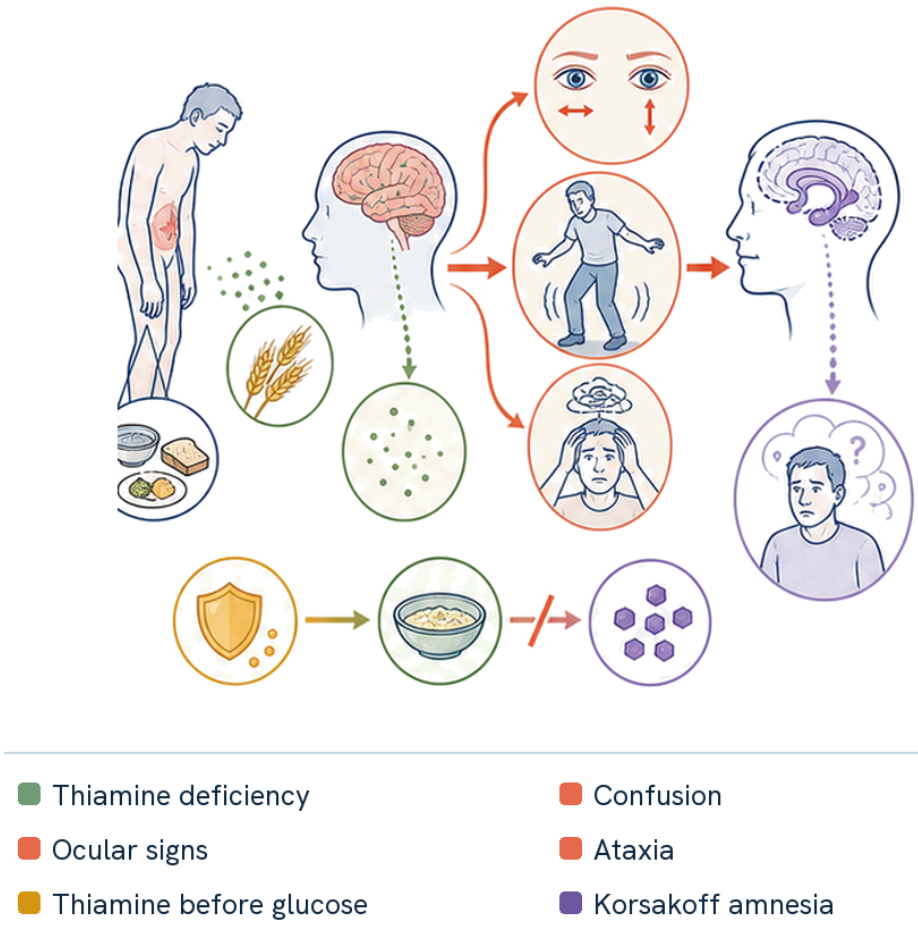


Fig 13.8 Thiamine deficiency can produce acute Wernicke encephalopathy with confusion, ocular abnormalities and ataxia. Immediate thiamine, before carbohydrate loading, reduces progression to persistent Korsakoff amnesia.

Why it matters clinically. Wernicke encephalopathy is an underdiagnosed medical emergency, the full triad is present in only about one patient in ten, and a single well-meant bag of intravenous dextrose given first can precipitate or worsen it. Get the two thiamine regimens (the small oral prophylaxis dose and the large parenteral treatment dose) and the glucose rule exact and you have the marks. The amnestic mechanism in the wider organic frame is developed in the Dementias and neurocognitive disorders notes and the Neuropsychiatry of systemic and neurological disease notes; here the task is to recognise the emergency and treat it by the number.

~10%	500	3 to 5	~50%
PRESENT WITH THE COMPLETE WERNICKE TRIAD	TREATMENT THIAMINE, IV MG, TWO TO THREE TIMES DAILY	DAYS OF PARENTERAL THIAMINE BEFORE SWITCHING TO ORAL	LEFT WITH PERMANENT KORSAKOFF AMNESIA

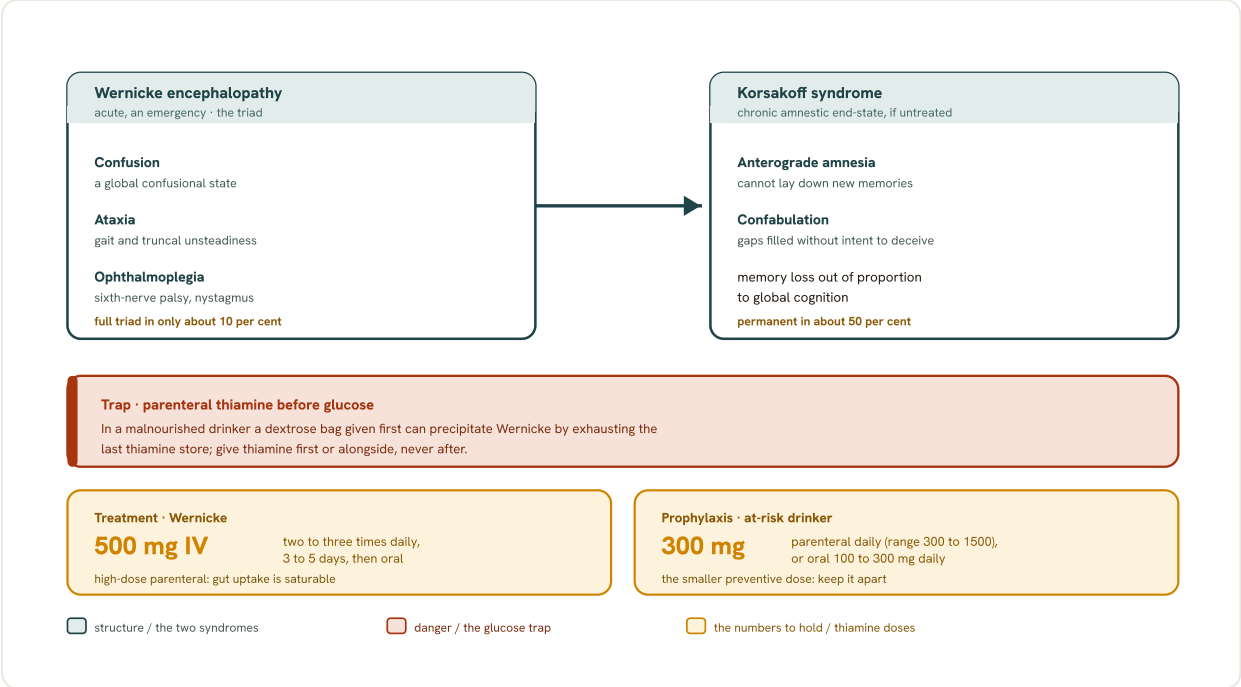

Fig 13.9 Wernicke encephalopathy to Korsakoff syndrome: the thiamine rule. The acute triad of confusion, ataxia and ophthalmoplegia is Wernicke, present in full in only about one patient in ten; untreated it fixes into Korsakoff, the chronic anterograde amnesia with confabulation. The non-negotiable rule is parenteral thiamine before any glucose in a malnourished drinker. Keep the two regimens apart: the large parenteral treatment dose (500 mg IV two to three times daily) versus the smaller preventive dose (300 mg parenteral, or 100 to 300 mg oral, daily).

11.1 The mechanism: why thiamine deficiency destroys the diencephalon

The cofactor that runs out. Thiamine (as thiamine pyrophosphate) is the essential cofactor for transketolase and for pyruvate and alpha-ketoglutarate dehydrogenase, so a deficient brain cannot run the pentose-phosphate shunt or oxidative glucose metabolism (Kaplan and Sadock 2024). The neurons that depend most heavily on this pathway, in the mammillary bodies, the medial thalamus, the periaqueductal grey and the cerebellar vermis, are the first to fail, which is exactly why the clinical picture is confusion, eye-movement palsy and ataxia rather than a diffuse global slowing.

Why some drinkers are more vulnerable. A genetically influenced **transketolase** abnormality lowers the enzyme's affinity for thiamine, so a subset of drinkers cross into deficiency at intakes others tolerate (Kaplan and Sadock 2024). Add the poor diet, malabsorption and vomiting of chronic alcohol use disorder and the marginal thiamine store empties quickly, especially under any metabolic stress.

11.2 Wernicke encephalopathy: the triad and why it is usually incomplete

The classic triad. Wernicke encephalopathy is defined by the triad of acute **confusion ataxia ophthalmoplegia**: a global confusional state, gait and truncal ataxia, and eye-movement signs, most characteristically a lateral rectus (sixth cranial nerve) palsy with nystagmus (Kaplan and Sadock 2024; Companion to Psychiatric Studies). The confusion tends to reverse fairly rapidly with vitamin supplementation, and the ophthalmoplegia is the sign that often responds first, sometimes within hours of parenteral thiamine.

Why waiting for the triad is a trap. The complete triad is present in only about **10 per cent** of cases (Indian Psychiatric Society CPG), so the diagnosis has to be made on any one of confusion, ophthalmoplegia or ataxia appearing in a malnourished or actively withdrawing drinker, not on the textbook three-together. This under-presentation is precisely why the condition is missed and why the treatment threshold is set so low.

RULE **Treat on suspicion, not on the full triad.** Any one of new confusion, ophthalmoplegia or ataxia in a malnourished or withdrawing drinker is enough to give parenteral thiamine immediately; the complete triad appears in only about one in ten.

GOOD TO REMEMBER

- **Wernicke encephalopathy:** the criterion picture is the triad of confusion, ataxia and ophthalmoplegia (a sixth-nerve palsy with nystagmus) driven by acute thiamine deficiency; the full triad is present in only about 10 per cent, so the discriminator is that any single element in a malnourished or withdrawing drinker is treated as the emergency; the first management step is immediate parenteral (not oral) thiamine, and it must precede any glucose.

11.3 Korsakoff syndrome: the chronic amnestic end-state

What it is. When Wernicke encephalopathy is untreated or undertreated, the acute lesion becomes fixed and the patient is left with Korsakoff syndrome, a chronic **amnestic** syndrome dominated by a dense *anterograde* amnesia (an inability to lay down new memories) with a variable retrograde component, in which the loss of recent memory is strikingly out of proportion to the overall level of cognitive impairment (Kaplan and Sadock 2024). Attention, procedural learning and general intellect can be relatively preserved, which is what makes the isolated memory failure so distinctive.

Confabulation, the signature sign. The classic accompaniment is **confabulation**: the patient fills the memory gap with fabricated or misplaced accounts, given without any intent to deceive and often without insight, so that a plausible but false narrative substitutes for the missing recollection. Confabulation is most prominent early and tends to fade as the syndrome settles, leaving the amnesia. Korsakoff syndrome is permanent, at least in partial form, in about **half** of those affected (Kaplan and Sadock 2024).

FEATURE	WERNICKE ENCEPHALOPATHY	KORSAKOFF SYNDROME
Tempo	**Acute, an emergency**	Chronic, an end-state
Core signs	Confusion, ataxia, ophthalmoplegia	**Anterograde amnesia with confabulation**
Lesion emphasis	Periaqueductal grey, medial thalamus, cerebellar vermis	Mammillary bodies, medial dorsal thalamus
Reversibility	**Often reversible with prompt parenteral thiamine**	Permanent in about 50 per cent
Management	High-dose parenteral thiamine as an emergency	Prolonged thiamine, supportive care, safeguarding

Wernicke and Korsakoff are two ends of one thiamine-deficiency continuum; the acute, treatable syndrome converts to the chronic amnestic one if thiamine is not replaced fast (Kaplan and Sadock 2024; Companion to Psychiatric Studies).

GOOD TO REMEMBER

- **Korsakoff syndrome:** the criterion feature is a chronic amnestic syndrome with dense anterograde amnesia and confabulation, the memory loss being out of proportion to global cognition; the discriminator from a global dementia is that recent memory fails selectively while other domains are relatively spared; it is the permanent sequel (in about 50 per cent) of untreated Wernicke encephalopathy, so the first step is prevention by treating Wernicke aggressively before the lesion fixes.

11.4 The glucose-first trap: the single most testable rule

The rule and its mechanism. In a malnourished or alcohol-dependent patient, **parenteral thiamine** must be given *before* any glucose load, because a carbohydrate load consumes the last of the marginal thiamine store as a cofactor and can precipitate or acutely worsen Wernicke encephalopathy (Indian Psychiatric Society CPG; Companion to Psychiatric Studies). The Companion frames it exactly this way: Wernicke can be precipitated on admission by the stress of withdrawal, an intercurrent illness, or *the first carbohydrate meal for some days*, which is why immediate parenteral thiamine is standard for any malnourished drinker.

Where it bites in practice. The trap is the collapsed or hypoglycaemic-looking drinker in whom the reflex is to hang intravenous dextrose. Give the thiamine first (or at least concurrently), never dextrose alone into an unreplenished drinker. This does not mean withholding glucose from a genuinely hypoglycaemic patient; it means the thiamine goes in alongside or ahead of it, not after.

TRAP **Never give glucose before thiamine in a malnourished drinker.** An intravenous dextrose bag given first can precipitate Wernicke encephalopathy by exhausting the residual thiamine; parenteral thiamine goes in first or alongside, never after.

11.5 Thiamine as treatment: the large parenteral emergency dose

The treatment regimen. Established or suspected Wernicke encephalopathy is a medical emergency treated with *high-dose parenteral* thiamine: about **500 mg** intravenously two to three times a day for 3 to 5 days, followed by a longer oral course (Kaplan and Sadock 2024; Indian Psychiatric Society CPG). The Indian CPG operationalises this as intravenous thiamine 500 mg three times daily for 2 to 3 days, then 250 mg daily intramuscularly or intravenously for a further 5 days. In UK practice the same is delivered as Pabrinex (a paired B-and-C ampoule preparation): two pairs of ampoules three times daily for 2 to 3 days, then one pair daily for a further 3 days, each ampoule diluted and infused over about 30 minutes with anaphylaxis facilities to hand (Companion to Psychiatric Studies).

Why parenteral and why high-dose. High-dose intravenous thiamine is superior to oral for both prevention and treatment because gut absorption of thiamine is limited and saturable, and high serum concentrations are needed to drive thiamine across the blood-brain barrier (Kaplan and Sadock 2024). Oral thiamine simply cannot achieve the brain levels an acute Wernicke lesion needs, which is the whole reason the emergency route is intravenous.

SETTING	ROUTE AND DOSE (THIAMINE)	DURATION
Established / suspected Wernicke (treatment)	**IV 500 mg two to three times daily**	3 to 5 days, then switch to oral
Indian CPG treatment schedule	IV 500 mg three times daily, then 250 mg daily IM/IV	2 to 3 days, then a further 5 days
Pabrinex treatment (UK)	2 pairs of ampoules three times daily, then 1 pair daily	2 to 3 days, then a further 3 days
At-risk drinker in withdrawal (prophylaxis)	Parenteral 300 mg daily (range 300 to 1500)	3 to 5 days, then oral
Low-risk ambulatory (prophylaxis)	Oral 100 to 300 mg daily	3 to 5 days; oral 100 mg daily to cover detoxification

The two thiamine regimens that must be kept apart: the large parenteral treatment dose for Wernicke, and the smaller prophylactic dose for the at-risk drinker (Kaplan and Sadock 2024; IPS CPG; BAP 2026; Companion to Psychiatric Studies). Units are in the header; cells carry bare numbers.

GOOD TO REMEMBER

- **Thiamine (treatment dose):** the cofactor whose deficiency causes the syndrome; for established or suspected Wernicke give it parenterally at about 500 mg IV two to three times daily for 3 to 5 days, then oral; parenteral and high-dose because gut absorption is saturable and high serum levels are needed to cross the blood-brain barrier; the one non-negotiable caution is to give it before any glucose.

11.6 Thiamine as prophylaxis: the smaller dose, and how it differs

The prophylaxis regimen. The dose given to *prevent* Wernicke in an at-risk but neurologically intact drinker is far smaller than the treatment dose. For a drinker in withdrawal with risk factors for Wernicke-Korsakoff, give parenteral thiamine (BAP quotes a wide 300 to 1500 mg/day band, in practice around 300 mg daily) for 3 to 5 days followed by oral thiamine; for those at very low risk in ambulatory settings, oral thiamine 100 to 300 mg daily for 3 to 5 days suffices (BAP 2026). The Indian CPG adds oral thiamine 100 mg daily continued for at least 3 months of any detoxification.

The examinable contrast. Keep the two doses and durations distinct: prophylaxis is a low dose (often oral, or modest parenteral) to stop the deficiency developing, whereas treatment is a large parenteral dose to reverse an established lesion. Confusing the two, giving a Wernicke patient only oral prophylactic thiamine, is a recognised cause of a preventable Korsakoff syndrome.

COMMON TRAP

Do not treat established Wernicke encephalopathy with the prophylactic dose. A confused, ataxic drinker needs the large parenteral treatment regimen (about 500 mg IV two to three times daily), not the 100 to 300 mg oral prophylaxis dose. Undertreating an acute lesion with a preventive dose lets it fix into a permanent Korsakoff amnesia.

11.7 Wernicke versus delirium tremens: the discrimination examiners love

Two confused drinkers, opposite treatments. Both Wernicke encephalopathy and delirium tremens present as an acutely confused drinker, but the discriminators and the treatments diverge. Delirium tremens is a hyperadrenergic withdrawal state (clouded consciousness, vivid visual and tactile hallucinations, coarse tremor and a gross autonomic storm) emerging 48 to 72 hours after the last drink, and its treatment is generously titrated benzodiazepine. Wernicke is a thiamine-deficiency state whose hallmark is the eye-movement palsy and ataxia rather than an autonomic storm, and its treatment is high-dose parenteral thiamine. The two frequently coexist, so the safe posture is to give thiamine to every confused or withdrawing drinker regardless, and to add benzodiazepine for the withdrawal component.

DISCRIMINATOR	WERNICKE ENCEPHALOPATHY	DELIRIUM TREMENS
Driver	Thiamine deficiency	Alcohol withdrawal (hyperadrenergic)
Timing	Any time in a malnourished drinker	**48 to 72 hours after the last drink**
Signature sign	**Ophthalmoplegia and ataxia**	Autonomic storm, vivid hallucinations
First treatment	**Parenteral thiamine**	**Titrated benzodiazepine**

Wernicke and delirium tremens can coexist; the safe rule is thiamine for every confused drinker plus benzodiazepine for the withdrawal (Kaplan and Sadock 2024; IPS CPG). The wider withdrawal spectrum sits in the alcohol-withdrawal topic.

WORKED EXAMPLE

A dishevelled man is brought to casualty drowsy and unsteady, smelling of alcohol, with a bruise over the occiput. The intern draws up intravenous dextrose for a presumed hypoglycaemia. The correct sequence is to give parenteral thiamine first (or alongside), because dextrose alone into a malnourished drinker can precipitate Wernicke encephalopathy; to examine the eyes for nystagmus and a lateral rectus palsy and the gait for ataxia; and, because of the head injury, to image the brain rather than attribute the confusion to alcohol alone. Confusion in a drinker is never assumed to be simple intoxication.

11.8 The Indian context: malnutrition, the treatment gap and where the vitamin gets missed

Why the syndrome is common and the diagnosis is missed. India carries a large burden of alcohol use disorder against a background of frequent baseline malnutrition, and the vast substance-use *treatment gap* means most dependent drinkers reach services late, malnourished, and often only when acutely unwell, exactly the profile in which Wernicke is precipitated. Detoxification happens across a patchwork of government de-addiction centres (the national Drug De-addiction Programme), the day care centre model, medical college psychiatry units and private facilities, and thiamine is the cheap, universally available intervention that most reliably prevents a lifelong Korsakoff disability.

The practical Indian rule. The Indian Psychiatric Society CPG makes parenteral thiamine standard for all suspected or high-risk Wernicke-Korsakoff cases and continues oral thiamine 100

to 200 mg for at least three months across all detoxification, with the same glucose-first caution. In a resource-limited casualty the highest-yield habit is simple: give thiamine before the dextrose, to every malnourished drinker, every time.

INDIA

Thiamine is one of the highest-value, lowest-cost interventions in Indian addiction practice: injectable and oral thiamine are inexpensive and universally stocked, whereas an established Korsakoff syndrome is an untreatable, lifelong disability. Against a wide treatment gap and a malnourished, late-presenting population, a standing casualty protocol of parenteral thiamine before glucose for every dependent drinker prevents far more disability than any anti-craving agent. The medico-legal and NDPS-Act frame for substance use sits in the Mental health legislation and forensic psychiatry notes.

HOLD THIS

In a malnourished drinker, parenteral thiamine goes in before any glucose; the acute triad of confusion, ataxia and ophthalmoplegia is Wernicke (full triad in only ~10 per cent, treat on any one sign with high-dose IV thiamine), and untreated it fixes into Korsakoff, the chronic anterograde amnesia with confabulation.

12 · Alcoholic hallucinosis and alcohol-induced psychosis

A chronic drinker who hears voices is one of the most misread presentations in the substance-use viva, because the same complaint sits astride three very different diagnoses. **Why it matters clinically.** The examiner wants you to separate **alcoholic hallucinosis** (persistent **auditory hallucinations** in a fully **clear sensorium**) from the clouded, autonomically stormy picture of delirium tremens, and to separate both from schizophrenia. Get that triangulation right and you have the highest-yield discrimination of the whole psychosis-substance interface; get it wrong and you either treat a self-limiting organic psychosis as schizophrenia for life, or miss a lethal delirium behind a "chronic drinker with voices".

This is a clinical (diagnosis and discrimination) topic. The wider substance-induced psychotic-disorder frame and the psychosis boundary are cross-referenced to the Other psychotic disorders, delusional syndromes and catatonia notes and are not re-derived here; the reward-pathway mechanics sit in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; the amnestic Wernicke-Korsakoff mechanism sits in the Dementias and neurocognitive disorders notes and the Neuropsychiatry of systemic and neurological disease notes. Here the task is to define the two named syndromes precisely, place them against their look-alikes, and know the management principle.

12.1 Alcoholic hallucinosis: the criterion definition

The definition. Alcoholic hallucinosis is the occurrence of hallucinations, characteristically **auditory**, in a **clear sensorium** in a person with a history of heavy drinking and alcohol dependence, usually following a prolonged drinking bout, in partial or complete abstinence (Kaplan and Sadock 2024; Shorter Oxford Textbook of Psychiatry). The term was coined by

Eugene Bleuler. The three load-bearing words are *auditory*, *clear sensorium* and *abstinence-related*: the voices are typically third-person, accusatory or threatening, and the patient is distressed, anxious and restless but fully alert and oriented.

The signature. Unlike the transient perceptual disturbances of simple withdrawal, alcoholic hallucinosis persists after the acute withdrawal syndrome is over and can continue for weeks; classically recovery occurs within one month and it is very rarely prolonged beyond six months. It is uncommon, occurring in roughly 2 per cent of dependent drinkers, and in the modern nosologies it is subsumed under alcohol-induced psychotic disorder, coded F10.5 in ICD-10 and 6C40.60 (with hallucinations) in ICD-11.

GOOD TO REMEMBER

- **Alcoholic hallucinosis:** the criterion picture is persistent, usually third-person accusatory or threatening *auditory* hallucinations arising in a *clear sensorium* in a dependent drinker, typically during abstinence after a heavy bout; the discriminator from delirium tremens is the intact sensorium and the discriminator from schizophrenia is the clear temporal link to alcohol and the good prognosis on abstinence; the first management step is abstinence plus an antipsychotic (haloperidol) with a benzodiazepine, and it usually resolves within one month.

12.2 The three-way discrimination: hallucinosis vs delirium tremens vs schizophrenia

The core carrier. This table is the topic. The single axis that separates alcoholic hallucinosis from delirium tremens is the state of the **sensorium**: hallucinosis occurs in a clear sensorium, delirium tremens in a clouded one. The axis that separates hallucinosis from schizophrenia is the *course* and the *temporal relation to alcohol*: hallucinosis clears on abstinence and leaves no primary thought disorder or enduring negative symptoms.

FEATURE	ALCOHOLIC HALLUCINOSIS	DELIRIUM TREMENS	SCHIZOPHRENIA
Sensorium	**Clear, fully oriented**	**Clouded, disoriented**	Clear
Dominant hallucination	**Auditory (voices, third-person, accusatory)**	Visual and tactile, vivid, frightening	Auditory (often running commentary, thought echo)
Autonomic storm	Absent or mild	**Gross (tachycardia, fever, sweating, hypertension)**	Absent
Onset relative to alcohol	During or after abstinence; persists beyond withdrawal	48 to 72 hours after the last drink	No consistent temporal link to alcohol
Course	**Resolves on abstinence, usually within one month**	Short, 3 to 5 days; medical emergency	Chronic, over 6 months; enduring negative symptoms
First-rank / thought disorder	Usually absent; insight often partly retained	Not the picture (this is a delirium)	May be present; formal thought disorder

FEATURE	ALCOHOLIC HALLUCINOSIS	DELIRIUM TREMENS	SCHIZOPHRENIA
Mortality	Low	**1 to 5 per cent even treated; higher untreated**	Not directly lethal

The three-way discrimination; the sensorium separates hallucinosis from delirium tremens, and the course plus the temporal link to alcohol separates hallucinosis from schizophrenia (Kaplan and Sadock 2024; Shorter Oxford Textbook of Psychiatry; AIIMS Clinical Methods in Psychiatry 2024).

RULE **Check the sensorium first.** Voices plus a clear, oriented sensorium in a drinker points to alcoholic hallucinosis; voices plus clouding and an autonomic storm points to delirium tremens, a medical emergency, no matter how "psychotic" the surface looks.

2%	**1 month**	**3%**
OF DEPENDENT DRINKERS DEVELOP ALCOHOLIC HALLUCINOSIS	TYPICAL TIME TO RESOLUTION ON ABSTINENCE	OF AUD DEVELOP AN ALCOHOL-INDUCED PSYCHOTIC DISORDER

12.3 Alcohol-induced psychotic disorder: the modern umbrella diagnosis

What it is. The alcohol-induced psychotic disorder (ICD-11 6C40.6; DSM-5-TR substance/medication-induced psychotic disorder) is the umbrella under which alcoholic hallucinosis now sits. About 3 per cent of people with an alcohol use disorder experience it: auditory hallucinations and/or paranoid delusions arising in a clear sensorium in the context of heavy drinking or withdrawal (Kaplan and Sadock 2024). ICD-11 lets you specify the presentation: 6C40.60 with hallucinations (the classic hallucinosis), 6C40.61 with delusions, and 6C40.62 with mixed psychotic symptoms.

The essential features. The diagnosis requires that the psychotic symptoms develop during or soon after alcohol intoxication or withdrawal; that alcohol is capable of producing such symptoms; that the symptoms are not better explained by an independent psychotic disorder such as schizophrenia; and that they are not confined to a delirium (ICD-11 CDDR; DSM-5-TR). Symptoms occurring exclusively during a delirium are coded as alcohol-induced delirium (6C40.5), not as a psychotic disorder, which is exactly why the sensorium check in 12.2 is the pivot of the whole topic.

GOOD TO REMEMBER

- **Alcohol-induced psychotic disorder:** the criterion is hallucinations and/or delusions in a clear sensorium developing during or soon after heavy drinking or withdrawal, judged the direct consequence of alcohol and not better explained by a primary psychotic disorder or confined to a delirium (ICD-11 6C40.6; DSM-5-TR); the specifiers are with hallucinations, with delusions and mixed; the first step is to establish the temporal link to alcohol and to reassess longitudinally on abstinence.

12.4 Alcoholic paranoia (the alcohol-paranoid state): morbid jealousy

The delusional cousin. Alongside the hallucinatory picture sits the alcohol-paranoid state (alcoholic paranoia), classically dominated by **delusional jealousy**, the fixed false belief that the spouse is unfaithful (the Othello theme). It develops in chronic dependent drinkers, in a clear

sensorium, and maps onto the "with delusions" specifier (ICD-11 6C40.61). It matters out of proportion to its frequency because morbid jealousy is a recognised risk factor for serious partner violence and homicide, so its detection carries a real-world safety weight.

How to place it. Delusional jealousy is not specific to alcohol: it also occurs in schizophrenia, in affective psychosis and in organic states. The alcohol attribution rests on the temporal link to heavy drinking and, as with hallucinosis, on whether it clears with abstinence. The fuller frame for delusional jealousy as a delusional syndrome belongs to the Other psychotic disorders, delusional syndromes and catatonia notes.

COMMON TRAP

Do not diagnose schizophrenia at the first assessment of a drinker with a clear-sensorium psychosis. Substance-induced psychosis and a primary psychotic disorder are hard to separate cross-sectionally; the anchor is the longitudinal course. Psychotic symptoms that *preceded* the drinking, that recur off alcohol, or that persist for one month or longer after intoxication and withdrawal have resolved point to an independent primary psychotic disorder rather than an alcohol-induced one (ICD-11 CDDR; DSM-5-TR). In one first-episode cohort about a third (35.6 per cent) of substance-induced psychosis diagnoses were later revised to a primary schizophrenia-spectrum or bipolar disorder, so the initial label is provisional and demands review.

12.5 Prognosis, diagnostic instability and the schizophrenia boundary

The prognosis. The prognosis of a genuinely alcohol-induced psychosis is good if abstinence is achieved: the picture typically clears spontaneously within a few days to a month of abstinence, and it is estimated that fewer than 5 per cent of these psychoses occur in individuals who later develop schizophrenia (Kaplan and Sadock 2024). This is the reassuring counterweight to the trap above: most true alcoholic hallucinosis is not incipient schizophrenia.

The boundary in one line. Duration is the arbiter. Clearance on abstinence within a month supports the alcohol-induced diagnosis; persistence beyond a month off alcohol, or a positive history predating the drinking, moves the diagnosis toward a primary psychotic disorder. The wider schizophrenia and delusional-disorder frame is developed in the Other psychotic disorders, delusional syndromes and catatonia notes.

HOLD THIS

Auditory hallucinations in a clear sensorium in a dependent drinker = alcoholic hallucinosis; they clear on abstinence (usually within one month), and persistence beyond a month off alcohol re-opens the schizophrenia question.

12.6 Management: abstinence, an antipsychotic and a benzodiazepine

The management principle. The foundation is abstinence: because the disorder is alcohol-induced, removing the offending agent is itself the definitive treatment, and the psychosis typically remits after abstinence. Symptomatic control while it settles uses an antipsychotic, classically haloperidol, which reduces the intensity of the delusions and hallucinations, together with a benzodiazepine (for example chlordiazepoxide or diazepam) to cover any concurrent

withdrawal and agitation; admission is usually necessary, the environment should be safe, uncluttered and uniformly lit, and parenteral thiamine plus attention to electrolytes and glucose is given (Companion to Psychiatric Studies). Antipsychotic treatment is escalated where there is severe agitation or suicidal or homicidal ideation (Kaplan and Sadock 2024).

Dosing anchor. Haloperidol is the standard agent for the psychotic symptoms; the concurrent benzodiazepine is dosed and tapered exactly as for alcohol withdrawal (the Companion example commences chlordiazepoxide at 100 to 150 mg/day or diazepam at 50 to 80 mg/day, reducing after the second or third day and stopping within one to two weeks). The full withdrawal-dosing detail sits in the alcohol withdrawal topic and is not re-derived here.

GOOD TO REMEMBER

- **Haloperidol (in alcohol-induced psychosis):** high-potency dopamine antagonist used to reduce the intensity of the hallucinations and delusions while abstinence does the definitive work; give with a benzodiazepine to cover concurrent withdrawal, never a benzodiazepine or antipsychotic alone for the whole picture; escalate for severe agitation or suicidal or homicidal ideation.
- **Chlordiazepoxide / diazepam (adjunct here):** long-acting benzodiazepine covering concurrent withdrawal and agitation; representative start chlordiazepoxide 100 to 150 mg/day or diazepam 50 to 80 mg/day, reducing from the second or third day and stopping within one to two weeks (Companion to Psychiatric Studies).

INDIA

Alcohol-induced psychoses present overwhelmingly to India's de-addiction system, the network of de-addiction centres and the Drug De-addiction Programme (DDAP) that anchor tertiary substance-use care, yet the national treatment gap for alcohol use disorders is very large, so most drinkers with a psychosis reach services late, often through the general hospital or a family-brought emergency. The Indian Psychiatric Society substance-use CPGs frame both the acute management and the strategic shift toward community and home-based delivery using trained non-specialist health workers to close that gap. The de-addiction context also carries the medico-legal frame of the NDPS Act, 1985; the Act, capacity and medico-legal aspects belong to the Mental health legislation and forensic psychiatry notes.

WORKED EXAMPLE

A 46-year-old man with 20 years of daily heavy drinking is brought in five days after his last drink, having stopped because of gastritis. He is fully alert and oriented, knows the date and the ward, and there is no tremor or autonomic disturbance, but he reports two male voices discussing him in the third person and calling him a thief, which frighten him and have been present for four days. Sensorium clear, no clouding: this is alcoholic hallucinosis, not delirium tremens (which would show clouding and an autonomic storm and would have peaked at 48 to 72 hours, not persisted clear on day five). You maintain abstinence, start haloperidol for the voices with a benzodiazepine to cover any residual withdrawal, give parenteral thiamine, and plan longitudinal review, expecting resolution within a month; if the voices persist beyond a month off alcohol you reconsider a primary psychotic disorder.

13 · Medical complications of alcohol use

Chronic heavy drinking is a whole-body disease, not just a psychiatric one, and the **medical complications of alcohol** are what actually kill most dependent drinkers. Ethanol and its metabolite acetaldehyde injure the liver, the peripheral and central nervous system, the heart, the gut and the marrow, so a single patient can carry a fatty liver, a numb-footed neuropathy, an enlarged heart and a macrocytic anaemia at once. Examiners test this as a systems checklist: they want you to name the organ, name the lesion, and know which lesions reverse with abstinence and which are terminal.

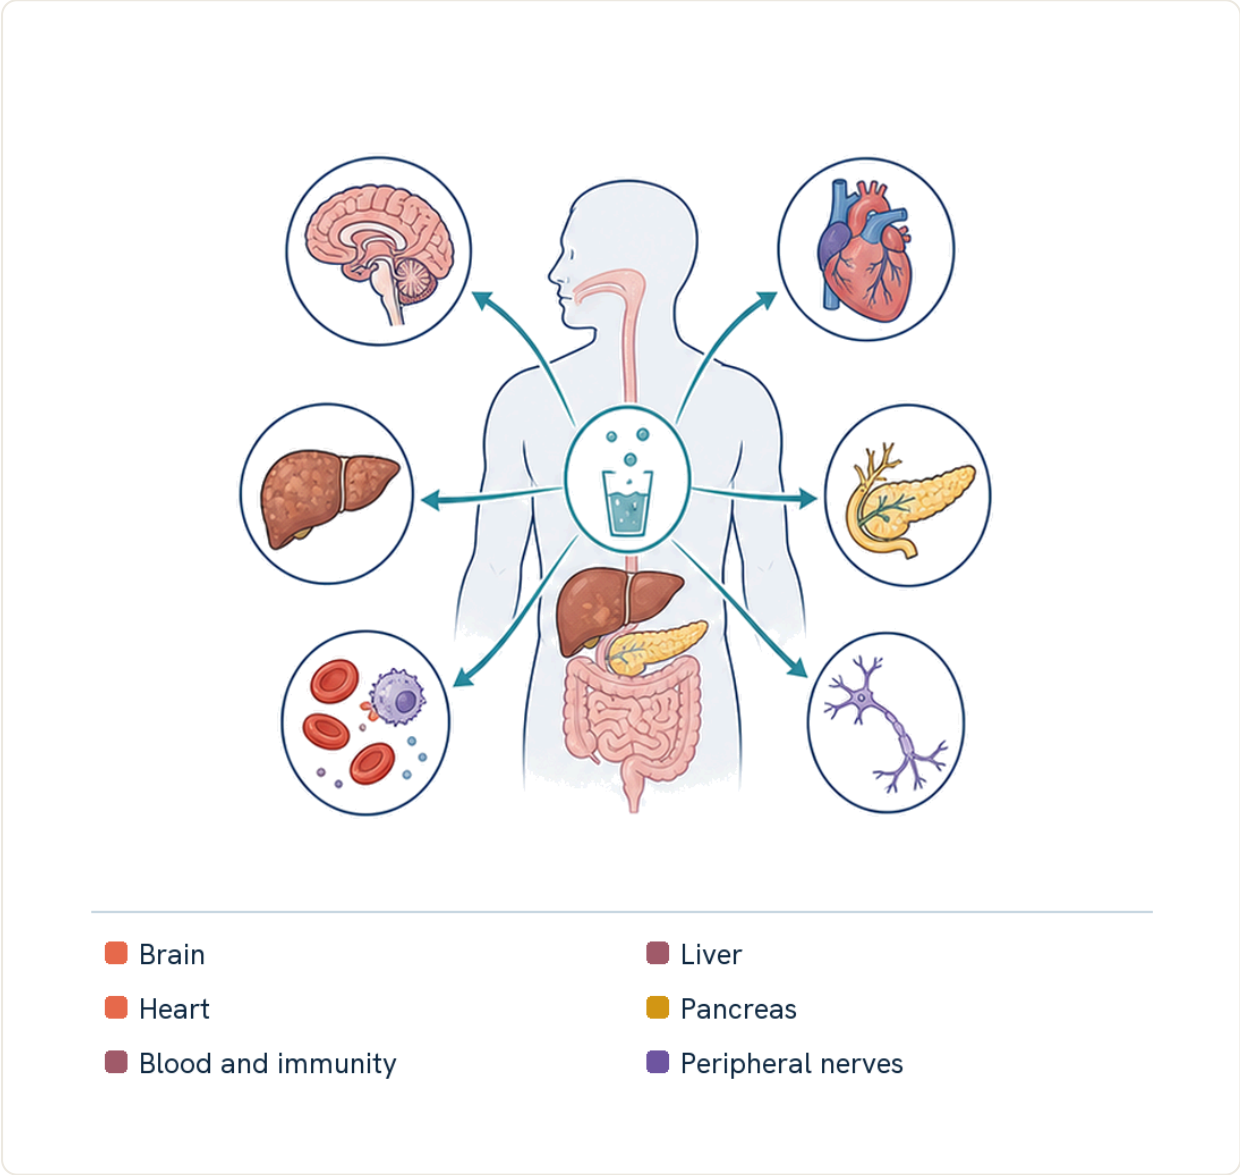

Fig 13.10 Alcohol-related harm is multisystemic, affecting the brain, liver, heart, pancreas, blood and immune function, and peripheral nerves in addition to its behavioural and social consequences.

Why it matters clinically. Recognising the physical sequelae changes management at the bedside, because the confused drinker may be encephalopathic rather than simply intoxicated, the anaemia may be a marrow effect rather than blood loss, and the raised **GGT** and **MCV** are the biochemical fingerprints that betray covert heavy drinking. The reward-pathway mechanics that drive the drinking sit in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic

Psychopharmacology notes; here the task is the somatic damage the drinking leaves behind, organ by organ.

>30	>100	~50%
ETHANOL G PER 24 HOURS IN MEN THAT RAISES HYPERTENSION RISK	MCV FEMTOLITRES DEFINING MACROCYTOSIS IN HEAVY DRINKERS	OF CHRONIC DRINKERS DEVELOP ALCOHOLIC MYOPATHY

13.1 The overall map: which organs, and what reverses

The systems affected. Cluster the complications by organ so the list is retrievable in an exam: *hepatic* (fatty liver, alcoholic hepatitis, cirrhosis), *neurological* (peripheral neuropathy, cerebellar degeneration, central pontine myelinolysis, Marchiafava-Bignami disease, and the Wernicke-Korsakoff pair), *cardiac* (dilated cardiomyopathy, atrial fibrillation, hypertension), *gastrointestinal* (gastritis, pancreatitis, variceal bleeding) and *haematological* (macrocytosis, thrombocytopenia) (Goodman and Gilman). The Wernicke-Korsakoff amnestic syndrome is the one neurological complication given its own topic, so it is only signposted here.

The reversibility rule that organises the whole list. Fatty liver and acute alcoholic hepatitis are usually reversible with abstinence, whereas cirrhosis is largely fixed and usually terminal without transplant (Goodman and Gilman). The same early-reversible, late-fixed logic runs through the other systems, which is why abstinence is itself the single most powerful treatment for almost every complication on the list.

RULE **Abstinence is the first-line treatment for the complication, not just the addiction.** Fatty liver, hepatitis, cardiomyopathy, neuropathy and marrow changes all improve or stabilise on stopping alcohol; the drug you reach for treats the organ, but the alcohol is the poison you must remove.

13.2 Hepatic complications: the fatty liver to cirrhosis sequence

The three stages. Alcohol perturbs hepatic lipid metabolism, and because ethanol and acetaldehyde metabolism generates excess NADH that inhibits fat oxidation, fat accumulates in the liver within a few days as fatty liver (steatosis) (Goodman and Gilman). A subset progress to alcoholic hepatitis, an inflammatory injury with hepatocyte necrosis, and repeated necrosis with chronic inflammation drives the fibrosis that becomes cirrhosis. Only a minority of drinkers with fatty liver ever reach cirrhosis, but cirrhosis is the end-stage that defines **alcohol-related liver disease**.

The sequelae of cirrhosis. Once the liver is cirrhotic, portal hypertension produces oesophageal **varices** that can bleed catastrophically, ascites, splenomegaly with hypersplenism, and hepatic encephalopathy; synthetic failure gives coagulopathy and hypoalbuminaemia, and there is a raised risk of hepatocellular carcinoma. Testicular atrophy and gynaecomastia follow from disordered sex-steroid handling. Cirrhosis is largely irreversible and usually terminal without a liver transplant (Goodman and Gilman).

GOOD TO REMEMBER

- **Alcoholic cirrhosis:** the criterion lesion is diffuse hepatic fibrosis with regenerative nodules ending the fatty-liver to hepatitis to cirrhosis sequence; the discriminator from the earlier stages is that fatty liver and hepatitis reverse with abstinence while cirrhosis does not; its high-yield sequelae are portal hypertension with bleeding varices, ascites, encephalopathy and hepatocellular carcinoma, and the first management step is complete abstinence, with transplant assessment for end-stage disease.

TRAP **A cirrhotic drinker cannot metabolise the usual detox drugs.** In hepatic impairment switch from long-acting chlordiazepoxide to a benzodiazepine needing minimal hepatic metabolism such as lorazepam, and prefer acamprosate or baclofen over naltrexone for relapse prevention (NICE 2011; IPS 2014).

13.3 Neurological complications: neuropathy and cerebellar degeneration

Peripheral neuropathy. A symmetrical, length-dependent sensorimotor peripheral neuropathy is one of the commonest neurological complications of chronic drinking, driven by direct ethanol toxicity compounded by thiamine and other B-vitamin deficiency. It presents with distal, glove-and-stocking numbness, burning dysaesthesia and reduced ankle reflexes, worst in the feet, and it is a mixed toxic-nutritional picture rather than a pure deficiency state, which is why B-vitamin replacement helps but abstinence matters most.

Cerebellar degeneration. Cerebellar degeneration from chronic alcohol targets the anterior superior vermis, producing a broad-based, unsteady gait and truncal ataxia with the legs affected far more than the arms or speech (Shorter Oxford). It is distinct from the acute cerebellar signs of Wernicke encephalopathy: this is a slowly evolving, largely fixed atrophy rather than an acute, thiamine-responsive lesion, though the two share a nutritional contribution.

GOOD TO REMEMBER

- **Alcoholic cerebellar degeneration:** the criterion feature is a chronic, broad-based gait ataxia with the legs affected out of proportion to arms and speech, from anterior-vermis atrophy; the discriminator from Wernicke is that it is slow-onset and largely fixed rather than acute and thiamine-responsive; the first step is abstinence plus B-vitamin replacement, with no dramatic reversal expected.

13.4 Neurological complications: the two demyelinating eponyms

Central pontine myelinolysis. Central pontine myelinolysis is a demyelinating lesion of the central pons that classically follows the *too-rapid correction of hyponatraemia* in a malnourished drinker, producing a rapidly evolving quadriparesis, pseudobulbar palsy, dysarthria and, in severe cases, a locked-in state (Shorter Oxford; Kaplan and Sadock 2024). The high-yield point is preventive: correct sodium slowly in the alcohol-dependent, chronically hyponatraemic patient, because it is the speed of correction, not the alcohol alone, that triggers the lesion.

Marchiafava-Bignami disease. Marchiafava-Bignami disease is a rare disorder of widespread demyelination and necrosis of the *corpus callosum* (with optic tracts and cerebellar peduncles), presenting with disorientation, seizures, ataxia, dysarthria, hallucinations, spastic limb paralysis

and a progressive dementia with personality change, and is attributed to alcohol-related nutritional deficiency (Shorter Oxford). The callosal signature is what makes it examinable, even though it is genuinely uncommon.

SYNDROME	LESION SITE	SIGNATURE CLUE
Peripheral neuropathy	Distal peripheral nerves	Glove-and-stocking sensory loss, absent ankle jerks
Cerebellar degeneration	**Anterior superior vermis**	Gait ataxia, legs > arms and speech
Central pontine myelinolysis	**Central pons**	Follows rapid correction of hyponatraemia; quadriparesis
Marchiafava-Bignami disease	**Corpus callosum**	Callosal demyelination, dementia with seizures
Wernicke-Korsakoff	Mammillary bodies, medial thalamus	Confusion, ophthalmoplegia, ataxia; then amnesia (own topic)

The neurological complications sorted by lesion site; matching the eponym to the site is the classic exam manoeuvre (Shorter Oxford; Kaplan and Sadock 2024).

GOOD TO REMEMBER

- **Marchiafava-Bignami disease:** the criterion lesion is demyelination and necrosis of the corpus callosum in a chronic malnourished drinker; the discriminator is the callosal signature with disconnection features, seizures and progressive dementia; management is nutritional replacement and abstinence, with a variable and often poor outcome.

13.5 Cardiac complications: cardiomyopathy, arrhythmia and hypertension

Dilated cardiomyopathy. Alcoholic cardiomyopathy is an acquired form of dilated cardiomyopathy from long-term heavy drinking, with a dilated left ventricle, increased mass, thin or normal wall, and a reduced ejection fraction in advanced disease, driven by oxidative stress, mitochondrial dysfunction and impaired contractile-protein handling (Goodman and Gilman). It presents as heart failure, and early disease can improve with sustained abstinence.

Arrhythmia and hypertension. Atrial fibrillation is the commonest alcohol-related **arrhythmia** and is characteristically precipitated by binge drinking, the pattern clinicians label holiday-heart syndrome, and it carries a stroke risk (Goodman and Gilman). Chronic heavy intake also raises blood pressure: risk climbs above roughly **30 g ethanol per day** in men and **20 g per day** in women, so alcohol is a genuinely reversible cause of hypertension worth asking about in any hypertensive patient (Goodman and Gilman).

GOOD TO REMEMBER

- **Alcoholic cardiomyopathy:** the criterion picture is an acquired dilated cardiomyopathy with a dilated, poorly contracting left ventricle and reduced ejection fraction from chronic heavy drinking; the discriminator is the alcohol history in a dilated heart with no other cause; binge-related atrial fibrillation (holiday heart) and reversible hypertension complete the cardiac triad, and the first management step is abstinence, which can reverse early disease.

13.6 Gastrointestinal complications: gastritis, pancreatitis and variceal bleeding

Upper-gut mucosal injury. Ethanol directly damages the oesophageal and gastric mucosa, lowers oesophageal sphincter pressure and alters acid secretion, producing reflux, peptic ulceration and acute or chronic **gastritis** (Goodman and Gilman). In an established cirrhotic the more dangerous upper-gut event is variceal bleeding from portal hypertension, a life-threatening haematemesis that is a downstream sequela of the liver disease rather than a primary mucosal lesion.

Pancreatitis. Heavy alcohol use is the commonest cause of both acute and chronic pancreatitis (Goodman and Gilman). Acute alcoholic pancreatitis presents with abrupt severe abdominal pain, vomiting and raised serum or urine pancreatic enzymes and is managed with fluids, analgesia and supportive care; recurrent attacks drive the progressive acinar destruction and fibrosis of chronic pancreatitis, mirroring the cirrhotic sequence in the liver and leaving exocrine and endocrine (diabetic) failure.

GOOD TO REMEMBER

- **Alcoholic pancreatitis:** the criterion picture is acute severe epigastric pain with vomiting and raised amylase or lipase, alcohol being the commonest cause of both acute and chronic disease; the discriminator for the chronic form is the recurrent-attacks-to-fibrosis course leaving exocrine insufficiency and secondary diabetes; management is supportive for the acute attack and abstinence to halt progression.

13.7 Haematological complications and the biochemical fingerprints of heavy drinking

The marrow effects. The two **haematological** hallmarks are macrocytosis (a raised MCV above about **100 fL**) and thrombocytopenia. Macrocytosis arises from a direct toxic effect of alcohol on developing red cells, compounded by folate deficiency, and it is a slow-turnover marker that stays raised for weeks after drinking stops. Alcohol-induced thrombocytopenia reflects direct marrow suppression plus, in cirrhotics, splenic sequestration, and it typically recovers within days to a couple of weeks of abstinence (Goodman and Gilman; Silczuk and Habrat 2020).

The biomarkers examiners want. A raised GGT (gamma-glutamyl transferase) and a raised MCV are the two classic laboratory pointers to covert heavy drinking, and combining them, ideally with carbohydrate-deficient transferrin where available, raises sensitivity (IPS 2014). The Indian CPG operationalises monitoring as baseline and three-monthly AST, ALT, GGT, MCV and full blood count, so GGT and MCV double as screening flags and as relapse-monitoring tools across treatment.

HOLD THIS

Fatty liver and alcoholic hepatitis reverse with abstinence; cirrhosis does not and is usually terminal without transplant. That single reversibility line organises the entire complication list.

INDIA

India carries a heavy and rising alcohol burden against a background of frequent baseline malnutrition, so complicated presentations (advanced cirrhosis, florid neuropathy, Wernicke) reach services late because of the large substance-use *treatment gap*. Care is delivered across government de-addiction centres under the national Drug De-addiction Programme, medical-college psychiatry units, the day care centre model and private facilities, framed by the NDPS Act and the Mental Healthcare Act. In this resource-limited setting GGT and MCV are cheap, widely available biomarkers, and universal thiamine plus abstinence-oriented care are the highest-yield, lowest-cost interventions; the NDPS and medico-legal frame is developed in the Mental health legislation and forensic psychiatry notes.

PEARL

Use the labs as a lie-detector for covert drinking: a macrocytosis with a raised GGT, in the absence of another cause, points to sustained heavy alcohol use even when the patient minimises intake. MCV falls slowly (weeks) and GGT faster (days to weeks) with abstinence, so tracking both across follow-up distinguishes genuine abstinence from ongoing relapse.

WORKED EXAMPLE

A 45-year-old man presents with ankle swelling, breathlessness and a distended abdomen. Examination shows spider naevi, gynaecomastia, ascites and pitting oedema; bloods show a macrocytosis, thrombocytopenia and a raised GGT with a low albumin. The picture is decompensated alcoholic cirrhosis with portal hypertension, and the immediate risks are variceal bleeding and hepatic encephalopathy. Management is complete abstinence, cautious use of hepatically-cleared drugs (lorazepam rather than chlordiazepoxide for any withdrawal, acamprosate or baclofen rather than naltrexone for relapse prevention), parenteral thiamine, and referral for transplant assessment, because the cirrhosis itself will not reverse.

14 · Fetal alcohol spectrum disorder

Alcohol is the commonest human teratogen, and the injury it does to the developing brain is entirely preventable, which is exactly why the **fetal alcohol** question recurs in the substance-use viva. **Why it matters clinically.** The examiner is not asking you to run a dysmorphology clinic; the point is that a drinker in front of you may be pregnant, that there is *no* established safe threshold of maternal alcohol, and that the classic phenotype is a triad you must be able to recite. Get the three cardinal facial features, the growth deficiency and the neurodevelopmental core right and you have the whole low-tier topic.

This is a clinical (recognition and definition) topic, kept deliberately brief. **Fetal alcohol spectrum disorder** (**fasd**) is the umbrella term; **fetal alcohol** syndrome is its most severe, fully expressed form. The wider perinatal frame, alcohol screening in the antenatal clinic, the management of maternal withdrawal in pregnancy and substance use in pregnancy generally are cross-referenced to the Perinatal/women's mental health and emergency psychiatry notes and are

not re-derived here; the Wernicke amnestic mechanism sits in the Dementias and neurocognitive disorders notes and the Neuropsychiatry of systemic and neurological disease notes.

14.1 The spectrum and the classic triad

The umbrella. Fetal alcohol spectrum disorder (FASD) is the collective term for the physical, behavioural and cognitive effects of prenatal alcohol exposure; the reported United States prevalence is between **1.1 and 5.0 per cent** (Kaplan and Sadock 2024). The full-blown severe end is fetal alcohol syndrome (FAS), first delineated by Jones and Smith in 1973. The mnemonic anchor for FAS is the *triad*: a characteristic pattern of **facial dysmorphism**, pre- or postnatal **growth deficiency**, and central-nervous-system involvement (deficient brain growth with neurodevelopmental impairment), on a background of prenatal ethanol exposure (Goodman and Gilman; Companion to Psychiatric Studies).

The subdiagnoses. Under the FASD umbrella sit five conditions (Hoyme criteria): FAS, partial FAS (PFAS), alcohol-related neurodevelopmental disorder (ARND), alcohol-related birth defects (ARBD, primarily physical), and neurobehavioral disorder associated with prenatal alcohol exposure (ND-PAE). ND-PAE is the DSM-5-TR construct that captures the neurobehavioural picture *without* the facial and growth findings, and it sits in the DSM appendix as a condition for further study (Kaplan and Sadock 2024). For the exam you need FAS cold; the others you name.

14.2 The facial dysmorphism: the three cardinal features

The load-bearing three. The **facial dysmorphism** of FAS is a specific pattern of minor anomalies, and three features do the diagnostic work: **short palpebral fissures** (at or below the 10th centile), a **smooth philtrum** (loss of the vertical ridges between nose and upper lip), and a **thin vermilion border** of the upper lip. The philtrum and lip are ranked 4 or 5 on a racially normed lip-philtrum guide (Kaplan and Sadock 2024). Two or more of these are required to satisfy the facial domain. Because this triad of facial features is so specific to heavy prenatal alcohol exposure, a diagnosis of FAS can be made even without documented confirmation of maternal drinking.

DOMAIN	CARDINAL FEATURE	THRESHOLD
Face	**Short (small) palpebral fissures**	≤ 10th centile
Face	**Smooth philtrum**	Rank 4 or 5 on lip-philtrum guide
Face	**Thin vermilion border (upper lip)**	Rank 4 or 5 on lip-philtrum guide
Growth	Pre- or postnatal growth deficiency (height or weight)	≤ 10th centile
Brain	Deficient brain growth / abnormal morphogenesis	Head circumference ≤ 10th centile or structural abnormality

The FAS diagnostic domains: two or more facial features plus growth and brain involvement carry the full syndrome (Hoyme criteria, per Kaplan and Sadock 2024).

MNEMONIC

Small eyes, Smooth philtrum, thin Lip

The three cardinal facial features of FAS: *short palpebral fissures*, a *smooth philtrum* and a *thin vermilion border* of the upper lip. Add growth deficiency and the CNS impairment and you have the syndrome.

14.3 Growth restriction and the neurodevelopmental core

Growth. Prenatal alcohol produces intrauterine growth retardation that persists postnatally; height or weight at or below the 10th centile satisfies the growth domain (Companion to Psychiatric Studies; Kaplan and Sadock 2024). Microcephaly (head circumference at or below the 10th centile) reflects the deficient brain growth that underlies the whole picture.

The neurobehavioural core is the clinically important part. The average IQ in FAS is around **72**, though most affected children do *not* score below 70; the signature deficits are in executive function, attention, verbal learning and memory, and visual-spatial processing (Kaplan and Sadock 2024). The single commonest comorbid psychiatric diagnosis is ADHD, present in **44 to 96 per cent** across studies, but FASD-attention is not identical to idiopathic ADHD: FASD children show more trouble *shifting* attentional sets and encoding, and generally perform worse than children with idiopathic ADHD on IQ and adaptive behaviour. This neurodevelopmental impairment, not the face, is what drives lifelong disability, school failure, and elevated rates of later substance use and suicide.

RULE **No safe amount, so counsel abstinence.** There is no established safe quantity or trimester of maternal alcohol; the only evidence-based advice to a pregnant woman is complete abstinence, and FASD is 100 per cent preventable by not drinking in pregnancy.

TRAP **The face is neither necessary nor the point.** Most alcohol-exposed children have *no* dysmorphism (ARND / ND-PAE); waiting for the classic facies means missing the majority of affected children, whose harm is the invisible neurodevelopmental one.

3	10th	72
CARDINAL FAS FACIAL FEATURES (SHORT FISSURES, SMOOTH PHILTRUM, THIN LIP)	CENTILE CUT-OFF FOR THE GROWTH AND PALPEBRAL-FISSURE CRITERIA	APPROXIMATE AVERAGE IQ IN FETAL ALCOHOL SYNDROME

14.4 The India frame: an under-recognised diagnosis

Why it is missed here. Alcohol use in Indian women of reproductive age is lower than in the West but is rising and is heavily under-reported because of stigma, so a maternal drinking history is rarely volunteered and rarely asked. FASD is correspondingly under-diagnosed: there is no systematic antenatal alcohol screening in most Indian obstetric settings, the racially normed lip-philtrum guides are Western-derived, and the neurodevelopmental presentation is easily filed under generic intellectual disability or idiopathic ADHD (Companion to Psychiatric Studies). The de-addiction and antenatal services rarely connect, so the pregnant drinker who could be counselled is often not identified.

The prevention message. The high-yield India point is upstream: systematic screening for maternal drinking at the first antenatal visit and clear abstinence advice, which is squarely within the reach of primary antenatal care. The screening instruments and their cut-offs are taught in the screening-instruments topic and the scales gallery; the antenatal-clinic and pregnancy-withdrawal detail sits in the Perinatal/women's mental health and emergency psychiatry notes.

INDIA

FASD is almost certainly under-diagnosed in India: female drinking is stigmatised and under-reported, antenatal alcohol screening is not routine, and the phenotype is misattributed to intellectual disability or ADHD. The actionable step is to *ask* every antenatal patient about alcohol and to advise abstinence, since the syndrome is wholly preventable and there is no pharmacological treatment once the damage is done.

HOLD THIS

FAS = facial dysmorphism (short palpebral fissures, smooth philtrum, thin vermilion border) + growth deficiency + CNS/neurodevelopmental impairment, on prenatal alcohol exposure; there is no safe amount, and abstinence is the only prevention.

GOOD TO REMEMBER

- **Fetal alcohol syndrome:** the criterion picture is the triad of characteristic facial dysmorphism (two or more of short palpebral fissures at or below the 10th centile, a smooth philtrum, and a thin vermilion border), pre- or postnatal growth deficiency (height or weight at or below the 10th centile), and deficient brain growth with neurodevelopmental impairment, on a background of prenatal alcohol exposure; the neurodevelopmental core (average IQ around 72, ADHD in up to 96 per cent) is what drives lifelong disability, the discriminator from ARND/ND-PAE is the presence of the face and growth findings, and the first and only effective step is prevention through maternal abstinence, since alcohol is the commonest human teratogen and there is no safe threshold.

15 · Assessment and laboratory markers of alcohol use

People with an alcohol problem *underreport*, and they do it reliably, so the clinical assessment of drinking cannot lean on the patient's own account alone. It has to triangulate: a structured history and a validated screen, a focused examination for end-organ damage, and a small panel of **laboratory markers** that betray heavy drinking the patient will not admit. This topic is the **assessment and markers** pair, and the exam mines it for two things: the logic of a good alcohol assessment, and the relative sensitivity and specificity of the four state markers, gamma-glutamyl transferase (GGT), carbohydrate-deficient transferrin (CDT), the mean corpuscular volume (MCV) and the AST to ALT ratio. Get the one discriminator right (CDT is the most specific) and you own the topic.

Why it matters clinically. A biomarker does three jobs a questionnaire cannot: it detects the drinker who denies, it corroborates a suspected history, and it monitors abstinence objectively over follow-up (a rising GGT or CDT after a fall is the fingerprint of relapse). None of these markers diagnoses alcohol use disorder, which is a criterion-based clinical diagnosis; they are

biomarkers of recent heavy consumption that support the picture. The screening instruments themselves (AUDIT, CAGE) are developed in the screening-instruments topic and the actual forms sit in the scales gallery; here the focus is the assessment as a whole and the laboratory markers of chronic use.

15.1 The structure of an alcohol assessment: history, examination, corroboration

The three legs. A complete alcohol assessment rests on a detailed drinking history (quantity in units, frequency, pattern, the timeline of dependence features and withdrawal), a physical examination directed at the systems alcohol damages first (cardiovascular, gastrointestinal, and the central and peripheral nervous systems), and objective corroboration from a screen plus laboratory markers (Companion 2009; Tasman). The history quantifies; the examination stages the end-organ harm; the markers catch what the patient minimises.

Quantify in units and map the timeline. Convert intake to standard units (roughly **8 g** of ethanol per UK unit) and build a timeline of tolerance, withdrawal, salience and loss of control, because the *severity* of dependence, not just its presence, drives the withdrawal risk and the management plan. Ask every newly admitted and referred patient, not only the obvious cases (Companion 2009).

RULE **Corroborate, do not interrogate.** Because self-report underestimates intake, a good alcohol assessment always pairs the history with an objective marker; the markers are there to detect and monitor, never to accuse.

15.2 State versus trait, and what a biomarker can and cannot do

State markers. GGT, CDT, MCV and the transaminases are **state markers**: they rise with recent heavy drinking and fall with abstinence, which is exactly what makes them useful for detection and for monitoring recovery. A positive marker means "has been drinking heavily", not "has an alcohol use disorder"; the diagnosis is still made against the ICD-11 or DSM-5-TR criterion set (developed in the dependence-syndrome topic).

The monitoring trick. Because both GGT and CDT normalise within days to weeks of stopping, serial values track abstinence. The clinically telling event is a marker that *rises* again after falling, which indicates a return to heavy drinking (Kaplan & Sadock 2024; DSM-5-TR). Present the trend to the patient graphically to reinforce motivation (Tasman).

15.3 Gamma-glutamyl transferase (GGT): the sensitive, early, non-specific workhorse

What it is. GGT is a hepatic enzyme induced by alcohol, and its rise is one of the *earliest* laboratory signs of heavy drinking, often before any clinical evidence of liver disease (Tasman; Companion 2009). It is cheap, widely available and the routine first-line marker. GGT and other liver enzymes are elevated in roughly **60 to 75%** of heavy drinkers, and a raised GGT may be the *only* laboratory finding (DSM-5-TR; Tasman). DSM-5-TR frames the sensitive indicator as a modest elevation or high-normal level (over **35 units**), and notes that at least 70% of people with a high GGT are persistent heavy drinkers consuming eight or more drinks daily.

Its limitation. GGT is *sensitive but not specific*. It also rises with non-alcoholic liver disease, biliary obstruction, obesity, and enzyme-inducing drugs, so a raised GGT never stands alone as proof of drinking. It reflects consumption over the preceding three to five weeks and returns toward normal after roughly four to five weeks of abstinence (Companion 2009; Tasman), which is what makes it a serviceable, if blunt, monitoring tool.

GOOD TO REMEMBER

- **GGT:** hepatic enzyme, the **earliest and most widely used** alcohol marker; elevated in ~60 to 75% of heavy drinkers (DSM cut ~>35 units); **sensitive but NOT specific** (rises in liver disease, obesity, enzyme-inducing drugs); reflects the last 3 to 5 weeks of drinking; normalises after ~4 to 5 weeks of abstinence, so useful for monitoring relapse.

15.4 Carbohydrate-deficient transferrin (CDT): the most specific marker

What it is. CDT (carbohydrate-deficient transferrin) is the transferrin isoform that accumulates with sustained heavy alcohol intake, and it is the **most specific** of the routine laboratory markers for heavy drinking (Tasman; Companion 2009). DSM-5-TR treats it as a marker of comparable or even higher sensitivity *and* specificity than GGT, with a level of **20 units** or higher identifying people who regularly consume eight or more drinks daily; the Companion, more conservatively, calls it more specific but *not* more sensitive than GGT. The safe exam line is that CDT is the *most specific* marker, and that its specificity, not extra sensitivity, is its selling point.

Why it is prized. CDT is little affected by the non-alcoholic liver disease that confounds GGT, so a raised CDT points more confidently at alcohol, and it detects relapse to heavy drinking more accurately than other laboratory tests (Tasman). Like GGT it returns toward normal within days to weeks of abstinence, so it also serves monitoring. Its practical weakness is availability and cost: it is not widely available in routine Indian (or UK) laboratories, so GGT and MCV remain the everyday panel.

PEARL

Combining CDT with GGT gives higher sensitivity and specificity than either test alone (DSM-5-TR). In practice the standard alcohol laboratory panel is GGT plus MCV plus the transaminases (with their ratio), and CDT is added where it is available and specificity is at a premium, for example to settle a diagnostic dilemma or to confirm suspected relapse.

GOOD TO REMEMBER

- **CDT:** the **most specific** laboratory marker of chronic heavy drinking (level >=20 units ~ 8+ drinks/day, DSM-5-TR); relatively unaffected by non-alcoholic liver disease; best single marker for detecting relapse; normalises in days to weeks; limited by cost and availability. CDT + GGT combined beats either alone.

15.5 Mean corpuscular volume (MCV): the slow, insensitive macrocytosis marker

What it is. The MCV (mean corpuscular volume) rises to high-normal or frankly macrocytic values in heavy drinkers through a *direct toxic effect of alcohol on erythropoiesis* (bone marrow), and characteristically the macrocytosis appears *without anaemia* (DSM-5-TR; Companion 2009). It is

raised in roughly **30 to 50%** of dependent drinkers and is a cheap, ubiquitous part of the full blood count.

Its two limitations. First, low sensitivity: it misses more than half of heavy drinkers. Second, and more examinable, it is a *poor marker for monitoring abstinence* because red cells have a long lifespan (about 120 days), so the MCV lags weeks to months behind a change in drinking. Macrocytosis is also non-specific, seen with folate and B12 deficiency, hypothyroidism and some drugs, so the alcohol interpretation needs the clinical context.

GOOD TO REMEMBER

- **MCV:** macrocytosis **without anaemia** from direct marrow toxicity; raised in ~30 to 50% of heavy drinkers; **insensitive** and **poor for monitoring abstinence** (RBC lifespan ~120 days, so it lags); non-specific (also folate/B12 deficiency, hypothyroidism).

15.6 The AST to ALT ratio and the transaminases

What it is. The transaminases AST (aspartate aminotransferase, formerly SGOT) and ALT (alanine aminotransferase, formerly SGPT) rise with alcohol-related liver injury but are *less sensitive* markers of heavy drinking than GGT (Tasman). Their diagnostic value lies less in the absolute values than in the **ratio**: an **AST to ALT ratio greater than 2** favours alcoholic liver injury, whereas a ratio at or below 1 points to a non-alcoholic cause (Tasman; standard hepatology). The mechanism worth knowing is that alcohol-associated pyridoxine (vitamin B6) deficiency depresses ALT synthesis more than AST, tipping the ratio upward.

How to use it. AST and ALT are part of the standard liver panel; read them alongside GGT rather than instead of it, and use the ratio, not the raw numbers, as the alcohol pointer. A markedly raised GGT with an AST:ALT over 2 and a high-normal MCV is a classic biochemical triad of chronic heavy drinking.

MARKER	WHAT IT REFLECTS	SENSITIVITY	SPECIFICITY	WINDOW / MONITORING NOTE
GGT	Hepatic enzyme induction / injury	**Good (earliest sign)**	Low (many confounders)	Last 3 to 5 weeks; normalises ~4 to 5 weeks abstinent
CDT	Transferrin glycosylation with sustained intake	Comparable (not more, per Companion)	**Highest of the routine markers**	Days to weeks; best single relapse marker; limited availability
MCV	Direct marrow toxicity (macrocytosis, no anaemia)	**Low (~30 to 50%)**	Low (folate/B12, thyroid)	Lags weeks to months; poor for monitoring (RBC ~120 days)
AST:ALT ratio	Pattern of hepatocellular injury	Low (transaminases less sensitive than GGT)	Moderate when ratio >2	Ratio >2 favours alcohol; <=1 suggests other cause

MARKER	WHAT IT REFLECTS	SENSITIVITY	SPECIFICITY	WINDOW / MONITORING NOTE
EtG / PEth (direct)	Direct alcohol metabolites	High (recent use)	High (alcohol-specific)	Urine EtG up to ~4 days; newer, less routine

The state markers of chronic alcohol use ranked by their examinable property: GGT is the sensitive workhorse, CDT the most specific, MCV the insensitive laggard, the AST:ALT ratio the pattern pointer (DSM-5-TR; Tasman; Companion 2009).

15.7 Direct biomarkers and blood alcohol as a tolerance gauge

Direct metabolites. Beyond the indirect state markers, direct alcohol biomarkers detect ethanol metabolites themselves: urinary **ethyl glucuronide** (EtG) evidences alcohol use for up to about **4 days** (Tasman), and phosphatidylethanol (PEth) in blood extends the window further; both are alcohol-specific and increasingly used to verify abstinence, though not yet routine in Indian practice.

Blood alcohol reads tolerance. The most direct cross-sectional test is the blood alcohol concentration, which doubles as a tolerance gauge. A person at **150 mg/dL** with no signs of intoxication has acquired tolerance; someone who appears sober at **200 mg/dL** or above is highly tolerant and will almost certainly withdraw on abrupt cessation (DSM-5-TR; Companion 2009). Concentrations around 300 mg/dL indicate a need for emergency care and levels over 400 mg/dL can be fatal (Tasman).

TRAP **Treating a normal GGT as a clean bill.** GGT is insensitive to lighter drinking and CDT is often unavailable, so normal markers never exclude an alcohol problem; the history and screen still stand. Equally, do not read a raised GGT alone as proof of drinking, since it is non-specific.

20	35	120	4
CDT UNITS FLAGGING ~8+ DRINKS DAILY (DSM-5-TR)	GGT UNITS, HIGH-NORMAL SENSITIVE CUT (DSM-5-TR)	RBC LIFESPAN IN DAYS, WHY MCV LAGS	DAYS URINE ETG DETECTS RECENT USE

INDIA

In the Indian de-addiction context the everyday alcohol laboratory panel is deliberately lean: baseline and three-monthly liver function tests (AST, ALT, GGT), MCV and a full blood count, with GGT and MCV as the workhorse biomarkers of recent heavy drinking and their combination raising sensitivity (IPS 2014). Carbohydrate-deficient transferrin, though the most specific marker, is used only "where available", which in most government de-addiction centres and Drug De-addiction Programme (DDAP) units means rarely, so GGT and MCV carry the load. This is the same treatment-gap logic that pushes Indian services toward brief, motivation-based assessment delivered by trained non-specialists: a validated screen plus a cheap GGT and full blood count are within reach of a district hospital in a way that CDT and PEth are not. The wider Narcotic Drugs and Psychotropic Substances (NDPS) Act frame and capacity issues around assessment are developed in the Mental health legislation and forensic psychiatry notes.

WORKED EXAMPLE

A 46-year-old man is admitted with dyspepsia and denies problem drinking. His GGT is three times the upper limit, AST:ALT is 2.4, and the MCV is high-normal at the top of the reference range, but he has no anaemia. The biochemical triad (raised GGT, AST:ALT over 2, macrocytosis without anaemia) corroborates heavy drinking despite the denial, and the AUDIT, administered next, scores 22, in the probable-dependence band. CDT is unavailable locally, so it is not sent. Two weeks into a supervised admission the GGT has fallen by half; a subsequent rise on follow-up would flag relapse. No single number diagnosed him; the pattern plus the screen did, and the diagnosis was then confirmed against the criteria.

HOLD THIS

Four markers, four properties: GGT is the sensitive-but-not-specific early workhorse, CDT is the most specific, MCV is the insensitive macrocytosis-without-anaemia laggard that is useless for monitoring (RBC lifespan ~120 days), and an AST:ALT ratio over 2 favours alcohol; every marker detects and monitors heavy drinking but none makes the diagnosis.

Opioid use disorder

16 · Opioid intoxication, overdose and naloxone

Of every acute presentation on this block, opioid overdose is the one where a single correct decision reverses death within minutes. The examiner wants three things off the top: the recognisable picture of **opioid intoxication**, the lethal **triad** that defines **opioid overdose**, and the antidote given by the number. Get the antidote and its titration right and you are competent at the bedside; get the dose or the re-dosing wrong and the patient dies after a false recovery.

Why it matters clinically. Opioids kill by suppressing the brainstem respiratory drive. Overdose is the leading cause of death in opioid use disorder, and much of that mortality clusters in a predictable window: the period after forced abstinence (post-detoxification, post-release from custody, after disengaging from opioid substitution treatment) when tolerance has fallen but the person returns to a previously tolerated dose. The reward-pathway mechanics that drive the use sit in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; the NDPS Act frame around possession and mandated treatment sits in the Mental health legislation and forensic psychiatry notes. Here the task is to recognise the state, reverse it safely, and understand why the reversal can wear off before the poison does.

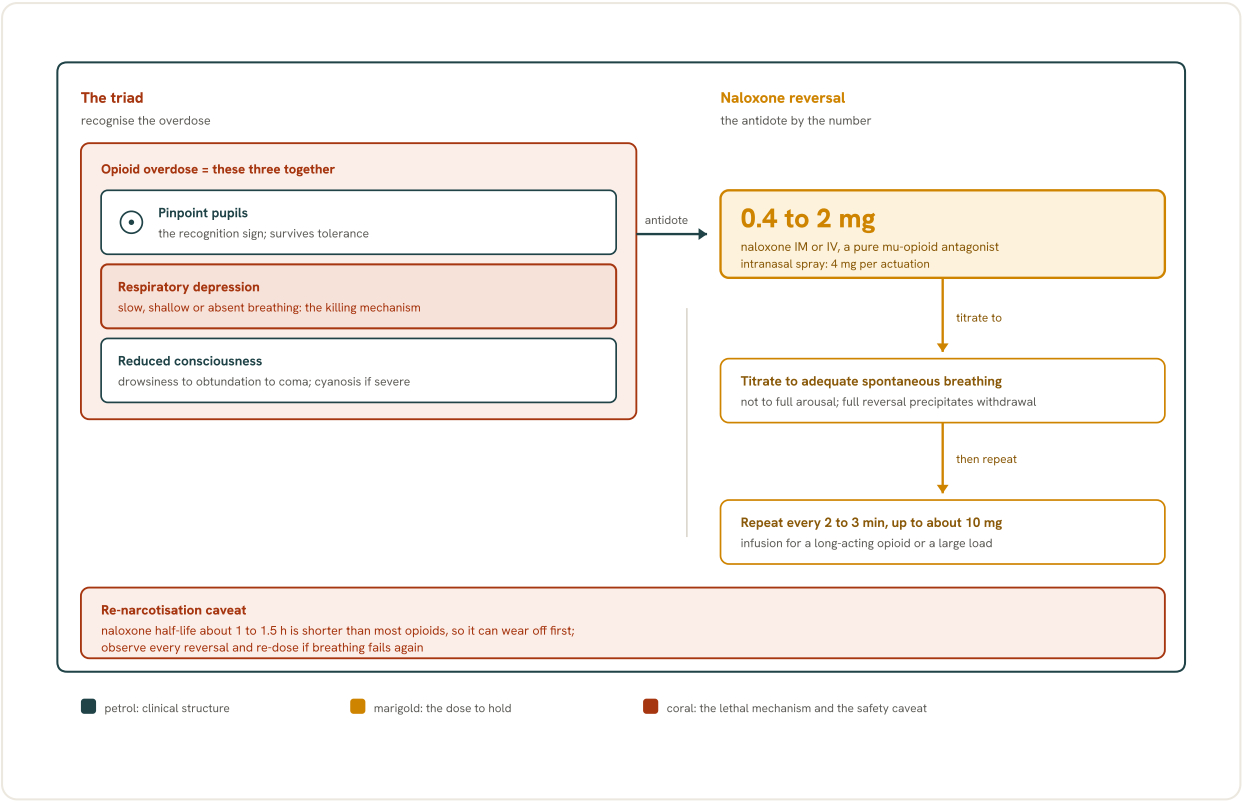

Fig 13.11 Opioid overdose: the triad and naloxone reversal. The overdose is the triad of pinpoint pupils, respiratory depression (the lethal component) and reduced consciousness taken together; the antidote is naloxone 0.4 to 2 mg IM or IV (intranasal 4 mg), titrated to adequate spontaneous breathing rather than full arousal and repeated every 2 to 3 minutes up to about 10 mg. Because naloxone's half-life of about 1 to 1.5 hours is shorter than most opioids', an apparently recovered patient must be observed and re-dosed for re-narcotisation.

16.1 Opioid intoxication: the recognisable clinical state

The picture. Opioid intoxication is a state of euphoria or apathy with psychomotor slowing, drowsiness or obtundation, slurred speech, impaired attention and memory, and pupillary constriction (Kaplan and Sadock 2024; Tasman). On examination the signs cluster as **miosis** (constricted pupils), a drowsy or obtunded sensorium, dry mouth and nose, and slowed gastrointestinal activity with constipation. It is a clinical diagnosis: the combination of a depressed, apathetic, drowsy patient with small pupils in the right context is opioid intoxication until proven otherwise.

The tolerance point that anchors the exam. Tolerance develops to the euphoric, analgesic, sedative and respiratory-depressant effects of opioids, but *not* to **miosis** and constipation (New Oxford Textbook of Psychiatry). That single fact is why constricted pupils remain a reliable sign even in a heavily tolerant chronic user, and why the pupil is the physical sign to look for first.

RULE **Small pupils survive tolerance.** Tolerance blunts euphoria and even respiratory depression, but never miosis, so pinpoint pupils remain a dependable pointer to opioids however chronic the user.

GOOD TO REMEMBER

- **Opioid intoxication (syndrome):** euphoria or apathy with psychomotor slowing, drowsiness or obtundation, slurred speech and impaired attention, plus the signature sign of **miosis**; the discriminator is that tolerance never develops to pupillary constriction, so small pupils persist even in a chronic user; the first management step is to assess airway, breathing and conscious level, because the danger is not the intoxication itself but its progression to respiratory depression.

16.2 Opioid overdose: the classic triad

The triad to say first. Opioid overdose is a clinical **triad** of *pinpoint (miotic) pupils*, *respiratory depression*, and *reduced consciousness* progressing to coma, with cyanosis in severe cases (Kaplan and Sadock 2024; Tasman; New Oxford Textbook of Psychiatry). This is the highest-yield line in the topic: severe intoxication tips into coma, slowed or absent respiration, and death. The **respiratory depression** is the killing mechanism; the **pinpoint pupils** are the recognition sign; the reduced conscious level is what brings the patient to attention.

TRIAD COMPONENT	WHAT YOU SEE
Pinpoint pupils	**Bilateral miosis (constricted, "pinpoint"); persists despite tolerance, so a reliable sign**
Respiratory depression	**Slow, shallow or absent breathing (brainstem respiratory-drive suppression); the killing mechanism**
Reduced consciousness	Drowsiness to obtundation to coma; cyanosis and pulmonary oedema in severe overdose

The classic triad of opioid overdose: pinpoint pupils, respiratory depression and reduced consciousness; respiratory depression is the lethal component (Kaplan and Sadock 2024; Tasman; New Oxford Textbook of Psychiatry).

The pupil caveat. Pupils may paradoxically *dilate* once hypoxia and cerebral anoxia are advanced, or when a mixed overdose (co-ingested stimulant or a hypoxic terminal state) is present, so a normal or dilated pupil does not exclude opioid overdose in an apnoeic patient. Treat the breathing, not the pupil, when respiration is failing.

WORKED EXAMPLE

A man in his twenties is found unresponsive at home shortly after release from custody. Respiratory rate 4, oxygen saturation 78 per cent, pupils pinpoint, GCS 5. This is the triad, in the classic high-risk window: tolerance fell during enforced abstinence, and a previously tolerated dose is now an overdose. Support ventilation with bag-valve-mask, give **naloxone**, and titrate to a return of adequate spontaneous breathing rather than to full wakefulness.

GOOD TO REMEMBER

- **Opioid overdose (emergency):** the criterion picture is the triad of pinpoint pupils, respiratory depression and reduced consciousness or coma; the discriminator from simple intoxication is failing respiration and a fall in conscious level; the antidote is **naloxone**; the first management step is airway and ventilatory support alongside naloxone, and the highest-risk window is the return to use after a period of lost tolerance.

16.3 Naloxone: the antidote and its verified dose

What it is. Naloxone (in India the 0.4 mg per 1 mL injectable ampoule; the intranasal spray branded Nexnal where available; internationally sold as **Narcan**) is a pure competitive mu-opioid receptor **antagonist** that displaces the opioid from the receptor and reverses **respiratory depression**, sedation and analgesia within minutes. It has essentially no effect in the absence of opioids, which makes empirical use in an undifferentiated coma with respiratory depression safe.

The dose, verified. Give naloxone **0.4 to 2 mg** intramuscularly (or intravenously), repeated every **2 to 3 minutes** up to a total of about **10 mg**; the intranasal preparation is **4 mg** per spray, repeated after 2 to 3 minutes if there is no response (BAP 2026; WHO; Maudsley Prescribing Guidelines). If there is no response by roughly 10 mg cumulative, reconsider the diagnosis (non-opioid cause, or a co-ingestant). Buprenorphine overdose is the exception: its high receptor affinity means *higher* naloxone doses, of the order of 2 to 4 mg with diminishing return beyond about 5 mg, and often ventilatory support are needed to reverse it (Maudsley Prescribing Guidelines).

TRAP **Titrate to breathing, not to full arousal.** Reversing a dependent patient all the way to wakefulness precipitates a violent, distressing acute withdrawal; the goal is adequate spontaneous respiration and airway protection, not a bright-eyed, agitated patient.

GOOD TO REMEMBER

- **Naloxone (mu-opioid antagonist):** competitive antagonist that reverses opioid respiratory depression within minutes; dose **0.4 to 2 mg** IM/IV repeated every 2 to 3 minutes up to about **10 mg**, or intranasal **4 mg** per spray; titrate to adequate respiration, not full arousal; short half-life (about 1 to 1.5 hours) means re-narcotisation risk; buprenorphine overdose needs higher doses (2 to 4 mg). Provide take-home naloxone with family rescue-breathing training for anyone with current or recent opioid use.

16.4 Titration and repeat dosing: adequate respiration is the endpoint

The endpoint that defines good practice. The management principle in overdose is to titrate naloxone *to restore adequate spontaneous respiration and airway protection*, not to full consciousness (BAP 2026; WHO). In an opioid-dependent patient, a large single bolus that fully reverses the receptor triggers a sudden, severe **precipitated withdrawal**: agitation, vomiting (with aspiration risk), pain, tachycardia and, occasionally, flash pulmonary oedema. Small, repeated increments titrated to breathing avoid this while still saving life.

Repeat dosing and the infusion. Because a single dose is short-acting, doses are repeated every 2 to 3 minutes until respiration is adequate, and where a long-acting opioid (methadone, slow-release morphine) or a large ingested load is involved, a continuous naloxone infusion is often required to hold the reversal (Maudsley Prescribing Guidelines). Every reversed overdose needs a period of observation, because the naloxone can wear off first (16.5).

16.5 Re-narcotisation: why naloxone can wear off before the opioid does

The pharmacokinetic mismatch. Naloxone has a short elimination half-life of about **1 to 1.5 hours**, which is shorter than that of most opioids it is used to reverse (heroin and its active

metabolites, and especially long-acting agents such as methadone with a half-life measured in tens of hours, or slow-release oral morphine) (New Oxford Textbook of Psychiatry; Maudsley Prescribing Guidelines). As the naloxone is cleared, unbound opioid still circulating re-occupies the receptor and the patient *re-narcotises*: respiratory depression and coma recur after an apparent recovery.

The practical consequence. A reversed patient is never simply discharged. They are observed (a minimum of several hours, longer after a long-acting opioid), re-dosed or placed on an infusion if respiration falls again, and in methadone or extended-release overdose admitted for prolonged monitoring, because a single reversal buys time, not cure.

RULE **Observe every reversal.** Naloxone outlives few opioids; the shorter-acting antidote can fade before the longer-acting poison, so an apparently recovered patient must be watched and re-dosed for re-narcotisation.

HOLD THIS

Opioid overdose is the triad of pinpoint pupils, respiratory depression and reduced consciousness; give naloxone 0.4 to 2 mg IM (intranasal 4 mg), titrated to adequate breathing not full arousal, repeated every 2 to 3 minutes, and observe for re-narcotisation because naloxone's half-life (about 1 to 1.5 hours) is shorter than most opioids'.

0.4 to 2 mg	4 mg	1 to 1.5 h	10 mg
NALOXONE IM/IV STARTING DOSE (REPEAT EVERY 2 TO 3 MIN)	NALOXONE INTRANASAL SPRAY DOSE PER ACTUATION	NALOXONE HALF-LIFE, SHORTER THAN MOST OPIOIDS (RE-NARCOTISATION)	CUMULATIVE NALOXONE BY WHICH A RESPONSE SHOULD HAVE APPEARED

16.6 The naltrexone contrast: an antagonist you must never give to a current user

Same class, opposite timing. Naloxone is the emergency reversal; naltrexone (in India Naltima or Nodict) is the long-acting oral or depot mu-antagonist for relapse *prevention* after detoxification, dosed at **50 mg/day** orally (Kaplan and Sadock 2024; Maudsley Prescribing Guidelines). The examiners pair them precisely to test one discrimination: naltrexone given to a patient with opioid still on board precipitates a severe, prolonged withdrawal, because unlike naloxone its long half-life means the withdrawal it triggers cannot be quickly outlasted.

The opioid-free window. Naltrexone is started only after a documented opioid-free interval (at least **7 to 10 days**, longer after methadone) confirmed by a negative urine opioid screen, and often after a small naloxone challenge (0.2 to 0.8 mg) to expose residual dependence safely with the short-acting drug before committing to the long-acting one (Maudsley Prescribing Guidelines; IPS 2014).

COMMON TRAP

Giving naltrexone to a current opioid user precipitates withdrawal. Naltrexone is a relapse-prevention agent for the abstinent patient, not a reversal agent and not something to start until the opioid-free window has passed and, where there is doubt, a naloxone challenge is clean. Confusing the emergency reversal (naloxone) with the maintenance antagonist (naltrexone) is a classic and dangerous error.

GOOD TO REMEMBER

- **Naltrexone (long-acting mu-antagonist):** for relapse prevention after detoxification, not for overdose reversal; oral dose **50 mg/day**; contraindicated in current opioid use and started only after a documented opioid-free interval (7 to 10 days, longer for methadone) with a negative urine screen and, if in doubt, a naloxone challenge; its long half-life is exactly why a precipitated withdrawal from it cannot be quickly reversed.

16.7 The Indian frame: treatment gap, NDPS and take-home naloxone

The gap and the epidemiology. India carries a large opioid burden (heroin, raw and processed opium, and pharmaceutical opioids), concentrated in the north-west and north-east, and a wide **treatment gap**: only a small fraction of people with opioid dependence reach any evidence-based care, and de-addiction services are unevenly distributed (IPS 2014). Opioid substitution treatment is delivered through the government **OST** programme and de-addiction centres, with buprenorphine the workhorse of accessible maintenance.

Access and the legal frame. Sublingual buprenorphine-naloxone in a 4:1 ratio (buprenorphine with a naloxone component that deters injection; branded Suboxone or Bunorph, buprenorphine alone as Tidigesic) is the first-line agonist maintenance option in Indian outpatient practice, inducted at **4 mg/1 mg** once the patient is in objective withdrawal (COWS at least 8 to 12) and titrated to a usual 8 to 16 mg/day (IPS 2014). Methadone remains restricted to licensed government OST clinics. All of this operates within the **NDPS Act 1985**, which frames possession offences, prescriber compliance and court-mandated treatment in lieu of conviction, and is developed in the Mental health legislation and forensic psychiatry notes. Take-home **naloxone** with family rescue-breathing training, long standard in high-income systems, is expanding in India as the single most cost-effective intervention against overdose death, particularly for patients leaving detoxification or custody with lowered tolerance.

INDIA

Buprenorphine, usually as the buprenorphine-naloxone 4:1 combination, is the accessible backbone of Indian opioid maintenance, inducted only in objective withdrawal to avoid precipitating it; methadone is confined to licensed government OST clinics. Against a heavy opioid burden and a wide treatment gap, and within the NDPS Act 1985 frame, take-home naloxone with family training is the highest-value overdose intervention, especially at the post-detoxification and post-release points where tolerance has fallen.

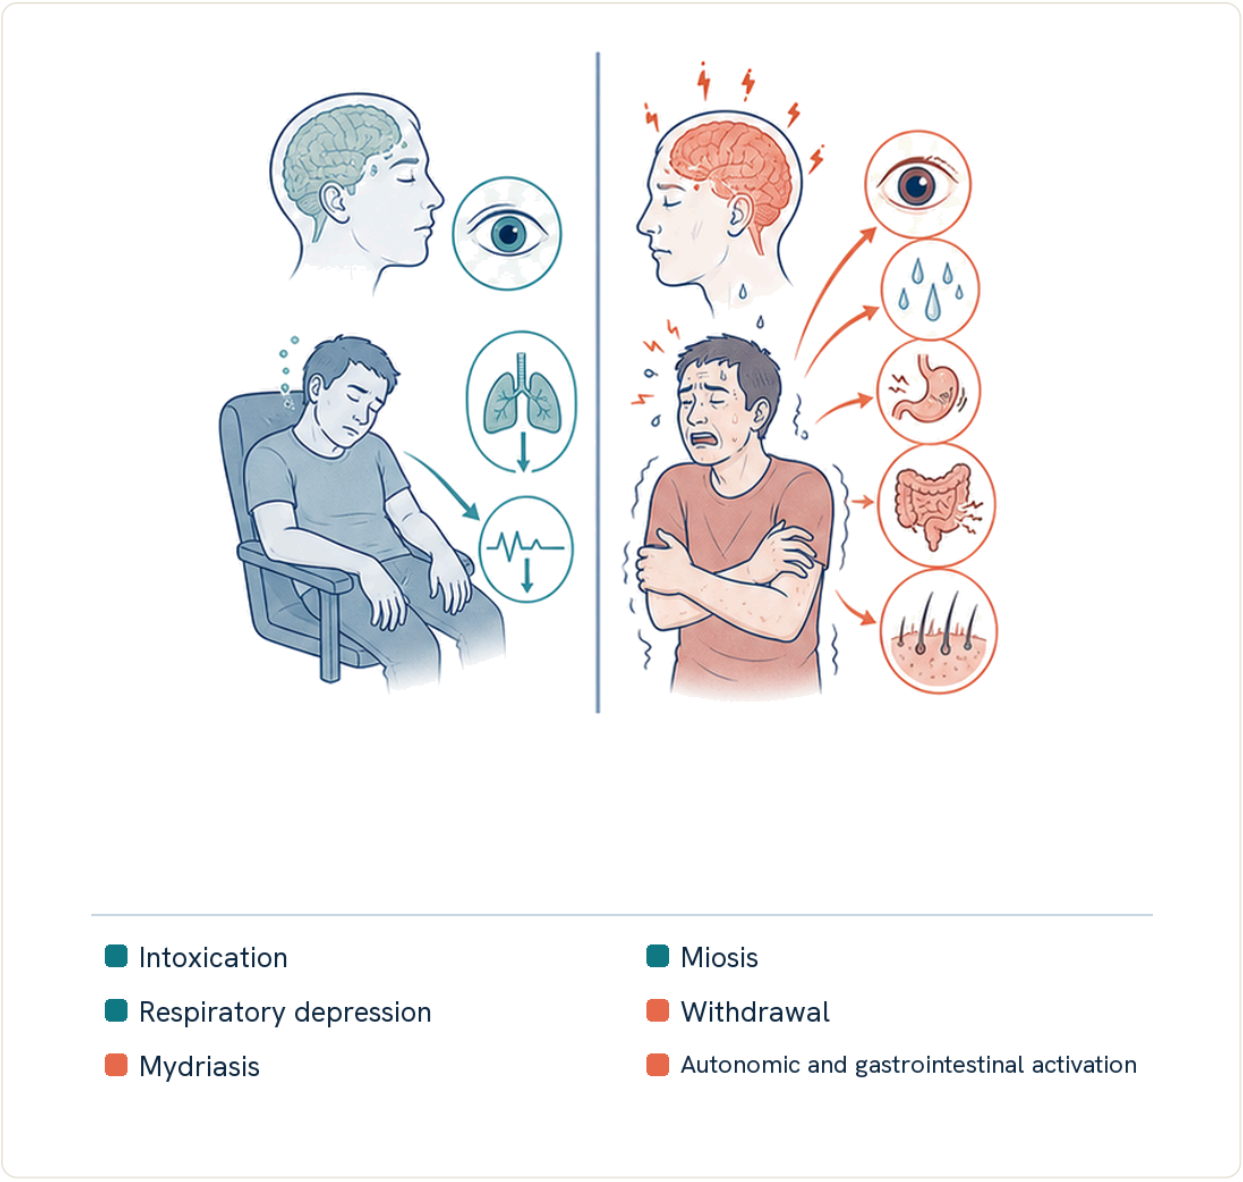
MNEMONIC

PPR then N

Pinpoint pupils, respiratory depression, reduced consciousness are the triad; then Naloxone, titrated to breathing. PPR flags the diagnosis, N is the antidote.

17 · Opioid withdrawal, COWS and its management

Stopping opioids in a physically dependent user unmasks a brain whose locus coeruleus has spent months suppressed by exogenous agonist, and the result is a florid, time-ordered but rarely lethal **noradrenergic storm**. The single most examinable contrast on this topic is with alcohol: **opioid withdrawal** is intensely uncomfortable but, in an otherwise healthy adult, not life-threatening, whereas alcohol and benzodiazepine withdrawal can kill. Examiners want the withdrawal features and their time-course by the clock (and the rule that onset and peak track the parent opioid's half-life), the **Clinical Opiate Withdrawal Scale** with its exact severity bands, and the management: buprenorphine-assisted withdrawal, the alpha-2 agonists, and the symptomatic agents. Get the COWS bands and the induction threshold exact and most of the viva follows.



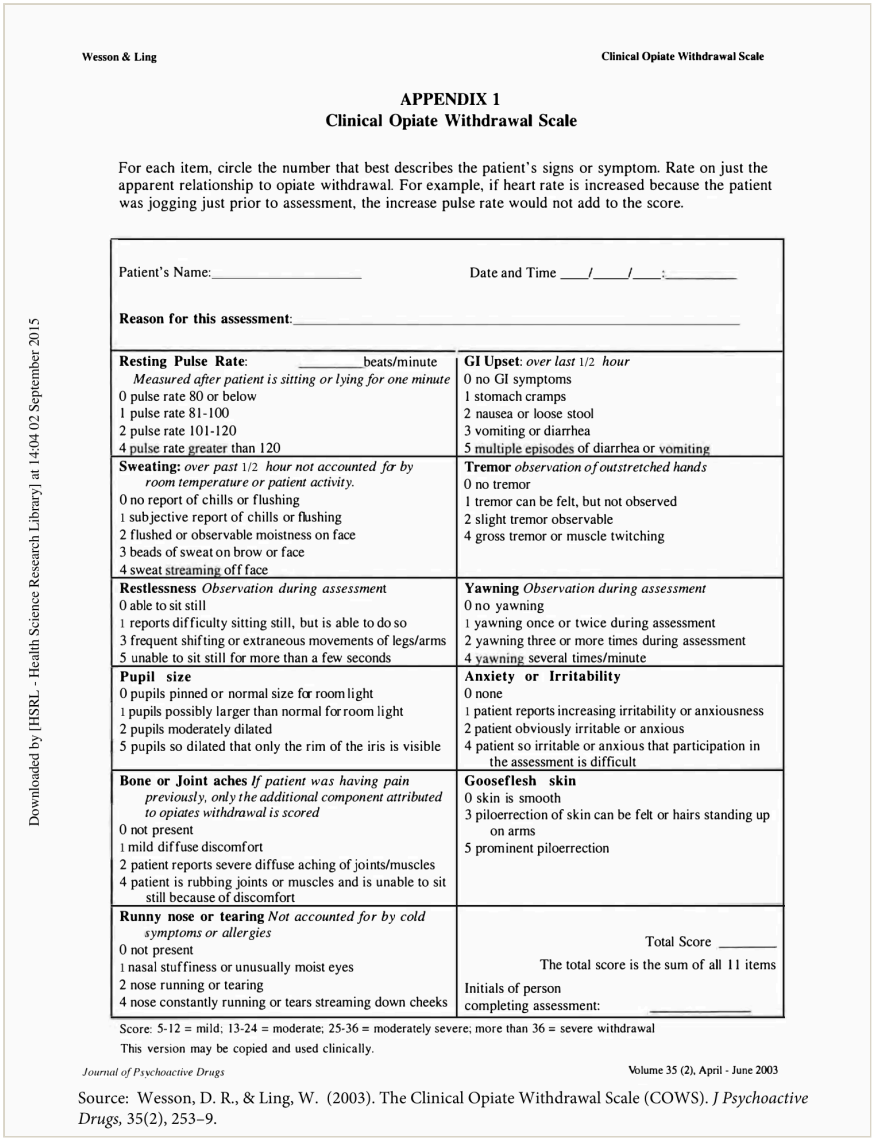


Fig 13.12 Opioid intoxication and withdrawal have opposing patterns: intoxication produces reduced consciousness, miosis and respiratory suppression, whereas withdrawal produces mydriasis, autonomic activation, piloerection, gastrointestinal distress and agitation.

Why it matters clinically. The **management of opioid withdrawal** is never an end in itself: withdrawal management alone, without ongoing opioid substitution or relapse-prevention pharmacotherapy, produces high relapse, morbidity and mortality (BAP 2026; NICE 2011; VA/DoD 2021). The two lethal windows are not the withdrawal itself but its aftermath, overdose after tolerance has fallen (post-detoxification, post-incarceration, post-disengagement) and withdrawal-induced suicidality (Indian Psychiatric Society). The reward-pathway and locus-coeruleus mechanics are developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and are not re-derived here; the NDPS Act frame sits in the Mental health legislation and forensic psychiatry notes. Here the task is to read the syndrome off the clock, stage it with the COWS, and manage it by the number.

Wesson & Ling — Clinical Opiate Withdrawal Scale

APPENDIX 1
Clinical Opiate Withdrawal Scale

For each item, circle the number that best describes the patient's signs or symptom. Rate on just the apparent relationship to opiate withdrawal. For example, if heart rate is increased because the patient was jogging just prior to assessment, the increase pulse rate would not add to the score.

Patient's Name:_____ Date and Time ____/____/____:_____

Reason for this assessment:_____

Resting Pulse Rate: _____beats/minute *Measured after patient is sitting or lying for one minute* 0 pulse rate 80 or below 1 pulse rate 81-100 2 pulse rate 101-120 4 pulse rate greater than 120	**GI Upset**: *over last 1/2 hour* 0 no GI symptoms 1 stomach cramps 2 nausea or loose stool 3 vomiting or diarrhea 5 multiple episodes of diarrhea or vomiting
Sweating: *over past 1/2 hour not accounted for by room temperature or patient activity.* 0 no report of chills or flushing 1 subjective report of chills or flushing 2 flushed or observable moistness on face 3 beads of sweat on brow or face 4 sweat streaming off face	**Tremor** *observation of outstretched hands* 0 no tremor 1 tremor can be felt, but not observed 2 slight tremor observable 4 gross tremor or muscle twitching
Restlessness *Observation during assessment* 0 able to sit still 1 reports difficulty sitting still, but is able to do so 3 frequent shifting or extraneous movements of legs/arms 5 unable to sit still for more than a few seconds	**Yawning** *Observation during assessment* 0 no yawning 1 yawning once or twice during assessment 2 yawning three or more times during assessment 4 yawning several times/minute
Pupil size 0 pupils pinned or normal size for room light 1 pupils possibly larger than normal for room light 2 pupils moderately dilated 5 pupils so dilated that only the rim of the iris is visible	**Anxiety or Irritability** 0 none 1 patient reports increasing irritability or anxiousness 2 patient obviously irritable or anxious 4 patient so irritable or anxious that participation in the assessment is difficult
Bone or Joint aches *If patient was having pain previously, only the additional component attributed to opiates withdrawal is scored* 0 not present 1 mild diffuse discomfort 2 patient reports severe diffuse aching of joints/muscles 4 patient is rubbing joints or muscles and is unable to sit still because of discomfort	**Gooseflesh skin** 0 skin is smooth 3 piloerrection of skin can be felt or hairs standing up on arms 5 prominent piloerrection
Runny nose or tearing *Not accounted for by cold symptoms or allergies* 0 not present 1 nasal stuffiness or unusually moist eyes 2 nose running or tearing 4 nose constantly running or tears streaming down cheeks	Total Score _____ The total score is the sum of all 11 items Initials of person completing assessment: _____

Score: 5-12 = mild; 13-24 = moderate; 25-36 = moderately severe; more than 36 = severe withdrawal

This version may be copied and used clinically.

COWS (Wesson and Ling, 2003); reproduced from the NIDA/SAMHSA form, freely reproducible with acknowledgement.

Fig 13.13 The Clinical Opiate Withdrawal Scale (COWS), the 11-item clinician-rated instrument that quantifies opioid withdrawal severity so that treatment, above all the timing of buprenorphine induction, is driven by a number rather than by impression. Each item is scored on the form and the total is read against four verified severity bands printed at the foot: 5 to 12 is mild, 13 to 24 moderate, 25 to 36 moderately severe, and above 36 severe withdrawal. The examinable threshold sits inside the mild band: buprenorphine is withheld until objective withdrawal is established at a COWS of about 8 to 12, because a partial agonist given too early precipitates withdrawal.

17.1 The withdrawal syndrome: the noradrenergic features

The clinical picture. Opioid withdrawal is a syndrome of autonomic and noradrenergic overactivity that is, in essence, the mirror image of intoxication. The frequently occurring signs and symptoms are sweating, **piloerection** (gooseflesh, the "cold turkey"), yawning, **rhinorrhoea**, sneezing, **lacrimation**, pupillary dilatation (mydriasis), nausea, vomiting, abdominal cramps, diarrhoea, tremor, muscle and bone aches, agitation, dysphoric mood, fever, piloerection and sleep disturbance (Kaplan and Sadock 2024; Stahl Substance Use; ICD-11 CDDR). None of these is dangerous in isolation; taken together they are so aversive that the person uses again simply to stop them, which is the engine of continued dependence.

Objective versus subjective signs. A useful examination distinction: the *objective* signs (mydriasis, lacrimation, rhinorrhoea, piloerection, yawning, sweating, tremor, raised pulse) can be observed and are what a withdrawal scale rates, whereas the *subjective* symptoms (anxiety, bone and muscle ache, restlessness, dysphoria, drug craving) are reported. Buprenorphine induction is timed to *objective* withdrawal precisely because subjective distress alone is unreliable.

GOOD TO REMEMBER

- **Opioid withdrawal syndrome:** the criterion picture is autonomic and noradrenergic overactivity, the mirror of intoxication, mydriasis, lacrimation, rhinorrhoea, sneezing, yawning, piloerection, sweating, nausea, vomiting, diarrhoea, muscle and bone aches, and dysphoria; the discriminator from alcohol and sedative withdrawal is that it is intensely uncomfortable but *not* life-threatening in the otherwise healthy; the first management step is to confirm objective withdrawal (a scale such as the COWS) before any opioid agonist is given.

17.2 The time-course by the clock: onset and peak track the half-life

The governing principle. The onset, peak and duration of opioid withdrawal are set by the pharmacokinetics of the parent opioid: withdrawal follows the rate at which the drug clears from its receptors, so the shorter the half-life, the sooner and sharper the syndrome (Tasman; Kaplan and Sadock 2024). This single rule lets you predict the course from the drug alone.

Short-acting opioids. For a short-acting opioid such as heroin (diamorphine), withdrawal begins about **6 to 8 hours** after the last dose (the wider range across opioids is 4 to 24 hours), peaks at roughly **36 to 48 hours**, and largely resolves by **5 to 7 days** (Tasman; Maudsley Prescribing Guidelines). This is the acute, dramatic "cold turkey" course.

Long-acting opioids. For a long-acting opioid such as methadone (half-life of the order of **24 to 36 hours** in maintenance), onset is delayed to **24 to 48 hours**, the peak comes later, and the syndrome is more protracted (often 10 to 14 days or more) but less intense. A protracted, low-grade phase (dysphoria, insomnia, craving, autonomic instability) can persist for weeks after either.

OPIOID	ONSET AFTER LAST DOSE	PEAK	BROAD DURATION
Heroin / short-acting	**6 to 8 hours**	**36 to 48 hours**	5 to 7 days
Methadone / long-acting	**24 to 48 hours**	4 to 6 days	10 to 14 days or more
Protracted phase (either)	days to weeks	-	weeks (dysphoria, insomnia, craving)

Opioid withdrawal time-course; onset and peak track the parent opioid's half-life, so heroin withdrawal is early and sharp while methadone withdrawal is delayed and protracted (Tasman; Kaplan and Sadock 2024; Maudsley Prescribing Guidelines).

RULE **Read the drug, then read the clock.** The half-life sets everything, short-acting opioids withdraw early, sharp and brief; long-acting opioids withdraw late, milder and protracted, so you time induction and taper to the parent drug, not to a fixed schedule.

17.3 The COWS: what it is and what it measures

What it is. The Clinical Opiate Withdrawal Scale (COWS, Wesson and Ling 2003) is the most commonly used clinician-rated instrument for quantifying the severity of opioid withdrawal, so that treatment (above all the timing of buprenorphine induction) can be driven by a number rather than by impression (Kaplan and Sadock 2024; Maudsley Prescribing Guidelines). It is an 11-item observer-rated scale scoring resting **pulse rate**, sweating, restlessness, pupil size, bone or joint aches, **rhinorrhoea or lacrimation**, gastrointestinal upset, tremor, yawning, anxiety or irritability, and **piloerection** (gooseflesh). The full instrument is reproduced in the scales gallery.

Why it is preferred. The COWS rates *objective* withdrawal, which is exactly what makes it the tool for timing agonist induction: because buprenorphine is a partial agonist that will displace a full agonist from the receptor, giving it too early precipitates withdrawal, so a scale that confirms the patient is already in objective withdrawal (rather than merely subjectively distressed) is the safeguard. The related Objective Opiate Withdrawal Scale (OOWS) rates observable signs only; the COWS is the default in most protocols.

17.4 The COWS severity bands: the numbers that drive treatment

The bands to memorise. The COWS total maps to four verified severity bands: **5 to 12** is mild withdrawal, **13 to 24** is moderate, **25 to 36** is moderately severe, and a score **above 36** is severe withdrawal (Wesson and Ling 2003; Kaplan and Sadock 2024; Maudsley Prescribing Guidelines). A score under 5 indicates little or no withdrawal. These bands are the anchor for the induction decision in the next subtopic.

COWS TOTAL SCORE	SEVERITY BAND	INTERPRETATION
5 to 12	Mild	Objective withdrawal present but mild; the usual minimum threshold to begin buprenorphine induction.
13 to 24	Moderate	Clearly established withdrawal; a comfortable window for buprenorphine first dose.
25 to 36	Moderately severe	Marked distress; symptomatic cover needed alongside agonist induction.
above 36	Severe	Severe withdrawal; intensive symptomatic management.

COWS severity bands (5 to 12 mild, 13 to 24 moderate, 25 to 36 moderately severe, above 36 severe); verified against two independent sources (Wesson and Ling 2003; Kaplan and Sadock 2024; Maudsley Prescribing Guidelines).

COMMON TRAP

The COWS band and the induction threshold are not the same number, and confusing them is the classic error. The mild band *starts* at a score of 5, but the accepted threshold to give the first dose of buprenorphine is higher, a COWS of about **8 to 12** (Indian Psychiatric Society; APA targets above 10). Inducting on a COWS of 5 to 7 risks precipitated withdrawal because the patient is not yet in sufficiently established withdrawal for the partial agonist to be a net improvement.

17.5 Management overview: withdrawal management is never a stand-alone

The overarching rule. Across every guideline, the first principle of the **management of opioid withdrawal** is that it must not be done in isolation. BAP, NICE, WHO mhGAP, VA/DoD and CANMAT are unanimous: do not undertake opioid withdrawal management without planned ongoing pharmacotherapy (agonist maintenance or naltrexone) and psychosocial support, because withdrawal alone carries a high risk of relapse and, through lost tolerance, of fatal overdose (BAP 2026; NICE 2011; WHO mhGAP 2016; VA/DoD 2021). Two approaches are legitimate: a supervised agonist taper (buprenorphine or methadone) for those choosing to detoxify, and, more often, continued opioid substitution therapy (OST). Ultra-rapid detoxification under anaesthesia or heavy sedation is contraindicated, it confers no benefit and carries life-threatening risk (BAP 2026; NICE 2011; WHO 2009).

The guideline positions, in order. BAP directs that for medically assisted withdrawal an agonist taper is used, delaying the first buprenorphine dose until objective withdrawal, and names lofexidine or clonidine as adjunctive or monotherapy where an agonist is not used, preferring lofexidine (BAP 2026). The **Indian Psychiatric Society** makes a buprenorphine taper the preferred medically assisted withdrawal regimen and buprenorphine-naloxone the first-line agonist maintenance option in Indian outpatient practice (IPS guidelines). NICE offers methadone or buprenorphine as first-line for detoxification, with lofexidine for those who decline them or have mild or uncertain dependence (NICE 2011). WHO mhGAP recommends tapered opioid agonists, with alpha-2 agonists as an alternative (WHO mhGAP 2016). None of these is contradicted here; the agonist-taper-first and continued-OST positions are verified across all four.

17.6 Buprenorphine-assisted withdrawal: the partial agonist and its induction rule

Why buprenorphine. Buprenorphine (Indian brand Tidigesic; as buprenorphine-naloxone, Suboxone or Bunorph) is a high-affinity *partial* mu-receptor agonist. Its ceiling effect on respiratory depression makes it substantially safer in overdose than methadone, and its high receptor affinity means it both relieves withdrawal and blocks the effect of further illicit opioid, which is why it is the workhorse of ambulatory Indian de-addiction practice. In India it is most often prescribed as the buprenorphine-naloxone sublingual combination (a 4:1 ratio), where the poorly absorbed naloxone deters injection misuse, the buprenorphine-naloxone combination (IPS guidelines).

The induction rule. The one non-negotiable is timing. Because buprenorphine will displace a full agonist from the receptor while only partially activating it, giving it while a full agonist is still on board *precipitates* withdrawal. The first dose is therefore delayed until the patient is in objective

withdrawal, operationally a COWS of about **8 to 12** and typically **12 to 24 hours** after the last short-acting opioid (IPS guidelines; BAP 2026; APA). The IPS induction is buprenorphine-naloxone 4 mg / 1 mg at that point, titrated by 2 to 4 mg/day to a usual maintenance of 8 to 16 mg/day, some patients needing up to 24 mg/day (IPS guidelines). For a supervised buprenorphine *taper* the IPS uses reductions of 2 to 4 mg/day over 7 to 14 days from the stabilisation dose (IPS guidelines).

WORKED EXAMPLE

A man dependent on injected heroin last used ten hours ago and is subjectively distressed but has a COWS of 6 (mild band): mild anxiety, a few yawns, faint sweating. The wrong move is to induct now, at a COWS of 6, with a full agonist likely still partly on the receptor, buprenorphine can precipitate an abrupt worsening. The correct move is to wait, giving symptomatic cover (an alpha-2 agonist, an antiemetic, loperamide), and to re-score; once the COWS reaches about 8 to 12 (usually by 12 to 24 hours after the last heroin dose), give buprenorphine-naloxone 4 mg / 1 mg and titrate.

GOOD TO REMEMBER

- **Buprenorphine (Tidigesic; buprenorphine-naloxone as Suboxone or Bunorph):** high-affinity *partial* mu-agonist with a ceiling on respiratory depression (safer in overdose than methadone); the signature caution is precipitated withdrawal, so delay the first dose until objective withdrawal (COWS about 8 to 12, roughly 12 to 24 hours after a short-acting opioid); IPS induction is buprenorphine-naloxone 4 mg / 1 mg titrated by 2 to 4 mg/day to a usual maintenance of 8 to 16 mg/day.

17.7 Methadone: the long-acting full agonist and its induction ceiling

Where it fits. Methadone is a long-acting *full* mu-agonist, an alternative first-line agent for both detoxification and maintenance (NICE 2011; WHO mhGAP 2016). It does not precipitate withdrawal, so it can be started without waiting for a high COWS, but as a full agonist it has no ceiling on respiratory depression and the first two weeks of treatment are a high-risk overdose window because of methadone's long half-life and accumulation (BAP 2026). Its half-life of roughly 24 hours or more is what makes it once-daily and smooth, but also what makes early induction dangerous.

The induction ceiling. The verified safety rule is a cautious start: WHO and WHO mhGAP set the initial daily dose by neuroadaptation, generally **not more than 20 mg** and certainly not more than 30 mg, increasing by no more than about 10 mg every few days (WHO 2009; WHO mhGAP 2016). Effective maintenance is usually **60 to 120 mg/day**, since doses below 60 mg/day carry a two- to three-fold higher risk of dropout (BAP 2026; WHO mhGAP 2016). Monitor the QT interval. In India, methadone maintenance is restricted to government OST clinics under the National AIDS Control Organisation (NACO) and select institutions, so the private psychiatrist refers rather than prescribes it (IPS guidelines).

FEATURE	BUPRENORPHINE (PARTIAL AGONIST)	METHADONE (FULL AGONIST)
Overdose safety	**Ceiling on respiratory depression; safer**	No ceiling; high-risk first 2 weeks
Induction timing	**Must wait for objective withdrawal (COWS about 8 to 12)**	No wait; can precipitate none, but start low
Initial dose	Buprenorphine-naloxone 4 mg / 1 mg	**20 mg/day or less (max 30)**
Usual maintenance	8 to 16 mg/day (up to 24)	**60 to 120 mg/day**
India access	Outpatient de-addiction first-line (as bup-naloxone)	Restricted to NACO OST clinics

Buprenorphine versus methadone for opioid withdrawal and substitution; buprenorphine is safer and India's outpatient first-line but must await objective withdrawal, methadone needs no wait but a low, cautious induction (IPS guidelines; NICE 2011; WHO mhGAP 2016; BAP 2026).

GOOD TO REMEMBER

- **Methadone:** long-acting *full* mu-agonist with no ceiling on respiratory depression, so the signature caution is overdose during the first two weeks of induction; start low (20 mg/day or less, never above 30 mg), increase by about 10 mg every few days, maintain at 60 to 120 mg/day, and monitor the QT interval; in India it is confined to NACO-licensed OST clinics.

17.8 Clonidine and lofexidine: the alpha-2 agonists

How they work. The alpha-2 adrenergic agonists clonidine and lofexidine suppress the noradrenergic hyperactivity that drives opioid withdrawal by reducing central sympathetic outflow at the locus coeruleus. They are non-opioid, so they neither substitute at the mu-receptor nor risk diversion, and they treat the autonomic features (sweating, tachycardia, lacrimation, rhinorrhoea, gastrointestinal upset) but not the craving or the aches as completely as an agonist taper (Kaplan and Sadock 2024; BAP 2026). They are second-line to agonists, used where methadone and buprenorphine are declined, contraindicated or unavailable, or where a shorter non-opioid detoxification is wanted (NICE 2011; VA/DoD 2021).

Lofexidine versus clonidine. The examinable discriminator: both work, but **lofexidine** is preferred over **clonidine** because clonidine's hypotension and sedation are dose-limiting, whereas lofexidine causes less postural hypotension (BAP 2026; WHO 2009; NICE 2011). NICE will consider lofexidine for people who decline methadone or buprenorphine, want a short detoxification, or have mild or uncertain dependence, but advises against using clonidine routinely. The clinical caution for both is blood pressure: check it before dosing and hold for hypotension. Lofexidine is not widely available in India, so clonidine (0.1 to 0.3 mg three times daily, titrated to blood pressure) is the practical alpha-2 agent here (IPS guidelines).

TRAP **Do not read opioid withdrawal as the medical emergency alcohol withdrawal is.** In an otherwise healthy adult opioid withdrawal is not life-threatening; the danger is the aftermath, overdose on lost tolerance and withdrawal-driven suicidality, so the emergency planning is take-home naloxone and suicide-risk assessment, not intensive medical rescue of the withdrawal itself.

GOOD TO REMEMBER

- **Clonidine and lofexidine (alpha-2 agonists):** non-opioid agents that damp the locus-coeruleus noradrenergic storm and treat the autonomic features of withdrawal; second-line to agonists; the signature caution is hypotension (check blood pressure before each dose); lofexidine is preferred (less postural hypotension) but clonidine 0.1 to 0.3 mg three times daily is the practical Indian choice; neither adequately covers craving, so pair with relapse-prevention planning.

17.9 Symptomatic agents and the buprenorphine taper regimen

The adjuncts. Whichever backbone is chosen, targeted symptomatic agents make withdrawal tolerable: **loperamide** for diarrhoea, an antiemetic (ondansetron or prochlorperazine) for nausea and vomiting, paracetamol or an NSAID for the muscle and bone aches, an antispasmodic (dicyclomine) for cramps, and hydroxyzine or a short course of a low-dose benzodiazepine or a sedative for insomnia (IPS guidelines; Kaplan and Sadock 2024). These target the individual features and are used alongside, not instead of, the agonist or alpha-2 backbone.

The IPS taper. The Indian Psychiatric Society's preferred medically assisted withdrawal is a buprenorphine taper, reductions of 2 to 4 mg/day over 7 to 14 days from the stabilisation dose, with clonidine 0.1 to 0.3 mg three times daily, loperamide as needed for diarrhoea, paracetamol or NSAIDs for myalgia, ondansetron as needed for nausea, and hydroxyzine or a short benzodiazepine course for insomnia (IPS guidelines).

WITHDRAWAL FEATURE	SYMPTOMATIC AGENT	NOTE
Autonomic overactivity (sweating, tachycardia, rhinorrhoea)	**Clonidine or lofexidine**	Alpha-2 backbone; monitor blood pressure.
Diarrhoea	Loperamide as needed	Peripheral opioid; does not cross into the CNS.
Nausea and vomiting	Ondansetron or prochlorperazine	As needed.
Muscle and bone aches	**Paracetamol or NSAID**	Regular dosing during the peak.
Abdominal cramps	Dicyclomine (antispasmodic)	As needed.
Insomnia	Hydroxyzine; short low-dose benzodiazepine or sedative	Short course only; avoid dependence-swapping.

Symptomatic agents for opioid withdrawal, matched to the feature; these are adjuncts to the agonist taper or alpha-2 backbone, never the whole treatment (IPS guidelines; Kaplan and Sadock 2024).

17.10 After withdrawal: naltrexone, the opioid-free window and take-home naloxone

Naltrexone for relapse prevention. Once withdrawal is complete, naltrexone (an oral mu-antagonist; Indian brands Nodict, Naltima, unconfirmed in this corpus) can be offered for relapse prevention to those wanting abstinence, at 50 mg/day orally (BAP 2026; IPS guidelines; WHO 2009). The absolute rule, and a favourite emergency-avoidance question: naltrexone must never be given to a current opioid user, because as an antagonist it precipitates immediate, severe withdrawal. It is started only after a documented **opioid-free window** of at least **7 to 10 days** (longer after methadone), confirmed by a negative urine opioid screen and, where uncertain, a naloxone challenge (IPS guidelines; Kaplan and Sadock 2024). A signature caution is that naltrexone strips tolerance, so relapse on stopping it carries a high overdose risk.

Naloxone for overdose. Naloxone is the rescue antagonist for opioid overdose. The IPS dosing is intramuscular 0.4 to 2 mg, repeated every 2 to 3 minutes up to 10 mg, or intranasal 4 mg per spray repeated after 2 to 3 minutes (IPS guidelines; WHO 2009). Every guideline recommends *take-home* naloxone with paired family training in rescue breathing and the recovery position for anyone with current or recent opioid use, especially in the high-overdose windows after detoxification or release from custody (BAP 2026; IPS guidelines; WHO 2009).

GOOD TO REMEMBER

- **Naltrexone (oral mu-antagonist, 50 mg/day; Nodict, Naltima):** for relapse prevention after abstinence only; the criterion contraindication is any current opioid use (it precipitates severe withdrawal), so start only after a documented opioid-free window of 7 to 10 days (longer post-methadone) with a negative urine screen; caution, it removes tolerance, so relapse afterwards risks fatal overdose.
- **Naloxone (mu-antagonist, overdose rescue; e.g. Nexnal, brand unconfirmed here):** IM 0.4 to 2 mg repeated every 2 to 3 minutes up to 10 mg, or intranasal 4 mg per spray; the dose-anchored action is take-home naloxone plus family rescue-breathing training for anyone with current or recent opioid use, especially post-detoxification or post-release.

17.11 The India frame: the treatment gap, NDPS and OST access

The clinical reality. India carries a very large opioid-use treatment gap, with most dependent users never reaching formal care, and opioid dependence (heroin in the north, and pharmaceutical opioids and, historically, natural-opium use in agrarian belts) concentrated in government de-addiction centres, the Drug De-addiction Programme, and the day care centre model rather than in general practice (IPS guidelines). The practical consequence is that buprenorphine-naloxone, inducted on a COWS of about 8 to 12, is the outpatient backbone the psychiatrist actually uses, while methadone maintenance is confined to NACO-licensed OST clinics and select institutions, so private practice refers for methadone rather than prescribing it.

Access and law. Buprenorphine and the other opioid agents are controlled under the Narcotic Drugs and Psychotropic Substances (NDPS) Act, 1985, whose scheduling and prescriber requirements shape access; the medico-legal detail, including treatment in lieu of conviction, sits in the Mental health legislation and forensic psychiatry notes. Harm-reduction services, needle and syringe programmes, safer-injecting education and take-home naloxone, are offered in addition to (not instead of) agonist maintenance for any current injector, alongside baseline and

annual screening for HIV, HBV, HCV, syphilis and tuberculosis (IPS guidelines). The wider CBT and motivational-interviewing technique that anchors the psychosocial arm is developed in the Psychotherapies, clinical assessment, MSE and nosology notes.

INDIA

Three India-specific points recur in the viva. First, buprenorphine-naloxone (the 4:1 sublingual combination) is the outpatient first-line agonist, inducted at 4 mg / 1 mg once the COWS reaches about 8 to 12 (roughly 12 to 24 hours after a short-acting opioid), because it is accessible, ambulatory and diversion-deterrent. Second, methadone is *not* a private-practice option, it is restricted to NACO OST clinics, so the correct answer to "how would you start methadone" often includes "refer to the nearest licensed OST centre". Third, lofexidine is largely unavailable, so clonidine is the practical alpha-2 agent despite its dose-limiting hypotension. Naltrexone (Nodict, Naltima) remains widely used for relapse prevention in supervised, family-monitored programmes, but only after a confirmed 7-to-10-day opioid-free window.

8 to 12 COWS THRESHOLD TO BEGIN BUPRENORPHINE INDUCTION (OBJECTIVE WITHDRAWAL)	**above 36** COWS SCORE DEFINING SEVERE OPIOID WITHDRAWAL	**6 to 12 h** ONSET OF HEROIN (SHORT-ACTING OPIOID) WITHDRAWAL AFTER THE LAST DOSE	**7 to 10 days** OPIOID-FREE WINDOW REQUIRED BEFORE STARTING NALTREXONE

HOLD THIS

Opioid withdrawal is a noradrenergic storm (mydriasis, lacrimation, rhinorrhoea, piloerection, aches) that is intensely uncomfortable but not life-threatening, with onset and peak tracking the parent opioid's half-life (heroin 6 to 8 hours, methadone 24 to 48 hours); stage it with the COWS (5 to 12 mild, 13 to 24 moderate, 25 to 36 moderately severe, above 36 severe), induct buprenorphine only once objective withdrawal is established (COWS about 8 to 12), use clonidine or lofexidine plus symptomatic agents where an agonist is declined, never give naltrexone to a current user (precipitated withdrawal; needs a 7 to 10 day opioid-free window), and give take-home naloxone for the post-detoxification overdose window.

18 · Opioid substitution therapy

Of all the management topics in this block, **opioid substitution therapy** is the one where a wrong number is dangerous, so examiners test it with confidence. The whole logic is simple: opioid dependence is a relapsing brain disorder, forced abstinence is followed by falling tolerance and a high risk of fatal overdose, and the single intervention that reliably keeps people alive and in care is a long-acting oral opioid agonist given daily under supervision. That is what **substitution therapy** means. The two agents to know cold are **buprenorphine**, a partial mu agonist with a ceiling on respiratory depression, and **methadone**, a full agonist with a slow titration and a QTc caution. Get their mechanisms, their **induction** doses and their **maintenance** targets exact, and the rest, from precipitated withdrawal to the Indian access story, follows.

Why it matters clinically. This is agonist maintenance, not a cure and not a detox: the goal is retention, blockade of illicit opioids and a fall in death risk, so the commonest exam error is to frame it as "getting the patient off drugs". The reward and mesolimbic-dopamine anatomy on

which the opioid pull is built is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and is not re-derived here. The medico-legal frame, the NDPS Act and OST prescriber licensing, is developed in the Mental health legislation and forensic psychiatry notes; here the concern is the drug, the dose, the line and the monitoring. One figure carries this topic: Fig 13.14, the buprenorphine induction and precipitated-withdrawal timeline.

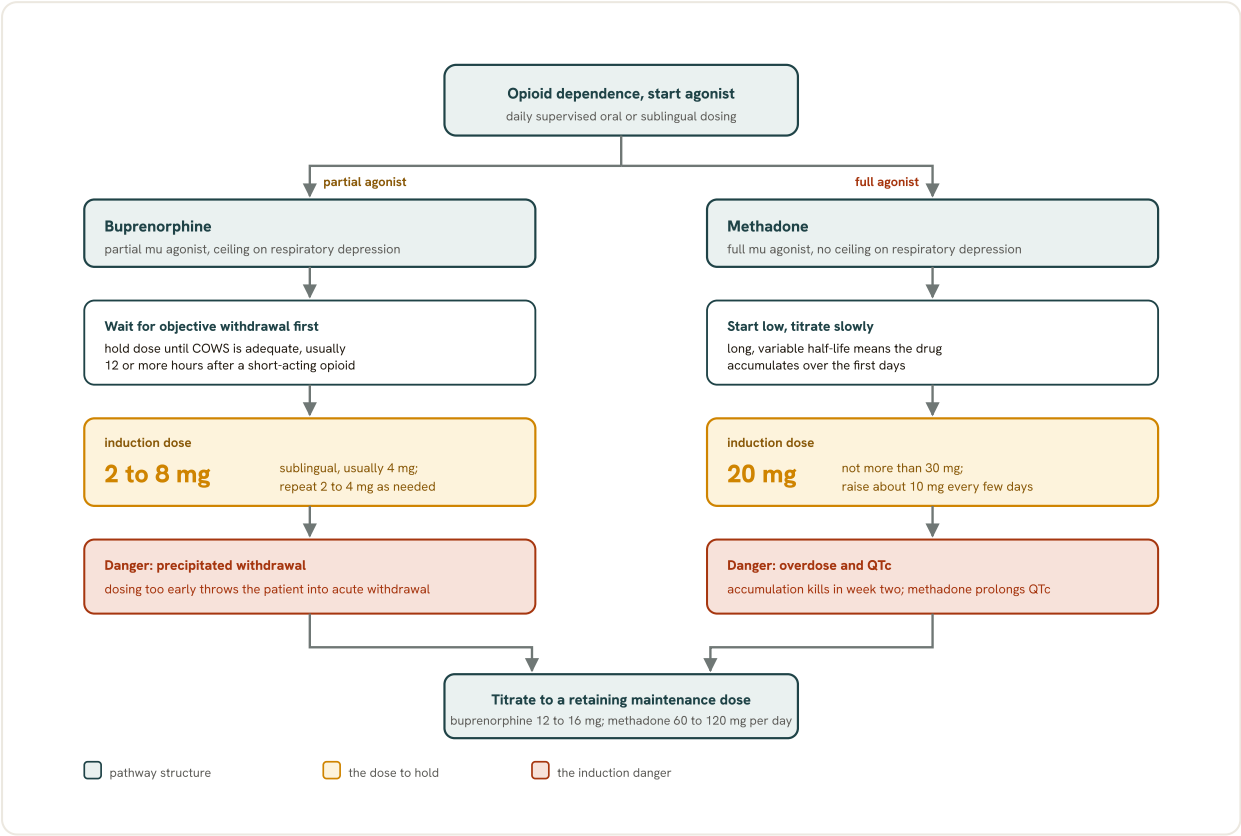

Fig 13.14 Opioid substitution: buprenorphine versus methadone induction. Buprenorphine is a partial mu agonist with a ceiling on respiratory depression: hold the first dose until objective withdrawal (an adequate COWS, usually 12 or more hours after a short-acting opioid), then induct at 2 to 8 mg sublingually, because dosing too early precipitates withdrawal. Methadone is a full agonist with no respiratory ceiling: start low at 20 mg (not more than 30) and titrate slowly by about 10 mg every few days, because its long half-life lets the drug accumulate into a fatal overdose in the second week, and it prolongs the QTc. Both then titrate to a retaining maintenance dose.

18.1 The principle: agonist maintenance keeps people alive and in care

What OST is for. Opioid agonist maintenance treatment (OATM, often just **OST**) substitutes a long-acting, orally or transmucosally delivered opioid for the short-acting injected drug, occupying the mu receptor steadily so that withdrawal and craving are suppressed and the "rush" of additional illicit opioid is blunted by tolerance and receptor occupancy (Kaplan and Sadock 2024). The evidence-based aims are retention in treatment, reduction of non-prescribed opioid use, and a fall in all-cause and overdose mortality; abstinence is a possible later goal, not the entry criterion.

The first-line position. The British Association for Psychopharmacology (BAP) recommends offering opioid substitution therapy, methadone or transmucosal buprenorphine or long-acting injectable buprenorphine, as the initial approach for opioid dependence, chosen with the patient,

because it delivers stabilisation, retention and reduced death risk (BAP 2026). This is a verified first-line and must anchor any answer.

RULE **Maintain, do not just detox.** Withdrawal management alone increases relapse and overdose death; every guideline (BAP, NICE, WHO, VA/DoD, CANMAT) says do not offer detoxification without planned ongoing agonist maintenance or naltrexone.

18.2 Buprenorphine: a partial mu agonist with a ceiling on respiratory depression

Mechanism and the ceiling. Buprenorphine is a high-affinity *partial* agonist at the mu-opioid receptor (and a kappa antagonist). Because it is a partial agonist, its effect on respiratory depression plateaus, a **ceiling effect**, so escalating the dose does not keep depressing respiration the way a full agonist does; this makes it markedly safer in overdose than methadone (Kaplan and Sadock 2024; Maudsley 2021). Its very high receptor affinity also means it displaces and blocks other opioids, which is why extra heroin "does nothing" on an adequate dose, but is exactly why it can trigger precipitated withdrawal.

Why it precipitates withdrawal. If buprenorphine is given while a full agonist still occupies the receptors, its high affinity knocks the full agonist off but replaces it with only a partial signal, so net opioid effect falls abruptly and the patient is thrown into acute withdrawal within minutes to an hour. The mandatory safeguard is to wait for objective withdrawal, an adequate COWS (Clinical Opiate Withdrawal Scale), before the first dose.

WORKED EXAMPLE

A man who last injected heroin 14 hours ago arrives sweating, with dilated pupils, yawning, gooseflesh and a runny nose; his COWS is 14. This is objective moderate withdrawal, so it is safe to induct: give buprenorphine **4 mg** sublingually, observe for an hour, and repeat 2 to 4 mg if withdrawal persists (APA 2021; IPS 2014). Had you dosed him at hour 4 with a COWS of 3, you would have precipitated severe withdrawal.

GOOD TO REMEMBER

- **Buprenorphine (Indian brand Tidigesic; buprenorphine-naloxone as Suboxone or Bunorph):** a high-affinity *partial* mu agonist / kappa antagonist with a ceiling on respiratory depression (safer in overdose than methadone); the signature caution is precipitated withdrawal, so the first dose waits for objective withdrawal (COWS at least 8 to 12, usually 12 or more hours after a short-acting opioid); induct at 2 to 4 mg (up to 8 mg), maintenance usually 12 to 16 mg/day (BAP target at or above 16 mg/day).

18.3 Buprenorphine induction: wait for withdrawal, then escalate fast

The induction protocol. Withhold the first dose until the patient is in objective opioid withdrawal, typically a COWS of at least 8 to 12 and roughly 12 to 24 hours after the last short-acting opioid (longer for methadone). Then give an initial dose of **2 to 8 mg** sublingually, most commonly 4 mg, observe, and repeat 2 to 4 mg every few hours as withdrawal allows on day one (WHO 2016; APA 2021; IPS 2014). Buprenorphine can reach a therapeutic dose of 12 to 16 mg within 2 to 3 days, far faster than methadone (Maudsley 2021).

The buprenorphine-naloxone combination. The combination product (buprenorphine with naloxone in a 4:1 ratio) is designed to deter injection: taken sublingually the naloxone is poorly absorbed and inert, but if the tablet is crushed and injected the naloxone becomes bioavailable and precipitates withdrawal, removing the incentive to divert. This is the first-line agonist maintenance option in Indian outpatient practice (IPS 2014).

OPIOID LAST USED	SPONTANEOUS WITHDRAWAL ONSET	SAFE TO START BUPRENORPHINE
Short-acting (heroin, morphine)	6 to 8 hours after last use	at COWS >= 8 to 12, usually 12 or more hours
Long-acting (methadone)	24 or more hours after last use	after taper to 30 mg/day or less, 24 to 36 hours, COWS 8 to 12
Long-acting (buprenorphine itself)	24 or more hours, milder syndrome	not applicable (already the agent)

Withdrawal-onset windows that set the mandatory wait before the first buprenorphine dose; starting too early precipitates withdrawal (Kaplan and Sadock 2024; BAP 2026).

18.4 Methadone: a full agonist needing slow titration and a QTc caution

Mechanism and the risk. Methadone is a long-acting *full* mu-opioid receptor agonist. Because it is a full agonist it has no ceiling on respiratory depression, so overdose in the induction fortnight is the principal danger, compounded by its long and variable half-life, which lets the drug accumulate over the first days even at a fixed dose (BAP 2026; Maudsley 2021). It is largely metabolised by CYP3A4, so inhibitors and inducers shift its level, and it prolongs the QT interval, so a baseline and monitoring ECG is prudent, especially above 100 mg/day or with other QT-prolonging drugs.

Slow titration, high maintenance. Methadone is started low and raised slowly: WHO advises an initial daily dose set by neuroadaptation, generally not more than **20 mg** and certainly not more than 30 mg, with increases of no more than about 10 mg every few days (WHO 2016). The therapeutic maintenance range is high, typically **60 to 120 mg/day**, because doses under 60 mg/day carry a two- to three-fold higher dropout (BAP 2026; WHO 2016).

COMMON TRAP

Do not titrate methadone quickly to "get on top of" withdrawal. Its long half-life means the drug keeps accumulating for days after a dose change, so a rapid rise stacks up into a fatal overdose in the second week, the highest-risk window. The rule is low start (20 to 30 mg), small increments (about 10 mg every few days), and supervised dosing during induction.

GOOD TO REMEMBER

- **Methadone:** a long-acting *full* mu agonist with no respiratory ceiling; the signature cautions are overdose during the first two weeks (long, variable half-life, accumulation) and QTc prolongation (CYP3A4-metabolised); induct at 20 mg (not more than 30 mg), raise by about 10 mg every few days, maintenance 60 to 120 mg/day; in India it is restricted to licensed government OST/NACO clinics, not private prescription.

18.5 Buprenorphine versus methadone: the head-to-head examiners want

How to choose. Both are first-line agonist maintenance (BAP, NICE, WHO, WFSBP, CANMAT all list both); the choice is by safety profile, patient preference and setting. Buprenorphine is safer in overdose and in cardiorespiratory comorbidity, has a milder withdrawal on cessation, and reaches a therapeutic dose within days; methadone gives greater treatment retention and suits patients at high diversion risk or those who destabilise on a partial agonist (Maudsley 2021; BAP 2026). WHO, weighing population-level retention, advises most patients use methadone in adequate doses; NICE treats the two as equivalent first-line choices.

FEATURE	BUPRENORPHINE (PARTIAL AGONIST)	METHADONE (FULL AGONIST)
Respiratory depression	ceiling effect, safer in overdose	no ceiling, overdose risk in induction
Start-of-treatment risk	precipitated withdrawal if started too early	accumulation and overdose in first 2 weeks
Time to therapeutic dose	2 to 3 days (fast)	several weeks (slow titration)
Initial (induction) dose	2 to 8 mg after COWS >= 8 to 12	20 mg (not more than 30 mg)
Usual maintenance dose	12 to 16 mg/day (BAP >= 16 mg/day)	60 to 120 mg/day
Cardiac	little QT effect	QTc prolongation, ECG monitoring
Retention vs the other	slightly lower retention	greater retention
Cessation withdrawal	milder, more delayed	more marked and prolonged

Buprenorphine versus methadone: the discriminators that decide agonist choice (Maudsley 2021; BAP 2026; WHO 2016).

18.6 Maintenance, monitoring and the exit routes

Maintenance targets. Optimise the dose to the level that retains the person in treatment and stops non-prescribed opioid use: buprenorphine typically at or above 16 mg/day (range 12 to 24 mg), methadone typically above 60 mg/day (60 to 120 mg/day), individualised and titrated to clinical response rather than a blood level (BAP 2026; WHO 2016). Continue for at least 12 months; open-ended long-term maintenance is appropriate and is not "failure" (IPS 2014).

What to monitor. Directly supervise dosing in the early phase (diversion and overdose risk), use random urine drug screens during induction and stabilisation, and screen for blood-borne viruses (HIV, HBV, HCV), syphilis and tuberculosis at baseline and annually in anyone with injecting use; check LFTs and, for methadone, the QTc (IPS 2014; BAP 2026). Provide take-home naloxone and overdose-reversal training to the patient and family, especially around the high-risk windows of post-detox, post-release and post-disengagement, when tolerance has fallen.

PEARL

Naltrexone is the opposite of substitution: a pure opioid antagonist (oral 50 mg/day) for relapse prevention in a patient who *wants* to be abstinent, started only after a documented opioid-free interval of at least 7 to 10 days (longer after methadone) confirmed by negative urine screen. Given to a current opioid user it precipitates severe withdrawal, and after any lapse the lost tolerance makes overdose more likely, so it is a different pathway from OST, not a maintenance agent.

18.7 The Indian OST context: the de-addiction programme, the DDAP model and buprenorphine access

The treatment gap and the setting. India carries a large opioid-use burden, much of it untreated, and services are concentrated in government de-addiction centres and Drug De-addiction Programme (DDAP) units rather than general practice; the apex training and treatment node is the National Drug Dependence Treatment Centre (NDDTC) at AIIMS, with NIMHANS and state centres alongside (IPS 2014). This is the **indian access** reality behind every prescribing choice.

Which agent, and the NDPS frame. In Indian outpatient practice the first-line agonist is *sublingual buprenorphine-naloxone* (4:1), inducted at 4 mg/1 mg once the patient shows objective withdrawal (COWS at least 8 to 12) and titrated to a usual 8 to 16 mg/day (IPS 2014). Methadone is available but restricted to licensed government OST clinics run under the National AIDS Control Organisation (NACO) and select institutions, so the private psychiatrist refers to the nearest licensed OST centre rather than prescribing it. The controlling statute throughout is the Narcotic Drugs and Psychotropic Substances (NDPS) Act, 1985, which governs scheduling, prescriber licensing and the treatment-in-lieu-of-conviction route; its detail sits in the Mental health legislation and forensic psychiatry notes.

INDIA

For an Indian exam, the clean line is: *buprenorphine-naloxone is the workhorse of Indian OST, methadone is largely confined to government OST/NACO clinics*. Buprenorphine's better safety, its take-home suitability in the 4:1 combination that deters injection, and the ease of dispensing it in outpatient de-addiction settings all fit a system with a large treatment gap and limited supervised-dosing capacity. Pair the medication with a needle and syringe programme referral and structured psychosocial treatment for any patient still injecting; harm reduction is offered *in addition to*, never instead of, agonist maintenance (IPS 2014). The whole framework operates under the NDPS Act, 1985.

MNEMONIC

"START LOW, WAIT for the COWS"

Methadone: START LOW (20 mg, not more than 30) and titrate slowly, because a full agonist accumulates and overdose lurks in week two. Buprenorphine: WAIT for the COWS (objective withdrawal, COWS at least 8 to 12) before the first dose, because a high-affinity partial agonist given too early precipitates withdrawal.

8 to 12	2 to 8 mg	20 mg	60 to 120 mg
COWS SCORE OF OBJECTIVE WITHDRAWAL NEEDED BEFORE THE FIRST BUPRENORPHINE DOSE	BUPRENORPHINE INDUCTION DOSE (USUALLY 4 MG)	METHADONE STARTING DOSE (NOT MORE THAN 30)	METHADONE MAINTENANCE RANGE PER DAY

TRAP **Never buprenorphine into a full agonist.** Dosing buprenorphine while a short-acting opioid still occupies the receptor precipitates acute withdrawal within the hour; wait for an objective COWS, do not dose on the clock or on the patient's word alone.

HOLD THIS

Opioid substitution therapy is agonist maintenance to retain people and cut overdose death: buprenorphine is a partial mu agonist with a respiratory ceiling, inducted at 2 to 8 mg only once objective withdrawal (COWS at least 8 to 12) appears and maintained at 12 to 16 mg/day; methadone is a full agonist started low at 20 mg (not more than 30) and titrated slowly to 60 to 120 mg/day with a QTc caution; in India buprenorphine-naloxone (4:1) is the outpatient first-line while methadone is restricted to government OST/NACO clinics, all under the NDPS Act.

19 · Naltrexone and antagonist relapse prevention

Substitution therapy keeps an opioid receptor *occupied*; antagonist therapy keeps it *blocked*. **Naltrexone** is the mirror image of an agonist maintenance drug: instead of giving a long-acting opioid to suppress craving, you give a pure **opioid antagonist** that sits on the mu receptor and makes any opioid the patient takes do nothing. That is the whole appeal for a highly motivated, abstinence-seeking patient, and it is the whole danger too, because putting an antagonist onto a receptor a full agonist still occupies rips the agonist off and throws the patient into acute withdrawal. This topic is examined on exactly two things: the mechanism (a competitive mu-opioid antagonist, oral and long-acting injectable) and the one rule that a wrong answer fails, the mandatory **opioid-free** window before you ever start it.

Why it matters clinically. Naltrexone is a management/drug topic, so the marks are in the drug, the dose, the line and the monitoring, not in a description of addiction. The single most tested, and most dangerous, error in the whole substance block is starting naltrexone in a current opioid user: it causes severe **precipitated withdrawal**. The mesolimbic-dopamine and opioid reward anatomy that antagonism interrupts is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and is not re-derived here; the NDPS Act frame behind Indian de-addiction prescribing sits in the Mental health legislation and forensic psychiatry notes.

19.1 The mechanism: a pure competitive mu-opioid antagonist

What it does. Naltrexone is a competitive, essentially pure opioid antagonist at the mu-opioid receptor (with weaker kappa and delta antagonism); it binds the receptor and initiates no signal, so it selectively competes with any exogenous opioid for central and peripheral opioid receptors and blocks their activity (Kaplan and Sadock 2024). It has no agonist action, so the patient gets no "high" from naltrexone itself, there is no reinforcement, no meaningful withdrawal on

stopping, and no diversion value. After an oral dose the opioid blockade lasts up to **72 hours**, which is why once-daily (or even alternate-day) dosing is feasible.

Antagonist versus agonist, the exam contrast. This is the conceptual opposite of opioid substitution therapy, developed in the Opioid substitution therapy notes: substitution occupies the receptor with a long-acting agonist (buprenorphine, methadone) so withdrawal and craving are suppressed; antagonism *blocks* the receptor so a lapse of heroin produces no reward, extinguishing the drug-taking behaviour over time. Naltrexone is therefore a **relapse prevention** agent for a patient who has already detoxified and *wants* to stay abstinent, not a maintenance agent for a patient still using.

PEARL

The three "nal-" opioid antagonists are worth separating: *naloxone* is the short-acting parenteral antidote for overdose reversal (minutes); *naltrexone* is the long-acting oral/injectable antagonist for relapse prevention (days); *nalmefene* is an as-needed antagonist licensed to reduce heavy drinking in alcohol dependence. All three precipitate withdrawal in a current opioid user, because all three are antagonists.

19.2 The oral form: 50 mg a day for relapse prevention

The dose and the two indications. Oral naltrexone is given at **50 mg/day** (available as 25 mg and 50 mg tablets), often started at 25 mg to check tolerability then raised to 50 mg (WHO 2016; NICE 2011). It has two licensed relapse-prevention roles: in *opioid* use disorder, to maintain the receptor blockade in an abstinent, motivated patient; and in *alcohol* use disorder, where it reduces craving and the return to heavy drinking by blunting the opioid-mediated reward of alcohol (Kaplan and Sadock 2024; Maudsley 2021). Oral bioavailability is about 60%, and the active metabolite 6-beta-naltrexol prolongs its action.

The adherence problem. Oral naltrexone's Achilles heel is adherence: a patient who wants to lapse simply stops the tablet a few days beforehand, and a Cochrane review found oral naltrexone no better than placebo for opioid relapse prevention largely because of poor retention (Kaplan and Sadock 2024). This is the entire rationale for the long-acting forms.

GOOD TO REMEMBER

- **Naltrexone (Indian brand Nodict or Naltima; oral):** a competitive pure mu-opioid antagonist (no agonist effect, non-scheduled, no diversion) for relapse prevention in opioid and alcohol use disorder; oral dose **50 mg/day** (start 25 mg), blockade lasts about 72 hours; the signature caution is precipitated withdrawal if given to a current opioid user, so it demands an opioid-free interval first; monitor LFTs (dose-related hepatotoxicity).

19.3 The long-acting injectable and implant: the answer to non-adherence

Extended-release naltrexone. The extended-release injectable form (XR-NTX, brand Vivitrol) delivers **380 mg** intramuscularly once every 4 weeks, giving total naltrexone exposure three- to fourfold higher than daily oral dosing, with an elimination half-life of 5 to 10 days (Kaplan and Sadock 2024). Because a single injection covers a month, it removes the daily decision to take the

tablet, and retention on XR-NTX is at least twice that on oral naltrexone. A subcutaneous naltrexone *implant* lasting about 6 months exists but is investigational, its safety and efficacy not yet established.

What the guidelines say about the forms. The British Association for Psychopharmacology (BAP) recommends, for relapse prevention after opioid withdrawal, *preferring* long-acting injectable naltrexone (monthly) or a naltrexone implant (6-monthly) over oral naltrexone, because the long-acting forms improve treatment retention; naltrexone as a whole is offered to people who wish to be abstinent, in preference to withdrawal management alone (BAP 2026). This is the verified first-line antagonist position and must anchor any answer.

FORM	ROUTE AND SCHEDULE	DOSE (MG)	NOTE
Oral naltrexone	tablet, once daily	50 (start 25)	adherence-limited; blockade ~72 h
XR-NTX injectable (Vivitrol)	deep IM, every 4 weeks	380	BAP-preferred; retention 2x oral
Naltrexone implant	subcutaneous, ~6-monthly	surgical insert	investigational, not established

The three naltrexone formulations and their dosing; the long-acting forms exist to solve the adherence failure of the daily tablet (Kaplan and Sadock 2024; BAP 2026).

INDIA

In India the daily *oral* tablet (naltrexone, marketed as Nodict or Naltima) is the practical option: it is non-scheduled, cheap, and prescribable in any clinical setting without the OST licensing that agonist maintenance requires under the Narcotic Drugs and Psychotropic Substances (NDPS) Act, 1985. The long-acting depot and implant forms are *not yet routinely available* in Indian practice (IPS 2014), so the adherence problem is real and the fix is a co-resident family supervisor who observes the dose, exactly the family-supervised model already used for disulfiram in Indian de-addiction settings. This is a genuine access gap: the form that works best (depot) is the one an Indian patient usually cannot get.

19.4 The critical contraindication: never start naltrexone in a current opioid user

Why it precipitates withdrawal. If naltrexone is given while opioids still occupy the mu receptors, its competitive antagonism displaces the agonist and abruptly strips away all opioid tone, plunging a physiologically dependent patient into acute, severe **precipitated withdrawal** within minutes, far more violent than the gradual spontaneous syndrome (Kaplan and Sadock 2024; Tasman 2024). This is the same mechanism by which naloxone reverses overdose, only here it is unwanted. It is the single most dangerous prescribing error in the substance block, and it is the one the examiner is testing.

The mandatory opioid-free window. Naltrexone can be started only after a documented period of complete opioid abstinence: about **7 to 10 days** opioid-free for short-acting opioids and heroin, and longer after a long-acting opioid such as methadone (Kaplan and Sadock 2024; IPS 2014). The Indian Psychiatric Society is explicit: naltrexone 50 mg/day PO for relapse prevention

only after a documented opioid-free interval of at least 7 to 10 days, confirmed by a negative urine opioid screen and a naloxone challenge, because premature initiation precipitates severe withdrawal (IPS 2014).

WORKED EXAMPLE

A man completed a buprenorphine taper and his last opioid was 4 days ago; he is keen to start naltrexone to "block" any lapse. You do *not* start it. Four days is inside the danger window: residual receptor occupancy means a 50 mg dose now would precipitate acute withdrawal. You wait until he is at least 7 to 10 days opioid-free, confirm a negative urine opioid screen, and, if occult use is a question, do a naloxone challenge, a subcutaneous injection of up to 0.8 mg naloxone with 20 minutes of observation for emergent withdrawal, before the first naltrexone dose (Kaplan and Sadock 2024; IPS 2014).

TRAP **Naltrexone into a current opioid user precipitates withdrawal.** An antagonist onto occupied mu receptors strips the agonist off and causes acute severe withdrawal; confirm an opioid-free interval of about 7 to 10 days (longer after methadone) with a negative urine screen, and never start it "to be safe" while opioids may still be on board.

19.5 Confirming the window: urine screen and the naloxone challenge

Two checks before the first dose. The opioid-free interval is verified objectively, never on the patient's word alone. First, a negative urine opioid screen. Second, where occult use is possible, a naloxone challenge test: give an SC injection of up to 0.8 mg naloxone and observe for 20 minutes; if no withdrawal emerges, the patient is opioid-free and naltrexone can be started (Kaplan and Sadock 2024). Naloxone is used for the challenge precisely because it is short-acting, so any precipitated withdrawal it uncovers is brief.

The rapid-detox alternative. Newer protocols compress the unprotected wait: a rapid or antagonist-assisted detoxification uses ascending low-dose oral naltrexone (starting 0.25 mg) with clonidine and other symptomatic cover over about a week, allowing XR-NTX induction on day eight after a negative naloxone challenge, so the patient is opioid-free from the outset and the vulnerable 7-to-10-day gap is removed (Kaplan and Sadock 2024). Note the guideline caution alongside this: WHO and NICE both warn against *ultra-rapid* antagonist-induced detoxification under heavy sedation or general anaesthesia, which adds risk without benefit (WHO 2016; NICE 2011).

19.6 Monitoring, cautions and the overdose paradox on stopping

What to monitor. Naltrexone is dose-relatedly hepatotoxic, so baseline and periodic liver function tests are required; before starting it in opioid use disorder, VA/DoD advise baseline transaminases and bilirubin repeated at 6 and 12 months, and it is avoided in acute hepatitis or hepatic failure (VA/DoD; BAP 2026). It is generally well tolerated otherwise, with nausea, headache and dysphoria the common complaints.

The lost-tolerance overdose risk. A crucial safety point: because naltrexone maintains a blockade and abstinence, opioid tolerance falls while the patient is on it. If the patient stops

naltrexone (or a depot dose wears off) and then lapses to their old opioid dose, that dose is now potentially fatal, the lost-tolerance overdose paradox (Kaplan and Sadock 2024; BAP 2026). Retention is therefore not just about efficacy but about survival, and the analgesia problem is the same in reverse: an emergency opioid analgesic will not work through the blockade.

COMMON TRAP

Do not read a stable, adherent patient's *falling* opioid tolerance as a good thing to relax about. The most dangerous moment on naltrexone is *stopping* it: a patient who lapses to their previous "usual" heroin dose after the blockade lifts can die, because tolerance is gone. Counsel this explicitly, pair the patient with a take-home naloxone kit, and prefer the long-acting depot to avoid gaps in cover.

GOOD TO REMEMBER

- **XR-NTX (long-acting injectable naltrexone, Vivitrol):** 380 mg deep IM every 4 weeks; BAP-preferred over oral for opioid relapse prevention because it roughly doubles retention; same absolute contraindication (must be opioid-free 7 to 10 days first, or the depot precipitates a month-long withdrawal); monitor LFTs; warn about lost-tolerance overdose if the injection lapses.

19.7 Where naltrexone sits against agonist maintenance, and the guideline lines

Antagonist or agonist? For most patients guidelines still favour *agonist* maintenance (buprenorphine, methadone) over antagonist therapy, because agonists retain more people in treatment and cut death more reliably; WHO advises offering withdrawal management, agonist maintenance *and* naltrexone, but tells most patients to choose agonist maintenance (WHO 2016). Naltrexone earns its place in the specific, highly motivated, abstinence-committed patient, or where external contingency exists (probation, professional monitoring), or where the patient refuses an agonist. The Australian coronial data are sobering: patients on oral naltrexone were several times more likely to overdose than those on agonist maintenance, driven by the lost-tolerance mechanism (Kaplan and Sadock 2024).

The four-guideline map. BAP: offer naltrexone to those wishing to be abstinent, preferring the long-acting injectable or implant over oral. The Indian Psychiatric Society (IPS guidelines): naltrexone 50 mg/day PO only after a documented 7-to-10-day opioid-free interval confirmed by negative urine screen and naloxone challenge, with adherence the main limitation and depot forms not yet routine in India (IPS 2014). NICE: use oral naltrexone for relapse prevention after alcohol withdrawal (start 25 mg, aim 50 mg/day) and, for opioids, do not offer rapid antagonist detoxification under sedation. WHO: oral naltrexone 50 mg/day after withdrawal is an option, monitored for delirium, vomiting and diarrhoea during induction, but agonist maintenance is preferred for most (WHO mhGAP 2016).

GUIDELINE	NALTREXONE POSITION (OPIOID RELAPSE PREVENTION)
BAP (2026)	Offer to abstinence-seeking patients; prefer long-acting injectable or implant over oral
Indian Psychiatric Society (2014)	50 mg/day PO only after 7 to 10 days opioid-free, confirmed by urine screen and naloxone challenge; depot not yet routine
NICE (2011)	Oral for alcohol relapse prevention (25 then 50 mg/day); avoid ultra-rapid antagonist detox under sedation
WHO mhGAP (2016)	Oral 50 mg/day an option after withdrawal; agonist maintenance preferred for most patients

The antagonist relapse-prevention position across the four guidelines; BAP leads with the long-acting form, all agree on the mandatory opioid-free start.

RULE **Block only an empty receptor.** Naltrexone is started only in a patient who is already fully detoxified and abstinent (about 7 to 10 days opioid-free, verified), never as a way to *achieve* abstinence in someone still using.

MNEMONIC

"7 to 10 CLEAN before you BLOCK"

Before you start the antagonist (BLOCK), the patient must be 7 to 10 days CLEAN (opioid-free), proven by a negative urine screen and, if in doubt, a naloxone challenge. Skip the CLEAN window and you precipitate withdrawal.

7 to 10 days OPIOID-FREE INTERVAL REQUIRED BEFORE STARTING NALTREXONE (LONGER AFTER METHADONE)	**50 mg** ORAL NALTREXONE DAILY RELAPSE-PREVENTION DOSE	**380 mg** XR-NTX DEPOT INJECTION, EVERY 4 WEEKS	**0.8 mg** SC NALOXONE CHALLENGE DOSE, OBSERVE 20 MINUTES

HOLD THIS

Naltrexone is a pure competitive mu-opioid antagonist for relapse prevention (oral 50 mg/day, or the BAP-preferred long-acting injectable XR-NTX 380 mg IM every 4 weeks) in a motivated, already-detoxified patient; it blocks opioid reward but never suppresses withdrawal, so starting it in a current opioid user precipitates severe withdrawal, and it may be started only after a documented opioid-free interval of about 7 to 10 days (longer after methadone) confirmed by a negative urine screen and, if needed, a naloxone challenge.

20 · Opioid detoxification and the rapid-detox controversy

Detoxification is the medically supervised process of taking a physically dependent person off opioids while covering the withdrawal, and it is examined less for its mechanics than for two things: the menu of legitimate **detox approaches** (an agonist taper with buprenorphine or methadone, and alpha-2-agonist-assisted withdrawal) and the hard line every guideline draws against detoxification carried out at speed under sedation or anaesthesia. The examinable spine is

a single sentence: **detoxification** is never the treatment, it is a gateway to ongoing agonist maintenance or to naltrexone, and the faster and more heroic the method, the worse and more dangerous it tends to be.

Why it matters clinically. A viva that opens "how would you detoxify this heroin user" is testing whether you know that withdrawal management alone produces high relapse and, through lost tolerance, fatal overdose (BAP 2026; NICE 2011; VA/DoD 2021), and whether you can name the two safe backbones and reject the two unsafe short-cuts. The withdrawal syndrome itself, its noradrenergic time-course, the COWS bands, and the buprenorphine and methadone induction and maintenance numbers are developed in the opioid-withdrawal and opioid-substitution material and are not re-derived here; this topic is about the *choice of detoxification method* and the **rapid detox** and **ultra-rapid detox** controversy that examiners love because it has a clean, evidence-anchored answer. The reward-pathway and locus-coeruleus mechanics sit in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; the NDPS Act frame sits in the Mental health legislation and forensic psychiatry notes.

20.1 What detoxification is (and what it is not)

The definition. Detoxification (increasingly called *medically assisted withdrawal*) is the supervised, symptom-covered removal of an opioid from a dependent person, achieved either by substituting a controlled agonist and tapering it, or by suppressing the withdrawal pharmacologically with a non-opioid while the illicit opioid clears (Tasman; Kaplan and Sadock 2024; Maudsley Prescribing Guidelines). It is a discrete, time-limited procedure, not a treatment for the disorder.

The governing rule. Every guideline is unanimous that detoxification must not be a stand-alone: do not undertake opioid withdrawal management without planned ongoing pharmacotherapy (agonist maintenance or naltrexone) and psychosocial support, because withdrawal alone carries a high risk of relapse and, through lost tolerance, of fatal overdose (BAP 2026; VA/DoD 2021; NICE 2011; CANMAT). The most serious drawback of detoxification, Tasman states plainly, is that the risk of relapse after completion is very high, so a strong aftercare plan (residential care, a solid outpatient programme, or pharmacological maintenance) is mandatory (Tasman; Kaplan and Sadock 2024).

RULE **Detoxify only into something.** Withdrawal management is a bridge, never a destination, so never detoxify without a planned onward arm (agonist maintenance or naltrexone) and take-home naloxone in place before you start.

20.2 The menu of legitimate detox approaches

The four modalities. Tasman frames the **detox approaches** as four: the alpha-2 agonists (clonidine, lofexidine); the long-acting full agonist methadone by taper; the partial agonist buprenorphine by taper; and rapid detoxification under general anaesthesia (Tasman). The first three are legitimate and guideline-endorsed; the fourth is the controversy this topic turns on. Methadone and buprenorphine double as the agents for post-detoxification agonist maintenance, which is why the "detoxify then maintain" and "just maintain" paths blur into one another.

The guideline default. NICE offers methadone or buprenorphine as the first-line treatment for opioid detoxification, with lofexidine reserved for those who decline them, want to detoxify within a short period, or have mild or uncertain dependence (NICE 2011). WHO mhGAP recommends tapered opioid agonists generally, with alpha-2 agonists as an alternative, and adds that agonist maintenance is usually more effective than detoxification at all (WHO mhGAP 2016). The Indian Psychiatric Society makes a buprenorphine taper the preferred medically assisted withdrawal regimen (IPS guidelines).

DETOX APPROACH	WHAT IT IS	GUIDELINE STANDING
Buprenorphine taper	**Stabilise on partial agonist, then reduce**	First-line (NICE; IPS preferred; BAP)
Methadone taper	Stabilise on long-acting full agonist, then reduce	First-line (NICE; WHO)
Alpha-2 agonist (lofexidine, clonidine)	Non-opioid suppression of noradrenergic storm	Second-line; lofexidine preferred
Rapid / ultra-rapid under sedation or anaesthesia	**Antagonist-precipitated withdrawal under sedation or general anaesthesia**	Not recommended (BAP; NICE; WHO)

The four opioid detox approaches; the first three are legitimate, the fourth is contraindicated across guidelines (Tasman; NICE 2011; WHO mhGAP 2016; BAP 2026).

20.3 The buprenorphine taper: the workhorse of tapering

Why it leads. A buprenorphine (Indian brand Tidigesic; as buprenorphine-naloxone, Suboxone or Bunorph) taper is the preferred medically assisted withdrawal because the partial agonist gives a ceiling on respiratory depression, blocks illicit top-ups, and tapers comfortably; it is the outpatient backbone of Indian de-addiction practice (IPS guidelines; BAP 2026). The one non-negotiable inherited from induction is timing: the first dose is delayed until objective withdrawal (COWS about **8 to 12**) because buprenorphine will precipitate withdrawal if a full agonist is still on the receptor.

The taper by the number. The IPS taper reduces buprenorphine by **2 to 4 mg/day** over **7 to 14 days** from the stabilisation dose, with symptomatic cover (IPS guidelines). NICE times buprenorphine detoxification over 14 days to a few weeks in the community and 7 to 14 days as an inpatient (NICE 2011; Maudsley Prescribing Guidelines). Maudsley graduates the reduction to the dose: above 16 mg by 4 mg every 1 to 2 weeks, 8 to 16 mg by 2 to 4 mg every 1 to 2 weeks, 2 to 8 mg by 2 mg per week or fortnight, and below 2 mg by 0.4 to 0.8 mg per week (Maudsley Prescribing Guidelines).

DAILY BUPRENORPHINE (MG)	REDUCTION STEP
Above 16	**4 mg every 1 to 2 weeks**
8 to 16	2 to 4 mg every 1 to 2 weeks
2 to 8	2 mg per week or fortnight
Below 2	**0.4 to 0.8 mg per week**

Maudsley buprenorphine reduction regime; the step shrinks as the dose falls, the final milligrams being the hardest (Maudsley Prescribing Guidelines).

GOOD TO REMEMBER

- **Buprenorphine (Tidigesic; buprenorphine-naloxone as Suboxone or Bunorph):** partial mu-agonist with a ceiling on respiratory depression, the preferred tapering agent for detoxification; the signature caution is precipitated withdrawal, so start only in objective withdrawal (COWS about 8 to 12); the IPS taper reduces by 2 to 4 mg/day over 7 to 14 days, and the final sub-2 mg steps (0.4 to 0.8 mg per week) are the hardest.

20.4 The methadone taper: the slow, long-acting backbone

Where it fits. A methadone taper is the alternative first-line detoxification, a long-acting full agonist that tapers slowly and smoothly (NICE 2011; WHO mhGAP 2016). Because it is a full agonist it needs no wait for a high COWS, but its long half-life makes the reduction protracted and the first two weeks of any methadone treatment a high-risk overdose window (BAP 2026).

The taper by the number. BAP tapers methadone at about **2 to 5 mg/day** every 1 to 2 weeks, switching to buprenorphine once the dose falls below 30 mg/day if the taper stalls (BAP 2026). Maudsley reduces methadone by 5 to 10 mg weekly or fortnightly, slowing to 1 to 2 mg/week near the end, and notes NICE guidance that methadone reduction is typically 14 to 21 days as an inpatient and up to about 3 months in the community (Maudsley Prescribing Guidelines; NICE 2011). WHO advises tapering opioid agonists over at least 3 days, roughly 5 days for buprenorphine and 10 days for methadone, to minimise rebound withdrawal (WHO 2009).

TRAP **Do not read a longer taper as a worse taper.** The evidence runs the other way, longer stabilisation and prolonged reduction schedules (up to a year) substantially improve the chances of sustained abstinence, so a slow methadone reduction is a feature, not a failure.

GOOD TO REMEMBER

- **Methadone (taper for detoxification):** long-acting full mu-agonist tapered slowly (BAP 2 to 5 mg/day every 1 to 2 weeks; Maudsley 5 to 10 mg weekly, slowing to 1 to 2 mg/week near the end); no wait for induction, but the signature caution is overdose in the first two weeks; switch to buprenorphine below 30 mg/day if the taper stalls, and in India refer to a NACO-licensed OST clinic rather than prescribing methadone in private practice.

20.5 Alpha-2-agonist-assisted withdrawal: the non-opioid route

How it works. The alpha-2 adrenergic agonists clonidine and lofexidine suppress the noradrenergic hyperactivity of withdrawal by reducing central sympathetic outflow at the locus coeruleus; they damp the autonomic features (insomnia, tachycardia, sweating, nausea) but not craving, muscle aches and pain as fully as an agonist taper (Tasman; Kaplan and Sadock 2024). Being non-opioid, they neither substitute at the mu-receptor nor risk diversion, which makes them the route for a shorter, opioid-free detoxification when an agonist is declined, contraindicated or unavailable (NICE 2011; VA/DoD 2021).

Lofexidine versus clonidine. The examinable discriminator: both work, but lofexidine is preferred because it causes less postural hypotension and sedation, effective at doses up to **2**

mg/day without the dose-limiting hypotension that caps clonidine (BAP 2026; WHO 2009; Tasman). NICE will consider lofexidine for a short detoxification but advises against using clonidine or dihydrocodeine routinely. The caution for both is blood pressure, checked before each dose. Lofexidine is not widely available in India, so clonidine **0.1 to 0.3 mg** three times daily, titrated to blood pressure, is the practical alpha-2 agent here (IPS guidelines).

GOOD TO REMEMBER

- **Clonidine and lofexidine (alpha-2 agonists for detoxification):** non-opioid agents that damp the locus-coeruleus noradrenergic storm; second-line to agonists and used for a shorter opioid-free detox; the signature caution is hypotension (check blood pressure before each dose); lofexidine is preferred (less postural hypotension, effective up to 2 mg/day) but clonidine 0.1 to 0.3 mg three times daily is the practical Indian choice, and neither adequately covers craving.

20.6 Rapid detox: antagonist-accelerated but not under anaesthesia

What "rapid detox" means. **Rapid detox** compresses the timeline by giving an opioid antagonist (naloxone or naltrexone) to precipitate and hasten withdrawal, so the person is opioid-free far sooner than a taper allows (Kaplan and Sadock 2024; Maudsley Prescribing Guidelines). The recognised outpatient protocol combines naltrexone with clonidine and adjuncts, allowing the patient to be opioid-free from the first day and to complete detoxification within **48 to 72 hours**, then to start naltrexone maintenance at once (Kaplan and Sadock 2024). Its appeal is that it removes the vulnerable, unprotected 7-to-10-day opioid-free window that ordinarily precedes naltrexone.

The catch. Precipitated withdrawal is abrupt and severe, so blood pressure must be watched for up to 8 hours on the first day and the method is best confined to patients with a *low* level of physiologic dependence, in settings with treatment rooms and adequate nursing (Kaplan and Sadock 2024). NICE is explicit: do not routinely offer rapid detoxification using precipitated withdrawal (NICE 2011). Rapid detox is thus a niche induction-into-naltrexone tool, not a routine detoxification.

COMMON TRAP

Do not conflate *rapid* detox with *ultra-rapid* detox. Rapid detox is antagonist-accelerated withdrawal (naltrexone plus clonidine) done *awake*, completing in 48 to 72 hours, and NICE merely advises against it routinely. Ultra-rapid detox adds general anaesthesia or heavy sedation with mechanical ventilation, and that is the one that is affirmatively contraindicated for causing life-threatening adverse events without any benefit. The word "anaesthesia" is the discriminator, and it is a favourite MCQ hinge.

20.7 Ultra-rapid detox under sedation or anaesthesia: the contraindicated procedure

What it is. **Ultra-rapid detox** (ultra-rapid opioid detoxification, UROD) places the opioid-dependent patient under light sedation or general anaesthesia, including mechanical ventilation, and then precipitates and completes withdrawal with full doses of an antagonist while the patient is unconscious (Kaplan and Sadock 2024; Tasman). The theory is to telescope the entire withdrawal into a few unconscious hours and induct naltrexone immediately.

Why it is condemned. The verdict is uniform. Kaplan and Sadock: ultra-rapid detoxification, although effective at reducing physiologic dependence, leads to a greater number of serious adverse events than the other approaches without superior outcomes, and is not recommended. Tasman: it was associated with more life-threatening adverse events and cannot be recommended. BAP (grade A): do not use ultra-rapid opioid detoxification under heavy sedation or anaesthesia, as it confers no benefit on withdrawal severity or naltrexone initiation and carries life-threatening risks; the named agents (propofol, midazolam, isoflurane) are not to be used for this purpose (BAP 2026). NICE: never offer ultra-rapid detoxification under general anaesthesia or heavy sedation (NICE 2011). WHO (strong): do not combine opioid antagonists with heavy sedation or anaesthesia for withdrawal, as this risks respiratory depression without superior benefit (WHO 2009; WHO mhGAP 2016). The documented harms include pulmonary and cardiac complications, aspiration, metabolic derangement and deaths, all incurred to shorten a syndrome that is uncomfortable but not itself life-threatening.

FEATURE	RAPID DETOX (AWAKE)	ULTRA-RAPID DETOX (UROD)
Method	Naltrexone plus clonidine and adjuncts, patient awake	**Antagonist under general anaesthesia or heavy sedation, ventilated**
Timeline	**Opioid-free from the outset; complete in 48 to 72 hours**	Hours, under anaesthesia
Guideline standing	Do not offer routinely (NICE)	**Contraindicated (BAP grade A; NICE; WHO strong)**
Main hazard	Precipitated withdrawal; hypotension (monitor 8 h)	**Life-threatening adverse events, no benefit**

Rapid versus ultra-rapid opioid detoxification; the anaesthesia step is what moves the method from "not routine" to "contraindicated" (Kaplan and Sadock 2024; Tasman; BAP 2026; NICE 2011; WHO 2009).

TRAP **The anaesthetic risk is not justified by the syndrome.** Opioid withdrawal is not life-threatening in an otherwise healthy adult, so subjecting a patient to general anaesthesia and ventilation to shorten it trades a non-lethal syndrome for a genuinely lethal procedure, the reason every guideline forbids it.

20.8 After detoxification: the two paths and the overdose window

Naltrexone or maintenance. Once detoxification is complete, the patient enters either agonist maintenance (methadone or buprenorphine, generally the more effective path) or antagonist relapse prevention with naltrexone (oral mu-antagonist, 50 mg/day; Indian brands Nodict, Naltima), offered to those who wish to be abstinent (BAP 2026; IPS guidelines; WHO 2009). The absolute rule: naltrexone must never be given to a current opioid user, because as an antagonist it precipitates immediate severe withdrawal, so it is started only after a documented **opioid-free window** of at least **7 to 10 days** (longer after methadone), confirmed by a negative urine screen and, where uncertain, a naloxone challenge (IPS guidelines; Kaplan and Sadock 2024). Rapid (antagonist-accelerated) detox exists precisely to shorten that unprotected window.

The lethal aftermath. Detoxification strips tolerance, so the deadliest period is *after* a completed detox: relapse onto a previously tolerated dose can be fatal. Take-home naloxone (IM 0.4 to 2 mg, repeated every 2 to 3 minutes up to 10 mg, or intranasal 4 mg per spray) with paired family rescue-breathing training is recommended for anyone with current or recent opioid use, especially in the high-overdose windows after detoxification or release from custody (IPS guidelines; WHO 2009; BAP 2026).

GOOD TO REMEMBER

- **Naltrexone (oral mu-antagonist, 50 mg/day; Nodict, Naltima):** relapse prevention after abstinence only; the criterion contraindication is any current opioid use (precipitated withdrawal), so start only after a documented 7-to-10-day opioid-free window (longer post-methadone) with a negative urine screen; it strips tolerance, so relapse afterwards risks fatal overdose, which is exactly why post-detox take-home naloxone is non-negotiable.

20.9 The India frame: the treatment gap, NDPS and the de-addiction model

The clinical reality. India carries a very large opioid-use treatment gap, with most dependent users never reaching formal care, and detoxification is delivered largely through government de-addiction centres, the Drug De-addiction Programme, and the day care centre model rather than general practice (IPS guidelines). The practical consequence is that a buprenorphine taper, inducted on a COWS of about 8 to 12, is the detoxification backbone the Indian psychiatrist actually uses; methadone tapering is confined to NACO-licensed OST clinics, so private practice refers rather than prescribes; and lofexidine being largely unavailable, clonidine is the practical alpha-2 agent despite its dose-limiting hypotension.

Access and law. Buprenorphine and the other opioid agents are controlled under the Narcotic Drugs and Psychotropic Substances (NDPS) Act, 1985, whose scheduling and prescriber requirements shape access; ultra-rapid anaesthesia-based detox has no place in Indian de-addiction practice, both because it is contraindicated and because it demands anaesthetic infrastructure the setting rarely has. The medico-legal detail, including treatment in lieu of conviction, sits in the Mental health legislation and forensic psychiatry notes, and the CBT and motivational-interviewing arm that must accompany any detoxification is developed in the Psychotherapies, clinical assessment, MSE and nosology notes.

INDIA

Three India-specific points recur. First, the practical detoxification is a buprenorphine-naloxone taper in a de-addiction centre or the day care centre, inducted at 4 mg / 1 mg once the COWS reaches about 8 to 12, then reduced by 2 to 4 mg/day over 7 to 14 days. Second, methadone tapering is *not* a private-practice option (NACO OST clinics only), so "refer to the nearest licensed OST centre" is often the correct answer. Third, ultra-rapid anaesthesia-based detox is both contraindicated and infrastructurally implausible here, so if a private "rapid detox under anaesthesia" clinic is described in a viva, the correct response is to name it as an unsafe, non-guideline practice.

48 to 72 h	7 to 10 days	2 to 4 mg/day
TIME TO COMPLETE AWAKE RAPID (ANTAGONIST-ACCELERATED) DETOX	OPIOID-FREE WINDOW BEFORE NALTREXONE (WHICH RAPID DETOX SHORTENS)	IPS BUPRENORPHINE TAPER REDUCTION STEP OVER 7 TO 14 DAYS

HOLD THIS

Opioid detoxification is a bridge, never a treatment: taper buprenorphine (IPS preferred, 2 to 4 mg/day over 7 to 14 days) or methadone (2 to 10 mg per step, slow), or use alpha-2 agonists (lofexidine preferred, clonidine the practical Indian choice) for a shorter opioid-free detox, always into planned maintenance or naltrexone with take-home naloxone for the post-detox lost-tolerance overdose window; awake rapid detox (naltrexone plus clonidine, opioid-free from the outset, complete in 48 to 72 hours) is not offered routinely, and ultra-rapid detox under sedation or general anaesthesia is contraindicated across BAP, NICE and WHO because it causes life-threatening adverse events with no benefit for a syndrome that is not itself lethal.

Other substances of misuse

21 · Cannabis

Cannabis is the most widely used illicit drug in the world and, in India, one that examiners return to because its clinical story is uniquely two-sided: an acute intoxication that is benign enough to look harmless, sitting on top of a dose-dependent link to **psychosis** and a genuine **cannabis withdrawal** syndrome that were both denied for decades. The high-yield task on this topic is to teach the acute effects and their receptor basis, to define **cannabis use disorder** against its criteria, to state the **psychosis link** as an odds ratio rather than a vague association, to settle the **amotivational** syndrome question honestly, and to give the withdrawal syndrome by its three signature symptoms and its clock.

Why it matters clinically. The plant *Cannabis sativa* yields over 100 **cannabinoid**s, of which delta-9-tetrahydrocannabinol (**THC**) is the one responsible for the psychoactive effect; cannabidiol (CBD) is only weakly active and may modulate THC. Because most young users perceive cannabis as safe, the disorder, the withdrawal, and the psychosis risk are all under-recognised, and a resident who can name the criteria and the dose-response numbers is doing real diagnostic work. The reward-pathway and dopamine mechanics that make THC reinforcing are developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and are not re-derived here; the boundary between a cannabis-induced psychotic disorder and a primary psychosis sits in the Other psychotic disorders, delusional syndromes and catatonia notes; the NDPS Act frame is in the Mental health legislation and forensic psychiatry notes.

21.1 THC, the cannabinoids and the receptor basis

The active molecule. THC (delta-9-tetrahydrocannabinol) is the principal psychoactive cannabinoid; it is fat-soluble, concentrated in the resin of the female plant's flowering tops, and produces its effects through an endogenous cannabinoid signalling system (Kaplan and Sadock 2024). There are two cannabinoid receptors: CB1, found primarily in the brain, mediates the

psychological and behavioural effects; CB2, mostly outside the central nervous system, is linked to the immune system. Both are G-protein-coupled receptors, and their natural ligands are anandamide and 2-arachidonyl-glycerol (2-AG).

Why the effects look the way they do. CB1 receptors are abundant in regions governing mood, motor control, memory, appetite, pain and sleep. Their density in the *hippocampus* is the neat explanation for cannabis's signature disruption of short-term memory (Kaplan and Sadock 2024). THC is highly fat-soluble, so it and its metabolites accumulate in fatty tissue and clear slowly, staying detectable in urine for weeks in frequent users; this slow, long half-life is precisely why the withdrawal syndrome is milder and more delayed than that of alcohol or opioids.

PEARL

The reason a urine cannabinoid screen (for 11-nor-9-carboxy-THC) can stay positive for weeks after last use in a daily user is the same reason cannabis withdrawal is slow to start and slow to clear: THC is fat-soluble and leaves the body's fat stores gradually. One fact explains both the lab result and the withdrawal time-course.

21.2 Acute intoxication: the criterion picture

The subjective high. Most users take cannabis for a "high" of mild euphoria, relaxation and perceptual alteration, with time distortion and intensification of ordinary experiences, often with talkativeness and infectious laughter in a social setting (Kaplan and Sadock 2024). Cognitively, short-term memory and attention are impaired and skilled psychomotor activity, reaction time and coordination degrade, which is what makes driving hazardous. When smoked, onset is within minutes and the effect lasts about 3 to 4 hours; when eaten, onset is delayed 1 to 3 hours and the effect is longer and harder to titrate (DSM-5-TR; Kaplan and Sadock 2024).

The examinable signs. DSM-5-TR anchors *cannabis intoxication* on clinically significant behavioural or psychological change plus two or more of four physical signs developing within **2 hours** of use: *conjunctival injection* (red eyes), *increased appetite*, *dry mouth*, and *tachycardia* (DSM-5-TR). Smoking cannabis produces a 20 to 50 per cent rise in heart rate within minutes, and a "with perceptual disturbances" specifier is added when hallucinations occur with intact reality testing (DSM-5-TR).

DOMAIN	ACUTE EFFECT OF CANNABIS INTOXICATION
Subjective	Euphoria, relaxation, time distortion, intensified perception; occasionally anxiety/panic in the naive user
Cognitive/motor	Impaired short-term memory and attention; impaired coordination, reaction time and psychomotor skill
Physical signs (DSM-5-TR)	**Conjunctival injection, increased appetite, dry mouth, tachycardia (two or more within 2 hours)**
Onset/duration	Smoked: minutes, lasts 3 to 4 h; oral: 1 to 3 h onset, longer and harder to titrate

Acute cannabis intoxication: the four DSM-5-TR physical signs (red eyes, increased appetite, dry mouth, tachycardia) are the criterion-level detail to name in a viva (DSM-5-TR; Kaplan and Sadock 2024).

GOOD TO REMEMBER

- **Cannabis intoxication (syndrome):** the criterion is significant behavioural or psychological change plus two or more of conjunctival injection, increased appetite, dry mouth, and tachycardia within 2 hours of use; onset is minutes when smoked (lasting 3 to 4 hours), delayed 1 to 3 hours when eaten; the acute toxicity is very low and there is no reliably lethal dose, so the first management step for a bad reaction is calm reassurance in a low-stimulus setting, not a drug.

21.3 Cannabis use disorder: definition and criteria

The construct. Cannabis use disorder is diagnosed on the same eleven criteria as the other substance use disorders, DSM-5-TR having merged the old abuse and dependence categories into a single severity-graded disorder (DSM-5-TR). The threshold is **2 or more** of the eleven criteria within a 12-month period, with severity graded mild (2 to 3), moderate (4 to 5) or severe (6 or more). The criteria cluster into impaired control (using more or longer than intended, unsuccessful efforts to cut down, craving, much time spent), social impairment (role failure, interpersonal problems, activities given up), risky use (hazardous use, use despite harm), and the pharmacological pair of tolerance and withdrawal (DSM-5-TR). ICD-11 frames the same territory as cannabis dependence, defined by impaired control, increasing priority of use, and physiological features, with a separate harmful-use category for problematic use that falls short of dependence.

Who develops it. Longitudinal data give roughly **1 in 10** of those who ever use cannabis developing dependence, rising to about **1 in 3** among regular users; the earlier the age of first use, and the heavier and longer the use, the higher the risk (Kaplan and Sadock 2024). There is no approved pharmacotherapy: management is psychosocial, chiefly cognitive behavioural therapy, motivational enhancement therapy and contingency management (Kaplan and Sadock 2024). The general MI technique is developed in the Psychotherapies, clinical assessment, MSE and nosology notes.

RULE **No drug is first-line for cannabis use disorder.** Unlike alcohol or opioids, there is no approved anti-craving or substitution agent; the evidence-based treatment is psychosocial (CBT, MET, contingency management), so the exam answer names a therapy, not a molecule.

GOOD TO REMEMBER

- **Cannabis use disorder (syndrome):** two or more of the eleven DSM-5-TR criteria within 12 months (mild 2 to 3, moderate 4 to 5, severe 6+); about 1 in 10 ever-users and 1 in 3 regular users become dependent; earlier onset and heavier use raise the risk; there is no approved pharmacotherapy, so the first management step is a psychosocial intervention (CBT, motivational enhancement therapy, contingency management).

21.4 The psychosis link: a dose-dependent association

Stating it as a number. The **psychosis link** is one of the most examined facts on this topic, and it must be given quantitatively. Meta-analyses of prospective studies show that people who have *ever* used cannabis carry about **1.4 times** higher odds of psychotic symptoms; the odds rise to

about **2.1 times** among regular users and to nearly **four times** in those using high-potency preparations (Kaplan and Sadock 2024). DSM-5-TR frames it as roughly a threefold increase in psychosis risk with cannabis use in critical developmental periods. The relationship is dose-dependent, is stronger with early-onset and high-THC use, and, in provocation studies, THC produces dose-related increases in psychotic symptoms in people with and without schizophrenia.

Contributory-cause, not the whole story. Young people with psychosis who use cannabis have a first episode on average about **2 years** earlier than non-users, and those who stop using after a first episode have better outcomes and fewer relapses (Kaplan and Sadock 2024). The careful reading is that cannabis is a *contributory* cause: it precipitates schizophreniform disorder in vulnerable individuals and worsens established illness, but only a small fraction of cases are attributable to it (in the Swedish conscript cohort, about 7 per cent). This is genuinely balanced against shared genetic vulnerability and reverse causation, and the substance-induced psychotic-disorder boundary is handled in the Other psychotic disorders, delusional syndromes and catatonia notes.

EXPOSURE	ODDS OF PSYCHOTIC SYMPTOMS (META-ANALYSIS)
Ever used cannabis	About 1.4 times
Regular use	**About 2.1 times**
High-potency preparations	**Nearly 4 times**
First episode in users	Onset about 2 years earlier than non-users

The dose-dependent cannabis-psychosis association: risk climbs from ever-use through regular use to high-potency use, and first-episode onset is earlier in users (Kaplan and Sadock 2024; DSM-5-TR gives a roughly threefold increase with use in critical periods).

INDIA

Cannabis psychosis is not a Western import into the Indian syllabus: "Indian hemp insanity" was first described by Dhunjibhoy in 1930 from Indian heavy users, characterised as an acute schizophreniform picture with disorientation and confusion and a good prognosis on abstinence. The traditional Indian preparations differ in potency, which matters for the dose-response above: bhang (dried leaves) is the weakest, ganja (cultivated flowering tops) intermediate, and charas or hashish (resin) the most potent plant form, with hash oil higher still.

21.5 The amotivational-syndrome question

The claim. The **amotivational** syndrome is the classic description, from case reports of chronic heavy users, of apathy, lethargy, loss of drive, blunted ambition and a narrowing of interest to little beyond using cannabis (Tasman). It is an attractive, tidy label, and DSM-5-TR still refers to cannabis-associated reduction in goal-directed activity and self-efficacy under that name.

The honest verdict. Controlled field and laboratory studies from the 1970s onward did not support a specific *amotivational* syndrome, and current empirical research does not either; the behaviour is better understood as the effect of *chronic daily intoxication* in a dependent user

rather than a distinct entity (Kaplan and Sadock 2024). The exam-safe position is to describe the phenomenon, name it, and then state that it is not established as a discrete syndrome and is best read as sustained intoxication plus, at times, cumulative cognitive impairment. That cognitive question is separate: long-term heavy use can produce deficits in memory and attention, clearest during intoxication, with incomplete evidence on full reversibility.

TRAP **Do not present the amotivational syndrome as an established diagnosis.** Controlled studies do not support a specific syndrome; describe it, then attribute the apathy to chronic daily intoxication, or you overstate the evidence.

21.6 Cannabis withdrawal: the syndrome and its clock

That it exists at all. For decades cannabis was thought to cause no withdrawal; the recognition of a genuine cannabis withdrawal syndrome is why DSM-5 added it as a diagnosis. The signature is that the symptoms are predominantly *behavioural and emotional* rather than physical, unlike alcohol or opioid withdrawal (DSM-5-TR). The three most examinable features to lead with are *irritability*, *sleep disturbance* (insomnia, disturbing dreams), and *appetite change* with weight loss.

The DSM-5-TR criteria. Criterion A requires cessation of heavy, prolonged use (usually daily or near-daily for at least a few months); Criterion B requires **3 or more** of seven signs within about a week: irritability/anger/aggression; nervousness or anxiety; sleep difficulty; decreased appetite or weight loss; restlessness; depressed mood; and at least one physical symptom causing significant discomfort (abdominal pain, tremor, sweating, fever, chills, or headache) (DSM-5-TR). Onset is within **24 to 48 hours** of cessation, symptoms peak at 2 to 5 days, and the syndrome resolves within 1 to 2 weeks, although sleep disturbance can outlast the rest (DSM-5-TR; Kaplan and Sadock 2024). It is not dangerous in an otherwise healthy person, and management is supportive; there is no licensed pharmacotherapy, although CB1 agonists such as nabiximols can attenuate symptoms in trials.

ELEMENT	DETAIL (DSM-5-TR)
Precondition (A)	Cessation of heavy, prolonged use (usually daily/near-daily for at least a few months)
Core requirement (B)	**Three or more of seven signs within about a week of stopping**
Signature three	**Irritability/anger; sleep disturbance (insomnia, vivid dreams); decreased appetite/weight loss**
Other emotional signs	Nervousness/anxiety, restlessness, depressed mood
Physical (at least one)	Abdominal pain, tremor, sweating, fever, chills, or headache causing discomfort
Onset	Within 24 to 48 hours of cessation
Peak	2 to 5 days
Resolution	Within 1 to 2 weeks (sleep disturbance may persist longer)

Cannabis withdrawal by DSM-5-TR: predominantly emotional and behavioural symptoms, onset 24 to 48 hours, peak 2 to 5 days, resolution within 1 to 2 weeks (DSM-5-TR; Kaplan and Sadock 2024).

2	24 to 48 h	1 to 2 wk	2.8
DSM-5-TR CRITERIA THRESHOLD FOR CANNABIS USE DISORDER IN 12 MONTHS	ONSET OF CANNABIS WITHDRAWAL AFTER CESSATION	TIME TO RESOLUTION OF CANNABIS WITHDRAWAL	PER CENT OF INDIANS AGED 10 TO 75 WHO USE CANNABIS (MAGNITUDE OF SUBSTANCE USE SURVEY)

GOOD TO REMEMBER

- **Cannabis withdrawal (syndrome):** three or more of seven signs within a week of stopping heavy, prolonged use; the discriminator from other withdrawals is that the picture is predominantly emotional and behavioural (irritability, sleep disturbance, appetite change) rather than physical; onset 24 to 48 hours, peak 2 to 5 days, resolution within 1 to 2 weeks; it is not dangerous in a healthy person, so the first management step is supportive care and sleep hygiene, with no licensed drug required.

21.7 The Indian frame: epidemiology, NDPS and the treatment gap

The numbers. The national Magnitude of Substance Use survey found that **2.8 per cent** of Indians aged 10 to 75 use cannabis, with about **72 lakh** people carrying a cannabis use disorder (AIIMS Clinical Methods in Psychiatry 2024). Cannabis is thus a mainstream Indian substance, not a fringe one, and traditional cultural use of bhang complicates both perception and detection.

The legal and service frame. Cannabis is controlled under the Narcotic Drugs and Psychotropic Substances (NDPS) Act, whose detailed medico-legal and capacity aspects are in the Mental health legislation and forensic psychiatry notes. The dominant service reality is the treatment gap: the treatment gap for substance use disorders in India runs at about **91 per cent** overall, and around 73 per cent specifically for the non-alcohol, non-tobacco substance use disorders that include cannabis, so the great majority of people with a cannabis use disorder never reach a de-addiction service (AIIMS Clinical Methods in Psychiatry 2024). Because there is no cannabis-specific medication, and because the buprenorphine-based substitution model that anchors opioid de-addiction has no cannabis equivalent, the Indian answer is squarely psychosocial and community-delivered, which fits the workforce constraint the treatment gap describes.

INDIA

Two India-specific facts to keep together: cannabis use disorder affects roughly 72 lakh Indians, yet the treatment gap for non-alcohol, non-tobacco substance use disorders is about 73 per cent, and the overall substance-use treatment gap is around 91 per cent. With no cannabis pharmacotherapy to offer and a de-addiction workforce spread thin, the realistic intervention is brief, motivation-based psychosocial work delivered close to the community rather than a specialist detoxification bed.

HOLD THIS

Cannabis withdrawal is real and predominantly emotional: three or more of irritability, sleep disturbance and appetite change within a week of stopping heavy use, onset 24 to 48 hours and resolving in 1 to 2 weeks; and the psychosis link is dose-dependent, rising from about 1.4 times odds for ever-use to nearly fourfold with high-potency cannabis.

22 · Stimulants: cocaine and amphetamine

Stimulants are the psychomotor accelerants of the drug world: **cocaine**, **amphetamine** and **methamphetamine** all drive dopamine, noradrenaline and serotonin into the synapse and produce a euphoriant, sympathomimetic high. DSM-5-TR and ICD-11 both fold amphetamine-type substances and cocaine into a single *stimulant* rubric because their psychoactive and sympathomimetic effects overlap almost completely; the pharmacology of that dopamine surge belongs to the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and is not re-derived here. The high-yield exam task is to name the **intoxication** picture and its physical signs, to recognise **stimulant psychosis** with its signature tactile hallucination of **formication**, to list the medical emergencies (cardiac, cerebrovascular, hyperthermic), to describe the withdrawal *crash*, and to state honestly that there is no approved anti-craving agent so management is psychosocial.

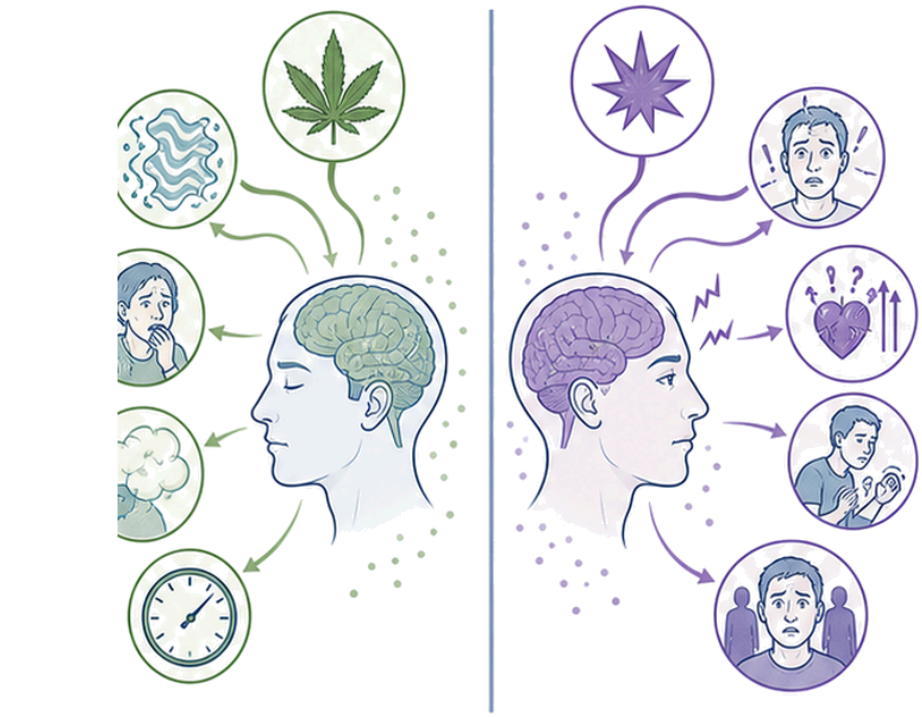

Fig 13.15 Acute cannabis effects may combine perceptual change, anxiety and cognitive slowing; stimulants more often produce intense arousal, sympathetic activation, stereotyped behaviour and paranoia or psychosis at higher exposure.

Why it matters clinically. A stimulant-intoxicated patient can look manic, look schizophrenic, or drop dead of an arrhythmia or a haemorrhagic stroke, so the discrimination is genuinely life-saving. The boundary between a stimulant-induced psychotic disorder and a primary psychosis is developed in the Other psychotic disorders, delusional syndromes and catatonia notes; the NDPS Act frame that governs access and prosecution sits in the Mental health legislation and forensic psychiatry notes. What this topic must nail down is the criterion set, the discriminators, and the one management truth: for stimulants, unlike alcohol or opioids, the drug cupboard is essentially empty.

22.1 The three drugs and how route sets the risk

The agents. Cocaine is a naturally occurring alkaloid of the coca plant, taken as snorted hydrochloride powder, injected in solution, or smoked as freebase or crack. Amphetamine and methamphetamine are synthetic phenylethylamines taken orally, nasally, intravenously or (methamphetamine) smoked; methylphenidate and modafinil are amphetamine-type substances

by mechanism (Kaplan and Sadock 2024; DSM-5-TR). **Route dictates danger.** Smoking and intravenous use give the fastest onset (seconds to blood-brain barrier), the most intense euphoria, and the steepest slide into compulsive use; cocaine euphoria correlates with the *rate of rise* of the serum level, not the absolute dose, which is exactly why crack and IV routes are the most addictive (Kaplan and Sadock 2024). **Kinetics.** Cocaine has a short half-life of roughly **50 to 90 minutes**, so intoxication is brief and bingeing is common; methamphetamine is far longer-acting, hence used fewer times a day but with a heavier dependence and worse prognosis (Kaplan and Sadock 2024).

PEARL

The single fact that unlocks stimulant addictiveness is the *rate* hypothesis: it is how fast the level rises, not how high it gets, that drives the reinforcing rush. That is why the same molecule (cocaine) is only moderately habit-forming snorted but ferociously so smoked as crack or injected. Combine cocaine with alcohol and the liver makes *cocaethylene*, a longer-acting, more cardiotoxic metabolite, which is why the drink-plus-cocaine combination kills more hearts than either alone.

22.2 Stimulant intoxication: the sympathomimetic euphoriant picture

The syndrome. Stimulant intoxication is the appearance of clinically significant behavioural or psychological change during or shortly after use, plus two or more physical signs (DSM-5-TR). The *psychological* change is euphoria with enhanced vigour, grandiosity, hypervigilance, talkativeness, interpersonal sensitivity, anxiety or anger, and stereotyped repetitive behaviour; chronic high-dose use flips this into affective blunting, fatigue and social withdrawal. The *physical* signs are frankly sympathomimetic: tachycardia (or bradycardia), pupillary dilation, raised (or lowered) blood pressure, sweating or chills, nausea, weight loss, psychomotor agitation or retardation, and at the severe end chest pain, arrhythmias, seizures, dyskinesias, dystonias or coma (DSM-5-TR). **The ICD-11 gloss** adds paranoid ideation (possibly delusional), transient auditory hallucinations, transient confusion and skin sores to the same core picture (ICD-11 6C46.3). A *with perceptual disturbances* specifier is added when hallucinations or illusions occur with intact reality testing.

GOOD TO REMEMBER

- **Stimulant intoxication (DSM-5-TR):** behavioural/psychological change (euphoria, hypervigilance, grandiosity, stereotypy) PLUS two or more physical signs (tachycardia, mydriasis, BP change, chills, nausea, weight loss, psychomotor change, chest pain, seizures) developing during or shortly after use.
- **The discriminator vs mania:** the physical sympathomimetic signs (mydriasis, tachycardia, sweating) and the short time-course, plus a positive urine screen, point to a substance rather than a primary manic episode.
- **Severe intoxication:** convulsions, cardiac arrhythmia, hyperpyrexia and death, the medical emergency that must be excluded first.

22.3 Stimulant psychosis and formication

The presentation. Heavy stimulant use produces paranoia in **50 to 70%** of people with cocaine use disorder and nearly 30% of methamphetamine users (Kaplan and Sadock 2024). Cocaine-

related psychosis characteristically involves *non-bizarre* persecutory delusions and misinterpretations (mistaking a car alarm for a police siren), and its signature perceptual sign is formication, the tactile hallucination of insects crawling in or under the skin, the classic *cocaine bugs*, which drives scratching and extensive skin excoriation (Kaplan and Sadock 2024; DSM-5-TR). **The label.** Brief paranoia within intoxication is *not* stimulant-induced psychotic disorder; the induced-disorder diagnosis is reserved for symptoms exceeding the quality or severity of intoxication (Kaplan and Sadock 2024). **Discriminators.** Prominent *visual* or *tactile* hallucinations point away from primary schizophrenia toward a toxic cause; methamphetamine psychosis is the hardest to separate from schizophrenia but usually remits within a week of abstinence. **Sensitisation.** Paranoia tends to appear *earlier* in successive binges (reverse tolerance), the opposite of ordinary tolerance.

WORKED EXAMPLE

A young man is brought in agitated, picking bleeding sores into his forearms, convinced the police have bugged his house. Pupils are dilated, pulse 118, BP 170/104. He describes bugs crawling under his skin. The dilated pupils, tachycardia and hypertension say sympathomimetic; the non-bizarre persecutory delusion plus formication say cocaine or methamphetamine, not primary schizophrenia. First move is a urine drug screen and an ECG, not an antipsychotic prescription for a presumed first-episode psychosis.

GOOD TO REMEMBER

- **Stimulant psychosis:** non-bizarre persecutory delusions plus tactile hallucinations; *formication* (cocaine bugs) is the pathognomonic clue and provokes skin excoriation.
- **The discriminator:** prominent visual/tactile hallucinations and remission within about a week of abstinence favour a stimulant-induced psychosis over primary schizophrenia (methamphetamine is the closest mimic).
- **First management step:** confirm with a urine drug screen, treat agitation, and observe for spontaneous remission before committing to a primary psychotic-disorder diagnosis.

22.4 The medical emergencies: cardiac, cerebrovascular, hyperthermic

Cardiovascular. Stimulants are potent sympathomimetics, so vasoconstriction plus raised myocardial demand can precipitate angina and myocardial infarction even in a young, otherwise healthy heart; methamphetamine additionally causes cardiomyopathy and cardiogenic shock (Kaplan and Sadock 2024). Chest pain is the single commonest reason a cocaine user reaches the emergency department. **Cerebrovascular.** Acute stimulant-driven hypertension predisposes to arterial haemorrhage, so *haemorrhagic stroke* and aortic dissection are on the table; ischaemic stroke and seizures also occur (Kaplan and Sadock 2024; DSM-5-TR). **Hyperthermic and neurologic.** Grand mal seizures are common in overdose, and severe intoxication produces *hyperpyrexia*, which together with rhabdomyolysis and cardiac arrhythmia is a recognised route to death (Kaplan and Sadock 2024). **Route-specific.** Snorting perforates the nasal septum; smoking causes bronchitis and pneumonitis; injecting brings HIV, hepatitis and endocarditis; methamphetamine's vasoconstriction-plus-bruxism produces *meth mouth*.

RULE **Treat the body before the mind.** In stimulant intoxication the first emergency is medical: get an ECG and check temperature and blood pressure, because MI, haemorrhagic stroke, seizure and hyperthermia kill faster than the psychosis.

GOOD TO REMEMBER

- **Cardiac:** vasoconstriction plus raised demand causes angina and MI even in young hearts; methamphetamine adds cardiomyopathy and cardiogenic shock.
- **Cerebrovascular:** acute hypertension precipitates haemorrhagic stroke and aortic dissection; ischaemic stroke and seizures also occur.
- **Hyperthermic:** severe intoxication gives hyperpyrexia, seizures and arrhythmia, the lethal triad; the first step is medical stabilisation, not sedation alone.

22.5 Stimulant withdrawal: the crash

The syndrome. Stimulant withdrawal is a mirror-image of intoxication: cessation or reduction of prolonged use, followed within a few hours to several days by *dysphoric mood* plus two or more of fatigue, vivid unpleasant dreams, insomnia or hypersomnia, increased appetite, and psychomotor retardation or agitation (DSM-5-TR). This is the *crash*, the profound low-energy, oversleeping, ravenous, anhedonic state that follows a binge; bradycardia is often present and is a reliable objective marker (DSM-5-TR). **The clinical hazard.** The crash is not, in itself, a medical emergency the way delirium tremens is, but its depressive symptoms can be severe and *suicidal ideation is a real risk* during withdrawal and in stimulant-induced mood disorders (Kaplan and Sadock 2024; DSM-5-TR). Craving is intense and cue-driven and may re-trigger use. **The mood trap.** Depressive symptoms cluster in withdrawal while manic-spectrum symptoms cluster in intoxication, so a binge-crash cycle can convincingly imitate bipolar disorder, and only a history and a drug screen separate them.

GOOD TO REMEMBER

- **Stimulant withdrawal (DSM-5-TR):** dysphoric mood PLUS two or more of fatigue, vivid unpleasant dreams, insomnia/hypersomnia, increased appetite, psychomotor change, within hours to days of stopping.
- **The signature:** the *crash*, with hypersomnia, hyperphagia and anhedonia; bradycardia is a reliable objective sign.
- **The first management priority:** screen for suicidality and manage supportively; withdrawal itself is not life-threatening but the depressive dip can be.

22.6 Making the diagnosis and the discriminators

The nosology. Both systems group cocaine and amphetamine-type substances under stimulants, with separate codes: DSM-5-TR uses stimulant use disorder plus stimulant intoxication, stimulant withdrawal and the stimulant-induced disorders; ICD-11 codes disorders due to cocaine (6C45) separately from disorders due to other stimulants including amfetamines and methamfetamine (6C46). **The key differentials.** Phencyclidine and cathinone (bath-salt) intoxication mimic stimulant intoxication and are separated only by the toxicology (Kaplan and Sadock 2024; DSM-5-TR). A primary manic, psychotic or anxiety disorder is separated by time-course: stimulant-induced symptoms attenuate over weeks of abstinence, so symptoms persisting

beyond a **1 month** abstinent period, or predating the drug, point to an independent disorder (DSM-5-TR).

Stimulant intoxication
euphoriant, sympathomimetic state during/after use; two or more physical signs required.

Stimulant-induced psychotic disorder
psychosis exceeding the quality/severity of intoxication; non-bizarre delusions and formication typical.

Stimulant withdrawal (crash)
dysphoria plus fatigue, hypersomnia, hyperphagia, vivid dreams after stopping prolonged use.

Reverse tolerance (sensitisation)
paranoia appearing earlier and at lower dose across successive binges.

FEATURE	INTOXICATION	WITHDRAWAL (CRASH)
Mood	**Euphoria, grandiosity (manic-like)**	**Dysphoria, anhedonia (depressive-like)**
Arousal	Hypervigilance, insomnia	Fatigue, hypersomnia
Appetite	Suppressed, weight loss	Increased (hyperphagia)
Pulse	Tachycardia (usually)	Bradycardia (reliable marker)
Pupils	Dilated (mydriasis)	Normal
Danger	MI, stroke, seizure, hyperthermia	Suicidal ideation, relapse craving

Intoxication and the crash are physiological opposites; the sympathomimetic signs and bradycardia are the quickest bedside discriminators.

TRAP **Do not diagnose bipolar disorder mid-binge.** A stimulant binge-crash cycle imitates mania then depression; commit to a mood-disorder label only after symptoms persist beyond a month of confirmed abstinence.

22.7 Management: no approved anti-craving agent, so treat supportively

The central truth. Unlike alcohol and opioids, there is *no* approved anti-craving or substitution pharmacotherapy for cocaine or amphetamine use disorder; prescription stimulants, dopamine agonists, anticonvulsants, antidepressants and antipsychotics have all failed to show conclusive benefit for cocaine use disorder, and prescription stimulants specifically should *not* be used for amphetamine dependence (BAP 2026, Level A). **So the evidence-based core is psychosocial:** for cocaine use disorder, community reinforcement approach, CBT, or contingency management combined with another behavioural intervention; for amphetamine or methamphetamine use disorder, contingency management combined with another behavioural intervention is the best-supported option (WHO mhGAP; BAP 2026). **Acute intoxication and agitation** are managed supportively with a calm environment and benzodiazepines for agitation and seizures, with cardiac and temperature monitoring. **Methamphetamine-associated psychosis** is treated with an antipsychotic, preferably olanzapine or quetiapine (BAP 2026, Level A/B). **Withdrawal (the**

crash) is managed supportively; no specific agent, including mirtazapine, modafinil or amantadine, has adequate evidence (BAP 2026). Only tentative, non-first-line signals exist (extended-release naltrexone plus bupropion, or atomoxetine, for methamphetamine), which is exactly what "no approved agent" means in practice.

50 to 90	50 to 70	1	0
COCAINE HALF-LIFE IN MINUTES (SHORT, HENCE BINGEING)	PER CENT OF COCAINE USERS WITH PARANOIA ON HEAVY USE	MONTHS ABSTINENT BEYOND WHICH PERSISTENT PSYCHOSIS SUGGESTS A PRIMARY DISORDER	APPROVED ANTI-CRAVING DRUGS FOR STIMULANT USE DISORDER

GOOD TO REMEMBER

- **Contingency management:** the best-evidenced intervention for stimulant use disorder; combine with another behavioural intervention (CBT, community reinforcement) (WHO mhGAP; BAP 2026). No approved anti-craving drug exists.
- **Olanzapine or quetiapine:** preferred antipsychotic for methamphetamine-associated psychosis (BAP 2026); most stimulant psychosis remits with abstinence and supportive care.
- **Benzodiazepine:** the workhorse for stimulant-induced agitation and seizures during acute intoxication, alongside cardiac and temperature monitoring (supportive care, not a specific antidote).

22.8 The India frame: a small but rising ATS problem inside a big treatment gap

The epidemiology and the gap. In Indian practice, cocaine and amphetamine-type stimulants are far less common than alcohol, opioids and cannabis, but amphetamine-type stimulants are a rising, mostly metropolitan and party-scene problem, and the psychiatrist is often the first clinician to recognise a stimulant psychosis brought in as a "first-episode schizophrenia". The dominant service reality is the treatment gap: the substance-use treatment gap in India runs at roughly **91 per cent** overall, and about 73 per cent for the non-alcohol, non-tobacco substance use disorders that include stimulants, so most people with a stimulant problem never reach a de-addiction service (AIIMS Clinical Methods in Psychiatry 2024). **The service and legal frame.** Care is concentrated in government de-addiction centres and Drug De-addiction Programme (DDAP) units and the day care centre model rather than general practice, framed by the Narcotic Drugs and Psychotropic Substances Act (NDPS Act, 1985); the medico-legal detail belongs to the Mental health legislation and forensic psychiatry notes. **Why this matters for stimulants specifically.** Because there is no substitution therapy for stimulants, the buprenorphine (Indian brand Tidigesic) model that anchors opioid de-addiction has no stimulant equivalent, so the Indian answer, like the global one, is squarely psychosocial and community-delivered, which fits the workforce constraint the treatment gap describes.

INDIA

Two facts to hold together for the Indian viva. First, stimulants sit low in the Indian substance hierarchy behind alcohol, opioids and cannabis, but amphetamine-type stimulants are climbing in cities and the clubbing scene, so a young metropolitan patient with paranoia, dilated pupils and formication deserves a stimulant screen before a schizophrenia label. Second, there is no substitution or anti-craving drug to offer, so unlike the opioid pathway there is no buprenorphine-style bridge, and the realistic intervention is contingency management and brief motivation-based psychosocial work delivered close to the community, inside a de-addiction system already stretched by a treatment gap of roughly 91 per cent (IPS_CPG; AIIMS Clinical Methods in Psychiatry 2024).

HOLD THIS

Stimulant intoxication is a euphoriant, sympathomimetic state whose signature psychosis carries non-bizarre delusions and formication (cocaine bugs), whose real killers are MI, haemorrhagic stroke, seizure and hyperthermia, whose withdrawal is a depressive crash with suicide risk, and for which there is no approved anti-craving drug, so management is supportive plus contingency management.

23 · Tobacco and nicotine dependence

Of every substance in this paper, **tobacco** kills the most people and is the least treated, which is exactly why it is examined. The dependence itself is unglamorous: no dramatic intoxication, no life-threatening withdrawal, no delirium. What makes it a management topic worth marks is that the pharmacology of **smoking cessation** is clean, evidence-heavy and testable, and India is the second-largest tobacco-consuming country in the world, so an Indian examiner will want the assessment tool, the first-line drugs and the doses, not a sermon on the harms of **nicotine**.

Why it matters clinically. Nicotine dependence is a drug-and-dose topic. The marks sit in three places: recognising the dependence, grading its severity with the **Fagerstrom** Test for Nicotine Dependence, and choosing pharmacotherapy from three verified first-line options, **nicotine replacement** therapy (**NRT**), **varenicline** and **bupropion**. The reward circuitry that nicotine hijacks (mesolimbic dopamine release driven by alpha4beta2 nicotinic receptors on ventral-tegmental neurons) is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and is not re-derived here. Two figures carry this topic: Fig 13.16, the FTND item map and its severity bands; and Fig 13.17, the three-drug cessation algorithm keyed to the quit date. The FTND form itself is reproduced in the scales gallery.

NIDA Clinical Trials Network

Fagerstrom Test for Nicotine Dependence (FND)

Segment: _ _

Visit Number: _ _

Date of Assessment: (mm/dd/yyyy) _ _/_ _/_ _ _ _

Do you currently smoke cigarettes?

☐No ☐Yes

If "yes," read each question below. For each question, enter the answer choice which best describes your response.

1. **How soon after you wake up do you smoke your first cigarette?**
   ☐Within 5 minutes ☐31 to 60 minutes
   ☐6 to 30 minutes ☐After 60 minutes
2. **Do you find it difficult to refrain from smoking in places where it is forbidden** (e.g., in church, at the library, in the cinema)**?**
   ☐No ☐Yes
3. **Which cigarette would you hate most to give up?**
   ☐The first one in the morning ☐Any other
4. **How many cigarettes per day do you smoke?**
   ☐10 or less ☐21 to 30
   ☐11 to 20 ☐31 or more
5. **Do you smoke more frequently during the first hours after waking than during the rest of the day?**
   ☐No ☐Yes
6. **Do you smoke when you are so ill that you are in bed most of the day?**
   ☐No ☐Yes

Comments:

Heatherton TF, Kozlowski LT Frecker RC (1991). The Fagerström Test for Nicotine Dependence: A revision of the Fagerström Tolerance Questionnaire. British Journal of Addiction 86:1119-27.

FTND (Heatherton et al., 1991); reproduced from the NIDA CTN government-hosted form, freely reproducible with acknowledgement.

Fig 13.16 The Fagerstrom Test for Nicotine Dependence (FTND)

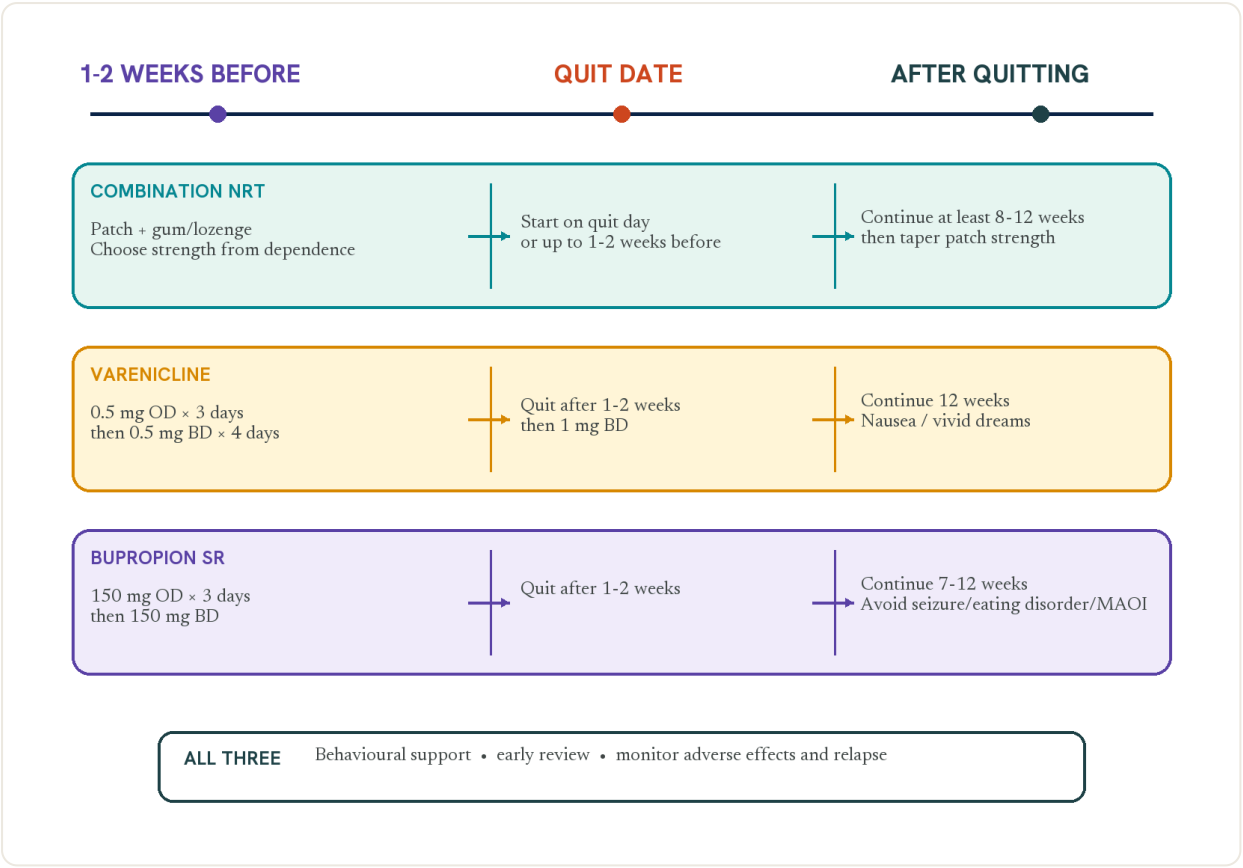

Fig 13.17 The three first-line smoking-cessation options keyed to the quit date. Combination NRT may start on or before the quit day; varenicline and bupropion are started 1 to 2 weeks beforehand, then continued with behavioural support and review after quitting.

23.1 What nicotine dependence is, and how it differs from other drugs

The dependence. Nicotine produces a genuine substance-use disorder that meets the same dependence criteria as any other drug: tolerance, a characteristic withdrawal syndrome, loss of control, and continued use despite harm (ICD-11 codes it under *disorders due to use of nicotine*; DSM-5-TR calls it *tobacco use disorder*). What separates it phenomenologically is the near-absence of a binge or intoxication phase, tobacco has little of the euphoric high/intoxication stage that dominates alcohol, opioid or stimulant use, so the disorder is driven almost entirely by withdrawal relief and by fast, heavily reinforced learning across dozens of daily doses (Tasman 2024, Kaplan and Sadock 2024).

The withdrawal syndrome. Nicotine withdrawal begins within hours of the last cigarette, peaks in the first few days and largely settles over 2 to 4 weeks: irritability, anxiety, restlessness, difficulty concentrating, increased appetite and weight gain, low mood and craving. It is unpleasant and drives relapse, but it is never a medical emergency, the contrast the examiner wants against alcohol and sedative withdrawal (Kaplan and Sadock 2024).

GOOD TO REMEMBER

- **Nicotine dependence (tobacco use disorder):** a true dependence syndrome (tolerance + a real withdrawal syndrome + loss of control) but with minimal intoxication phase (tobacco use disorder in DSM-5-TR); withdrawal is irritability, anxiety, poor concentration, appetite/weight gain and craving, begins within hours, peaks in days, resolves over 2 to 4 weeks, and is *never* life-threatening, the discriminator against alcohol/sedative withdrawal.

23.2 The receptor target: the alpha4beta2 nicotinic receptor

Where the drugs act. Nicotine binds neuronal nicotinic acetylcholine receptors, and the subtype that carries the reward is the alpha4beta2 receptor on dopaminergic neurons of the ventral tegmental area, whose activation drives dopamine release in the nucleus accumbens (Stahl; KDT). This single receptor is the reason the whole pharmacology hangs together: NRT occupies it with clean nicotine, varenicline is a *partial agonist* at it, and bupropion works around it entirely. Chronic exposure upregulates and desensitises these receptors, which is the molecular substrate of tolerance and of the withdrawal that appears when they are unoccupied.

23.3 Assessing severity: the Fagerstrom Test (FTND)

What it is. The Fagerstrom Test for Nicotine Dependence (FTND, Heatherton 1991) is the standard, most widely used measure of the *physical* severity of nicotine dependence. It is a brief 6-item self-report questionnaire; scores run from 0 to 10, and a higher score means heavier physiological dependence and predicts a worse withdrawal syndrome and greater difficulty quitting (Tasman 2024). It does not diagnose the disorder, it grades it, and the grade guides how intensive the pharmacotherapy needs to be (IPS guidelines direct clinicians to document the FTND for exactly this purpose).

The two heaviest items. The two items that carry most of the weight are the number of cigarettes smoked per day and the time from waking to the first cigarette; these two alone form the abbreviated 2-item Heaviness of Smoking Index (HSI). The single most useful clinical marker is time-to-first-cigarette: a smoker who lights up within **30 minutes** of waking is highly dependent and should be offered the higher-strength forms (the 4 mg gum or lozenge rather than the 2 mg) (Tasman 2024).

FTND SCORE (0 TO 10)	DEPENDENCE BAND	PRACTICAL IMPLICATION
0 to 2	very low / minimal	brief advice may suffice
3 to 4	low	behavioural support, consider NRT
5 to 6	**moderate**	offer pharmacotherapy; FTND >= 6 = high severity
7 to 10	high / very high	higher-strength NRT or varenicline; combination NRT

FTND severity bands; a score of 6 or higher marks high-severity dependence and a heavier withdrawal, so pharmacotherapy is intensified accordingly (Tasman 2024). The instrument form is reproduced in the scales gallery.

GOOD TO REMEMBER

- **FTND (Fagerstrom Test for Nicotine Dependence):** 6-item self-report, scored 0 to 10, grades *physical* dependence (not a diagnosis); score **>= 6** = high severity and heavier withdrawal; the two key items (cigarettes/day + time-to-first-cigarette) form the Heaviness of Smoking Index; first cigarette within 30 minutes of waking = high dependence, choose the higher-strength forms.

RULE **Grade before you treat.** Document the FTND (or at least cigarettes/day and time-to-first-cigarette) on every tobacco user, then match pharmacotherapy intensity to the score, high dependence gets combination NRT or varenicline, not a single low-dose patch.

23.4 The three verified first-line options and how to choose

The BAP position (lead). The British Association for Psychopharmacology (BAP) states the first-line treatments for nicotine dependence in adults are, alongside behavioural support, combination NRT, varenicline, cytisine, or a nicotine e-cigarette, offered with behavioural support but still offered if behavioural support is declined (BAP 2026). Crucially, BAP tells clinicians *not* to withhold varenicline over the outdated neuropsychiatric-safety concerns, including in people with mental illness. This is the verified first-line set and must anchor any answer.

What the other guidelines say. The Indian Psychiatric Society (IPS guidelines) frames every clinical contact around the 5As (Ask, Advise, Assess, Assist, Arrange), documents the FTND to set pharmacotherapy intensity, and names NRT as first-line with varenicline the most effective monotherapy and bupropion an alternative (IPS 2014). NICE recommends, combined with behavioural support, combination short-plus-long-acting NRT, varenicline, cytisinicline or a nicotine-containing e-cigarette as the options most likely to achieve stopping, and prescribing bupropion, NRT or varenicline before the quit date (NICE 2021). WHO mhGAP endorses brief intervention for all tobacco users in general settings and NRT/bupropion/varenicline where available (WHO mhGAP 2016).

AGENT	MECHANISM	LINE (PER BAP/IPS)
NRT (patch + gum/lozenge)	clean nicotine agonist, occupies alpha4beta2	first-line; combination > single-form
Varenicline	alpha4beta2 *partial* agonist	first-line; most effective monotherapy
Bupropion	noradrenaline-dopamine reup-take inhibitor	first-line alternative; less effective

The three cessation pharmacotherapies mapped to mechanism and guideline line; all three are verified first-line (varenicline the most effective single agent, combination NRT the strongest NRT approach) (BAP 2026, IPS 2014).

23.5 Nicotine replacement therapy: the patch, gum and lozenge

The principle. Nicotine replacement therapy gives back clean, slow-delivered nicotine to occupy the alpha4beta2 receptor and suppress withdrawal and craving, without the tar, carbon monoxide and carcinogens of combusted tobacco, then the dose is tapered off. It roughly doubles quit rates over placebo (Kaplan and Sadock 2024). NRT splits into a long-acting form (the transdermal patch, steady background level) and short-acting forms (gum, lozenge, spray, inhaler, for breakthrough craving).

The patch. The transdermal patch (Indian brand Nicotinell, generic nicotine) delivers continuous nicotine and comes in **21, 14 and 7 mg** per 24-hour strengths; a smoker of more than 10 cigarettes a day starts on the **21 mg/24 h** patch, then steps down through 14 and 7 mg over the

course of treatment (IPS 2014; KDT). It is started on the quit day or 1 to 2 weeks before, and continued for at least 8 to 12 weeks. Its weakness is that it cannot be self-titrated for sudden craving, which is why it is paired with a short-acting form.

Gum and lozenge. Nicotine gum (Indian brand Nicotex, generic nicotine polacrilex) and the lozenge each come in **2 mg and 4 mg** pieces; the 4 mg strength is for the highly dependent smoker (first cigarette within 30 minutes of waking), the 2 mg for the lighter smoker. Gum is chewed slowly and "parked" against the cheek, not chewed continuously, and acidic drinks (coffee, cola, juice) must be avoided for 15 minutes before use because they block buccal absorption (Tasman 2024). The evidence-based headline is that *combination* NRT, a long-acting patch plus a fast-acting gum or lozenge, is more effective than any single-form NRT, and this is what the guidelines now recommend as first-line (BAP 2026, NICE 2021).

WORKED EXAMPLE

A 44-year-old man smokes 25 cigarettes a day and lights his first within 5 minutes of waking; his FTND is 8 (high). You do not reach for a single 7 mg patch. You set a quit date, start a 21 mg/24 h patch (Nicotinell) for the background level, and add 4 mg nicotine gum (Nicotex) for breakthrough craving, this combination NRT, plus brief behavioural support, is first-line for a heavily dependent smoker (BAP 2026). You plan at least 8 to 12 weeks, then a stepped taper of the patch strength.

GOOD TO REMEMBER

- **NRT (nicotine patch Nicotinell; gum Nicotex; generic nicotine):** clean agonist replacement that occupies alpha4beta2 and roughly doubles quit rates; patch **21/14/7 mg**/24 h stepped down, gum/lozenge **2 mg or 4 mg** (4 mg for the highly dependent); combination (patch + fast-acting form) beats single-form NRT and is first-line; NRT is the only pharmacotherapy licensed in pregnancy (prefer intermittent forms, after behavioural support).

23.6 Varenicline: the alpha4beta2 partial agonist, most effective monotherapy

Mechanism. Varenicline (Indian brand Champix, generic varenicline) is a selective *partial agonist* at the alpha4beta2 nicotinic receptor. As a partial agonist it does two useful things at once: it mildly stimulates the receptor, giving enough dopamine to blunt withdrawal and craving, while simultaneously *blocking* nicotine from binding, so that a cigarette smoked on treatment delivers little reward (KDT; Stahl). It is the most effective single cessation agent (IPS 2014, BAP 2026).

The dose and titration. Varenicline is titrated up to avoid nausea, then held at the target dose for 12 weeks. The verified regimen: **0.5 mg once daily for 3 days**, then **0.5 mg twice daily for 4 days**, then **1 mg twice daily for 12 weeks** (target 1 to 2 mg/day) (IPS 2014, BAP 2026). The quit date is set for 1 to 2 weeks after starting the drug, so the receptor is already partly occupied when the patient stops. Nausea is the commonest side effect; abnormal dreams and insomnia are frequent.

The neuropsychiatric-safety question. Varenicline carried a historic black-box warning for mood change and suicidal ideation. The large EAGLES trial did not confirm an excess of serious neuropsychiatric events, and the warning has since been downgraded; BAP is explicit that

varenicline should *not* be withheld over these outdated concerns, including in people with mental illness, though monitoring of mood remains sensible in major mental illness (BAP 2026, IPS 2014).

GOOD TO REMEMBER

- **Varenicline (Champix; generic varenicline):** selective alpha4beta2 nicotinic *partial* agonist, the most effective cessation monotherapy; dose **0.5 mg OD x3 days, 0.5 mg BD x4 days, then 1 mg BD for 12 weeks**, quit date set 1 to 2 weeks after starting; nausea is the commonest adverse effect; the old neuropsychiatric black-box warning is downgraded (EAGLES), so do not withhold it in mental illness but monitor mood.

TRAP **Do not deny varenicline to the mentally ill.** The neuropsychiatric black-box warning has been downgraded and BAP says not to withhold it, refusing the most effective cessation drug to a smoker with depression or schizophrenia (the group who smoke most and die soonest) is now a guideline error, not a caution.

23.7 Bupropion: the NDRI alternative and its seizure caution

Mechanism and place. Bupropion (Indian brand Bupron SR, generic bupropion; the smoking-cessation brand internationally is Zyban) is an atypical antidepressant that inhibits noradrenaline and dopamine reuptake (an NDRI). In cessation it works around the nicotinic receptor entirely, providing dopaminergic tone without nicotine. It is a first-line *alternative*, less effective than varenicline, and it earns its keep when a smoker also has depression, because it treats both (a dual indication) (IPS 2014, BAP 2026).

The dose. Verified regimen: bupropion SR **150 mg once daily for 3 days**, then **150 mg twice daily** (target 150 to 300 mg/day), started **1 to 2 weeks before the quit day** and continued 7 to 12 weeks; it can be combined with NRT (IPS 2014, BAP 2026). The dose-limiting hazard is seizures: bupropion lowers the seizure threshold, so it is contraindicated in anyone with a seizure history, an eating disorder (anorexia or bulimia raise seizure risk), or on a MAOI, and is used with caution in bipolar disorder.

GOOD TO REMEMBER

- **Bupropion (Bupron SR / Zyban; generic bupropion):** noradrenaline-dopamine reuptake inhibitor, first-line *alternative* (less effective than varenicline), doubly useful when depression coexists; dose **150 mg OD x3 days then 150 mg BD** (150 to 300 mg/day), start 1 to 2 weeks before quit day, 7 to 12 weeks; the signature caution is *lowered seizure threshold*, so it is contraindicated in seizure history, eating disorders and concurrent MAOI.

23.8 The smoking-cessation CYP1A2 interaction: the trap after quitting

Smoke, not nicotine, induces CYP1A2. The polycyclic aromatic hydrocarbons in tobacco *smoke* (not the nicotine) induce the hepatic enzyme CYP1A2. Several psychotropics are CYP1A2 substrates, above all clozapine and olanzapine, but also haloperidol, fluvoxamine and duloxetine. A smoker on clozapine runs a lower plasma level because the enzyme is induced; when that patient *stops smoking*, the induction lifts over about a week and plasma levels rise, potentially to toxicity (Maudsley 2021, BAP 2026).

The management point. On stopping smoking, monitor and consider dose reduction of CYP1A2-metabolised drugs (clozapine and olanzapine first), guided by therapeutic drug monitoring; a rough guide is a possible need to reduce clozapine by up to a quarter over the first week of abstinence. Note that NRT does *not* prevent this, because it is the combustion products, not the nicotine, that drive the induction (Maudsley 2021). This is a classic examined interaction and a genuine ward hazard when an inpatient is made to stop smoking.

COMMON TRAP

Do not assume a patient on clozapine who quits smoking is now "safer". Stopping smoking removes the CYP1A2 induction, clozapine and olanzapine levels climb over the following week, and a stable patient can tip into toxicity (sedation, seizures, myocarditis risk). Anticipate it, monitor levels, and reduce the dose, and remember nicotine replacement will not shield the level, because smoke, not nicotine, was the inducer.

INDIA

India is one of the largest tobacco-consuming nations, and the pattern is distinctive: *smokeless* tobacco (khaini, gutkha, zarda, betel-quid, applied between gum and cheek) rivals or exceeds smoked forms (bidi, cigarette). Two consequences for the exam. First, varenicline is the guideline choice for *smokeless* tobacco users, where it raises quit rates by about 35% over placebo (BAP 2026), and the FTND, built around cigarettes, fits smokeless use poorly. Second, there is a large treatment gap: the National Tobacco Control Programme and tobacco-cessation clinics exist but reach a fraction of users, and while varenicline (Champix), bupropion (Bupron) and NRT (Nicotinell patch, Nicotex gum) are all marketed in India, cost keeps varenicline out of reach for many, so an NRT-plus-brief-intervention approach delivered through the general OPD, the 5As model IPS endorses, is the realistic default. Tobacco is not scheduled under the NDPS Act, which is why it is sold openly despite being the deadliest, the medico-legal frame for NDPS-scheduled drugs sits in the Mental health legislation and forensic psychiatry notes.

6	21	1	12
FTND HIGH-SEVERITY CUT-OFF (OUT OF 10)	PATCH STARTING STRENGTH, MG PER 24 H	VARENICLINE TARGET, MG TWICE DAILY	WEEKS OF PHARMACOTHERAPY

MNEMONIC

V beats B, and Combo beats Single

For choosing a cessation drug: *V*arenicline is the most effective single agent; *B*upropion is the weaker alternative (and the one with the seizure caution); and for NRT, *Combo* (patch + gum/lozenge) beats any *Single* form. That one line encodes the whole first-line hierarchy the examiner wants.

23.9 Special populations and the behavioural backbone

Pregnancy. In pregnancy, behavioural support is preferred; NRT (intermittent forms preferred over the patch) is offered only if behavioural support alone is insufficient, because NRT is the *only* pharmacotherapy licensed in pregnancy, varenicline and bupropion are not used (BAP 2026).

The pregnancy-and-substance frame more broadly sits in the Perinatal/women's mental health and emergency psychiatry notes.

Adolescents. Under-18s should not be offered varenicline, bupropion or cytisinicline (NICE 2021); behavioural treatment (motivational interviewing, brief intervention, CBT, contingency management) is the mainstay, and if any NRT is used the patch is the only form with demonstrated adolescent benefit (IPS 2014).

Behavioural support is not optional. Every guideline pairs the drug with behavioural support: brief telephone/quit-line counselling and structured 4-to-8-session counselling added to pharmacotherapy roughly double abstinence over drug alone (IPS 2014). The general MI and CBT technique behind this sits in the Psychotherapies, clinical assessment, MSE and nosology notes. The clinical rule is simple: offer pharmacotherapy *and* behavioural support, but still offer the drug if the patient declines the support (BAP 2026).

HOLD THIS

Grade with the FTND (>= 6 = high severity), then offer a first-line drug plus behavioural support: varenicline (Champix) 0.5 mg OD, up to 1 mg BD for 12 weeks is the most effective single agent; combination NRT (Nicotinell patch 21 mg + Nicotex gum) beats single-form NRT; bupropion (Bupron SR) 150 mg OD then BD is the alternative but is contraindicated with a seizure history, and after quitting, clozapine/olanzapine levels rise as smoke-induced CYP1A2 lifts.

24 · Sedative-hypnotic (benzodiazepine) dependence

The class that a psychiatrist most often makes dependent is one the psychiatrist prescribed. A **sedative** or **hypnotic** drug (the benzodiazepines, the older barbiturates, and the newer non-benzodiazepine "z-drug" hypnotics) is given for anxiety or insomnia, works well for a few weeks, and then, kept going for months, produces tolerance, dose-escalation and a physical dependence that is difficult to reverse. Examiners like this topic precisely because it is iatrogenic and preventable: they can ask you to name the withdrawal features (rebound anxiety and insomnia, the characteristic perceptual disturbances, and seizures on abrupt cessation), to explain why a short-acting agent withdraws worse than a long-acting one, and to lay out the one management principle that carries the whole answer, a gradual, individualised taper, usually after a switch to an equivalent dose of a long-acting agent.

Why it matters clinically. This is the mirror image of the alcohol story: the same GABA-A receptor, the same cross-tolerance, and the same hyperexcitable rebound when the drug is removed, which is why a benzodiazepine covers alcohol withdrawal and why **benzodiazepine withdrawal** itself looks like a slow-motion alcohol withdrawal. The receptor pharmacology behind the GABA-A adaptation is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and is assumed here. The management is guideline-anchored and unusually clean, so this is a place to be exact: get the taper principle, the equivalence conversions and the withdrawal time-course cold.

24.1 What the dependence is: iatrogenic low-dose versus non-iatrogenic high-dose

The two clinical pictures. Benzodiazepine dependence splits into two forms that behave differently (Maudsley Prescribing Guidelines 2021). The *iatrogenic* (therapeutic-dose) form arises from low daily doses prescribed over many years for anxiety or insomnia; the patient is often not drug-seeking, takes the drug as prescribed, and is dependent in the sense that stopping produces a withdrawal syndrome. The *non-iatrogenic* form is high-dose, often illicitly obtained and intermittently consumed, frequently as part of polysubstance use, where daily intake may exceed **100 mg diazepam-equivalent**. The distinction sets the setting and pace: the low-dose patient can usually be tapered as an outpatient over months, the high-dose polysubstance user often needs a structured inpatient or specialist withdrawal.

Dependence is not the same as addiction. Physical dependence (neuroadaptation producing withdrawal on cessation) is the expected consequence of chronic exposure and can occur at therapeutic doses without any addiction, that is, without craving or compulsive use (Companion to Psychiatric Studies). The best estimate is that after **6 months** of continuous benzodiazepine exposure the risk of dependence is in the region of **45%**, and the single most important determinant is duration of treatment, the longer the exposure the higher the risk.

GOOD TO REMEMBER

- **Benzodiazepine dependence:** a physical dependence (neuroadaptation, not necessarily addiction) that splits into iatrogenic low-dose (therapeutic doses over years, not drug-seeking) and non-iatrogenic high-dose (illicit, often more than 100 mg diazepam-equivalent per day, usually polysubstance); the risk is roughly 45% after 6 months of continuous use, and duration of treatment is the strongest determinant; the discriminator from addiction is the absence of craving and compulsion in the typical therapeutic-dose patient.

24.2 The z-drugs: same receptor, same dependence, marketed as different

What they are. The z-drug hypnotics, zolpidem, zopiclone, zaleplon and eszopiclone, are non-benzodiazepine agents that act at the same benzodiazepine site of the GABA-A receptor and were introduced with a reputation for less tolerance, dependence and rebound. That reputation was based on short-term studies (Kaplan and Sadock 2024). More recent data show that tolerance, physical dependence and rebound insomnia all do occur with z-drugs, along with the class hazards of falls and complex sleep-related behaviours (sleep-driving, sleep-eating with amnesia). Because zolpidem has a short elimination half-life it causes little daytime carry-over but can produce next-morning memory impairment, and concern about adverse effects lowered the recommended zolpidem immediate-release dose to **5 mg**.

Why they matter for the exam. Treat a z-drug dependence exactly like a benzodiazepine dependence: convert to a diazepam equivalent and taper, or, where inter-dose withdrawal is a problem, switch to a longer-acting benzodiazepine first. A useful equivalence is that **zopiclone 7.5 mg** is about diazepam 5 mg, and eszopiclone 3 mg is about diazepam 10 mg (Maudsley Deprescribing Guidelines 2024).

PEARL

The "z" in z-drugs stands for the drug names (Zolpidem, Zopiclone, Zaleplon, esZopiclone), not for "zero dependence". They bind the benzodiazepine site of GABA-A, so they share cross-tolerance with benzodiazepines and alcohol, and are managed with the same taper. An Irish methadone-programme sample found 23% were misusing zopiclone, so do not assume a hypnotic is "safe" because it is not called a benzodiazepine.

24.3 The withdrawal syndrome: rebound anxiety and insomnia, perceptual disturbance, seizures

The core features. Benzodiazepine withdrawal is a hyperexcitable state that resembles alcohol withdrawal but is unusual in two ways: it is *delayed* compared with most withdrawal states, and it combines affective features with distinctive *perceptual disturbances* (Companion to Psychiatric Studies). The affective and physical core is rebound anxiety, insomnia (rebound anxiety and insomnia are the commonest early features), anxious dysphoria, daytime fatigue and a flu-like phase (sweating, anorexia, muscle aches, headache). The perceptual features are characteristic: heightened sensitivity to sound, light and touch (hyperacusis, photophobia), a "temporal-lobe" distortion of the environment (doors or walls appearing to slope), depersonalisation, and bizarre paraesthesiae including a sensation of "walking on cotton wool" (Kaplan and Sadock 2024; Companion). The dangerous end of the spectrum is seizures and, rarely, a withdrawal delirium.

Seizures and the abrupt-cessation risk. Fits are rare when a therapeutic-dose regimen is stopped but the risk rises sharply with abrupt cessation, high dose and short-acting high-potency agents; abrupt discontinuation of alprazolam can cause seizures and be life-threatening (Maudsley Deprescribing Guidelines 2024). This is the single reason a benzodiazepine or z-drug is never stopped abruptly from a dependent patient: the taper exists to prevent the seizure and the perceptual crisis, not merely to ease discomfort.

FEATURE CLUSTER	WHAT THE PATIENT REPORTS	EXAM DISCRIMINATOR
Rebound affective	Rebound anxiety, insomnia, anxious dysphoria, irritability, poor concentration	**rebound anxiety and insomnia are the earliest and commonest features**
Physical / flu-like	Sweating, tremor, nausea, anorexia, muscle aches, headache, hyperreflexia	overlaps alcohol withdrawal (shared GABA-A basis)
Perceptual (near-specific)	Hyperacusis, photophobia, distorted surroundings, depersonalisation, "cotton-wool" paraesthesiae	**perceptual distortion and depersonalisation are the near-signature of benzodiazepine withdrawal**
Severe / dangerous	Myoclonus, seizures, delirium	seizures mainly with abrupt cessation of high-dose or short-acting agents

Benzodiazepine withdrawal clusters; the affective rebound plus unique perceptual disturbance is what distinguishes it (Companion to Psychiatric Studies; Kaplan and Sadock 2024).

GOOD TO REMEMBER

- **Benzodiazepine withdrawal syndrome:** a delayed hyperexcitable state whose triad is rebound anxiety and insomnia, a distinctive perceptual disturbance (hyperacusis, photophobia, depersonalisation, "cotton-wool" paraesthesiae, temporal-lobe environmental distortion), and, at the severe end, seizures on abrupt cessation; the first management step is never to stop abruptly, so a dependent patient is always tapered; the discriminator from alcohol withdrawal is the delayed onset and the perceptual-distortion component.

24.4 The time-course: why the half-life sets the onset

Onset tracks elimination half-life. The onset of withdrawal is governed by the drug's elimination half-life, shorter half-life means quicker and often more severe onset, while its duration is set by how long the brain takes to re-adapt, not by how fast the drug clears (Maudsley Deprescribing Guidelines 2024). With a short-acting, high-potency agent (lorazepam, alprazolam) withdrawal begins within a day or so and is more intense, sometimes with inter-dose withdrawal even before the drug is stopped. With a long-acting agent (diazepam, with its long-acting active metabolite) symptoms are delayed, and after stopping a long-acting benzodiazepine the classic perceptual-affective phase described above starts some **5 to 7 days** later (Companion to Psychiatric Studies). This is the pharmacological reason for switching to a long-acting agent before tapering: it smooths and delays the withdrawal so the reduction is tolerable.

A trap hidden in the co-drinker. An alcohol-dependent patient also taking a long-acting benzodiazepine can have the onset of alcohol-withdrawal seizures or delirium postponed by up to several weeks, because the benzodiazepine holds the GABA-A receptor; when its level finally falls, delirium can emerge late and be misread as a postoperative or medical complication (Kaplan and Sadock 2024).

COMMON TRAP

Do not taper too fast, and do not read a slow-onset withdrawal as "the patient is fine". Because a long-acting benzodiazepine delays withdrawal by days to weeks, a reduction that looked well tolerated at review can precipitate the perceptual-affective syndrome, or a seizure, only later. The corresponding error in the co-drinker is calling a late-emerging delirium a surgical or medical complication when it is delayed alcohol or benzodiazepine withdrawal unmasked as the long-acting agent clears.

24.5 The management principle: switch to a long-acting agent, then taper gradually

The one rule that carries the answer. The guideline-verified management of sedative-hypnotic dependence is a *gradual, individualised dose reduction*, and abrupt discontinuation is avoided (VA/DoD, strong recommendation to gradually taper the benzodiazepine; NICE safe-prescribing guidance). The standard method is to convert the patient's benzodiazepine (or z-drug) to an equivalent dose of a long-acting agent, usually diazepam, because its long duration of action mitigates the inter-dose peaks and troughs and smooths withdrawal (Maudsley Deprescribing and Prescribing Guidelines). Then reduce in a slow, step-wise manner, proportionate to the current dose so the decrements get *smaller as the dose falls*, a common rule of thumb being a

reduction of about one-eighth of the daily dose per step, with the next step only when symptoms from the last have settled.

How long, and what does not help. Tapering is titrated to the individual: some patients can complete it in under 6 months, many take longer, and it is minimised but not always prevented by slow reduction over **3 to 6 months** or more (Kaplan and Sadock 2024). Two negatives are examinable: a 2018 Cochrane review found no add-on drug that reliably facilitates the withdrawal, and you should not treat withdrawal with another dependence-forming drug, or with sodium valproate or buspirone (Maudsley Deprescribing Guidelines 2024). What does help is psychosocial support, patient education and CBT alongside the dose reduction. Alprazolam withdrawal is notoriously the hardest, as the dose falls below about 1 to 1.5 mg the receptor down-regulates paradoxically and symptoms intensify even on a slow taper; substituting an equivalent dose of a longer-acting agent for the last steps can help.

AGENT	APPROX. DOSE EQUAL TO DIAZEPAM 5 TO 10 MG	NOTE FOR TAPERING
Diazepam	5 to 10 (the reference agent)	long-acting, active metabolite; the switch target
Chlordiazepoxide	25 (about diazepam 10)	long-acting; also the alcohol-withdrawal agent
Lorazepam	1 (about diazepam 10)	short-acting, high potency; harder withdrawal
Alprazolam	1 (about diazepam 10 to 20)	high potency; hardest taper, switch for final steps
Temazepam	10 (about diazepam 5)	short-acting hypnotic
Zopiclone (z-drug)	7.5 (about diazepam 5)	convert then taper as diazepam
Eszopiclone (z-drug)	3 (about diazepam 10)	convert then taper as diazepam

Approximate diazepam-equivalence for the common switch-and-taper; values are guide figures for planning, individualise to response (Maudsley Deprescribing Guidelines 2024).

GOOD TO REMEMBER

- **Diazepam (the taper agent):** the long-acting benzodiazepine to which the patient's shorter-acting agent is switched at an equivalent dose before a slow step-wise reduction (reductions become smaller as the dose falls, roughly one-eighth per step, over 3 to 6 months or longer); chlordiazepoxide 25 mg, lorazepam 1 mg and zopiclone 7.5 mg are each roughly diazepam 5 to 10 mg; the signature caution is never to stop abruptly (seizure risk) and not to add valproate, buspirone or another dependence-forming drug, none of which reliably helps.

24.6 What the guidelines say: BAP, the Indian Psychiatric Society, NICE and WHO

BAP. The British Association for Psychopharmacology (BAP) evidence-based framework for substance misuse endorses the standard approach of a gradual, medically supervised benzodiazepine withdrawal rather than abrupt cessation, with psychosocial support, and treats sedative-hypnotic dependence within the general principle of managing withdrawal, substitution

where needed, and prevention of complications (BAP 2012). BAP does not endorse an add-on pharmacotherapy that reliably eases the taper, consistent with the Cochrane finding above.

The Indian Psychiatric Society, NICE and WHO. NICE safe-prescribing and withdrawal guidance is the most explicit: convert to an equivalent diazepam dose where helpful, then reduce gradually and step-wise with shared decision-making and scheduled review, avoiding abrupt discontinuation (NICE). The VA/DoD guideline makes it a strong recommendation to gradually taper the benzodiazepine for patients needing withdrawal management, and NICE separately addresses the harder case of co-existing alcohol and benzodiazepine dependence, best managed with *one* benzodiazepine (chlordiazepoxide or diazepam), the dose covering both requirements, over an extended inpatient period of 2 to 3 weeks or longer (NICE; Maudsley 2021). The WHO mhGAP frame keeps sedative use short-term and cautions against long-term prescribing, reinforcing the prevention side. At the level of the Indian Psychiatric Society (IPS guidelines), the substance-use CPGs (Basu, Ghosh, Lal, Murthy) set out the general assessment-and-management architecture, the SBIRT screening frame, the ASI-based biopsychosocial assessment, the NDPS Act and Mental Healthcare Act interface, and MI as the foundational counselling style, all of which apply to sedative-hypnotic dependence; a benzodiazepine-specific IPS taper recommendation could not be confirmed from the available corpus and is flagged under gaps rather than stated.

INDIA

Benzodiazepine dependence is a genuinely Indian problem because these drugs are cheap, widely prescribed for anxiety and insomnia, and, despite scheduling under the Narcotic Drugs and Psychotropic Substances (NDPS) Act, 1985, often accessible over the counter in practice; alprazolam (Indian brand Alprax, also Restyl) is among the most prescribed. The Indian substance-use treatment gap and the concentration of formal care in de-addiction centres and Drug De-addiction Programme units mean many dependent patients are managed in general practice with little structured tapering, so the exam-safe message, switch to a long-acting agent and taper gradually with psychosocial support, is exactly the practice point to carry into an Indian clinic. The NDPS scheduling and prescriber compliance detail sits in the Mental health legislation and forensic psychiatry notes.

MNEMONIC

"SWITCH then SLIP"

SWITCH to a long-acting agent (diazepam) at an equivalent dose; then SLIP the dose down, Slow, step-wise, Longer as needed, Individualised, Psychosocial support alongside. Never a cliff; always a slope.

24.7 Assessment, monitoring and the special situations

What to assess and monitor. Establish the drug, dose, duration and any polysubstance use (especially opioids and alcohol), and estimate the total diazepam-equivalent daily dose. During the taper, monitor withdrawal symptoms and level of sedation at each review, and slow or pause

the reduction if symptoms are intolerable rather than pushing through. There is no scale specific to benzodiazepine withdrawal in routine use analogous to CIWA-Ar; the assessment is clinical, though the general SUD screening instruments (AUDIT for alcohol, DAST for drugs, ASSIST for general use) belong in the wider workup and their cut-offs are reproduced in the scales gallery.

The situations that change the plan. In pregnancy, benzodiazepines are not major teratogens but should ideally be discontinued gradually before conception; if a woman is found pregnant on a benzodiazepine, withdraw gradually over as short a time as is safe, mindful of withdrawal-seizure risk (Maudsley Deprescribing Guidelines 2024). In overdose, flumazenil reverses benzodiazepine-induced sedation and respiratory depression but is used selectively, it can precipitate seizures (particularly in mixed overdose, for example with tricyclics, or in the benzodiazepine-dependent patient) and has a much shorter half-life than most benzodiazepines, so the patient must be observed for re-sedation (Maudsley Prescribing Guidelines 2021). In the co-existing alcohol-and-benzodiazepine patient, use one benzodiazepine to cover both and extend the inpatient regimen.

RULE **Never a cliff, always a slope.** A sedative-hypnotic or z-drug is never stopped abruptly in a dependent patient; switch to an equivalent dose of a long-acting agent and reduce gradually and step-wise, titrated to the patient's withdrawal symptoms.

TRAP **Do not reach for an add-on to "cover" the taper.** No add-on drug reliably eases benzodiazepine withdrawal (Cochrane 2018), and you must not use another dependence-forming agent, sodium valproate or buspirone; the taper itself, plus psychosocial support and CBT, is the treatment.

5 to 7 days	45%	3 to 6 months	100 mg
ONSET AFTER STOPPING A LONG-ACTING BENZODIAZEPINE	DEPENDENCE RISK AFTER 6 MONTHS CONTINUOUS USE	TYPICAL GRADUAL TAPER DURATION, OR LONGER	DIAZEPAM-EQUIVALENT PER DAY MARKING NON-IATROGENIC DEPENDENCE

HOLD THIS

Sedative-hypnotic (benzodiazepine and z-drug) dependence is a physical dependence whose withdrawal is a delayed hyperexcitable syndrome of rebound anxiety and insomnia, a distinctive perceptual disturbance, and seizures on abrupt cessation; the one management principle, guideline-verified across BAP, NICE and VA/DoD, is a gradual individualised taper, usually after switching to an equivalent dose of a long-acting agent such as diazepam, never an abrupt stop.

25 · Inhalants, hallucinogens, NPS and caffeine

This is the tail of the substance paper, the group of drugs that never carry a whole question but reliably supply a one-line MCQ or a "compare and contrast" limb. The examiner wants three discriminations kept crisp: the **inhalant** that kills a healthy adolescent on the first sniff, the **hallucinogen** that produces no physical dependence and no dangerous withdrawal, and the fact that everyday **caffeine** has two formal DSM-5-TR diagnoses with numbered criteria. Get those three right and the low-yield block is safe.

Why it matters clinically. Two of these substances kill (inhalants by sudden cardiac death, high-dose caffeine by seizures and arrhythmia) and the rest are examined as pure discriminators: no withdrawal for hallucinogens, a bladder for ketamine, an unpredictable label for **novel psychoactive** substances. The reward-pathway anatomy behind why any of these are reinforcing sits in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; the substance-induced-psychosis boundary (LSD, PCP, cannabinoids) sits in the Other psychotic disorders, delusional syndromes and catatonia notes. Figure opportunities are flagged in metadata for Ra to draw.

25.1 Inhalants and solvents: what they are and how they act

The class. Inhalants are volatile substances that are sniffed or "huffed" for a rapid intoxication: **solvent**s and glues containing toluene, aerosols, cleaning fluids, nail-polish remover, lighter fluid, paint thinner, petrol, and the gases (butane, propane, nitrous oxide). ICD-11 codes them as *disorders due to use of volatile inhalants* (6C4B). The defining features for the exam are that this is overwhelmingly a drug of *adolescents and street children*, that it is cheap and legal, and that intoxication is fast on and fast off (Kaplan and Sadock 2024, Tasman 2024).

The intoxication. **Inhalant use** produces a brief alcohol-like intoxication that begins within about **5 minutes** and clears in **1 to 2 hours**: euphoria then disinhibition, belligerent or assaultive behaviour, apathy and impaired judgement, with dizziness, nystagmus, slurred speech, unsteady gait, depressed reflexes, tremor, blurred vision and diplopia, progressing at higher doses to stupor and coma. Physical give-aways are a perioral rash ("glue-sniffer's rash"), solvent breath odour and residue on the face and hands (Kaplan and Sadock 2024).

GOOD TO REMEMBER

- **Inhalant/volatile-solvent intoxication:** volatile inhalants (toluene glue, aerosols, petrol, butane, nitrous oxide) sniffed mainly by adolescents/street children; intoxication onset within **5 minutes**, clears in **1 to 2 hours**; alcohol-like picture (euphoria then belligerence, ataxia, nystagmus, slurred speech), with the diagnostic clues of perioral "glue-sniffer's rash", solvent breath and facial residue; management is supportive in a low-stimulation setting.

25.2 Sudden sniffing death syndrome

The emergency. The single highest-yield inhalant fact is sudden sniffing death syndrome: a young, physically healthy solvent user drops dead, typically after a startle or sudden exertion during or just after huffing. The mechanism is catecholamine-sensitised myocardium, the volatile hydrocarbon sensitises the heart to adrenaline, so a surge of catecholamines (from being startled, chased or exercising) triggers a fatal ventricular arrhythmia (ventricular fibrillation) and cardiac arrest (Kaplan and Sadock 2024, Tasman 2024). It can happen on the first exposure, which is what makes it examinable and tragic. The practical corollary: do *not* startle or chase an intoxicated huffer, and adrenaline-driven resuscitation is relatively contraindicated because the heart is already catecholamine-sensitised.

The other lethal routes. Beyond the arrhythmia, inhalants kill by asphyxiation and suffocation (bag over the head), aspiration of vomitus, and direct CNS/respiratory depression; chronic use

causes toluene leukoencephalopathy, peripheral neuropathy, cerebellar signs, and hepatic, renal and bone-marrow toxicity (Kaplan and Sadock 2024).

WORKED EXAMPLE

A 15-year-old is caught by a shopkeeper sniffing correction fluid, bolts when chased, runs 50 metres and collapses. He has no cardiac history. This is sudden sniffing death syndrome: the toluene has sensitised his myocardium and the adrenaline surge of being chased has thrown him into ventricular fibrillation. The teaching point the examiner wants is the sequence, healthy adolescent, solvent, startle/exertion, arrhythmic sudden death, and that the person who chased him inadvertently triggered it.

GOOD TO REMEMBER

- **Sudden sniffing death syndrome:** sudden cardiac death in a young, healthy inhalant user, precipitated by a startle or exertion during/after huffing; mechanism is myocardial catecholamine sensitisation by the volatile hydrocarbon leading to fatal ventricular fibrillation; can occur on the first use; the management rule is do not startle or chase the user, and avoid adrenergic drugs in resuscitation.

RULE **Keep an intoxicated huffer calm.** The one management principle for inhalant intoxication is a low-stimulation, non-confrontational approach, startling, chasing or agitating the user can precipitate the fatal arrhythmia of sudden sniffing death.

TRAP **Do not give a benzodiazepine to sedate an agitated inhalant user.** Benzodiazepines potentiate the CNS and respiratory depressant effect of inhalants; marked agitation is controlled with a low-dose antipsychotic (for example haloperidol), not a benzodiazepine (Kaplan and Sadock 2024).

25.3 Hallucinogens: LSD, psilocybin and mescaline

The class. The classical hallucinogens are serotonergic agonists acting principally at the **5-HT2A** receptor: LSD (lysergic acid diethylamide), psilocybin (magic mushrooms), mescaline (peyote) and DMT. They produce a "trip", perceptual intensification and distortion, synaesthesia, depersonalisation and derealisation, altered time sense and mood lability, in a *clear sensorium* without delirium (Tasman 2024). The two facts that carry the marks are pharmacological, not phenomenological.

The two examined facts. First, hallucinogens produce *rapid tolerance* (tachyphylaxis, a trip loses potency over consecutive daily doses, with cross-tolerance between LSD, psilocybin and mescaline) but *no clinically significant physical dependence and no dangerous withdrawal syndrome*, the sharp discriminator against alcohol, opioids and sedatives (Tasman 2024). Second, the acute danger is behavioural, not physiological: the "bad trip" (acute panic/dysphoric reaction, managed by reassurance/"talking down" in a calm environment, with a benzodiazepine if needed and an antipsychotic reserved for frank psychosis), and rarely a prolonged hallucinogen-induced psychosis.

GOOD TO REMEMBER

- **Classical hallucinogens (LSD, psilocybin, mescaline):** 5-HT2A agonists producing perceptual distortion in a clear sensorium; key discriminators, *rapid tolerance* with cross-tolerance but *no physical dependence and no dangerous withdrawal*; the acute problem is the panic "bad trip" (managed by talking down plus a benzodiazepine, antipsychotic only for psychosis), not autonomic instability.

25.4 Hallucinogen persisting perception disorder (flashbacks)

The syndrome. Hallucinogen persisting perception disorder (HPPD) is the re-experiencing, *after the drug has cleared* and while sober, of perceptual symptoms first felt during intoxication: geometric hallucinations, flashes and trails of colour, haloes around objects, false peripheral movement, intensified colours, positive after-images, and macropsia/micropsia. To be a disorder these "flashbacks" must cause distress or impairment (DSM-5-TR; Tasman 2024). Reality testing is intact, the person knows the perception is not real, which separates HPPD from a psychosis. Flashbacks can be triggered by stress, cannabis, or emergence into a dark environment.

GOOD TO REMEMBER

- **HPPD (hallucinogen persisting perception disorder):** spontaneous re-experiencing of drug-era perceptual disturbance (trails, haloes, geometric/colour hallucinations, micropsia) occurring sober, days to years after use; reality testing is preserved (the discriminator from psychosis); commonest after LSD, often triggered by stress/cannabis/darkness.

25.5 Dissociatives: PCP and ketamine

The class. The **dissociative** anaesthetics are NMDA-receptor antagonists: phencyclidine (PCP, "angel dust") and ketamine. They block the NMDA-receptor channel, producing dissociation, analgesia and anaesthesia with a distinctive intoxication quite unlike the serotonergic hallucinogens (Kaplan and Sadock 2024). PCP intoxication is the dangerous one for the exam: violence and unpredictability, analgesia (loss of pain response, so self-injury), and the near-pathognomonic sign of *vertical and horizontal nystagmus* with hypertension, plus ataxia, at higher doses catatonia, rigidity, myoclonus, hyperthermia and rhabdomyolysis, and death from respiratory failure or arrhythmia. Management is a low-stimulation environment, a benzodiazepine for agitation, an antipsychotic for psychosis, and avoidance of restraint (which worsens rhabdomyolysis) (Kaplan and Sadock 2024).

Ketamine misuse. **Ketamine misuse** ("Special K") gives a shorter dissociative "K-hole"; the signature chronic harm the examiner wants is *ketamine-induced ulcerative cystitis*, a painful, contracted, ulcerated bladder from heavy recreational use (Maudsley 2021). Note the double life: the same molecule, at sub-anaesthetic dose, is an approved rapid-acting antidepressant (esketamine), so ketamine appears in both the mood and the substance papers.

GOOD TO REMEMBER

- **PCP / ketamine (dissociatives):** NMDA-receptor antagonists; PCP intoxication is violent and unpredictable with analgesia and the near-signature *vertical + horizontal nystagmus with hypertension*, risking rhabdomyolysis (avoid restraint) and death from respiratory failure; the examined chronic harm of ketamine misuse is *ulcerative cystitis* (contracted, ulcerated bladder); manage with low stimulation, benzodiazepine for agitation, antipsychotic for psychosis.

25.6 Novel psychoactive substances (NPS)

The category. Novel psychoactive substances (**nps**, "legal highs", "designer drugs") are synthetic compounds engineered to mimic a traditional drug's effect while staying one step ahead of scheduling law. The exam-relevant families are the synthetic cannabinoid receptor agonists ("Spice", "K2", far more potent and toxic than natural cannabis, causing agitation, psychosis, seizures and deaths), the synthetic cathinones ("bath salts", mephedrone/MCAT, MDPV, amphetamine-like stimulants driving the "chem-sex" scene), and novel dissociatives and psychedelics (New Oxford; Maudsley NEPTUNE guidance 2015).

Why they are hard. The teaching point is unpredictability: potency, contamination and content vary wildly, harm profiles are poorly characterised, and many NPS (like GHB) are *not detected on routine urine drug screens*, so a stimulant-toxidrome patient with a negative screen should raise NPS. There is no specific antidote; management is supportive, benzodiazepine-led symptomatic care as per the NEPTUNE framework (Maudsley 2021).

GOOD TO REMEMBER

- **NPS (novel psychoactive substances / "legal highs"):** synthetic drugs mimicking traditional agents, chiefly synthetic cannabinoids ("Spice"/"K2", more toxic than cannabis, cause psychosis/seizures) and synthetic cathinones ("bath salts", mephedrone); unpredictable potency and content, frequently *missed on routine urine drug screens*; no specific antidote, supportive benzodiazepine-led care (NEPTUNE).

25.7 Caffeine intoxication

The drug. Caffeine is the most widely used psychoactive substance in the world, an adenosine-receptor antagonist metabolised by CYP1A2 with a half-life of about **4 to 6 hours**. DSM-5-TR recognises four formal caffeine diagnoses, of which **caffeine intoxication** and caffeine withdrawal are the two to memorise (caffeine-induced anxiety disorder and caffeine-induced sleep disorder are the other two; caffeine use disorder remains a condition for further study) (Kaplan and Sadock 2024, DSM-5-TR).

The criteria. The DSM-5-TR criteria for caffeine intoxication are recent consumption usually well in excess of **250 mg** (about 2 to 3 cups of brewed coffee), plus *five or more* of twelve signs, restlessness, nervousness, excitement, insomnia, flushed face, diuresis, GI disturbance, muscle twitching, rambling thought/speech, tachycardia or arrhythmia, periods of inexhaustibility, psychomotor agitation, causing distress or impairment. The key differential is that this mimics a panic attack, generalised anxiety, mania, stimulant intoxication and akathisia, so ask about the coffee/energy-drink before diagnosing anxiety (DSM-5-TR). Very high doses (grams) cause

seizures and arrhythmia; serum levels above **100 mcg/mL** may be lethal and the lethal dose is roughly 10 g.

GOOD TO REMEMBER

- **Caffeine intoxication (DSM-5-TR):** recent intake usually > **250 mg** plus *5 or more* of 12 signs (restlessness, nervousness, insomnia, flushing, diuresis, GI upset, twitching, rambling speech, tachycardia/arrhythmia, inexhaustibility, psychomotor agitation) with distress; mimics panic/GAD/mania/akathisia (ask about the coffee first); very high doses cause seizures and arrhythmia; management is supportive as the short half-life (4 to 6 h) lets it self-resolve.

25.8 Caffeine withdrawal

The syndrome. **Caffeine withdrawal** is a genuine, DSM-recognised physical-dependence phenomenon that follows abrupt cessation of prolonged daily use: within **24 hours**, *three or more* of headache, marked fatigue/drowsiness, dysphoric or irritable mood, difficulty concentrating, and flu-like symptoms (nausea, vomiting, muscle pain/stiffness). *Headache is the hallmark*, diffuse, throbbing, movement-sensitive. It can follow doses as low as 100 mg/day, peaks over the first day or two and settles within about a week, and is a well-documented cause of post-operative and weekend headaches when the usual intake is missed (DSM-5-TR, Kaplan and Sadock 2024). It is unpleasant but never dangerous, and taper rather than abrupt stop prevents it.

GOOD TO REMEMBER

- **Caffeine withdrawal (DSM-5-TR):** abrupt cessation of prolonged daily use → within **24 hours**, *3 or more* of headache, fatigue/drowsiness, dysphoric/irritable mood, poor concentration, flu-like symptoms; *headache is the hallmark*; can occur from doses as low as 100 mg/day; benign and self-limiting; prevent by tapering; a classic cause of the post-operative and weekend headache.

COMMON TRAP

Do not misread a new-onset panic or anxiety presentation, or an inpatient's "unexplained" headache, without taking a caffeine history. High-dose caffeine intoxication is a textbook mimic of panic disorder, GAD and akathisia; caffeine-related headache from a missed morning coffee is a textbook mimic of a fresh headache disorder on the ward. The caffeine question is cheap and the diagnosis is missable.

INDIA

Two India-specific threads. Inhalants are the drug of India's street children and the urban poor: correction fluid, glue (the "dendrite"/tik-based adhesives), petrol and shoe-solution are cheap and unscheduled, and this is a paediatric-social problem the de-addiction services are poorly configured for, part of the wider substance-use *treatment gap*. Legally, most inhalants sit outside the Narcotic Drugs and Psychotropic Substances (NDPS) Act, which is precisely why they are freely available to minors, whereas LSD, ketamine and many NPS *are* scheduled, the NDPS/medico-legal frame is developed in the Mental health legislation and forensic psychiatry notes. Caffeine, delivered here mainly as strong tea (chai) and increasingly energy drinks among the young, is unscheduled everywhere and matters chiefly as a symptom-mimic in the OPD.

5	250	5	24
INHALANT INTOXICATION ONSET, MINUTES	CAFFEINE INTOXICATION THRESHOLD, MG	SIGNS NEEDED FOR CAFFEINE INTOXICATION (OF 12)	CAFFEINE WITHDRAWAL ONSET WINDOW, HOURS

HOLD THIS

Inhalants can kill a healthy adolescent on the first sniff (sudden sniffing death, a catecholamine-sensitised arrhythmia, so never chase or startle the user); hallucinogens do the opposite, no physical dependence and no dangerous withdrawal, only a panic "bad trip" and later flashbacks (HPPD); and caffeine is the everyday drug with two numbered diagnoses, intoxication (> 250 mg plus 5 of 12 signs) and withdrawal (3 of 5 within 24 hours, headache the hallmark).

26 · Behavioural addictions

A **behavioural addiction** is a disorder in which a rewarding *behaviour*, not a psychoactive substance, is pursued compulsively to the point of harm. The signal conceptual shift of ICD-11 was to carve out a small chapter called **Disorders due to addictive behaviours** and place **gambling disorder** and **gaming disorder** there, alongside the substance-use disorders, on the argument that the same reward-circuit machinery drives both (the dopamine and mesolimbic circuit mechanics belong to the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and are not re-derived here). This is a low-yield topic worth a compact, criterion-anchored pass: the exam task is to know that gambling moved from the impulse-control chapter into addiction, to state the three-part addiction template that both new syndromes share, and to know that gaming disorder is the genuinely new ICD-11 category while DSM-5-TR still parks internet gaming disorder in its research appendix.

Why it matters. The discrimination that earns marks is nosological. A **non-substance addiction** looks like a substance-use disorder shorn of the pharmacology: impaired control, escalating priority, and continuation despite harm, but with no ingested drug and (for gambling and gaming) no true physiological withdrawal. Getting the ICD-11-versus-DSM-5 placement right, and separating a genuine disorder from ordinary heavy gambling or gaming, is the whole of the topic. The medico-legal frame around online gambling and the NDPS Act sits in the Mental health legislation and forensic psychiatry notes.

26.1 The concept: what makes a behaviour an addiction

The template. ICD-11 defines a disorder due to addictive behaviours by three essential features that map exactly onto substance dependence minus the drug: impaired control over the behaviour (onset, frequency, intensity, duration, termination, context); *increasing priority* given to the behaviour so it takes precedence over other interests and daily activities; and *continuation or escalation despite negative consequences* (ICD-11 6C50/6C51; Clinical Methods in Psychiatry, AIIMS 2024). The pattern is present over an extended period, usually **12 months**, and causes significant distress or functional impairment. **What is deliberately absent.** Tolerance and withdrawal are *not* part of the ICD-11 essential features for gambling or gaming; there is no ingested substance and no pharmacological withdrawal syndrome, so the diagnosis rests on the behavioural triad, not on physiology (ICD-11 CDDR). **The move that examiners test.** In ICD-10,

pathological gambling (F63.0) sat among the habit and impulse-control disorders; ICD-11 reclassified it as a behavioural addiction because the accumulated evidence aligned it with the addictions rather than with pyromania and kleptomania (Clinical Methods in Psychiatry, AIIMS 2024).

RULE **Three features, not a drug.** A behavioural addiction is diagnosed on impaired control, escalating priority, and continuation despite harm, sustained over about 12 months, with no substance and no required physiological withdrawal.

PEARL

The reason gambling moved into the addictions and not, say, obsessive-compulsive disorder is *reward, not relief*: the gambler and the gamer chase a positively reinforcing high, whereas the person with OCD performs a ritual to *reduce* anxiety. Ego-syntonic pursuit of pleasure points to addiction; ego-dystonic neutralising of dread points to the compulsive spectrum.

26.2 Gambling disorder: the ICD-11 and DSM-5-TR criteria

ICD-11 (6C50). Gambling disorder is a persistent pattern of gambling behaviour, predominantly offline (6C50.0) or predominantly online (6C50.1), showing the three-feature addiction template applied to betting money or valuables, over an extended period of typically 12 months, with significant distress or impairment; it is not diagnosed if the behaviour is better explained by a manic episode (ICD-11 CDDR). **DSM-5-TR (F63.0).** DSM-5-TR keeps the name gambling disorder and places it as the sole non-substance disorder inside the Substance-Related and Addictive Disorders chapter. It requires **4 or more of 9** criteria in a 12-month period: needing to gamble with increasing amounts (tolerance), restlessness or irritability on cutting down (a withdrawal analogue), repeated unsuccessful efforts to stop, preoccupation, gambling when distressed, *chasing losses* (returning another day to get even), lying to conceal involvement, jeopardising a relationship or job, and relying on others for a financial bailout (DSM-5-TR). **Severity.** Mild is 4 to 5 criteria, moderate 6 to 7, severe 8 to 9. The most-endorsed criteria in mild disease are preoccupation and chasing losses (DSM-5-TR). **A DSM-5 change.** The old DSM-IV "illegal acts to finance gambling" criterion was dropped, taking the count from 10 to 9 and the threshold from 5 to 4.

FEATURE	ICD-11 GAMBLING DISORDER (6C50)	DSM-5-TR GAMBLING DISORDER (F63.0)
Chapter placement	**Disorders due to addictive behaviours**	**Substance-Related and Addictive Disorders (only non-substance member)**
Diagnostic logic	Three essential features (impaired control, priority, continuation despite harm)	Polythetic: 4 or more of 9 criteria
Time frame	Extended period, typically 12 months	Within a 12-month period
Online/offline	Specifiers 6C50.0 offline, 6C50.1 online	No online/offline specifier
Severity / course	Coded by remission; no criterion count	Mild 4-5, moderate 6-7, severe 8-9; episodic vs persistent
Exclusion	Not better explained by a manic episode	Not better explained by a manic episode

Gambling disorder across the two systems: the same construct reached by a feature list (ICD-11) or a criterion count (DSM-5-TR).

GOOD TO REMEMBER

- **Gambling disorder (DSM-5-TR):** 4 or more of 9 criteria over 12 months; the pathognomonic behaviour is *chasing losses* (returning to get even) and the desperation criterion is relying on others for a financial bailout.
- **The discriminator vs mania:** gambling driven only during a manic or hypomanic episode is *not* gambling disorder; the pattern must persist outside mood episodes (both systems exclude this).
- **The nosology point:** ICD-11 moved it from impulse-control (ICD-10 F63.0) into behavioural addiction; DSM-5-TR made it the only non-substance disorder in the addictions chapter.
- **First management step:** screen for the very high rates of comorbid mood, anxiety, substance and personality disorder and for suicidal ideation, which is common among treatment-seekers.

26.3 Gaming disorder: the genuinely new ICD-11 category

ICD-11 (6C51). Gaming disorder is the same three-feature template applied to digital or video gaming, predominantly online (6C51.0) or offline (6C51.1), over an extended period of typically 12 months, causing distress or impairment (ICD-11 CDDR). It is the flagship new addition to the chapter and, unlike gambling, does *not* involve wagering money; if the gaming is focused on wagers (for example internet poker), gambling disorder is the better label (ICD-11 CDDR). **DSM-5-TR status.** DSM-5-TR does not accept gaming as a formal disorder: it lists internet gaming disorder only in Section III, "Conditions for Further Study," with proposed criteria of **5 or more of 9** over 12 months (preoccupation, withdrawal, tolerance, unsuccessful control, loss of other interests, continued use despite problems, deception, mood-modification, and jeopardising a relationship or opportunity); it explicitly covers only non-gambling games (DSM-5-TR). **The demographic.** Gaming disorder is most prevalent in adolescent and young-adult males aged roughly 12 to 20 years, commonly co-occurs with ADHD, mood and anxiety disorders, and can be diagnosed after less than 12 months (for example 6 months) when the presentation is severe

(ICD-11 CDDR). Reported prevalence of internet gaming disorder averages about **4.7%** across countries (range 0.7 to 15.6%), with adolescent boys higher than girls (DSM-5-TR).

TRAP **Heavy gaming is not gaming disorder.** Daily long-duration play, common in adolescent males and during holidays, is not a disorder without the impaired control, escalating priority, and harm; cultural and peer-group norms must be weighed before diagnosing.

GOOD TO REMEMBER

- **Gaming disorder (ICD-11 6C51):** impaired control, increasing priority, continuation despite harm over about 12 months; *no wagering* (that would be gambling), and it can be diagnosed sooner than 12 months if severe.
- **DSM-5-TR internet gaming disorder:** still only a Section III condition for further study, 5 or more of 9 criteria, non-gambling games only.
- **The discriminator:** gaming disorder vs normal enthusiast play turns on functional harm and loss of control, not on hours alone; peer and cultural norms are considered.
- **Typical patient:** adolescent or young-adult male, often brought by parents, frequently with comorbid ADHD, mood or anxiety disorder.

26.4 Screening scales and the assessment

What the scales do. Behavioural addictions are rare in the general clinic, so routine screening is not required; assess comprehensively when a patient or family flags problematic gambling or gaming, and screen all substance-use patients for gambling given the overlap (Clinical Methods in Psychiatry, AIIMS 2024). **Gambling instruments.** The most widely used screen is the South Oaks Gambling Screen (SOGS); the Problem Gambling Severity Index (PGSI) and the Gambling Symptom Assessment Scale (G-SAS) are also used for severity and monitoring (Clinical Methods in Psychiatry, AIIMS 2024). The instrument forms are reproduced in the scales gallery; treat a positive screen as a prompt for full clinical assessment, never as the diagnosis. **The assessment core.** Map the behaviour onto the three features (control, priority, continuation despite harm), then document harm across the seven domains used for substance disorders (physical, psychological, social, occupational, financial, familial, legal), the significant abstinent attempts, and the comorbid psychiatric picture, distinguishing an independent mood disorder from behaviour occurring only within a manic episode (Clinical Methods in Psychiatry, AIIMS 2024).

INDIA

There is no national prevalence study of behavioural addictions in India, but interest is rising as smartphone and online-gaming penetration grows; the AIIMS clinical-methods teaching flags gaming disorder as an adolescent presentation and gambling as an adult one, and folds both into the standard addiction assessment rather than a separate service. The wider addiction treatment gap is stark: the national survey estimates a treatment gap around **91%** for substance use disorders, and behavioural addictions, being less recognised and rarely presenting, are even less likely to reach the de-addiction centre or the district day care service. When gambling or gaming does present, it is managed within the existing DDAP and de-addiction framework, not a bespoke pathway.

26.5 Management: psychosocial first, naltrexone the one drug

The mainstay is psychological. Cognitive-behavioural therapy and motivational interviewing are the evidence-based core for gambling disorder, supported by peer resources such as Gamblers Anonymous; the general MI and CBT technique is developed in the Psychotherapies, clinical assessment, MSE and nosology notes. **The one drug with likely effect.** No medicine is licensed for gambling disorder, but the opioid antagonist naltrexone (Indian brands Naltima or Nodict) is the only agent with likely effectiveness and is recommended by international and draft NICE guidance to reduce gambling severity, working by dampening mesolimbic dopamine release via GABAergic disinhibition in the ventral tegmental area (Maudsley 15th edition; Kaplan and Sadock 2024). It should be started in a specialist setting after baseline biochemistry, at **25 mg/day** increasing to **50 mg/day**, with efficacy reviewed at **4 to 6 weeks** and 6-monthly renal and liver monitoring (Maudsley 15th edition). Patients must be warned about the interaction with any concomitant opioid. **Alternatives.** Nalmefene, SSRIs, N-acetylcysteine, topiramate, lithium and modafinil have all been trialled with weaker evidence; naltrexone remains first among them (Maudsley 15th edition). Gaming disorder management is chiefly psychosocial and family-based; no drug is established.

TRAP **Dopamine agonists can cause gambling.** Pramipexole, ropinirole and aripiprazole (and other dopamine partial agonists) can induce or worsen an impulse-control disorder, including pathological gambling; always take a gambling history before and during dopaminergic prescribing, especially in Parkinson disease.

GOOD TO REMEMBER

- **Naltrexone (Naltima, Nodict) for gambling:** the only drug with likely effect; start 25 mg/day, titrate to 50 mg/day, review at 4 to 6 weeks; monitor LFTs and renal function; warn about the opioid interaction and do not start in a current opioid user.
- **Mechanism:** mu-opioid antagonism disinhibits GABA input to VTA dopamine neurons, cutting reward-related dopamine and gambling urges.
- **First-line overall:** CBT and motivational interviewing are the psychosocial mainstay; medication is adjunctive and unlicensed.

HOLD THIS

ICD-11 created a behavioural-addiction chapter holding gambling disorder (moved out of impulse control) and the new gaming disorder, both diagnosed on impaired control, escalating priority, and continuation despite harm over about 12 months; DSM-5-TR keeps gambling disorder (4 of 9 criteria) but leaves internet gaming disorder in the research appendix (5 of 9), and naltrexone titrated 25 to 50 mg/day is the one drug with likely benefit for gambling.

27 · Substance use in special populations

The generic assessment-and-management frame you have built for alcohol and opioids has to be re-tuned when the patient is a teenager, a pregnant woman, an older adult, or someone whose body is already carrying a serious medical illness. **Why it matters clinically.** The examiner uses **special populations** as a rapid probe of whether you can bend the rules safely: the screening tool changes, the drug you reach for changes, and the one contraindication that is inert in a fit 30-year-old becomes decisive. This is a low-tier recognition topic, so the aim is a short, confident list of the population-specific twists, with the deeper frames cross-referenced rather than re-derived.

Kept deliberately brief. The full **substance use in pregnancy** and fetal-alcohol detail, the antenatal-clinic workup and maternal withdrawal management sit in the Perinatal/women's mental health and emergency psychiatry notes; the underlying reward-circuit vulnerability of the adolescent brain sits in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; the NDPS Act and the medico-legal frame around minors and capacity sit in the Mental health legislation and forensic psychiatry notes. Here we teach only what is population-specific: the tool, the dose, the caution.

27.1 The four populations and the single governing principle

The governing principle. In every special population the diagnosis of a substance use disorder is made by the *same* ICD-11 or DSM-5-TR criteria; what changes is the screening instrument, the pharmacotherapy that is safe, and the balance of risk. The four high-yield groups are the **adolescent**, the pregnant woman, the older adult, and the patient with serious **comorbid medical illness**. Get the population-specific tool and the population-specific drug caution for each and you have the whole topic.

Adolescent substance use

Substance use disorder with onset in the teens; screen with CRAFFT, treat with a family- and psychosocial-first approach, medication reserved and evidence-limited.

Substance use in pregnancy

Any maternal use in gestation; the priority is retention in agonist treatment (opioids) and safe managed withdrawal (alcohol, sedatives), never abrupt unsupervised detoxification.

Elderly substance use

Under-recognised late-onset or continuing use in older adults; alcohol and prescribed benzodiazepines dominate, pharmacokinetics shift, and interactions and falls are the danger.

Comorbid medical illness

Substance use alongside liver disease, HIV, hepatitis, cardiac or renal disease; the illness constrains both the withdrawal agent and the relapse-prevention drug.

27.2 Adolescents: CRAFFT, the developmental stakes, and a family-first approach

Screen with the right tool. Adult instruments such as AUDIT and CAGE are not validated for teenagers; the population-specific screen is the CRAFFT (Car, Relax, Alone, Forget, Family/Friends, Trouble), a six-item interview covering alcohol and other drugs together. A score of **2 or more** positive answers is the cut-off that flags a need for fuller assessment (Clinical Methods in Psychiatry, AIIMS 2024; Kaplan and Sadock 2024). The related BSTAD and S2BI screens serve the same purpose. The actual instrument form is in the scales gallery.

Why adolescence is the danger window. Roughly **80 per cent** of people with a substance use problem began using as teenagers, and the estimated risk of developing a disorder by age 18 is about **24 per cent** (Kaplan and Sadock 2024). Earlier onset means a higher chance the disorder persists into adulthood, and repeated use interferes with the rapid prefrontal and reward-circuit maturation still under way through the early twenties. Childhood ADHD, trauma and oppositionality are the strongest antecedent risks, so screening for a co-occurring psychiatric disorder is not optional.

Treatment is family- and psychosocial-first. The evidence base in **adolescent substance** use rests on family-based and psychosocial interventions (multidimensional family therapy, attachment-based family therapy, motivational and cognitive-behavioural work), not medication. Where pharmacotherapy is used it is narrow: buprenorphine-naloxone (Suboxone) is approved for opioid dependence in those **16 years and older** (Woody 2008), and bupropion (Bupron) at **300 mg/day** and nicotine replacement have adolescent tobacco-cessation evidence (Moolchan 2005; Muramoto 2007). Dual diagnosis is treated integrated and concurrently, never "get sober first".

WORKED EXAMPLE

A 16-year-old is brought after a road-traffic accident; he admits he had been drinking and had smoked cannabis, and that he uses alone and has forgotten things he did while high. That is three CRAFFT items (Car, Alone, Forget), well above the cut-off of 2, so he needs a full substance and psychiatric assessment, family engagement and a psychosocial plan, not a one-off warning.

GOOD TO REMEMBER

- **CRAFFT:** the six-item adolescent alcohol-and-drug screen (Car, Relax, Alone, Forget, Family/Friends, Trouble); the discriminator is that it is validated for teenagers where AUDIT and CAGE are not, the cut-off is a score of 2 or more positive answers, and a positive screen triggers full assessment plus screening for the near-universal comorbid psychiatric disorder (ADHD, trauma, conduct), with family-based psychosocial treatment as the first and main step.

27.3 Pregnancy: keep the agonist, manage withdrawal safely, never precipitate it

Opioids: maintain agonist treatment. The governing rule of **substance use in pregnancy** for opioid dependence is to *retain* the woman on opioid agonist maintenance, because unsupervised

withdrawal risks miscarriage, preterm labour and relapse. Methadone is the traditional first-line agonist in pregnancy and is preferred over buprenorphine in several guidelines, though buprenorphine (Tidigesic) may also be offered and is increasingly used; the woman already stable on one agent is kept on it (BAP; NICE). Two hard cautions: do *not* switch a stabilised woman from methadone to buprenorphine during pregnancy because of the precipitated-withdrawal risk, and split the methadone dose in the third trimester to blunt peak-and-trough fetal exposure. Naltrexone is not used for maintenance in pregnancy.

Alcohol and sedatives: hospitalise and taper gently. Pregnant women in alcohol or sedative withdrawal are admitted; benzodiazepines are used at the lowest effective dose for the shortest duration, and oxazepam is preferred for its intermediate half-life and absence of active metabolites (BAP). Parenteral thiamine is given before any glucose load, exactly as in the non-pregnant drinker. The teratogenic fetal-alcohol picture and neonatal abstinence syndrome are covered in the Perinatal/women's mental health and emergency psychiatry notes.

RULE **In pregnant opioid dependence, keep her on the agonist.** Retention on methadone or buprenorphine maintenance protects the pregnancy; supervised managed withdrawal, not abrupt detoxification, is the fallback if withdrawal is truly needed.

TRAP **Switching methadone to buprenorphine mid-pregnancy.** Buprenorphine is a partial agonist and will precipitate withdrawal in a woman stabilised on full-agonist methadone; do not switch agents in pregnancy, and never give naltrexone to a pregnant opioid-dependent woman.

GOOD TO REMEMBER

- **Opioid agonists in pregnancy:** methadone (traditional first-line, split the dose in the third trimester) or buprenorphine (Tidigesic) maintenance is continued through pregnancy at a retaining dose; the discriminators are that you never precipitate withdrawal by switching a methadone-stable woman to the partial agonist buprenorphine, you never use naltrexone, and for alcohol or sedative withdrawal you hospitalise and use the lowest-dose shortest-course benzodiazepine (oxazepam preferred) with parenteral thiamine before glucose.

27.4 Elderly and comorbid medical illness: the same drug, a different margin of safety

Elderly substance use is under-recognised. In older adults the picture is dominated by alcohol and long-prescribed benzodiazepines rather than illicit drugs, and it is routinely missed because the presentation is confounded with falls, confusion and "ageing". Age-related pharmacokinetic change (reduced volume of distribution, slower clearance, greater CNS sensitivity) means a "normal" dose behaves like a larger one, so withdrawal management shifts toward shorter-acting agents such as lorazepam and the whole approach is delivered in a supportive, non-confrontational, brief-intervention style (IPS_CPG). Anti-craving and detoxification doses are started lower and titrated more slowly.

Comorbid medical illness constrains the drug. With serious **comorbid medical illness** the diagnosis is unchanged but the agent is dictated by the organ that is failing. In established hepatic compromise the withdrawal benzodiazepine is switched from chlordiazepoxide to lorazepam or oxazepam, which lack oxidative hepatic metabolism; disulfiram is avoided in significant liver

disease and in cardiac disease; and every patient with current or past injecting use is screened at baseline and annually for HIV, hepatitis B and C, syphilis and tuberculosis. The comorbid psychiatric-illness (dual-diagnosis) frame is treated in the dual-diagnosis topic.

2	16	300
CRAFFT POSITIVE-ANSWER CUT-OFF FLAGGING NEED FOR FULL ASSESSMENT	MINIMUM AGE (YEARS) FOR APPROVED BUPRENORPHINE-NALOXONE IN OPIOID DEPENDENCE	BUPROPION DOSE (MG/DAY) WITH ADOLESCENT TOBACCO-CESSATION EVIDENCE

PEARL

The single organ that most often rewrites your prescription across all these populations is the liver: it pushes you off chlordiazepoxide onto lorazepam or oxazepam for withdrawal, off disulfiram for relapse prevention, and toward the lowest-dose shortest-course strategy you would already use in the pregnant woman and the older adult.

27.5 The India frame: reaching the special populations across the treatment gap

The gap is the theme. India's substance-use treatment gap is very large, and it falls hardest on exactly these special populations: adolescents outside any screening system, pregnant women whose drinking or opioid use is stigmatised and unasked, and older adults whose alcohol use is normalised. The response is organised around the de-addiction and drug-de-addiction programme (DDAP) network of centres, the Indian Psychiatric Society substance-use clinical practice guidelines, and delivery through the day care centre and trained non-specialist community workers (IPS_CPG). The NDPS Act frames access to controlled agonists and is covered in the Mental health legislation and forensic psychiatry notes.

Buprenorphine access shapes what is possible. In Indian outpatient practice buprenorphine-naloxone (4:1) is the first-line agonist, which matters for the pregnant and adolescent opioid-dependent patient because it is the accessible maintenance option; methadone is restricted to government OST clinics run under the National AIDS Control Organisation and select institutions (for example AIIMS NDDTC, NIMHANS), so a pregnant woman needing methadone is referred to a licensed OST centre rather than managed in private practice (IPS_CPG). Assessment in the Indian setting commonly uses the Addiction Severity Index or its Indian short-form.

INDIA

The special-population priority in India is upstream identification: ask every adolescent (CRAFFT), every antenatal patient, and every older adult about alcohol and drugs, because the treatment gap means most never reach a de-addiction service. Buprenorphine-naloxone is the accessible first-line agonist; methadone maintenance for a pregnant opioid-dependent woman must go through a NACO-licensed OST clinic, not a private prescription.

HOLD THIS

Same diagnostic criteria, different tool and different drug: CRAFFT (cut-off 2) for the adolescent, keep the agonist and never precipitate withdrawal in the pregnant opioid user, lorazepam or oxazepam and lower-and-slower for the elderly and the liver, screen for blood-borne virus in every injector.

Psychosocial treatment and relapse prevention

28 · Motivational interviewing

Almost every substance-use answer ends with a psychosocial limb, and the one the examiner most wants named is **motivational interviewing**. It matters because the core problem in addiction is not ignorance but **ambivalence**: the person genuinely wants to change and genuinely wants to keep using, at the same time. Confront that ambivalence head-on and it hardens; work *with* it and the person argues themselves toward change. Motivational interviewing (**MI**) is the collaborative, goal-directed conversational method, developed by William Miller and Stephen Rollnick, that does exactly this, and its manualised four-session research form is **motivational enhancement therapy**. For an Indian exam this is the highest-yield psychotherapy of the whole block, because it is deliverable by trained non-specialist workers, needs no drug, and is written into the IPS clinical practice guidelines as a first-line psychosocial intervention for the treatment gap.

Why it matters clinically. MI is where the guideline word "offer motivational enhancement therapy or brief intervention" turns into a technique you can actually do (IPS 2014). It is owned and fully taught here as a substance-use skill; the wider psychotherapy frame (general CBT, the broader MI evidence base) is developed in the Psychotherapies, clinical assessment, MSE and nosology notes and is not re-derived here. One figure carries this topic: Fig 13.18, the spirit-OARS-change-talk schematic. Get four things exact and you can answer anything asked: the spirit, the OARS micro-skills, what change talk is and how you evoke it, and how MET packages it all.

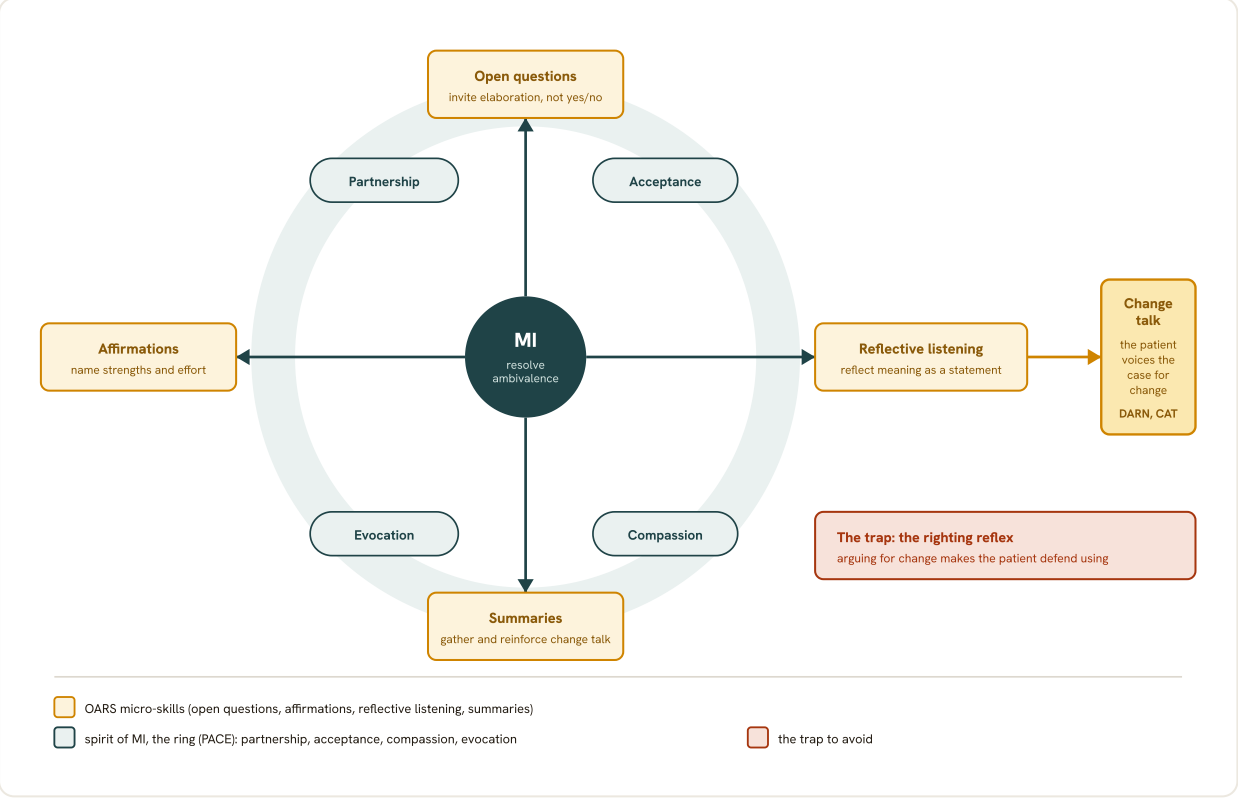

Fig 13.18 Motivational interviewing: the spirit and the OARS skills. The method sits at the centre, resolving ambivalence in favour of change. Around it are the four OARS micro-skills, open questions, affirmations, reflective listening and summaries, the moment-to-moment tools. Behind them is the ring that must hold them, the spirit of MI (PACE): partnership, acceptance, compassion and evocation. The whole point is to evoke the patient's own change talk (DARN, then CAT), while avoiding the righting reflex of arguing for change.

28.1 The definition: a collaborative method that resolves ambivalence in favour of change

What MI is. Motivational interviewing is "a collaborative, person-centred form of guiding to elicit and strengthen motivation for change" (Miller and Rollnick). It is *directional* without being directive: the clinician is steering toward a specific target (reduced or stopped use) but does so by drawing the arguments for change out of the patient rather than supplying them. It grew out of Miller's 1983 work with problem drinkers and became the standard motivational method across all addictive behaviours (Kaplan and Sadock 2024; Tasman 2015).

What MI is not. It is not persuasion, not education, not confrontation, and not a warm-up before the "real" therapy. The single most important error to avoid is the **righting reflex**, the clinician's instinct to fix the patient by arguing for change; because ambivalent people resolve tension by defending whichever side is attacked, arguing for change makes the patient argue for the status quo.

RULE **Let the patient voice the argument for change.** In MI the person, not the clinician, makes the case for changing; your job is to evoke and reinforce that self-motivational speech, never to supply it.

28.2 The spirit of MI: partnership, acceptance, compassion, evocation

The underlying stance. Before any technique comes the **spirit of mi**, the mindset without which the skills are hollow. Miller and Rollnick define it by four elements: *partnership* (a collaboration between two experts, the clinician on change and the patient on their own life, not an expert

acting on a passive recipient); *acceptance* (absolute worth, accurate empathy, autonomy support, and affirmation); *compassion* (actively promoting the patient's welfare, not the clinician's agenda); and *evocation* (drawing motivation out of the patient rather than installing it) (Tasman 2015; Kaplan and Sadock 2024).

Autonomy is the load-bearing idea. The clinician repeatedly affirms that the choice is the patient's, which paradoxically lowers defensiveness and frees the person to consider change. This is why MI works in mandated and reluctant patients where confrontation fails.

MNEMONIC

PACE

Partnership, **A**cceptance, **C**ompassion, **E**vocation, the four elements of the spirit of MI. If a technique is delivered without PACE it is not motivational interviewing, it is just a checklist.

28.3 The four processes: engaging, focusing, evoking, planning

The flow of a session. MI unfolds through four sequential-yet-recursive processes. *Engaging* builds the working relationship. *Focusing* agrees the change target (which behaviour, which direction). *Evoking* draws out the patient's own reasons for change, the heart of MI and what distinguishes it from generic counselling. *Planning* develops commitment and a concrete plan once the patient signals readiness (Tasman 2015). Move to planning too early and you re-open ambivalence; the plan must follow, not force, readiness.

WORKED EXAMPLE

A 34-year-old sent by his family for daily drinking says "I don't have a problem, my wife does." Rather than correcting him (the righting reflex), you *engage* ("tell me what a normal day looks like for you"), *focus* ("would it be alright to spend a few minutes on the drinking specifically?"), then *evoke* ("what do you notice is different on the mornings after you've drunk?"). His own answer, "I can't get to work on time," is change talk you elicited, not advice you imposed. Only when he says "maybe I should cut down" do you move to *planning*.

28.4 OARS: the four core micro-skills

The toolkit. The moment-to-moment skills of MI are captured by **oars**: **open questions**, **affirmations**, **reflective listening**, and **summaries**. These are the concrete verbal behaviours the examiner expects you to list and unpack (Miller and Rollnick; Tasman 2015).

Open questions

Questions that cannot be answered "yes/no", inviting the patient to elaborate ("what worries you about your smoking?") rather than closed interrogation.

Affirmations

Genuine statements recognising the patient's strengths, efforts and worth ("it took real effort to come today"), building self-efficacy, not empty praise.

Reflective listening

Reflecting back the patient's meaning as a statement, from simple repetition to complex reflection of underlying feeling; the signature MI skill and the main vehicle for empathy.

Summaries

Pulling together what the patient has said, especially their change talk, to reinforce it and steer the conversation ("so on one hand..., and on the other...").

MNEMONIC

OARS row you toward change

Open questions, **A**ffirmations, **R**eflective listening, **S**ummaries. Reflective listening is the paddle you use most; the others set direction.

28.5 Change talk and sustain talk: the currency of the method

Listen for the language of change. **Change talk** is any patient speech that favours change; *sustain talk* is speech that favours the status quo. MI is, at core, systematically evoking and reinforcing change talk while not amplifying sustain talk. Preparatory change talk is remembered as *DARN*, Desire ("I want to stop"), Ability ("I could stop"), Reasons ("my liver is suffering"), and Need ("I have to for my kids"); mobilising change talk is *CAT*, Commitment, Activation, and Taking steps, and predicts actual behaviour change (Miller and Rollnick).

How you evoke it. Ask evocative open questions, use the importance and confidence rulers ("on 0 to 10, why a 4 and not a 2?", which forces the patient to voice reasons for change), explore values, and look back or forward. Then reflect and summarise the change talk so the patient hears their own motivation echoed.

PEARL

The confidence and importance "rulers" are the single most exam-quotable MI technique. Asking "why are you at a 4 and not a 0?" makes the patient list reasons they *are* motivated (change talk); asking "why not a 10?" would elicit sustain talk, so you deliberately ask the lower-anchor version.

28.6 Rolling with resistance: working with discord, not against it

Do not wrestle. What older MI called "rolling with resistance" (now reframed as responding to *sustain talk* and *discord*) means: when the patient pushes back, you do not argue, you flow with it. Techniques are simple reflection, amplified reflection (reflecting the sustain talk slightly stronger so the patient themselves qualifies it), double-sided reflection (holding both sides of the ambivalence), shifting focus, and emphasising personal autonomy and choice (Miller and Rollnick; McCrady alcohol therapist guide). Resistance in MI is read as a signal that the clinician is pushing too hard, not as patient pathology.

TRAP **Do not argue with denial.** Meeting "I can quit any time" with "no you can't, look at your history" hardens the position; reflect it, roll with it, and let the discrepancy between the patient's goals and their behaviour do the work.

28.7 Developing discrepancy: the engine of motivation

The mechanism. Motivation rises when the patient perceives a gap between their present behaviour and their broader goals or values ("I want to be a present father" versus "I'm drunk most evenings"). The MI clinician gently develops and amplifies this *discrepancy*, letting the patient, not the clinician, articulate it. This is the classic Miller and Rollnick principle set, historically summarised as express empathy, develop discrepancy, roll with resistance, and support self-efficacy.

COMMON TRAP

Developing discrepancy is not shaming or guilt-tripping. If the patient feels judged, defensiveness returns and change talk dries up. The discrepancy must be surfaced within an accepting, affirming stance, the patient noticing the gap themselves, not the clinician rubbing their nose in it.

28.8 Motivational enhancement therapy: MI in its manualised form

What MET is. **Motivational enhancement therapy** (MET) is the standardised, manualised, brief form of MI developed for and validated in Project MATCH. It packages the MI spirit and OARS skills into a short structured course, classically **four sessions**, whose distinctive added ingredient is *personalised assessment feedback*: the patient's own results (for example liver enzymes, quantity-frequency, a scale score) are fed back in an MI style to evoke change talk (Kaplan and Sadock 2024; Tasman 2015). The IPS guidelines specify **met** as four structured sessions and place it, alongside CBT and relapse prevention, as a first-line psychological intervention for substance use in India (IPS 2014).

MET versus brief intervention versus FRAMES. MET is the full four-session package; a *brief intervention* is the shorter 5 to 15 minute opportunistic version for hazardous or harmful use not yet meeting dependence, distilled by the FRAMES acronym: Feedback, Responsibility (the choice is yours), Advice, Menu of options, Empathy, and Self-efficacy (IPS 2014).

MNEMONIC

FRAMES

Feedback, **R**esponsibility, **A**dvice, **M**enu of options, **E**mpathy, **S**elf-efficacy, the active ingredients of an effective brief intervention, the short-contact cousin of MET.

INDIA

MI and MET are the parts of the substance-use toolkit that scale to India's treatment gap. The IPS clinical practice guidelines direct services to deliver "brief, motivation-based psychosocial interventions" with a strategic shift to community and home-based delivery by trained non-specialist health workers, precisely because MI needs no drug, no laboratory and no specialist, and works in the primary-care and de-addiction-centre settings where most Indian care happens (IPS 2014). WHO mhGAP likewise lists motivational interventions among the structured psychosocial options for alcohol dependence. So in an Indian answer, MET (four sessions) and brief intervention (5 to 15 minutes) are not optional extras, they are the front line of the psychosocial limb that pairs with every anti-craving drug and every OST induction.

28.9 Where MI fits: not a stand-alone cure but the motivational front end

The place in the pathway. MI/MET is most powerful early, to convert ambivalence into engagement and readiness, and it improves outcomes when combined with pharmacotherapy and with more skills-based work such as CBT and relapse prevention (IPS 2014). It is transdiagnostic across substances, so the same spirit and OARS skills serve alcohol, opioids, tobacco (motivational interviewing with personalised feedback is an evidence-based way to move ambivalent smokers toward cessation) and behavioural addictions. It is a way of being with the patient that can be layered onto any other intervention, not a rival to them.

4	4	5 to 15 min
STRUCTURED SESSIONS IN A STANDARD MET COURSE (IPS)	ELEMENTS OF THE SPIRIT OF MI: PARTNERSHIP, ACCEPTANCE, COMPASSION, EVOCATION	A BRIEF MOTIVATIONAL INTERVENTION FOR HAZARDOUS OR HARMFUL USE

GOOD TO REMEMBER

- **Motivational interviewing (MI):** a collaborative, person-centred, goal-directed method (Miller and Rollnick) that resolves ambivalence in favour of change; spirit = partnership, acceptance, compassion, evocation (PACE); skills = OARS (open questions, affirmations, reflective listening, summaries); the discriminating feature is that the patient, not the clinician, voices the change talk, and the cardinal error is the righting reflex.
- **Motivational enhancement therapy (MET):** the manualised, four-session brief form of MI validated in Project MATCH; its added ingredient is personalised assessment feedback; IPS lists MET (four sessions), CBT and relapse prevention as first-line psychological interventions and it scales to India's treatment gap via non-specialist delivery.

HOLD THIS

Motivational interviewing works with ambivalence, not against it: spirit is PACE (partnership, acceptance, compassion, evocation), skills are OARS (open questions, affirmations, reflective listening, summaries), the aim is to evoke and reinforce the patient's own change talk while rolling with sustain talk, and its manualised first-line form is MET, four structured sessions built around personalised feedback.

29 · The stages of change

Behaviour change in addiction is not an on-off switch but a process a person moves through over time, and the **stages of change** model, the core of the **transtheoretical** model (TTM) of

Prochaska and DiClemente, is the framework that names the steps of that process (Kaplan & Sadock 2024; Clinical Methods in Psychiatry, AIIMS 2024). First developed to explain why some smokers quit and others never even begin, it now organises how we think about any health behaviour, and in the addictions it does two jobs at once: it lets you *place* a patient (what is their readiness?) and it tells you what to *do* next (the stage-matched intervention). The model calls the process transtheoretical because it sits above and cuts across every school of therapy rather than belonging to one.

Why it matters in the exam. Examiners test whether you can name the stages in order, define each one crisply (especially the discriminators between **precontemplation** and **contemplation**, and between **preparation** and **action**), state the two verified time-anchors (action lasts one day to 6 months; maintenance is behaviour change sustained beyond 6 months), and, above all, match the intervention to the stage. The classic viva trap is giving an action-stage task to a contemplation-stage patient. The India device is genuine: the AIIMS assessment method makes the stage of change a formal item of the addiction interview, alongside the locus of control, and the IPS treatment-gap strategy leans on brief, motivation-based interventions that are explicitly stage-driven.

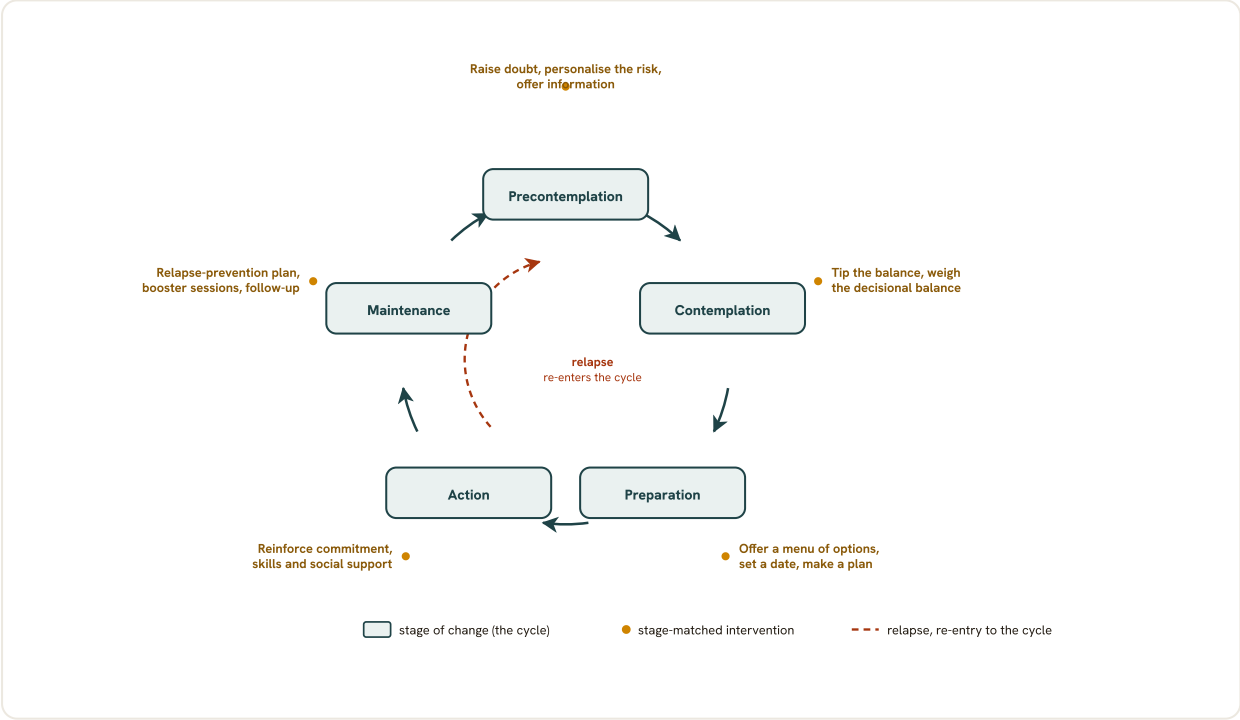

Fig 13.19 The stages of change and the stage-matched interventions. Change is a cycle, not a switch: a person moves from precontemplation through contemplation, preparation, action and maintenance, and relapse is a normal re-entry rather than a failure. Each stage calls for a different move, so the clinician matches the intervention to the stage rather than pushing action on someone who is still weighing it up: raise doubt in precontemplation, tip the decisional balance in contemplation, build a concrete plan in preparation, reinforce commitment and skills in action, and shore up the gains with relapse-prevention and follow-up in maintenance.

29.1 The transtheoretical model: change as a process, not an event

The idea. The transtheoretical model (TTM), proposed by Prochaska and DiClemente in 1983, postulates that adopting a new behaviour involves an evolution through a series of distinct **stages of readiness to change**, and that behaviour change develops over time rather than in a

single decisive moment (Kaplan & Sadock 2024). It grew out of work on why smoking-cessation interventions failed, and its enduring clinical value is that it reframes a "non-compliant" or "unmotivated" patient as simply someone at an earlier stage than the treatment assumes.

Two mediators drive movement. Progress between stages is pushed by two constructs. The **decisional balance** is the weighing of the pros against the cons of change: in the earlier stages (precontemplation, contemplation) patients see more cons than pros, and the balance tips toward pros as they move up (Kaplan & Sadock 2024). **Self-efficacy**, the person's confidence they can change, rises roughly linearly across the stages. Reading a patient's decisional balance and self-efficacy tells you which way they are about to move.

RULE **Assess the stage before you prescribe the task.** Motivation is a stage, not a trait; identify where the patient is on the cycle first, then choose the intervention that fits that stage.

29.2 Precontemplation: no intention to change, often here under pressure

Definition. In precontemplation the person has no intention to change in the foreseeable future. They may deny or be unaware that their substance use is a problem, and they often present only because of pressure from others, feeling coerced or threatened by treatment (Kaplan & Sadock 2024; Clinical Methods in Psychiatry, AIIMS 2024). The discriminator from contemplation is the absence of any recognised problem: the precontemplator does not yet see a reason to change.

What this looks like clinically. The family drags the man in; he insists his drinking is normal and the appointment a waste of time. Confrontation here provokes resistance and dropout. The AIIMS text notes that in exactly this precontemplation presentation, motivational-interviewing technique is what builds rapport and retains the patient in treatment.

29.3 Contemplation: aware of the problem, ambivalent, not yet committed

Definition. In contemplation the person is aware a problem exists and is seriously considering change, but has made no commitment to action. They are stuck between the wish to change and the perceived effort or loss it would cost, the hallmark **ambivalence** of this stage (Kaplan & Sadock 2024). Patients can dwell in contemplation for a long time; one study found people commonly remain contemplative for at least two years before moving on.

The discriminator. Contemplation differs from precontemplation by the presence of problem-recognition, and from preparation by the absence of a near-term plan or commitment. "I know I should cut down, but..." is the contemplation sentence. Pushing an action plan now, before ambivalence is resolved, is premature.

29.4 Preparation: committed and taking the first "baby steps"

Definition. In preparation the person intends to take measurable action in the near future (typically within the next month) and may already be taking small steps, the "baby steps", or reporting minor reductions in use; they may also have made an unsuccessful attempt in the past year (Kaplan & Sadock 2024; Clinical Methods in Psychiatry, AIIMS 2024). This is the stage of intention plus early behaviour, where the commitment that contemplation lacked has formed.

The discriminator. Preparation differs from contemplation by the presence of a plan and near-term commitment, and from action by the fact that the full, overt behaviour change has not yet begun; the changes so far are preparatory and partial.

29.5 Action and maintenance: overt change, then holding the gain past six months

Action. In action the person makes overt modifications to behaviour, experiences or environment to overcome the problem, the visible behaviour change everyone recognises as "doing something about it". The verified time-window for the action stage is **one day to 6 months** (Kaplan & Sadock 2024). Because the change is public, this is where patients get the most external reinforcement (compliments, praise), which itself helps sustain the effort.

Maintenance. After roughly six months of consistent change the person enters maintenance, where the work shifts to consolidating gains and preventing relapse; the operational threshold is remaining free of the problem behaviour, or consistently engaging in the incompatible behaviour, for **more than 6 months** (Kaplan & Sadock 2024; Clinical Methods in Psychiatry, AIIMS 2024). For many addictive behaviours maintenance is effectively lifelong. The purest end-point, **termination** (exiting the cycle with full confidence in every high-risk situation and no relapse-prevention work), is reached by few, which is why the working sixth stage in the addictions is relapse rather than termination.

WORKED EXAMPLE

A woman with alcohol dependence stops drinking and rebuilds her routine (action). Four months in she is clearly changed but not yet at the six-month mark, so she is still in the action stage, not maintenance. At a family wedding she drinks, and over the next weeks slides back into ambivalence, a lapse that becomes relapse and drops her to the contemplation stage. The clinician normalises this as the spiral nature of change, not as failure, and helps her re-enter preparation. The single skill on display is placing her correctly at each turn and matching the response to the stage.

29.6 Relapse as a stage: change spirals, and relapse is the rule not the exception

Definition. Relapse is the stage in which a person who had changed their behaviour falls back into the old pattern of problematic use (Clinical Methods in Psychiatry, AIIMS 2024). The AIIMS text explicitly lists six stages, precontemplation, contemplation, preparation, action, maintenance and relapse, treating relapse as a formal stage of the addiction model, which is the framing this topic teaches.

The spiral, not the line. People move through the stages in a spiral rather than a linear pattern; relapse is the rule rather than the exception, and it is common to regress to an earlier stage and cycle through again (Kaplan & Sadock 2024). The clinical instruction that follows is to educate the patient from the outset about the spiral nature of change and to normalise relapse, because a relapse read as total failure drives the patient out of treatment, whereas a relapse read as a re-entry point keeps them in the cycle.

TRAP **Treating relapse as failure.** Relapse is a predictable stage of the spiral; framing it as the end of treatment, rather than as a return to contemplation or preparation, loses the patient at the moment they most need to re-engage.

STAGE	CORE DEFINITION	TIME-ANCHOR / DISCRIMINATOR
Precontemplation	**No intention to change; problem not recognised; often here under pressure**	No problem-recognition (vs contemplation)
Contemplation	Aware of problem; ambivalent; no commitment	**Can persist about 2 years**
Preparation	Intends to act soon; making "baby steps"	Action intended within the next month
Action	**Overt behaviour change in progress**	One day to 6 months
Maintenance	Consolidating gains; preventing relapse	**Sustained beyond 6 months**
Relapse	Return to the old problematic pattern	Re-enters the spiral (to contemplation / preparation)

The six stages of change of the transtheoretical model, with the verified time-anchors and the key inter-stage discriminators (Kaplan & Sadock 2024; Clinical Methods in Psychiatry, AIIMS 2024). Relapse is treated as a stage per the AIIMS assessment framing.

6	1 day to 6	>6
STAGES: PRECONTEMPLATION, CONTEMPLATION, PREPARATION, ACTION, MAINTENANCE, RELAPSE	ACTION-STAGE DURATION, IN MONTHS	MONTHS OF SUSTAINED CHANGE DEFINING MAINTENANCE

29.7 Stage-matched interventions: the whole clinical payoff of the model

The principle. The reason to stage a patient is to deliver matched interventions: treatment is most effective when the clinician matches the goal and technique to the patient's current stage of change (Kaplan & Sadock 2024). Most treatments, including many addiction programmes, are action-oriented and wrongly assume everyone is in the action stage; giving action tasks to a contemplation-stage patient predictably produces failure or dropout. Aiming to move a patient just one stage can roughly double the chance they will engage in change on their own later.

The stage-to-technique map. The motivational-interviewing strategies are keyed to the stage, and the specific technique for each is what the wider Psychotherapies, clinical assessment, MSE and nosology notes develop as the general MI frame. Here the point is the pairing: *precontemplation* gets non-confrontational awareness-raising, rolling with resistance and developing discrepancy; *contemplation* gets the pros-and-cons of change (tipping the decisional balance), normalising ambivalence and building self-efficacy; *preparation* gets goal-setting, exploring options, reinforcing personal choice and drafting a concrete plan; *action* gets active support of self-efficacy and problem-solving; *maintenance* and *relapse* get relapse-prevention work (the Marlatt high-risk-situation and lapse-versus-relapse model, developed alongside this topic).

STAGE	MATCHED INTERVENTION (WHAT TO ACTUALLY DO)
Precontemplation	**Raise awareness, roll with resistance, develop discrepancy; do not confront**
Contemplation	Weigh pros and cons, normalise ambivalence, explore barriers, build self-efficacy
Preparation	**Clarify goals, explore options, reinforce choice, develop a plan**
Action	Support self-efficacy, problem-solve, reinforce the change
Maintenance / relapse	**Relapse prevention: identify high-risk situations, coping, re-entry after a lapse**

Stage-matched motivational-interviewing strategies (Kaplan & Sadock 2024, Table 27.4-8, adapted); the general MI technique is taught in the Psychotherapies, clinical assessment, MSE and nosology notes.

PEARL

The single most testable clinical rule of the model is the mismatch failure: an action task handed to a contemplation-stage patient. Whenever an addiction patient is labelled "unmotivated" or "non-compliant", re-read it as a staging error, they are almost always in precontemplation or contemplation, and the fix is a stage-matched motivational, not an action-oriented, intervention.

29.8 The Indian assessment context: staging is a formal item of the addiction interview

The frame. In the AIIMS Clinical Methods method, motivation is assessed as a dynamic phenomenon in three domains: whether motivation is fair, poor or doubtful; the *stage of change* per the transtheoretical model of Prochaska and DiClemente; and the **locus of control**, internal (change depends on my actions) versus external (it depends on fate, luck or powerful others) (Clinical Methods in Psychiatry, AIIMS 2024). Motivation must be assessed *per substance*: the same patient may have fair motivation to quit opioids but poor motivation to quit tobacco, and separately for quitting versus harm reduction (a man may be motivated to stop drink-driving but not to stop drinking).

Why it fits the treatment gap. India carries a very large substance-use treatment gap, and the IPS strategy to close it leans on brief, motivation-based psychosocial interventions delivered by trained non-specialist workers, with motivational enhancement therapy and relapse-prevention CBT as core, evidence-supported components (IPS 2014). Because those interventions are explicitly stage-driven, the transtheoretical model is the scaffold on which motivation-based Indian addiction care is built. The wider medico-legal and NDPS frame for coerced or diverted patients (who often present in precontemplation) sits in the Mental health legislation and forensic psychiatry notes.

INDIA

The AIIMS Clinical Methods in Psychiatry (2024) makes staging a formal, recorded item of the addiction history: stage of change (six stages, relapse included), the fair-poor-doubtful motivation grade, and internal-versus-external locus of control, assessed separately for each substance and for the quit-versus-harm-reduction goal. This dovetails with the IPS treatment-gap strategy of brief, motivation-based, non-specialist-deliverable care (motivational enhancement therapy, relapse-prevention CBT), so the transtheoretical model is the working backbone of Indian motivation-based addiction practice.

MNEMONIC

Please Come Prepared And Maintain Recovery

Precontemplation, Contemplation, Preparation, Action, Maintenance, Relapse, the six stages in order, with Relapse as the sixth stage feeding back into the spiral.

GOOD TO REMEMBER

- **Transtheoretical model (Prochaska and DiClemente, 1983):** six stages of change, precontemplation (no intention, no problem recognised), contemplation (aware, ambivalent, uncommitted, can last about 2 years), preparation (committed, near-term plan, baby steps), action (overt change, one day to 6 months), maintenance (sustained beyond 6 months), and relapse (return to the old pattern); movement is a spiral, driven by decisional balance and self-efficacy; the clinical payoff is stage-matched intervention, and the classic error is an action task given to a contemplation-stage patient.

HOLD THIS

Six stages in order, precontemplation, contemplation, preparation, action (one day to 6 months), maintenance (beyond 6 months), relapse, moving as a spiral in which relapse is the rule; match the intervention to the stage, and never hand an action task to a contemplation-stage patient.

30 · Relapse prevention (Marlatt)

Getting a person sober is the easy part; keeping them sober is the whole of the work, and **relapse prevention** is the cognitive-behavioural model that turns "staying stopped" from a matter of willpower into a set of teachable skills. Built by Alan Marlatt and Judith Gordon in the 1980s, the Marlatt model reframes relapse not as a moral collapse but as the predictable end-point of a chain: a **high-risk situation** meets a person who lacks a coping response, confidence drops, the substance is used, and a distorted appraisal of that first slip (the **abstinence violation effect**) tips a single lapse into a full relapse (Companion to Psychiatric Studies; Kaplan & Sadock 2024). Because every link in that chain is a target, the model is the theoretical spine under the relapse-prevention module of almost every structured addiction programme.

Why it matters in exams. Examiners want you to know that relapse prevention is a specific, named, evidence-based cognitive-behavioural intervention (not a vague "avoid triggers" homily), to reproduce the three empirical **determinants of relapse** that account for most slips, to define the **abstinence violation effect** and the **seemingly irrelevant decisions** that feed it, and to list

the two arms of treatment: the reactive **coping**-skills arm for the high-risk moment and the proactive lifestyle-balance arm for the background risk. The India device is genuine here: against a very large treatment gap, relapse prevention and motivation enhancement are named by the Indian Psychiatric Society as the core, non-specialist-deliverable psychosocial interventions for addiction (IPS 2014). This topic carries Fig 13.20, the Marlatt relapse-prevention model as a chain from high-risk situation through coping (or its failure) to lapse and the abstinence violation effect.

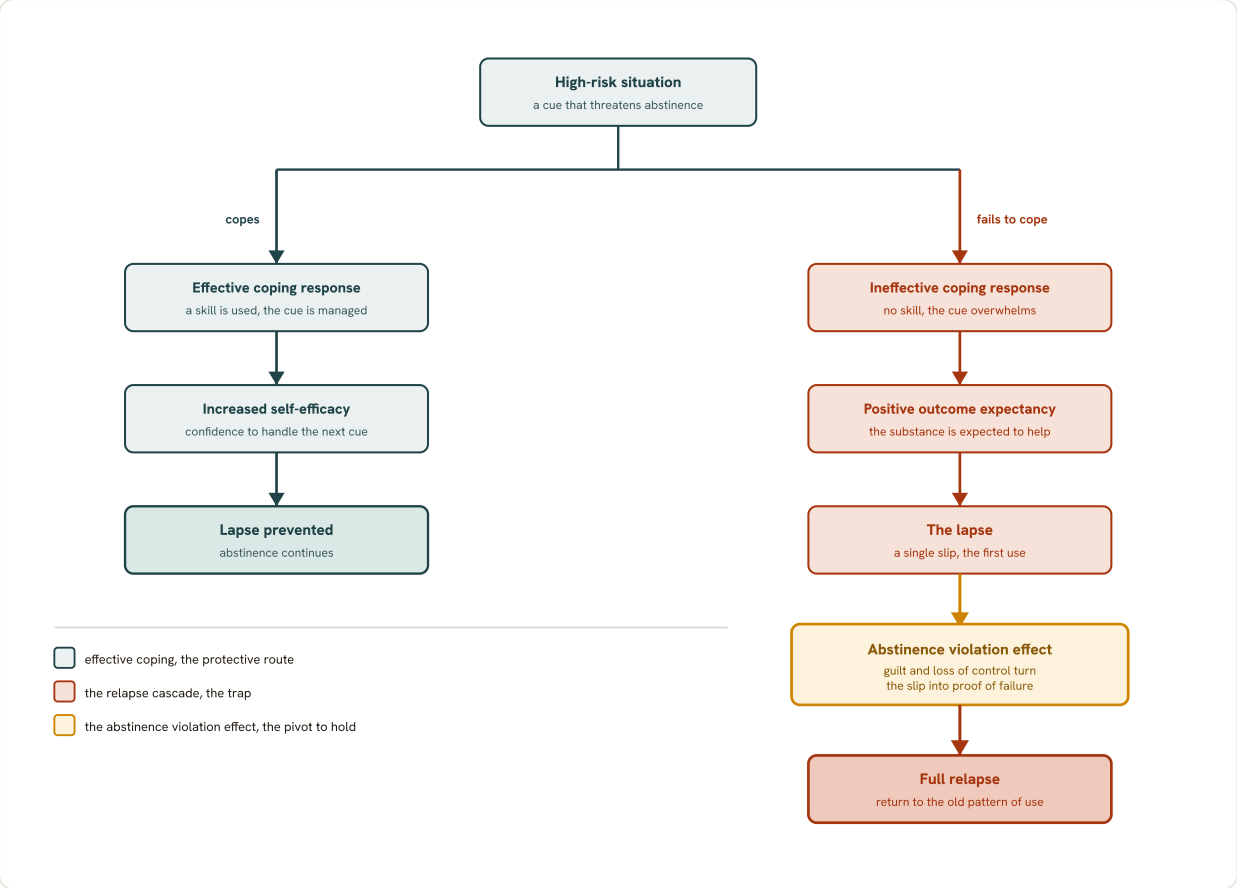

Fig 13.20 The Marlatt relapse-prevention model and the abstinence violation effect. A high-risk situation forces a choice. An effective coping response raises self-efficacy and the lapse is prevented, so abstinence holds. An ineffective response, driven by a positive outcome expectancy that the substance will help, leads to a lapse, a single slip. What decides whether that slip becomes a full relapse is the abstinence violation effect: guilt and a sense of lost control reframe the slip as proof of personal failure, and that self-attribution drives the return to the old pattern of use.

30.1 What relapse prevention is: a cognitive-behavioural self-management model

The definition. Relapse prevention is a cognitive-behavioural, self-management approach that teaches a person recovering from a substance use disorder to anticipate the situations that threaten abstinence, to build and rehearse the coping responses that carry them through, and to limit the damage if a slip occurs (Marlatt & Gordon; Companion to Psychiatric Studies). It sits in the **maintenance** phase of the stages-of-change cycle, the phase whose defining task is precisely to prevent a return to use and to keep the changes already made (the transtheoretical wheel is developed elsewhere in this chapter).

The premise. The model rests on a single reframe: relapse is a *process*, not an event. It does not descend out of nowhere; it is the visible end of a chain of antecedents that begins long before the

drink or the injection, which means each antecedent is a point at which the chain can be broken. That is what makes it teachable and testable (Kaplan & Sadock 2024).

RULE **Relapse is a process, not an event.** Treat every slip as the end of an identifiable chain of antecedents, and prevention becomes a matter of teaching skills at each link rather than exhorting willpower.

30.2 The high-risk situation: the pivot of the whole model

What it is. A high-risk situation is any circumstance that threatens a person's sense of control and raises the risk of a return to use (Marlatt & Gordon). It is the pivot of the model: what happens next depends entirely on whether the person has a coping response for it. If they do, and use it, self-efficacy rises and the risk of relapse falls; if they lack one or fail to deploy it, self-efficacy falls, an *expectancy* of the substance's positive effects moves to the front of the mind, and the probability of a lapse climbs sharply (Companion to Psychiatric Studies).

The clinical use. The first practical task of relapse prevention is therefore to help the patient identify *their own* personal high-risk situations, because these are idiosyncratic, and to catch the early warning signs that one is approaching, before the coping window has closed (Daley & Douaihy, Managing Your Substance Use Disorder; IPS 2014).

30.3 The determinants of relapse: the three that account for most slips

The taxonomy. When Marlatt and Gordon classified the situations in which relapses actually occurred, three **determinants of relapse** accounted for the large majority of them: **negative emotional states** (anger, anxiety, boredom, depression, frustration), **interpersonal conflict** (arguments and confrontations, most often with family or partner), and **social pressure** (both direct offers to use and the indirect pull of being around others who are using) (Companion to Psychiatric Studies; Kaplan & Sadock 2024). Negative emotional states are consistently the single commonest category. These three are the answer to "name the determinants of relapse".

Why it is high-yield. Naming these three lets you map any given patient's slips onto a known structure and pick the coping skill that fits: emotion-regulation and distress-tolerance for the affective determinant, communication and assertiveness training for the interpersonal one, and drink- and drug-refusal skills for the social-pressure one (Daley & Douaihy).

DETERMINANT OF RELAPSE	TYPICAL TRIGGER	COPING SKILL IT CALLS FOR
Negative emotional states	Anger, anxiety, boredom, depression, frustration (the commonest category)	Emotion regulation, distress tolerance, urge-surfing
Interpersonal conflict	Argument or confrontation, usually with family or partner	Communication and assertiveness training, conflict resolution
Social pressure	Direct offer to use, or indirect pull of a using peer group	Drink- and drug-refusal skills, avoiding using company

Marlatt and Gordon's three high-yield determinants of relapse, the trigger each represents and the coping skill it demands (Companion to Psychiatric Studies; Kaplan & Sadock 2024).

30.4 The abstinence violation effect: how one lapse becomes a relapse

The distinction first. The model draws a sharp line between a **lapse** (a single, discrete slip, one drink, one use) and a **relapse** (a full return to the prior pattern of dependent use). A lapse is not a relapse, and the whole point of the model is that the space between the two is where prevention still works (Daley & Douaihy).

The effect itself. The abstinence violation effect is the cognitive-affective reaction that turns a lapse into a relapse. After breaking a self-imposed rule of abstinence, the person experiences a burst of guilt and self-blame plus an *all-or-nothing* attribution, "I've blown it, my willpower has failed, I have no control, so I might as well keep going" (Companion to Psychiatric Studies; the McCrady CBT programme). The lapse is attributed internally, globally and to a stable personal failing rather than to the specific situation, which drives the mood lower and makes continued use feel inevitable. Left unchallenged, this appraisal, not the pharmacology of the first drink, is what converts the slip into a full relapse. The countermeasure is to pre-teach the patient that a lapse is a predictable, correctable event to learn from, not proof of failure, so the thought can be disputed the moment it appears.

TRAP **Treating a lapse as a relapse.** The clinician (or patient) who reads a single slip as total failure enacts the abstinence violation effect and helps cause the very relapse they fear; frame the lapse as a learning point and intervene in the gap.

30.5 Seemingly irrelevant decisions: the covert set-up for a lapse

The concept. Seemingly irrelevant decisions (also called apparently irrelevant decisions) are the small, individually innocent-looking choices that, in series, steer a person into a high-risk situation while preserving the illusion that the eventual lapse was unplanned and unavoidable. Marlatt's example is the recovering drinker who chooses the route home that happens to pass the old bar, or keeps alcohol in the house "for guests": each decision is defensible on its own, but together they set up the encounter with the high-risk situation (Marlatt & Gordon; Companion to Psychiatric Studies).

The clinical use. Teaching patients to spot their own seemingly irrelevant decisions moves prevention *upstream* of the high-risk situation itself: the safest place to break the chain is at the small choice, hours or days earlier, not at the moment of maximum craving. Each such decision is a fork with a low-risk and a high-risk branch, and the work is to make the low-risk choice consciously (Daley & Douaihy).

WORKED EXAMPLE

A man three months abstinent from alcohol agrees to host a cricket-match gathering, buys beer "for the friends", and keeps it chilled in his own fridge. Each step felt trivial and hospitable. By match-time he is alone in the kitchen beside cold beer after an argument with his wife: a seemingly-irrelevant-decision chain (host, buy, chill, keep) has delivered him into a high-risk situation stacked with two determinants at once, social pressure and interpersonal conflict. The lapse that follows will feel like it "just happened"; the model shows it was set up several innocent choices earlier.

30.6 Coping skills: the reactive arm for the high-risk moment

The core intervention. The reactive arm of relapse prevention is coping-skills training: equipping the person with a specific, rehearsed response for each high-risk situation so that when it arrives the response fires instead of the substance. The presence or absence of an effective coping response at the high-risk moment is, in the model, the single strongest predictor of whether that situation ends in a lapse (Marlatt & Gordon; Companion to Psychiatric Studies).

The toolkit. Coping skills are cognitive, behavioural and interpersonal: managing cravings by **urge-surfing** (riding the craving out on the knowledge that urges peak and fall within minutes rather than acting on it), challenging permission-giving thoughts, refusing offers assertively, resolving interpersonal conflict, regulating negative affect, and using a rehearsed emergency plan (leave the situation, wait it out, phone a support) (Daley & Douaihy; McCrady CBT programme). Crucially the skills are *practised*, often by role-play, before they are needed, and each successful use raises self-efficacy, which is itself protective.

PEARL

Cravings are self-limiting. The single most useful thing to tell a patient is that an urge is a wave, not a straight line: it rises, crests within a few minutes and falls whether or not they use. Urge-surfing exploits exactly this, and it reframes "I can't stand this craving" into "I only have to outlast it".

30.7 Lifestyle balance: the proactive arm that lowers background risk

The idea. The proactive arm targets the person's whole life, not just the high-risk moment. Marlatt framed it as **lifestyle balance**: the ratio of perceived "shoulds" (duties, obligations, stressors) to "wants" (pleasures, satisfactions). A life heavy with shoulds and starved of wants breeds a background sense of deprivation and a felt entitlement to indulge ("I deserve this"), which primes both the negative emotional states and the permission-giving thoughts that fuel relapse (Marlatt & Gordon; Daley & Douaihy).

The intervention. Restoring balance means deliberately building in non-chemical sources of pleasure and mastery, so-called *positive addictions* such as exercise, and using regular activities, relaxation, structured routine and a supportive recovery network to lower the baseline stress from which high-risk situations grow (Daley & Douaihy, Strategies for Balanced Living). Where the coping arm defuses the acute high-risk situation, the lifestyle arm reduces how often those situations arise in the first place.

GOOD TO REMEMBER

- **Abstinence violation effect (syndrome/concept):** the guilt-plus-loss-of-control cognitive reaction after a lapse ("I've blown it, might as well continue"), with an internal, global, stable attribution to personal failing; it is what converts a single lapse into a full relapse; the discriminator is that it is a cognitive-affective response to a slip, not the pharmacological effect of the substance; first management step is to pre-teach that a lapse is a correctable learning point and to dispute the all-or-nothing thought immediately.

30.8 Putting it together and the India frame: the two-arm model and the treatment gap

The whole model in one line. Relapse prevention runs on two arms: a reactive arm (identify high-risk situations and their determinants, spot the seemingly irrelevant decisions that lead into them, deploy a rehearsed coping response, and reframe any lapse to disarm the abstinence violation effect) and a proactive arm (lifestyle balance, positive addictions and a recovery network to lower background risk). Both are delivered on top of, not instead of, anti-craving pharmacotherapy where indicated (the disulfiram, naltrexone and acamprosate detail sits with the anti-craving topics of this chapter).

The India lens. India carries a very large substance-use **treatment gap**, with the national survey estimating that roughly **91%** of people with a substance use disorder receive no structured treatment, and care concentrated in government de-addiction centres and Drug De-addiction Programme units rather than general practice. Against that gap the Indian Psychiatric Society names cognitive-behavioural, motivation-enhancement and relapse-prevention approaches as the core, evidence-based psychosocial interventions for addiction, and pushes them toward community and home-based delivery by trained non-specialist workers precisely because relapse prevention is a structured, manualisable skill set that does not require a specialist to teach (IPS 2014). The NDPS Act frame and the wider medico-legal detail sit in the Mental health legislation and forensic psychiatry notes; the wider MI and general-CBT technique sits in the Psychotherapies, clinical assessment, MSE and nosology notes.

INDIA

Relapse prevention is the most exportable of the addiction psychotherapies for the Indian context: it is protocol-driven, teachable to a counsellor or trained non-specialist, and family-embeddable, which matters where a co-resident relative is often the recovery monitor. The IPS clinical practice guidelines pair a structured relapse-prevention and motivation-enhancement package with anti-craving pharmacotherapy and family-based supervision as the standard maintenance offer, and the community and home-based delivery model is the strategic response to the roughly 91% treatment gap. The de-addiction centre and the district day care service are where the model is most often taught.

3	2	91%
DETERMINANTS OF RELAPSE (NEGATIVE AFFECT, INTERPERSONAL CONFLICT, SOCIAL PRESSURE)	ARMS: COPING SKILLS PLUS LIFESTYLE BALANCE	INDIA SUBSTANCE-USE TREATMENT GAP (NATIONAL SURVEY)

MNEMONIC

A HALT before you slip

The classic recovery cue **HALT** (Hungry, Angry, Lonely, Tired) names the everyday states that most often become high-risk situations; "Angry" and "Lonely" map onto Marlatt's negative-emotional-state and interpersonal determinants. Teaching the patient to HALT and check is a simple, non-specialist-deliverable coping trigger.

HOLD THIS
Marlatt's chain is: high-risk situation to no coping response to lapse to abstinence violation effect to relapse, so the three intervention points are coping skills at the situation, seemingly-irrelevant-decision awareness upstream of it, and reframing the lapse to break the abstinence violation effect.

31 · Brief interventions and FRAMES

Most hazardous drinkers and drug users are found not in a de-addiction bed but in a general clinic, presenting for something else, and caught only if someone screens and then *says something useful in the ten minutes that follow*. That short, structured, opportunistic conversation is the **brief intervention**, and the examiner's favourite way to test whether you know its anatomy is the acronym **FRAMES**. It matters because brief intervention is the highest-reach tool in the whole substance block: it needs no drug, no laboratory and no specialist, it works precisely at the reversible hazardous-and-harmful stage, and it is written into the Indian guidelines as the front line against the treatment gap (IPS 2014). Get the six FRAMES elements, the delivery model that wraps around them, and how they relate to motivational enhancement therapy, and you can answer anything asked here.

Why it matters clinically. A screen only labels risk; the brief intervention is what you actually *do* about a positive AUDIT before the person is dependent. Its verified place is hazardous and harmful use not yet meeting dependence criteria, delivered in roughly **5 to 15 minutes** (IPS 2014). The underlying conversational skill is motivational interviewing, owned and taught fully in the Psychotherapies, clinical assessment, MSE and nosology notes and applied to substances alongside this topic; here the focus is the packaged short-contact structure, its scaffold FRAMES, and the delivery frame **SBIRT**.

31.1 What a brief intervention is: the short opportunistic conversation for the not-yet-dependent

The definition. A brief intervention is a time-limited, structured conversation, typically one to four short contacts of **5 to 15 minutes**, that aims to reduce risky substance use in people who are not seeking treatment and are not yet dependent (Tasman 2015; IPS 2014). It is opportunistic: it is delivered off the back of a positive screen, in the setting where the person already is, by whoever is there, rather than requiring a referral to a specialist first.

Who it is for. The evidence base is strongest for **hazardous** and **harmful** drinking, and by extension risky use of other substances, in people who have not yet crossed into dependence (Tasman 2015; IPS 2014). For dependence, a brief intervention is not enough on its own; it becomes the motivational front end that leads into fuller psychosocial treatment and pharmacotherapy.

RULE **Brief intervention targets hazardous and harmful use, not dependence.** Its job is early, at the reversible end flagged by a positive screen; established dependence needs assisted withdrawal, anti-craving pharmacotherapy and structured psychosocial treatment, with the brief intervention only as the motivational entry point.

31.2 FRAMES: the six active ingredients of an effective brief intervention

The scaffold. When researchers dismantled the brief interventions that actually worked, the common components distilled into the acronym FRAMES: **feedback responsibility advice menu empathy self-efficacy** (Bien, Miller and Tonigan 1993; Tasman 2015). It is the single most exam-quotable structure in this topic, because it converts a vague "give some advice" into a checkable six-part conversation.

Feedback

Personalised, non-judgmental feedback about the person's own use and its risks, ideally against population or clinical norms ("your intake is in the top few per cent for men your age").

Responsibility

Explicit emphasis that the choice to change is the patient's own ("it's up to you what you do with this"); this autonomy statement lowers defensiveness.

Advice

Clear, specific advice to cut down or stop, given plainly rather than implied.

Menu of options

A menu of alternative strategies and goals to choose from, so the person picks the route rather than being prescribed one.

Empathy

A warm, reflective, empathic counselling style throughout, not confrontation.

Self-efficacy

Active support for the person's optimism and belief that they *can* change, the ingredient that turns intention into action.

MNEMONIC

FRAMES

Feedback, **R**esponsibility, **A**dvice, **M**enu of options, **E**mpathy, **S**elf-efficacy, the six components that a brief intervention must contain to be effective. Responsibility (the choice is yours) and Empathy are what stop it collapsing into confrontation or a lecture.

31.3 Where FRAMES came from: the drinker's check-up and personalised feedback

The origin. With FRAMES as a guidepost, William Miller and colleagues built the "drinker's check-up", in which people received *feedback about their own drinking relative to population or clinical norms* and were then helped to explore what that feedback might mean for their motivation to cut down or stop (Miller et al. 1988; Tasman 2015). That personalised-feedback engine is the direct ancestor of the feedback step in motivational enhancement therapy.

Why feedback is the load-bearing element. The feedback is delivered in a motivational, non-confrontational way so the person, not the clinician, draws the conclusion. This is the hinge between a brief intervention and simple advice-giving: the discrepancy between the person's use and the norm does the persuading, evoking their own reasons to change rather than the clinician supplying them.

PEARL

Feedback and the empathic style are what separate a real brief intervention from a health lecture. Reeling off risks at a patient ("you'll wreck your liver") is advice without FRAMES; feeding back their own figures against a norm and letting them respond, while affirming that the choice is theirs, is the intervention that actually shifts drinking.

31.4 SBIRT: the delivery model that wraps around the brief intervention

The frame. The brief intervention lives inside a delivery model called SBIRT, for **screening brief intervention**, referral and treatment (Kaplan and Sadock 2024; APA practice guideline). It formalises a three-step pathway that a non-specialist can run in a general setting: *screen* everyone with a validated tool, deliver a *brief intervention* to those who screen positive at the risky level, and make a *referral to treatment* for those whose use is severe or dependent.

How the steps map to severity. The screen sorts people by risk, and the response is matched to it: reassurance and reinforcement for no or minimal use, a brief intervention for the moderate-risk hazardous or harmful user, and a warm referral to specialist treatment for the high-risk or dependent user (Kaplan and Sadock 2024). SBIRT was developed for and widely adopted in primary care and now runs in a broad range of clinical settings, including mental health services.

WORKED EXAMPLE

A 40-year-old man attends a general clinic for hypertension. You screen with the AUDIT and he scores **12**, in the hazardous-drinking band. You run FRAMES in ten minutes: *feedback* ("your score puts your drinking in the harmful range, well above most men"), *responsibility* ("what you do about that is entirely your call"), *advice* ("my clear advice is to cut down to within safe limits"), a *menu* ("some people set a daily cap, some have alcohol-free days, some use an app, which appeals?"), delivered with *empathy*, and closing on *self-efficacy* ("you managed to quit smoking two years ago, that same resolve will serve you here"). Had he scored above the dependence range you would instead have made a warm referral to treatment, the R and T of SBIRT.

31.5 Screening cut-offs that trigger a brief intervention

The numbers that launch the conversation. A brief intervention is not offered at random; a screening cut-off triggers it. On the AUDIT, a total of **8 to 15** suggests simple brief advice aimed at reducing hazardous drinking, **16 to 19** suggests brief counselling with continued monitoring, and **20 or more** warrants full diagnostic evaluation for dependence (Kaplan and Sadock 2024; Tasman 2015). On the WHO ASSIST, a per-substance involvement score in the **4 to 26** moderate-risk band (11 to 26 for alcohol) is the signal to deliver a brief intervention, with 27 or more directing to more intensive treatment. The scales themselves (the AUDIT, CAGE, DAST and ASSIST forms) are reproduced in the scales gallery.

SCREEN AND SCORE	RISK LEVEL	SBIRT RESPONSE
AUDIT 0 to 7	Low	Reassure, reinforce
AUDIT 8 to 15	**Hazardous / harmful**	**Brief intervention (brief advice)**
AUDIT 16 to 19	Harmful	Brief counselling, monitor
AUDIT 20 or more	Probable dependence	Refer for diagnostic evaluation / treatment
ASSIST 4 to 26 (11 to 26 alcohol)	**Moderate**	**Brief intervention**
ASSIST 27 or more	High	More intensive treatment / referral

Screening scores map onto the graded SBIRT response; the brief intervention lives in the moderate-risk middle band.

31.6 Brief intervention, MET and referral: three points on one continuum

How they relate. The three sit on a single continuum of intensity. A *brief intervention* is the shortest, 5 to 15 minutes of FRAMES for the not-yet-dependent. Motivational enhancement therapy (MET) is the fuller, manualised course, classically **four sessions**, that expands the same motivational spirit and adds structured personalised assessment feedback (Kaplan and Sadock 2024; IPS 2014). *Referral to treatment* is the onward step of SBIRT for those who need specialist care. FRAMES is the shared DNA: its feedback-and-autonomy engine runs through both the brief intervention and MET.

The Indian guideline placement. The IPS clinical practice guidelines list brief interventions (5 to 15 minutes) as evidence-based for hazardous and harmful use, and MET (four structured sessions) alongside CBT and relapse prevention as first-line psychological interventions for dependence, with combined psychosocial-plus-pharmacological care improving outcomes (IPS 2014).

TRAP **Do not deploy a brief intervention as the whole treatment for dependence.** Offering only FRAMES to a dependent drinker, instead of assisted withdrawal, an anti-craving agent and structured psychosocial treatment, is undertreatment; brief intervention is for the hazardous-harmful band, not for entrenched dependence.

31.7 Why brief interventions matter in India: the treatment gap and the non-specialist

The reach argument. Brief interventions are the part of the substance-use toolkit that scales to India's treatment gap, where the large majority meeting dependence criteria never reach the government de-addiction centres or the Drug De-addiction Programme (DDAP) units that hold most formal services. They need no drug, no laboratory and no specialist, which is exactly why the IPS guidelines direct services to deliver "brief, motivation-based psychosocial interventions" with a strategic shift toward community and home-based delivery by trained non-specialist health workers (IPS 2014). WHO mhGAP likewise places motivational and brief interventions among the structured psychosocial options for alcohol use.

INDIA

In an Indian answer, screening plus brief intervention is the front line against the substance-use treatment gap: a validated screen (AUDIT, ASSIST) in a primary-care or general-clinic hand, followed by 5 to 15 minutes of FRAMES, catches the hazardous drinker or user long before they would ever reach a de-addiction centre. The IPS substance-use guidelines build the pathway explicitly around brief, motivation-based intervention by non-specialist workers with community and home-based delivery (IPS 2014). Once a screen flags opioid use, the onward referral runs into opioid-agonist treatment, where buprenorphine is the Indian workhorse, prescribed within the Narcotic Drugs and Psychotropic Substances Act framework; that medico-legal and access detail is developed in the Mental health legislation and forensic psychiatry notes.

5 to 15	8	4
BRIEF-INTERVENTION CONTACT TIME IN MINUTES	AUDIT CUT-OFF TRIGGERING BRIEF ADVICE	MET STRUCTURED SESSIONS (FULLER FORM)

HOLD THIS

A brief intervention is 5 to 15 minutes of FRAMES (Feedback, Responsibility, Advice, Menu of options, Empathy, Self-efficacy) for hazardous and harmful use flagged by a positive screen (AUDIT 8 to 15), delivered inside the SBIRT model (screen, brief intervention, referral, treatment); MET is its four-session manualised sibling.

GOOD TO REMEMBER

- **Brief intervention:** 5 to 15 minute opportunistic FRAMES conversation for hazardous and harmful use not yet dependent; triggered by a positive screen (AUDIT 8 to 15), delivered inside SBIRT (IPS 2014).
- **FRAMES:** Feedback (personalised, against norms), Responsibility (choice is yours), Advice (clear), Menu of options, Empathy (non-confrontational), Self-efficacy (support optimism); the six components an effective brief intervention must contain.
- **SBIRT:** Screening, Brief Intervention, Referral to Treatment, the primary-care delivery model matching response to screened risk; brief intervention for moderate risk, referral for high risk / dependence (Kaplan and Sadock 2024).
- **MET:** motivational enhancement therapy, the manualised four-session expansion of FRAMES with structured personalised feedback; first-line psychosocial intervention in the IPS guidelines (IPS 2014).

32 · Twelve-step facilitation and self-help groups

Most of a person's recovery does not happen in a clinic; it happens in the weeks and months between appointments, and the oldest and most widely spread scaffold for that stretch is the mutual-help fellowship. **Alcoholics Anonymous** and its offspring turned the lived experience of recovering people into a free, ever-present, non-professional support network, and the **twelve-step** philosophy they run on has since been packaged by clinicians into a formal, manualised therapy, **twelve-step facilitation**, whose job is simply to get a patient engaged with the fellowship (Kaplan & Sadock 2024; Shorter Oxford Textbook of Psychiatry). For the exam this is a small but reliably tested cluster: know what a **self-help group** is, name the twelve steps'

organising idea, distinguish the fellowship (AA) from the clinician-delivered therapy that points people at it (TSF), and quote the evidence.

Why it matters in exams. Examiners want a clean separation of three things that candidates routinely blur: the peer fellowship (**aa**, **narcotics anonymous** and the wider family of anonymous groups), the twelve-step programme itself (the spiritual, abstinence-based recovery framework), and **twelve-step facilitation** therapy (a structured, professional intervention that is not the same as attending meetings). They also want the Project MATCH result, the one finding about who does best with TSF, and the India frame: a very large treatment gap in which free, self-sustaining, non-specialist mutual-help groups are exactly the kind of resource a resource-poor system needs.

32.1 What a self-help group is: peer-led, non-professional, free

The definition. A self-help group (mutual-help or mutual-aid group) is a voluntary association of people who share a common problem and meet, without professional leadership, to give each other support, information and encouragement toward recovery (Kaplan & Sadock 2024). The defining features are that it is *peer-led* (members help members; there is no therapist in charge), *non-professional* and unpaid, *free* and open-ended, and organised around a shared identity rather than a treatment contract. In addiction the archetype is Alcoholics Anonymous, and the model has since spread to Narcotics Anonymous, Cocaine Anonymous, Gamblers Anonymous, Nicotine Anonymous and family fellowships.

Why it matters. Because it costs nothing, needs no specialist and is available long after formal treatment ends, the self-help group is the maintenance-phase resource that fills the gap a time-limited clinical service cannot. Its strength, in the textbook's words, lies in the social support and the concrete plan for recovery it gives the member (Kaplan & Sadock 2024).

RULE **Refer, do not just recommend.** A self-help group is a maintenance-phase intervention in its own right; the clinician's job is active linkage (name the group, help find a local meeting, follow up on attendance), not a one-line "you could try AA".

32.2 Alcoholics Anonymous: the founding fellowship

What it is. Alcoholics Anonymous (AA) is a self-help organisation founded in the United States in 1935 (in Akron, Ohio) by two alcoholic men, a stockbroker (Bill Wilson) and a surgeon (Dr Bob Smith), and now present in most countries of the world (Shorter Oxford Textbook of Psychiatry; Tasman Psychiatry). Members attend group meetings, usually twice-weekly, on an open-ended long-term basis; in a crisis a member can obtain immediate help from other members by telephone. The organisation works on the firm belief that recovery requires *complete abstinence*, and it is explicitly non-professional and anonymous.

How it works. Newer members are paired with an experienced **sponsor** who guides them through the programme and is available between meetings; the group provides both confrontation and support for the newcomer (Kaplan & Sadock 2024). The alcoholic is asked to

accept powerlessness over alcohol, to draw on a "power greater than ourselves", and to work through the steps in fellowship with others in recovery.

PEARL

AA is a fellowship, not a treatment a doctor delivers, and it is not for everyone. The Shorter Oxford is candid that the emotional, confessional character of meetings and the evangelical, quasi-religious flavour of the twelve-step approach put some problem drinkers off. The correct exam line is that "anyone with a drink problem should be encouraged to try it", while recognising it will not suit all.

32.3 The twelve steps: the organising philosophy

The idea. Alcoholics Anonymous is built on a set of twelve steps, the fundamental principles to which members adhere (Shorter Oxford Textbook of Psychiatry). The programme is best remembered not as twelve items to recite but as a movement through three phases: an opening admission of powerlessness and unmanageability and a turning to a higher power (steps 1 to 3), a searching moral inventory, confession and readiness to change and to make amends (steps 4 to 9), and an ongoing maintenance of the new way of living plus carrying the message to others (steps 10 to 12). It is an abstinence-based, spiritually framed model of recovery.

What examiners test. That the first step is the admission "we were powerless over alcohol, that our lives had become unmanageable", that the model invokes a "power greater than ourselves", that step twelve is carrying the message to other alcoholics, and that the whole is a spiritual (though non-denominational) rather than a medical framework (Tasman Psychiatry, Table 72-10).

PHASE	STEPS	ORGANISING TASK
Surrender	1 to 3	Admit powerlessness and unmanageability; come to believe a greater power can restore; decide to turn will and life over to that power
Inventory and amends	4 to 9	Searching moral inventory, confession of wrongs, readiness to change defects, list those harmed and make direct amends
Maintenance and service	10 to 12	Continue personal inventory, prayer and meditation, and (having had a spiritual awakening) carry the message to other alcoholics

The twelve steps of Alcoholics Anonymous grouped into their three functional phases; the full step wording is reproduced centrally (Tasman Psychiatry, Table 72-10; AA World Services).

32.4 Narcotics Anonymous and the wider family of anonymous groups

What it is. Narcotics Anonymous (NA) is the drug-focused fellowship that grew directly out of AA, applying the same twelve-step structure and abstinence philosophy to recovery from opioids

and other drugs (Kaplan & Sadock 2024; Tasman Psychiatry). Alongside it sit Cocaine Anonymous, Nicotine Anonymous (NicA) and others, each a peer fellowship for a specific substance, all sharing the AA template: sponsorship, meetings, steps, complete abstinence.

The family groups. The model also extends to the people around the user. Al-Anon is a parallel fellowship (not formally affiliated with AA but sharing its structure and tenets) that supports the partners and family members of drinkers, and Alateen, sponsored by Al-Anon, does the same for their teenage children; Adult Children of Alcoholics (ACOA) is a related group (Tasman Psychiatry; Shorter Oxford). Al-Anon and AA meetings are often held jointly.

WORKED EXAMPLE

A man on buprenorphine maintenance for opioid dependence is stable on medication but isolated and bored, the classic background for a lapse. The clinician does not stop at the prescription: he links the man to a local Narcotics Anonymous meeting for peer support and a sponsor, and points the man's wife toward Al-Anon so the family stress that so often triggers relapse has its own outlet. Medication and mutual-help are complementary, not alternatives, and pairing them is standard maintenance practice (Kaplan & Sadock 2024).

32.5 Twelve-step facilitation therapy: the professional intervention, distinct from the fellowship

The definition. Twelve-step facilitation (TSF) is a structured, manualised, professionally delivered counselling programme whose explicit goal is to help a patient become actively engaged with a twelve-step fellowship such as Alcoholics Anonymous (Project MATCH; Epstein & McCrady, therapist guide). It is *not* the same as attending AA: it is a therapy the clinician runs, typically over about twelve sessions, that promotes the two behaviours known to matter, attending meetings and working the steps, and addresses the patient's ambivalence and obstacles to doing so.

Why the distinction is examinable. AA is a free peer fellowship; TSF is an evidence-based psychotherapy that points the patient at that fellowship. Twelve-step facilitation is described as a standard evidence-based treatment in most addiction services (Kaplan & Sadock 2024), whereas AA itself is a mutual-help organisation, not a clinical treatment. Confusing the two is the classic error here.

TRAP **Equating "going to AA" with "twelve-step facilitation".** TSF is a clinician-delivered, manualised therapy that *facilitates* engagement with the fellowship; AA attendance is the peer activity it promotes. They are tested as two separate things.

32.6 The evidence: Project MATCH and who does best with TSF

Project MATCH. The landmark trial was Project MATCH, a large randomised controlled comparison of three manualised psychological treatments for alcohol problems: twelve-step facilitation, motivational enhancement therapy (MET) and cognitive-behavioural coping-skills therapy (Project MATCH Research Group 1997; Shorter Oxford). The headline result was that the three treatments were broadly *equal* in efficacy, that the trial found few strong patient characteristics predicting which treatment suited whom (the "matching" hypothesis it was

designed to test largely failed), and that outcomes overall were good, with the brief four-session MET as effective as the two more intensive therapies.

The one matching finding to keep. One robust exception did emerge and it is high-yield: patients whose social network strongly supported drinking did particularly well with twelve-step facilitation, plausibly because AA gives them a new, abstinence-supporting social network to replace the drinking one (Epstein & McCrady; Longabaugh 1998). More broadly, TSF is associated with a greater likelihood of maintaining complete abstinence than other outpatient counselling (Project MATCH), and patients with fewer comorbid psychiatric problems tend to do better with the AA-type approach (Shorter Oxford).

GOOD TO REMEMBER

- **Project MATCH (trial):** RCT of TSF vs MET vs CBT for alcohol use disorder; the three were roughly equal and brief MET was as good as the intensive treatments; the discriminator to quote is that patients whose social network supported drinking did best with twelve-step facilitation; TSF is linked to higher rates of complete abstinence than other outpatient counselling.

32.7 Secular alternatives: SMART Recovery and the non-spiritual route

Why they exist. Because the spiritual, higher-power framing of the twelve steps does not suit everyone, a set of secular mutual-help alternatives has grown up. The most prominent is SMART Recovery (Self-Management And Recovery Training), a group programme built on cognitive-behavioural and motivational principles rather than surrender to a higher power; others include Rational Recovery, Women for Sobriety, Men for Sobriety and Moderation Management (Kaplan & Sadock 2024; Daley & Douaihy, Managing Your Substance Use Disorder). SMART Recovery is not incompatible with formal CBT and is a reasonable offer for the patient who declines AA on grounds of its religious tone.

The exam point. Know that a credible secular, CBT-based alternative to the twelve-step fellowships exists (SMART Recovery is the name to give), and that the choice between a twelve-step and a secular group can be matched to the individual patient's beliefs and preferences.

32.8 The India frame: the treatment gap and the place of mutual-help

The gap. India carries a very large substance-use **treatment gap**. The national survey found that roughly **14.6%** of Indians aged 10 to 75 use alcohol, with about 5.7 crore people having an alcohol use disorder, and the National Mental Health Survey put the treatment gap for substance use disorders at about **91.1%** overall (around **86.3%** for alcohol use disorder), meaning the large majority of affected people receive no structured care (Companion to Psychiatric Studies; Clinical Methods in Psychiatry, AIIMS 2024). Care that does exist is concentrated in government de-addiction centres and Drug De-addiction Programme (DDAP) units under the NDPS Act frame rather than in general practice.

Where mutual-help fits. Against that gap, free, self-sustaining, non-professional fellowships are structurally attractive: they need no specialist, cost nothing and continue indefinitely. The Indian Psychiatric Society guidelines name Alcoholics Anonymous referral, alongside twelve-step facilitation and the Community Reinforcement Approach, as evidence-supported components of

relapse prevention, embedded in a family-based model where a co-resident relative acts as recovery monitor (IPS 2014). AA and NA meetings do operate in Indian cities, though coverage is uneven and thinner outside metros, and the fellowships remain a useful adjunct rather than a substitute for pharmacotherapy and structured psychosocial care.

INDIA

Mutual-help groups map neatly onto India's constraints: they are free, run by peers, and outlast the brief window a stretched service can offer, which matters when roughly 9 in 10 people with a substance use disorder get no formal treatment. The IPS clinical practice guidelines fold AA referral and twelve-step facilitation into a family-embedded relapse-prevention package delivered through de-addiction centres and, increasingly, community and home-based non-specialist care. The NDPS Act and the de-addiction-programme structure sit in the Mental health legislation and forensic psychiatry notes; the wider MI and general-CBT technique sit in the Psychotherapies, clinical assessment, MSE and nosology notes.

1935	3	91.1%
AA FOUNDED (AKRON, OHIO) BY A STOCKBROKER AND A SURGEON	PROJECT MATCH TREATMENTS COMPARED: TSF, MET, CBT (ROUGHLY EQUAL)	INDIA SUBSTANCE-USE TREATMENT GAP (NATIONAL MENTAL HEALTH SURVEY)

MNEMONIC

HOW: Honesty, Open-mindedness, Willingness

The recovery-community cue **HOW** (Honesty, Open-mindedness, Willingness) names the three attitudes the twelve-step programme asks of a newcomer: honesty about powerlessness, open-mindedness to a power greater than oneself, and willingness to work the steps and make amends. It is a compact way to remember what "working the programme" actually demands.

HOLD THIS

Keep three things apart: the peer fellowship (AA and Narcotics Anonymous, free, non-professional, abstinence-based, twelve steps), the clinician-delivered therapy that engages patients with it (twelve-step facilitation, evidence-based, roughly equal to MET and CBT in Project MATCH), and the one matching finding worth quoting (patients whose social network supports drinking do best with twelve-step facilitation).

33 · Contingency management and community reinforcement

Two of the behavioural pillars of addiction psychotherapy sit on the same operant idea: if using a substance is a behaviour that has been powerfully reinforced, then not-using has to be reinforced back. **Contingency management** does this narrowly and directly, by paying out a tangible reward every time an objective marker of abstinence is met, while the **community reinforcement approach** does it broadly, by re-engineering the person's whole social world so that a sober life becomes more rewarding than a using one. Both are named, manualised, evidence-based interventions, and both are examinable as the concrete operant answer to "what psychosocial treatment, beyond CBT and motivation enhancement, has the strongest trial

evidence in substance use disorders" (Kaplan & Sadock 2024; New Oxford Textbook of Psychiatry).

Why it matters in exams. Examiners want the operant definition of **contingency management** (reinforcement of a target behaviour, not exhortation), the two reward formats (the **voucher** system and the prize-draw variant) with the idea of an escalating, reset-on-relapse schedule, the fact that it is the single most effective psychosocial approach for stimulant use disorder where no anti-craving drug exists, and the four things that make up the **community reinforcement approach** (**cra**). The India device is genuine: against a very large treatment gap these are low-cost, non-specialist-deliverable, family-embeddable methods, and CRA-style monitored disulfiram supervision by a co-resident relative is already standard practice in the Indian de-addiction model (IPS 2014). This is a brief, low-tier topic; keep the operant spine and the two named interventions.

33.1 Contingency management: the operant definition

The definition. Contingency management is the general application of operant principles to behaviour change: a target behaviour is reinforced by the consistent, immediate delivery of a reward, which strengthens that behaviour and displaces the undesired one (Kaplan & Sadock 2024). In substance use disorders the target is an objective marker of abstinence, most often a negative urine drug screen or a negative breath alcohol reading, and treatment attendance can be reinforced the same way. The reinforcement is delivered by *another person* who monitors the behaviour, which distinguishes it from self-reward and self-control techniques where the patient reinforces themselves (Shorter Oxford Textbook of Psychiatry).

The premise. Drug use is a reinforced behaviour, so abstinence has to compete on the same currency. Contingency management makes the reward for abstinence **immediate, tangible and certain**, precisely the properties that make the drug itself so reinforcing, so that in the moment of choice the reinforced alternative can win (New Oxford Textbook of Psychiatry).

RULE **Reinforce the objective marker, not the promise.** Contingency management rewards a verified negative test or attended session, delivered immediately by a monitor, never a self-reported or future intention to stay clean.

33.2 The four operational stages of contingency management

How it is actually run. A contingency-management programme is built in four stages: (1) *define and record* the target behaviour, with a trained monitor recording an objective marker; (2) choose the **reinforcer** and the schedule; (3) deliver the reinforcer consistently and immediately when the behaviour is met, and withhold it when it is not; and (4) fade the tangible reward toward natural social reinforcers (praise, feeling well, restored relationships) as gains consolidate (Shorter Oxford Textbook of Psychiatry; Kaplan & Sadock 2024). The fading step matters because a programme that never transfers to natural reinforcers cannot be sustained once the vouchers stop.

The token-economy cousin. The formalised, ward-based form of contingency management is the **token economy**, in which specified behaviours earn tokens redeemable for goods or

privileges; some add **response cost**, the withdrawal of a reward after a problem behaviour, and the combination of token reinforcement with response cost can be more effective than either alone (Kaplan & Sadock 2024).

33.3 The voucher system and the prize-draw variant

The voucher model. The classic form is the voucher-based system (Higgins): each negative drug screen earns a voucher of monetary value exchangeable for retail goods or services, never cash, and the value *escalates* with each consecutive negative screen so that a long clean run is worth progressively more, while a positive screen **resets** the voucher value to baseline. That escalate-and-reset schedule is the engine of the method, it makes each additional clean test more valuable than the last and makes a single lapse costly (Kaplan & Sadock 2024; New Oxford Textbook of Psychiatry).

The prize-draw variant. Because vouchers are expensive, a cheaper prize-based ("fishbowl") variant lets each negative screen earn a draw from a bowl of slips, most worth a small prize and a few worth a large one, so the same **incentive** effect is delivered at lower cost through intermittent, variable-magnitude reinforcement. Both formats reward the same objective abstinence marker; they differ only in how the reward is scheduled (Kaplan & Sadock 2024).

FEATURE	VOUCHER SYSTEM	PRIZE-DRAW (FISHBOWL) VARIANT
Reward earned for	Negative drug/alcohol screen or attendance	Negative drug/alcohol screen or attendance
Reward form	**Escalating-value voucher for goods (never cash)**	**Draw for a prize of variable magnitude**
Schedule	Escalates with consecutive negatives; resets on a positive	Intermittent, variable-magnitude reinforcement
Trade-off	Strong effect, higher cost	Lower cost, exploits variable reinforcement

The two reward formats of contingency management: the escalating voucher and the lower-cost prize draw, both reinforcing the same objective abstinence marker (Kaplan & Sadock 2024; New Oxford Textbook of Psychiatry).

33.4 Where contingency management earns its place: the stimulant gap

The high-yield indication. Contingency management is one of only three behavioural approaches (with CBT and twelve-step facilitation) that carry the strongest empirical grounding for **stimulant use disorder**, and it matters most there precisely because *no effective anti-craving medication exists* for cocaine or amphetamine dependence, so a robust psychosocial method carries the treatment (Kaplan & Sadock 2024; Tasman). Head-to-head, contingency management often outperforms other psychosocial approaches such as CBT for reducing drug use and improving treatment retention, and its benefit holds even in patients with comorbid serious mental illness (Shorter Oxford Textbook of Psychiatry; New Oxford Textbook of Psychiatry). It also works for smoking cessation and cannabis use disorder.

The limitation. Its main weakness is durability: the effect can fade once the reinforcement schedule ends, which is exactly why the fourth stage, fading to natural reinforcers, and pairing

with a skills-based intervention such as relapse prevention are built in (New Oxford Textbook of Psychiatry).

TRAP **Reading contingency management as "bribing addicts".** The reflex objection (paying people to do what they should do anyway) misreads an operant treatment with strong trial evidence, especially in stimulant use where it may be the single most effective psychosocial option; the real constraints are cost and durability, not principle.

33.5 The community reinforcement approach: re-engineering the social world

The definition. The community reinforcement approach (**cra**) is a broad behavioural, social-network treatment whose overall aim is to rearrange the drinker's or user's environment so that a sober life is more rewarding than a using one (Shorter Oxford Textbook of Psychiatry; Companion to Psychiatric Studies). Where contingency management reinforces one narrow marker, CRA reinforces a whole sober lifestyle by making the person's family, work, and social contacts the source of reward for positive change (Kaplan & Sadock 2024).

The four working parts. CRA is an amalgam of components: (1) *skills training*, including communication, problem-solving and assertive drink- or drug-refusal skills; (2) *relationship and family therapy*, engaging the partner and social network to reward sobriety; (3) *vocational and recreational* counselling to build non-using sources of satisfaction; and (4) frequently, disulfiram with *monitored compliance*, plus contingency management embedded within it (New Oxford Textbook of Psychiatry; Shorter Oxford Textbook of Psychiatry). Crucially, in CRA the family members are part of the therapist's working team, not themselves the subject of treatment (Companion to Psychiatric Studies).

WORKED EXAMPLE

A man with alcohol dependence starts supervised disulfiram, his wife agreeing to watch him take the morning dose and to praise each dosed, sober day rather than nag about past drinking. In clinic he rehearses refusing a drink at a family function, and the counsellor helps him re-enter a cricket club and pursue a job lead so his week fills with non-drinking rewards. Each element is a CRA component: monitored disulfiram, family as reward-monitor, refusal-skills training, and vocational and recreational re-engagement, together tilting his environment so sobriety pays.

33.6 CRA and family training, and the India frame

CRAFT. A named extension, **community reinforcement and family training** (CRAFT), works through the concerned family member of a person who will not yet engage in treatment, teaching the relative to reinforce non-using behaviour, withdraw reward around using, and guide the person toward help; it is one of the more effective ways of getting a treatment-refusing person into care (Daley & Douaihy). This family-as-agent logic maps closely onto Indian practice.

The India lens. India carries a very large substance-use **treatment gap**: the national survey estimated that around **91%** of people with a substance use disorder receive no structured treatment, with care concentrated in government de-addiction centres and Drug De-addiction Programme units under the NDPS-era policy framework rather than in general practice. CRA

and contingency management fit this setting well because they are low-cost, protocol-driven and deliverable by trained non-specialist workers, and the Indian Psychiatric Society already names the community reinforcement approach and twelve-step facilitation as evidence-supported options alongside family-based treatment in which a co-resident relative acts as recovery monitor and as the supervisor for any prescribed disulfiram (IPS 2014). The NDPS Act and the wider medico-legal frame sit in the Mental health legislation and forensic psychiatry notes; the general MI and CBT technique sits in the Psychotherapies, clinical assessment, MSE and nosology notes.

INDIA

Both methods are unusually exportable to the Indian de-addiction context. Contingency management needs only a monitor, an objective test and a modest reward, and CRA's core, family-supervised disulfiram plus refusal-skills and social re-engagement, is already how a district de-addiction centre or the day care service runs relapse prevention through a co-resident relative. Against the roughly 91% treatment gap the IPS clinical practice guidelines push exactly this non-specialist, community and home-based, family-embedded delivery (IPS 2014). Buprenorphine access under the opioid-substitution programme has widened the pharmacological base onto which these psychosocial methods are layered.

MNEMONIC

CRA has SORT

Skills training, **O**ccupational (vocational and recreational) counselling, **R**elationship and family therapy, and **T**ablet with monitored compliance (disulfiram). SORT recalls the four working parts of the community reinforcement approach.

GOOD TO REMEMBER

- **Contingency management (intervention):** operant reinforcement of an *objective* abstinence marker (negative drug screen or attendance) with an immediate, tangible reward delivered by a monitor; two formats, the escalating *voucher* that resets on a positive test and the lower-cost prize-draw variant; the discriminator is that another person delivers the reward for a verified behaviour (unlike self-reward); strongest-evidence psychosocial method for stimulant use disorder where no anti-craving drug exists; main limitation is fade after the schedule ends, so fade to natural reinforcers and pair with relapse prevention.
- **Community reinforcement approach (CRA, intervention):** broad social-network behavioural treatment that rearranges the environment so sobriety out-rewards using; four parts, skills/refusal training, family and relationship therapy, vocational and recreational counselling, and monitored-compliance disulfiram with embedded contingency management; the discriminator is that family are part of the treatment team, not the patients; CRAFT is the family-engagement extension for the treatment-refusing person; first practical step in the Indian model is enlisting a co-resident relative as recovery monitor and disulfiram supervisor.

HOLD THIS

Contingency management reinforces one objective abstinence marker with an immediate reward (escalating voucher or prize draw) and is the top psychosocial method for stimulant use where no drug helps; the community reinforcement approach reinforces the whole sober lifestyle through skills training, family/relationship therapy, vocational counselling and monitored disulfiram, with the family as the reward-delivering team.

Anti-craving and aversive pharmacotherapy

34 · Disulfiram

Disulfiram is the oldest medication for alcohol dependence, and it is examined less for pharmacological cleverness than for the one thing that makes it dangerous: it does nothing to the brain's craving, it only makes drinking *punishing*. It is an **aversive** (deterrent) agent, not an anti-craving agent. A patient who stays away from alcohol feels nothing; a patient who drinks on it suffers a violent, sometimes lethal, physical reaction. That single fact drives every exam point on this drug, the mechanism, the reaction, the dose and above all the **cautions**, so this fragment teaches the drug as a management decision, not a description.

Why it matters clinically. This is a management/drug topic, so the marks sit in the mechanism, the dose, the line and the monitoring. The two most tested, and most dangerous, errors are starting disulfiram in a patient who is still drinking (or intoxicated) and starting it in a patient with cardiac disease: both can precipitate a fatal reaction. Disulfiram is never a withdrawal treatment and never an emergency drug; it is a supervised, consented, maintenance-phase choice for a specific kind of patient. The mesolimbic reward anatomy that anti-craving agents act on, and that disulfiram deliberately does *not*, is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; the NDPS Act frame behind Indian de-addiction prescribing sits in the Mental health legislation and forensic psychiatry notes.

34.1 The mechanism: irreversible aldehyde-dehydrogenase inhibition

Where it acts. Alcohol is metabolised in the liver in two steps: alcohol dehydrogenase (ADH) converts ethanol to **acetaldehyde**, and then aldehyde dehydrogenase (ALDH) converts that toxic acetaldehyde to harmless acetate. Disulfiram *irreversibly* inhibits ALDH, blocking the second step (Stahl 2021; Maudsley 2021; New Oxford 2020). Because the inhibition is irreversible, the effect does not switch off when the drug is stopped: enzyme activity returns only as new ALDH is synthesised, which is why disulfiram's deterrent effect begins within about **12 hours** of the first dose and persists for roughly **7 to 14 days** after the last dose (Stahl 2021).

What accumulates. With ALDH blocked, any ingested ethanol is metabolised to acetaldehyde that cannot be cleared, so blood acetaldehyde rises to 5 to 10 times the level seen when the same amount of alcohol is metabolised normally (New Oxford 2020). Acetaldehyde is the noxious pivot: its accumulation, not disulfiram itself, produces the reaction. This is a deliberate,

pharmacological reproduction of the flush that people with an inherited inactive ALDH variant experience naturally.

MNEMONIC

"ALDH BLOCKED, ACETALDEHYDE STACKED"

Disulfiram irreversibly BLOCKS aldehyde dehydrogenase (ALDH), so acetaldehyde STACKS up when the patient drinks. Everything unpleasant in the disulfiram-ethanol reaction is acetaldehyde toxicity. Because the block is irreversible, stopping the tablet does not stop the danger for up to two weeks.

34.2 The disulfiram-ethanol reaction (DER): what the patient feels

The reaction defined. If a patient drinks alcohol while taking disulfiram, the accumulated acetaldehyde produces the **disulfiram-ethanol reaction** (the **der**, also called the disulfiram-alcohol reaction). Its cardinal features are cutaneous flushing, a throbbing headache, nausea and vomiting, and cardiovascular effects, tachycardia with hypotension, together with sweating, palpitations, tachypnoea (shortness of breath), giddiness and a distinctive sense of impending doom with severe anxiety (Maudsley 2021). The reaction is dose-dependent on both the disulfiram dose and the amount of alcohol taken.

Time-course. The onset is rapid, within about **30 minutes** of drinking; it becomes full-blown within roughly **1 hour** and usually subsides within about **2 hours** in a mild reaction, though it can last several hours. A crucial safety point for counselling and prescribing: because reactions can be triggered by alcohol-containing preparations the patient does not think of as "a drink", cough syrups, tonics, mouthwashes, aftershave, the patient must be warned about these, and warned that a reaction can occur if they drink for up to two weeks after stopping the drug (Stahl 2021).

WORKED EXAMPLE

A motivated man on disulfiram 250 mg daily for four months attends a family wedding and, under pressure, takes "just a small peg". Within twenty minutes his face is flushed and pounding, he is nauseated and vomiting, sweating, breathless, his heart is racing and his blood pressure has dropped. This is the disulfiram-ethanol reaction, the intended aversive consequence. In a mild case it is managed supportively (lie flat, fluids, observe) and settles within a couple of hours. The teaching point is that this is the drug *working*, and it is also exactly why a patient with cardiac disease must never be on it, because the same reaction there can mean a myocardial infarction or arrhythmia.

GOOD TO REMEMBER

- **Disulfiram-ethanol reaction (DER):** the acetaldehyde-mediated reaction on drinking, flushing, throbbing headache, nausea and vomiting, tachycardia with hypotension, sweating, dyspnoea and a sense of impending doom; onset about 30 minutes, full-blown within 1 hour, usually settling within 2 hours; the first management step is supportive (lie flat, fluids, monitor), and a severe reaction (shock, myocardial infarction, arrhythmia, seizures, coma) is a medical emergency.

34.3 How disulfiram works clinically: aversion, not craving

An aversive agent. The therapeutic effect is the *anticipation* of the reaction: knowing that a drink will make them violently ill, the patient does not drink. Disulfiram is therefore an aversive deterrent, an assisted form of behavioural control, rather than a neurochemical anti-craving drug like acamprosate or naltrexone (New Oxford 2020). It does not reduce craving at all, which is both its limitation and the reason compliance is poor: a patient who wants to drink simply stops the tablet a few days beforehand.

Why supervision is the whole game. Because the drug only works if it is actually taken, the evidence is stark: *supervised* disulfiram outperforms placebo and, in some analyses, out-performs acamprosate and naltrexone for maintaining abstinence, whereas *unsupervised* disulfiram is little better than placebo (New Oxford 2020; Maudsley 2021). This is why every guideline ties disulfiram to observed dosing by a reliable family member or carer, a model that fits Indian de-addiction practice especially well.

34.4 The dose and the Indian brands

Standard dosing. The usual oral dose is **250 to 500 mg daily**, typically 250 to 500 mg daily in the first week and **250 mg daily** for maintenance, with a maximum of 500 mg daily (Stahl 2021; IPS 2014). It is often taken at night because it can cause mild sedation, and no taper is needed to stop it (though the enzyme block, and therefore the risk of a reaction, persists for up to two weeks after the last tablet). Guidelines differ slightly on the maintenance figure, NICE anchors to 200 mg daily, IPS to 250 mg daily, which is a legitimate range rather than a contradiction; the safe, examinable core is 250 mg daily with a 200 to 500 mg daily range.

The Indian brands. In Indian practice disulfiram is prescribed as the brands Esperal or Dizone (each a 250 mg scored tablet); the generic is disulfiram (KDT 2019). Lead with the brand at the bedside, but the generic stays primary. Note the older Indian textbook practice of an alcohol *challenge test* under supervision to demonstrate the reaction before discharge, now largely abandoned as unsafe and unnecessary.

PARAMETER	VALUE
Mechanism	irreversible aldehyde-dehydrogenase (ALDH) inhibition
Starting / first-week dose (mg daily)	250 to 500
Maintenance dose (mg daily)	250 (range 200 to 500; NICE anchors 200)
Maximum dose (mg daily)	500
Onset of deterrent effect	within about 12 hours of first dose
Effect persists after stopping	about 7 to 14 days (irreversible block)
Indian brands	Esperal, Dizone (250 mg tablet)
Baseline monitoring	liver function tests, urea and electrolytes

The examinable disulfiram data: an ALDH-inhibiting aversive agent, 250 to 500 mg daily, effect lasting up to two weeks after stopping (Stahl 2021; NICE 2011; IPS 2014).

TRAP **Disulfiram is not a craving drug and not a withdrawal drug.** It has no anti-craving action and no role in detoxification or the acute withdrawal syndrome; giving it to "help withdrawal" or expecting it to reduce urges is wrong, it is a maintenance-phase aversive deterrent that only works when taken under supervision.

34.5 The critical cautions: never in a drinking or cardiac patient

Never while still drinking. The first absolute rule is that disulfiram is *never* started in a patient who is still drinking or intoxicated: with alcohol already on board, the first dose triggers the reaction directly, and it must be begun only after a documented period of abstinence, at least **24 hours** after the last drink (BAP 2026; IPS 2014; NICE 2011; Stahl gives at least 12 hours as the minimum). This is why a still-drinking patient is a hard exclusion and a wrong answer if you start it there.

The cardiac contraindication and other exclusions. The **cardiac contraindication** is the second absolute: disulfiram is contraindicated in ischaemic heart disease (coronary artery disease), heart failure and significant arrhythmia, because the tachycardia and hypotension of a reaction can precipitate myocardial infarction, dangerous arrhythmia or cardiovascular collapse (Stahl 2021). The other important exclusions are significant hepatic impairment or cirrhosis (disulfiram is itself hepatotoxic), current psychosis (past or present), severe renal impairment, peripheral neuropathy, and pregnancy, particularly the first trimester (Stahl 2021). Because the drug is hepatotoxic, baseline and follow-up liver function tests are mandatory, along with baseline urea and electrolytes (NICE 2011; Stahl 2021).

Consent and supervision. Two procedural safeguards are examinable in their own right. First, informed consent: the patient must be fully and explicitly informed about the disulfiram-ethanol reaction, the hidden sources of alcohol, and the two-week carry-over, and must never be given the drug covertly. Second, supervised administration: ideally a co-resident family member or carer observes each dose, because the drug's whole efficacy depends on it actually being taken (BAP 2026; IPS 2014; NICE 2011).

COMMON TRAP

The single most dangerous prescribing error with disulfiram is starting it in a patient who has not stopped drinking (or who has coronary artery disease). Do not be reassured by a patient who says "I'll stop from tonight", confirm at least 24 hours of documented abstinence first, and screen the heart and liver before the first tablet. Starting disulfiram in a still-drinking or cardiac patient can be fatal, and that is exactly the scenario the examiner builds.

GOOD TO REMEMBER

- **Disulfiram (Indian brands Esperal, Dizone):** an irreversible aldehyde-dehydrogenase inhibitor that makes acetaldehyde accumulate on drinking, producing the aversive disulfiram-ethanol reaction; oral 250 to 500 mg daily (maintenance 250 mg daily) as a supervised, consented maintenance option in a motivated, abstinence-goal patient started at least 24 hours after the last drink; the signature cautions are that it is never given to a still-drinking or intoxicated patient, is contraindicated in cardiac disease and significant hepatic impairment, and requires baseline and follow-up liver function tests.

34.6 The guideline position: BAP, Indian Psychiatric Society, NICE and WHO

BAP leads. The British Association for Psychopharmacology (BAP) recommends reserving disulfiram for highly motivated, abstinence-goal patients with family or social support, ideally under supervised administration, and starting it at least 24 hours after the last drink (BAP 2026). BAP rates the evidence for supervised disulfiram highly (strength A in the supplement) but frames it as an option for a specific patient rather than a routine first choice, with acamprosate and naltrexone the first-line anti-craving agents for most people.

The other three. The Indian Psychiatric Society (IPS guidelines) offers disulfiram 250 to 500 mg daily under supervision as an aversive-therapy option, but *only* in motivated patients with a reliable family supervisor, after at least 24 hours of abstinence and with informed consent regarding the disulfiram-ethanol reaction, an explicitly family-supervised model (IPS 2014). NICE positions disulfiram as a second-line relapse-prevention option (200 mg daily, started at least 24 hours after the last drink, overseen by a family member or carer) for patients who want abstinence but for whom acamprosate or naltrexone is unsuitable or not preferred, with monitoring every two weeks for the first two months (NICE 2011; Maudsley 2021). WHO recommends disulfiram only in close-supervision settings for patients motivated for abstinence (WHO mhGAP). All four agree on the same spine: motivated abstinence-goal patient, supervised dosing, informed consent, started only after abstinence.

GUIDELINE	DISULFIRAM POSITION (ALCOHOL RELAPSE PREVENTION)
BAP (2026)	Reserve for highly motivated abstinence-goal patients with support; ideally supervised; start at least 24 hours after last drink (strength A)
Indian Psychiatric Society (2014)	250 to 500 mg daily supervised aversive therapy, only with a reliable family supervisor, after 24 hours abstinence and informed consent re the DER
NICE (2011)	Second-line option (200 mg daily) when acamprosate or naltrexone unsuitable or not preferred; carer-overseen; start at least 24 hours after last drink
WHO (mhGAP)	Only in close-supervision settings for patients motivated for abstinence

The disulfiram position across the four guidelines; BAP leads, and all four converge on a supervised, consented, motivated-abstinence use after documented sobriety.

INDIA

Disulfiram (Esperal, Dizone) fits Indian de-addiction practice unusually well precisely because its one requirement, an observer, is culturally available: a co-resident relative acts as the recovery monitor who supervises each dose, exactly the family-based model the Indian Psychiatric Society recommends (IPS 2014). In the wider treatment-gap picture, where the vast majority of Indians with alcohol dependence never reach specialist care and community and home-based delivery by trained non-specialists is being scaled up, a cheap, non-scheduled tablet supervised by a family member is a pragmatic anti-relapse tool. But the caution cuts the same way: in a de-addiction camp or busy outpatient setting the temptation to start it fast, before the patient has truly stopped drinking or before the heart and liver are checked, is exactly the error that turns a helpful drug into a lethal one.

RULE **Dry first, consented, supervised.** Start disulfiram only in a motivated abstinence-goal patient who has been off alcohol for at least 24 hours, only after screening out cardiac and significant hepatic disease, only with explicit informed consent about the reaction, and only where a reliable person can supervise the dose.

250 to 500 mg	24 hours	7 to 14 days	30 minutes
USUAL DISULFIRAM DAILY DOSE, MAINTENANCE 250 MG DAILY	MINIMUM ABSTINENCE AFTER LAST DRINK BEFORE STARTING	REACTION RISK PERSISTS AFTER STOPPING (IRREVERSIBLE ALDH BLOCK)	ONSET OF THE DISULFIRAM-ETHANOL REACTION AFTER DRINKING

HOLD THIS

Disulfiram (Esperal, Dizone) is an irreversible aldehyde-dehydrogenase inhibitor and an aversive deterrent, not an anti-craving or withdrawal drug: on drinking, acetaldehyde accumulates and produces the disulfiram-ethanol reaction (flushing, throbbing headache, nausea and vomiting, tachycardia and hypotension); give it 250 to 500 mg daily, supervised and consented, only to a motivated abstinence-goal patient started at least 24 hours after the last drink, and never to a patient who is still drinking, intoxicated, or has cardiac or significant hepatic disease, because there the reaction can kill.

35 · Naltrexone for alcohol use disorder

Alcohol is rewarding partly because it releases **endogenous opioids** that, in turn, drive dopamine release into the nucleus accumbens; block the opioid receptor and you blunt that reward, and the drinking loses its pull. That single idea is the whole of **naltrexone for alcohol**. It is the prototype **anti-craving** drug of alcohol use disorder, examined not as a description of dependence but as a management/drug topic: the marks are in the mechanism, the dose, the line and the monitoring. Naltrexone is not a detox drug and not a sedative; it is a relapse-prevention agent that reduces heavy-drinking days and craving in a patient who has already come through withdrawal (or who is cutting down), which is exactly why it earns its place beside acamprosate and disulfiram.

Why it matters clinically. This is the most tested anti-craving agent because it has the cleanest mechanism, a landmark trial (the **COMBINE study**), two dosage forms (oral daily and a monthly long-acting injectable), and one hard contraindication that a wrong answer fails, that it must

never be given to a current opioid user. The opioid and mesolimbic-dopamine reward anatomy it interrupts is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and is not re-derived here; the NDPS Act frame behind Indian de-addiction prescribing sits in the Mental health legislation and forensic psychiatry notes.

50	380	7 to 10	12
ORAL DAILY DOSE (MG), START AT 25	XR INJECTABLE DOSE (MG) MONTHLY IM	OPIOID-FREE DAYS NEEDED BEFORE STARTING	NUMBER-NEEDED-TO-TREAT, HEAVY-DRINKING RELAPSE

35.1 The mechanism: a mu-opioid antagonist that blunts alcohol's reward

How it works. Naltrexone is a competitive, essentially pure mu-opioid antagonist (with weaker kappa and delta antagonism); it binds the mu receptor and initiates no signal (Kaplan and Sadock 2024). Drinking alcohol triggers the release of endogenous opioids (beta-endorphin), which disinhibit ventral-tegmental dopamine neurons and increase dopamine release into the nucleus accumbens, the felt "reward" of a drink. Because a mu-opioid antagonist sits on that receptor and blocks the opioid step, it blunts the enjoyment of heavy drinking and can increase abstinence (Stahl's Substance Use). The upshot is that a lapse produces less reward, so the drive to keep drinking through to intoxication is weakened.

What it is not. Naltrexone has no agonist action, so it produces no "high", no reinforcement, no meaningful withdrawal on stopping and no diversion value; it is a non-scheduled drug prescribable in any clinical setting (Kaplan and Sadock 2024). Crucially, it can be used not only in an abstinent patient but also in one who is still drinking and trying to cut down, because its job is to strip the reward from the alcohol rather than to enforce a prior abstinence (Stahl's Substance Use).

> **PEARL**
>
> Separate naltrexone's mechanism from acamprosate's: naltrexone is a mu-*opioid* antagonist that reduces the *reward* of drinking and best suits the "reward drinker" who drinks for the buzz; acamprosate is a glutamate/NMDA modulator that dampens the protracted *hyperglutamatergic* negative-affect state and best suits the abstinent patient staying dry. They act on different arms of addiction, which is why combining them adds no benefit (COMBINE study).

35.2 The clinical effect: reduces heavy-drinking days and craving

What it actually delivers. Naltrexone's signature effect is that it **reduces heavy drinking**: across a large meta-analysis (53 trials, n = 9,140) its most consistent benefit is preventing the return to heavy drinking and reducing the percentage of drinking days and heavy-drinking days (Kaplan and Sadock 2024). The two original 1990s double-blind trials, in which 50 mg/day was started after at least 7 days abstinent, found naltrexone-treated patients more likely to stay abstinent (**54% vs 31%**) and much less likely to relapse to heavy drinking (**25% vs 52%**); a patient who did lapse was less likely to progress to heavy drinking on naltrexone than on placebo (Kaplan and Sadock 2024).

Craving and the modest overall effect. By reducing the opioid-mediated reward, naltrexone also lowers cue-induced craving, and it works best in high-craving patients and "reward drinkers" (positive-reinforcement drinkers, PREDICT study). Honestly framed, the effect size is modest, with a number-needed-to-treat of about **12** to prevent one return to heavy drinking (VA/DoD), but its good safety profile means it should be offered to essentially any patient with alcohol use disorder who has no contraindication (Kaplan and Sadock 2024).

RULE **Offer an anti-craving agent to every alcohol-dependent patient after withdrawal.** Naltrexone (or acamprosate) plus a structured psychosocial intervention is the standard of care for relapse prevention; the pharmacotherapy is an adjunct to psychosocial treatment, never a substitute for it.

35.3 The evidence base and the COMBINE study

The landmark trial. The COMBINE study (Anton et al, JAMA 2006) was a large multisite US trial (11 academic sites) that tested naltrexone and acamprosate, alone and combined, against placebo, each with either medical management or a more intensive combined behavioural intervention. Its headline result: a **100 mg** dose of naltrexone with medical management was more effective than placebo at increasing percent days abstinent and reducing heavy-drinking days (Kaplan and Sadock 2024). This is the single most quotable trial for naltrexone in alcohol use disorder.

The two negatives worth memorising. COMBINE found *no* benefit from adding acamprosate, either alone or on top of naltrexone, and *no* added benefit from combining naltrexone with acamprosate over naltrexone alone (Tasman 2024; Kaplan and Sadock 2024). It also showed that specialist behavioural therapy added little once naltrexone plus medical management was in place. The exam-safe summary is: naltrexone plus medical management works; adding acamprosate to it does not.

FINDING IN COMBINE (2006)	RESULT
Naltrexone 100 mg + medical management vs placebo	better: more abstinent days, fewer heavy-drinking days
Acamprosate vs placebo	no significant benefit
Naltrexone + acamprosate vs naltrexone alone	no added benefit of the combination
Intensive behavioural therapy added to naltrexone + MM	little additional benefit

The COMBINE study in one table: naltrexone with medical management is the effective arm; adding acamprosate adds nothing (Anton et al 2006; Kaplan and Sadock 2024).

MNEMONIC

COMBINE = Naltrexone wins, combo adds nothing

Read the trial name against its own result: it "combined" drugs and behavioural therapy, and the lesson is that the *combinations* did not help, only naltrexone-with-medical-management beat placebo. Acamprosate neither worked alone nor added to naltrexone.

35.4 The oral form: 50 mg a day (start 25 mg)

The dose. Oral naltrexone for alcohol use disorder is given at **50 mg/day** (25 mg and 50 mg tablets), usually started at 25 mg for a few days to check tolerability, then raised to 50 mg (IPS 2014; NICE 2011). It is begun after medically assisted withdrawal, combined with a structured psychosocial intervention, and typically continued for around 6 months (NICE 2011). Oral bioavailability is about 60%; the active metabolite 6-beta-naltrexol prolongs its action, and the mu blockade after an oral dose lasts up to about 72 hours (Kaplan and Sadock 2024).

Tolerability and monitoring. The common complaints are nausea, headache, dizziness and low mood; these usually settle. Naltrexone is *dose-relatedly* hepatotoxic, but at the therapeutic 50 mg/day it is not hepatotoxic in practice; the documented liver injury was at a sixfold higher 300 mg dose (Kaplan and Sadock 2024). Nonetheless baseline and periodic liver function tests are advised, and it is avoided in acute hepatitis or hepatic failure (NICE 2011; BAP 2026).

GOOD TO REMEMBER

- **Naltrexone (oral; commonly-used Indian brands Nodict or Naltima):** competitive pure mu-opioid antagonist that blunts the opioid-mediated reward of alcohol and reduces heavy-drinking days and craving; oral dose **50 mg/day** (start 25 mg), continued about 6 months with a psychosocial intervention; first-line anti-craving agent after detox; signature caution is precipitated withdrawal if given to a current opioid user (needs a 7-to-10-day opioid-free window), and monitor LFTs for dose-related hepatotoxicity.

35.5 The long-acting injectable: 380 mg IM monthly

Extended-release naltrexone. The long-acting injectable form (XR-NTX, brand Vivitrol) delivers **380 mg** deep intramuscularly once every 4 weeks, using a Medisorb microsphere depot that gives total naltrexone exposure three- to fourfold higher than daily oral dosing, with an elimination half-life of 5 to 10 days (Kaplan and Sadock 2024). A pivotal multisite trial of IM long-acting naltrexone in alcohol dependence showed the 380 mg preparation produced about a **25%** reduction in heavy-drinking days over 6 months, and the effect was larger in patients who had a few days of lead-in abstinence before the first injection (Kaplan and Sadock 2024).

Why the injectable matters. The daily tablet's weakness is adherence, a patient who wants to lapse simply skips it; a single monthly injection removes that daily decision and roughly doubles treatment retention versus oral (Kaplan and Sadock 2024). That is the whole clinical case for the depot: not greater intrinsic efficacy, but guaranteed exposure across the month.

FORM	ROUTE AND SCHEDULE	DOSE (MG)	NOTE
Oral naltrexone	tablet, once daily	50 (start 25)	first-line; adherence-limited; blockade ~72 h
XR-NTX injectable (Vivitrol)	deep IM, every 4 weeks	380	for poor adherence; retention ~2x oral

The two naltrexone forms for alcohol use disorder; the monthly injectable exists to solve the adherence failure of the daily tablet (Kaplan and Sadock 2024).

35.6 The guideline position: BAP first, then IPS, NICE and WHO

BAP (lead position). The British Association for Psychopharmacology (BAP) rates naltrexone strength A and recommends *preferring* naltrexone (oral daily or the monthly extended-release injection) for people with high craving or who are still drinking; it must not be started within a week of any opioid use, and it is avoided for 12 months after long-acting buprenorphine (BAP 2026). BAP also notes that in comorbid bipolar disorder naltrexone is preferred first-line, and that combining acamprosate and naltrexone gives no added benefit. This is the verified first-line anti-craving position and must anchor any answer.

IPS, NICE and WHO. The Indian Psychiatric Society is explicit that naltrexone 50 mg/day PO (titrated from 25 mg) is first-line anti-craving pharmacotherapy after detoxification, combined with a structured psychosocial intervention (IPS guidelines 2014). NICE recommends oral naltrexone after assisted withdrawal in moderate-to-severe dependence, starting 25 mg/day to a 50 mg/day maintenance dose, with an individual psychological intervention and at least monthly supervision for 6 months (NICE 2011). WHO mhGAP offers naltrexone to reduce the return to heavy drinking, and recommends the long-acting injectable where adherence is poor (WHO mhGAP 2016). WFSBP likewise rates oral naltrexone 50 mg/day at its highest recommendation grade for relapse prevention (WFSBP).

GOOD TO REMEMBER

- **Guideline line for naltrexone in alcohol:** BAP prefers it (strength A) for high craving or still-drinking patients, oral daily or monthly injectable; the Indian Psychiatric Society makes oral naltrexone 50 mg/day (start 25 mg) first-line anti-craving after detox; NICE and WHO mhGAP concur, WHO adding the injectable where adherence is poor. All pair it with a psychosocial intervention.

35.7 The critical contraindication: never in a current opioid user

Why it precipitates withdrawal. Because naltrexone is a competitive antagonist, giving it while opioids still occupy the mu receptor displaces the agonist and abruptly strips away all opioid tone, throwing a physiologically opioid-dependent patient into acute, severe **precipitated withdrawal** within minutes (Kaplan and Sadock 2024). This applies even when naltrexone is being prescribed for *alcohol*, so a drinker who is also using opioids (or on an opioid analgesic) cannot simply be started on it. The required opioid-free window is about **7 to 10 days** for short-acting opioids, longer after methadone, and BAP specifically warns to avoid naltrexone for 12 months after long-acting buprenorphine (Kaplan and Sadock 2024; BAP 2026).

The other cautions. Naltrexone is avoided in acute hepatitis and hepatic failure and monitored with LFTs (dose-related hepatotoxicity), and a patient on it cannot be given opioid analgesia through the blockade, so an alternative analgesic plan is needed for surgery or trauma (BAP 2026; VA/DoD).

TRAP **Naltrexone into a current opioid user precipitates withdrawal, even when prescribed for alcohol.** An antagonist onto occupied mu receptors strips the agonist off and causes acute severe withdrawal; confirm an opioid-free interval of about 7 to 10 days (longer after methadone) with a negative urine opioid screen before the first dose, and never start it "to be safe" while opioids may still be on board.

INDIA

In Indian de-addiction practice naltrexone is one of the workhorse anti-craving drugs, because the daily oral tablet is cheap, non-scheduled and prescribable in any setting without the OST licensing that agonist maintenance requires under the Narcotic Drugs and Psychotropic Substances (NDPS) Act, 1985. Against the country's enormous alcohol treatment gap, an affordable oral tablet backed by a co-resident family supervisor who observes the dose (the same family-supervised model used for disulfiram in Indian de-addiction centres and the DDAP model) is a genuinely scalable option. The long-acting depot injection is *not yet routinely available* in Indian practice, so the adherence problem is real and is managed socially rather than pharmacologically. The IPS substance-use guideline places oral naltrexone 50 mg/day first-line for anti-craving after detox (IPS guidelines 2014).

HOLD THIS

Naltrexone is a mu-opioid antagonist that blunts alcohol's reward: oral 50 mg/day (start 25 mg) or 380 mg IM monthly, first-line anti-craving after detox, reduces heavy-drinking days and craving (COMBINE), and must never be started until the patient has been opioid-free for at least 7 to 10 days.

36 · Acamprosate

Where disulfiram works by punishment and naltrexone by blunting reward, **acamprosate** works by repair: it is a neuromodulator that damps down the over-active **glutamate** system left behind by chronic drinking, and so belongs squarely to **abstinence maintenance** in the patient who has *already* been detoxified. It is one of the three classic anti-craving agents, and examiners test it on a small set of exact facts: what it does to the excitatory-inhibitory balance (its **nmda modulation** of the glutamatergic system), that it is a maintenance drug and never a withdrawal treatment, the three-times-daily schedule, the weight-banded dose, and the one contraindication that a wrong answer fails, its **renal dosing** and the renal contraindication (Kaplan and Sadock 2024; Maudsley 2021).

Why it matters clinically. This is a management/drug topic, so the marks are in the drug, the dose, the line and the monitoring, not in a description of alcohol dependence. The two things that make acamprosate clean to answer are its mechanism (it normalises a hyperglutamatergic state rather than aversion or reward) and its safety signature (it is renally, not hepatically, cleared, which flips the usual liver-caution on its head and moves the caution to the kidney). The reward and mesolimbic-dopamine anatomy on which alcohol's pull is built is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and

is not re-derived here; the NDPS Act frame behind Indian de-addiction prescribing sits in the Mental health legislation and forensic psychiatry notes.

36.1 What it is: a glutamatergic neuromodulator for maintaining abstinence

The one-line identity. Acamprosate (calcium acetyl-homotaurinate; Indian brand Acamprol, also marketed as Campral in the West) is a synthetic structural analogue of the amino-acid neurotransmitters, licensed to *maintain abstinence* in the detoxified alcohol-dependent patient (Kaplan and Sadock 2024; Maudsley 2021). It does not sober a person up, does not treat withdrawal, and produces no aversive reaction if the patient drinks; its whole role is to hold a patient who has stopped drinking in abstinence and to help them regain it after a slip.

Where it sits among the three agents. Of the classic trio, disulfiram (Indian brands Esperal, Dizone) is aversive, naltrexone (Indian brands Nodict, Naltima) is reward-blunting, and acamprosate is the neuromodulator that restores disturbed brain chemistry. It is best in the *relief* drinker, the person who drinks to quell the negative affect and hyperexcitability of protracted withdrawal, rather than the *reward* drinker who is better matched to naltrexone (Kaplan and Sadock 2024).

36.2 The mechanism: glutamate, NMDA modulation and the excitatory-inhibitory balance

The neuroadaptation it corrects. Alcohol is a central nervous system depressant that inhibits the NMDA glutamate receptor and enhances GABA. The brain compensates for chronic exposure by up-regulating NMDA receptors and increasing synaptic glutamate release, so that when alcohol is withdrawn there is unopposed excitation, a hyperglutamatergic state that underlies craving, negative affect, disturbed sleep and, at the extreme, withdrawal seizures and delirium tremens (Kaplan and Sadock 2024). Acamprosate acts on exactly this imbalance: it damps the excitatory **glutamate** signalling that persists after drinking stops and so helps restore the excitatory-inhibitory balance the chronic drinker has lost.

The NMDA modulation specifically. Its **nmda modulation** is subtle rather than a simple block: acamprosate behaves as an NMDA partial co-agonist, activating the receptor when glutamatergic tone is low but becoming inhibitory when NMDA activity is pathologically high, which is how it *restores equilibrium* in a disrupted system rather than shutting it down (Kaplan and Sadock 2024). It also acts on metabotropic glutamate receptors (mGluR5), releases the inhibitory neuromodulator taurine, and there is compelling recent evidence that the calcium moiety of the salt is itself important. Structurally it resembles GABA, glycine, aspartate and glutamate, so more than one system is engaged, but the examinable headline is glutamatergic, NMDA-modulating restoration of the excitatory-inhibitory balance, with no aversion and no reward-blockade.

> **PEARL**
>
> The three anti-craving drugs map cleanly onto three mechanisms: disulfiram is aversion (blocks aldehyde dehydrogenase, acetaldehyde piles up), naltrexone is anti-reward (blocks the opioid-mediated pleasure of alcohol), and acamprosate is neuromodulation (damps the hyperglutamatergic, NMDA-driven excitation of protracted withdrawal). Only acamprosate is a pure repair drug: no punishment, no receptor block, just normalisation of disturbed chemistry.

36.3 The indication: abstinence maintenance in the already-detoxified patient

Timing is the whole indication. Acamprosate is for **abstinence maintenance** and is started only after medically assisted withdrawal, once abstinence has been achieved, in moderate-to-severe dependence, and always alongside a psychosocial intervention (NICE 2011; IPS 2014). It should be begun as soon as possible after detoxification, because its effect is time-sensitive: the glutamate dysregulation it targets is highest in early abstinence and normalises over the following weeks, so a drug started late has less to correct (Kaplan and Sadock 2024). One nuance to hold: the British Association for Psychopharmacology notes a potential neuroprotective effect and suggests it can even be started *during* detoxification, whereas trial data show no benefit, and possibly harm, if it is used to treat acute withdrawal itself; the safe examinable line is start early, after abstinence, never as a withdrawal agent (BAP 2026; Maudsley 2021).

What it is not. Acamprosate does not diminish withdrawal symptoms, is not indicated for delirium tremens, and produces no disulfiram-type reaction on relapse. If the patient continues to drink for 4 to 6 weeks after starting it, treatment should be stopped (NICE 2011). It is usually continued for up to 6 months, longer where the patient perceives benefit (Maudsley 2021).

TRAP **Acamprosate is not a withdrawal drug.** It does not touch the acute withdrawal syndrome and is not for delirium tremens; started during active withdrawal it gives no benefit and may worsen outcomes. Detoxify first with a benzodiazepine, achieve abstinence, then start acamprosate to maintain it.

36.4 The dose and the three-times-daily schedule

The weight-banded dose to memorise. Acamprosate comes as a **333 mg** enteric-coated tablet and is given three times daily. For a patient over 60 kg the dose is two tablets three times a day, that is 666 mg three times daily, a total of **1998 mg/day**; for a patient under 60 kg the dose is reduced to **1332 mg/day** (typically two tablets in the morning and one at midday and one at night, or 666 mg twice daily) (Maudsley 2021; NICE 2011; Stahl). The three-times-daily schedule is a genuine limitation: absorption is poor and slow so frequent dosing is needed, and adherence suffers, with about half of patients discontinuing before 6 months, partly because of the TID burden (Kaplan and Sadock 2024).

Why the schedule is what it is. Bioavailability is only about 11%, food reduces absorption slightly (not enough to change dosing), and the drug is so slowly absorbed it behaves like a modified-release preparation, so steady state takes 5 to 7 days; pairing each dose with a meal is a practical adherence tip (Kaplan and Sadock 2024). A useful reframe for the patient is to make the act of taking the tablet, rather than the act of drinking, the frequent daily ritual (Stahl).

BODY WEIGHT	SCHEDULE	TOTAL DOSE (MG/DAY)
Over 60 kg	666 mg (two 333 mg tablets) three times daily	1998
Under 60 kg	reduced schedule (e.g. two tablets AM, one midday, one night)	1332

Weight-banded acamprosate dosing; tablet strength 333 mg, always three-times-daily, for abstinence maintenance after detoxification (Maudsley 2021; NICE 2011).

36.5 Renal dosing and the renal contraindication

The safety fact that flips the usual caution. Acamprosate bypasses the liver almost entirely: it is not hepatically metabolised, does not induce or inhibit cytochrome enzymes, and the absorbed fraction is excreted unchanged in the urine (Kaplan and Sadock 2024). Two consequences follow, and both are examinable. First, because it spares the liver, it is *safe in alcohol-related liver disease* and needs no dose change in Child-Pugh A or B cirrhosis, which is why it is preferred over naltrexone where hepatic function is deranged (BAP 2026; Stahl). Second, because it is renally cleared, the kidney becomes the organ of caution.

The renal rule. Acamprosate is *contraindicated in severe renal impairment*, and in mild-to-moderate impairment the dose is reduced, with 333 mg three times daily recommended for moderate impairment (Stahl; BAP 2026; WFSBP). In practice this means a baseline renal check before starting: NICE requires baseline urea and electrolytes (alongside liver function tests including GGT) and periodic monitoring, and severe renal impairment (broadly a creatinine clearance below the low-30s mL/min) rules the drug out (NICE 2011; Maudsley 2021). The single most serious adverse effect on record is acute renal failure, so renal function, not the liver, is what you monitor (Kaplan and Sadock 2024).

RENAL STATUS	ACAMPROSATE ACTION
Normal renal function	Standard weight-banded dose (1998 or 1332 mg/day)
Moderate impairment	Reduce to 333 mg three times daily
Severe impairment	Contraindicated, do not use
Hepatic impairment (Child-Pugh A/B)	No dose change needed, preferred where liver disease limits other agents

Acamprosate is renally cleared: reduce in moderate renal impairment, contraindicated in severe, but safe in liver disease (Stahl; BAP 2026; Maudsley 2021).

RULE **Check the kidney, not the liver.** Acamprosate is renally excreted and hepatically safe, so it is the anti-craving agent of choice in alcohol-related liver disease, but it must be dose-reduced in moderate renal impairment and stopped altogether in severe renal impairment.

36.6 Where the guidelines place it: BAP, IPS, NICE and WHO

Lead with BAP. The British Association for Psychopharmacology (BAP) positions acamprosate as a core relapse-prevention agent offered after medically assisted withdrawal to increase abstinence, usable safely in alcohol-associated liver disease but requiring dose adjustment in renal impairment and avoidance in severe renal impairment; it also flags that combining acamprosate with naltrexone gives no added benefit over either alone (BAP 2026). Within a WHO-mhGAP-style primary-care frame, BAP goes further and calls acamprosate the maintenance intervention with the strongest evidence of benefit for holding alcohol abstinence after detoxification (BAP 2026). This is the verified first-line-by-goal position and anchors any answer.

Then the other bodies. The Indian Psychiatric Society substance-use clinical practice guidelines (the Basu, Ghosh, Lal and Murthy tradition) grade acamprosate at strength A and offer it to maintain abstinence and prevent relapse, noting it also reduces heavy drinking in those who relapse; the IPS guidelines make it a parallel first-line anti-craving option alongside naltrexone 50 mg/day, particularly favoured where opioid co-use is anticipated or where hepatic enzymes are deranged, always combined with a structured psychosocial intervention (IPS 2014). NICE offers acamprosate (or oral naltrexone) after successful withdrawal in moderate-to-severe dependence, at 1998 mg/day reducing to 1332 mg/day if under 60 kg, with a comprehensive medical assessment and baseline urea/electrolytes and liver function first (NICE 2011). WHO recommends considering acamprosate, naltrexone or disulfiram to prevent relapse in alcohol dependence (WHO mhGAP 2016), and WFSBP grades it RG1, first-line with naltrexone, contraindicated in severe renal impairment (WFSBP).

GUIDELINE	ACAMPROSATE POSITION (ALCOHOL RELAPSE PREVENTION)
BAP	Core agent after assisted withdrawal; strongest maintenance evidence in primary care; liver-safe, renal dose-adjust
Indian Psychiatric Society (IPS guidelines)	Strength A; parallel first-line with naltrexone; favoured where opioid co-use or deranged LFTs; with psychosocial care
NICE 2011	Offer after withdrawal in moderate-severe dependence; 1998 mg/day (1332 if under 60 kg); baseline U&E and LFTs
WHO mhGAP 2016	Consider acamprosate, naltrexone or disulfiram to prevent relapse
WFSBP	RG1, first-line with naltrexone; contraindicated in severe renal impairment

Guideline-level placement of acamprosate; BAP-led, then Indian Psychiatric Society, NICE, WHO and WFSBP (verified from the drug-guideline supplement).

36.7 The India lens: the treatment gap, brand access and the de-addiction setting

Where it fits Indian practice. In the Indian de-addiction context, acamprosate (Acamprol) is a practical maintenance agent: it is non-scheduled and so falls outside the Narcotic Drugs and Psychotropic Substances (NDPS) Act, 1985 prescriber constraints that bind agonist opioid-substitution therapy, and its hepatic safety matters in a population where alcohol-related liver disease is common (IPS 2014). Against the large substance-use treatment gap, where most dependent drinkers never reach formal care and services cluster in government de-addiction centres and Drug De-addiction Programme (DDAP) units, acamprosate combines usefully with the community and home-based, non-specialist-delivered model the Indian guidelines push, and with the family-supervised approach already used for disulfiram.

The honest caveat. The three-times-daily schedule is a real adherence obstacle in this setting, and acamprosate's modest effect size (number needed to treat around 12 to prevent a return to

drinking) means it is offered as one option, chosen by patient preference and comorbidity, not as a magic bullet; the drug works only when it rides on a structured psychosocial intervention (IPS 2014; Kaplan and Sadock 2024).

INDIA

Acamprosate (Acamprol) is the anti-craving agent to reach for in the Indian drinker with liver disease: it bypasses the liver, so it is safe in cirrhosis where naltrexone (hepatotoxic, and blocked by any opioid co-use) is problematic. It is non-scheduled, prescribable in any de-addiction setting without NDPS-linked OST licensing, but the twice-or-thrice-daily dosing is a genuine adherence problem, so pair it with a co-resident family supervisor and a structured psychosocial programme, exactly the model Indian de-addiction care already runs on. Watch renal function, not the liver.

MNEMONIC

"CALM the glutamate, spare the LIVER, mind the KIDNEY, dose by THIRDS"

Acamprosate CALMs the hyperglutamatergic, NMDA-driven excitation of early abstinence; it SPAREs the liver (renally cleared, safe in cirrhosis); you must mind the KIDNEY (reduce in moderate, avoid in severe renal impairment); and it is dosed by THIRDS, 666 mg three times a day (1998 mg/day over 60 kg; 1332 mg/day under 60 kg).

1998 mg DAILY ACAMPROSATE DOSE IF OVER 60 KG (666 THREE TIMES DAILY)	**1332 mg** REDUCED DAILY DOSE IF UNDER 60 KG	**333 mg** TABLET STRENGTH; THE MODERATE-RENAL-IMPAIRMENT DOSE IS ONE THREE TIMES DAILY	**6 months** USUAL DURATION OF MAINTENANCE TREATMENT

GOOD TO REMEMBER

- **Acamprosate (Indian brand Acamprol; oral):** a glutamatergic neuromodulator (NMDA partial co-agonist that restores the excitatory-inhibitory balance disturbed by chronic alcohol) for abstinence maintenance in the already-detoxified patient, never for withdrawal or delirium tremens; dose 666 mg three times daily (1998 mg/day if over 60 kg; 1332 mg/day if under 60 kg), tablet 333 mg; the signature caution is that it is renally cleared, so it is safe in liver disease but must be dose-reduced in moderate and is contraindicated in severe renal impairment; combine with a psychosocial intervention and stop if drinking continues 4 to 6 weeks after starting.

HOLD THIS

Acamprosate is a glutamatergic, NMDA-modulating neuromodulator that restores the excitatory-inhibitory balance of protracted withdrawal, used for abstinence maintenance in the detoxified patient (not for withdrawal); it is dosed 666 mg three times daily, 1998 mg/day if over 60 kg and 1332 mg/day if under 60 kg, and because it is renally excreted and hepatically safe it is the anti-craving agent of choice in liver disease but is dose-reduced in moderate and contraindicated in severe renal impairment.

37 · Comparing the anti-craving agents

Three drugs dominate the maintenance-phase pharmacotherapy of alcohol use disorder, and the examinable skill is not knowing each one in isolation but placing them side by side: the

comparison of disulfiram, naltrexone and acamprosate as three fundamentally different strategies against the same illness. Disulfiram makes drinking *punishing* (aversive deterrence), naltrexone makes drinking *less rewarding* (reward-craving reduction), and acamprosate makes staying dry *easier* (abstinence maintenance). The individual drugs are taught in their own fragments; here the marks are in the head-to-head, so this is written as a comparison and a selection decision.

Why it matters clinically. The single highest-yield fact is that the anti-craving agents (naltrexone and acamprosate) are the two first-line choices after detoxification, and disulfiram is a deliberately second-choice, supervised agent for a specific motivated patient, not a default. A wrong first-line here is a critical error. The examiner tests the **anti-craving comparison** by contrasting mechanism, target, evidence and the one caution that excludes each drug, then by asking which agent for which patient. The mesolimbic-dopamine reward anatomy these drugs act on (and that disulfiram deliberately does not) is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; the NDPS Act frame behind Indian de-addiction prescribing sits in the Mental health legislation and forensic psychiatry notes. One figure carries this topic: Fig 13.21, a three-column concept map of the aversive versus reward-blunting versus abstinence-stabilising strategies with each drug's target, dose and key caution.

2	50	1998	24
FIRST-LINE ANTI-CRAVING AGENTS AFTER DETOX (NALTREXONE, ACAMPROSATE)	NALTREXONE ORAL DOSE (MG), START AT 25	ACAMPROSATE DOSE (MG OVER 60 KG), 666 THREE TIMES DAILY	HOURS ABSTINENT REQUIRED BEFORE STARTING DISULFIRAM

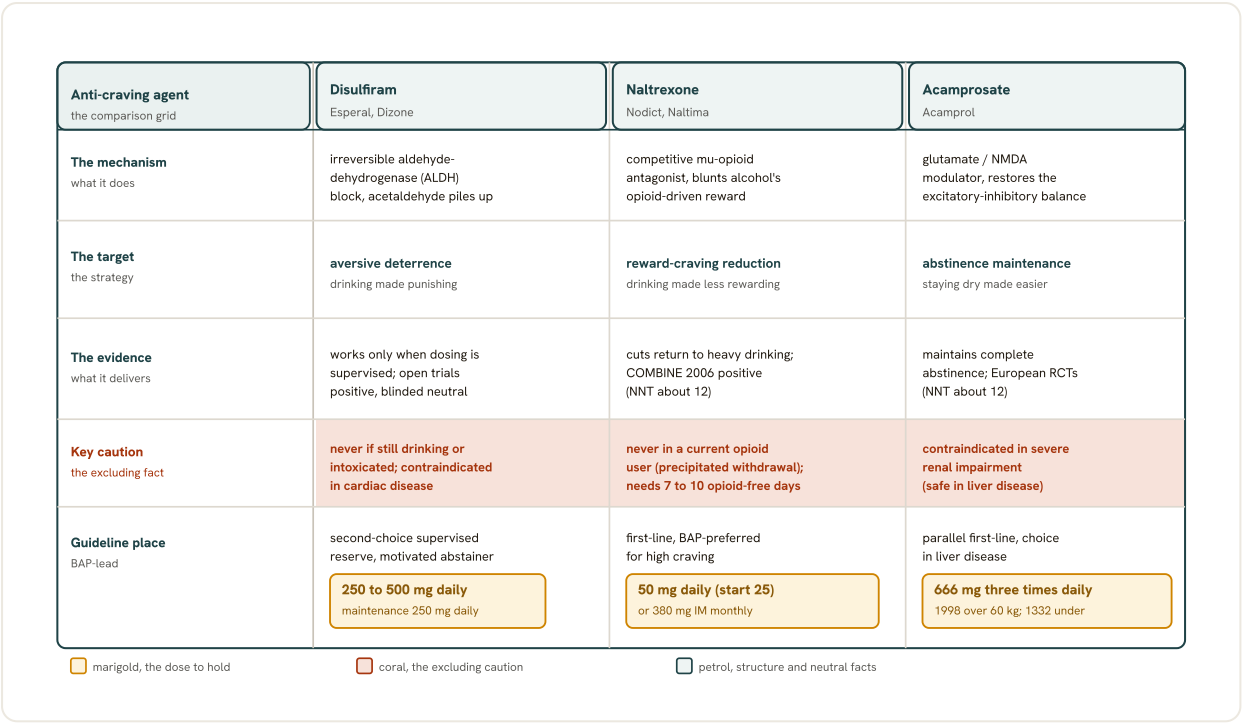

Fig 13.21 Anti-craving pharmacotherapy: disulfiram, naltrexone and acamprosate compared. Read down each column: disulfiram deters (ALDH block, aversive, supervised-only, never in a drinking or cardiac patient), naltrexone de-rewards (mu-opioid antagonist, first-line, never in an opioid user), and acamprosate anchors abstinence (glutamate/NMDA modulator, first-line, contraindicated only in severe renal impairment). Naltrexone and acamprosate are the two first-line anti-craving agents after detox; disulfiram is the supervised reserve. The marigold chips carry the examinable doses.

37.1 The three strategies at a glance: aversion, reward-blunting, abstinence-stabilising

Three different jobs. The clean framing is that the three agents attack three different arms of dependence. Disulfiram is an **aversive** deterrent: it does nothing to craving and instead makes drinking physically punishing, so it works by threat. Naltrexone is a reward-blunting anti-craving agent: it removes the pleasure from a drink, so a lapse yields less reward and the drive to keep drinking weakens. Acamprosate is an abstinence-maintaining neuromodulator: it settles the hyperglutamatergic negative-affect state of protracted withdrawal, so staying dry is easier (Kaplan and Sadock 2024; New Oxford). Only the last two are true anti-craving agents; disulfiram is grouped with them by indication (relapse prevention) but not by mechanism.

Why the distinction is examined. Candidates lose marks by calling disulfiram an "anti-craving" drug or by treating the three as interchangeable. They are not: they suit different patients, carry different contraindications, and sit on different guideline lines. The selection question flows directly from the mechanism, which is why the comparison is worth memorising as a single grid rather than three separate drug cards.

AGENT	STRATEGY / TARGET	MECHANISM (VERIFIED)	BEST-MATCHED PATIENT
Disulfiram (Esperal, Dizone)	aversive deterrence	irreversible aldehyde-dehydrogenase (ALDH) inhibitor → acetaldehyde accumulates on drinking	highly motivated, abstinence-goal, with a supervisor
Naltrexone (Nodict, Naltima)	reward-craving reduction	competitive mu-opioid antagonist → blunts alcohol's opioid-mediated dopamine reward	high-craving "reward drinker"; still drinking / cutting down
Acamprosate (Acamprol)	abstinence maintenance	glutamate / NMDA modulator (partial co-agonist) → restores excitatory-inhibitory balance	detoxified "relief drinker" holding abstinence; liver disease

The three-strategy grid: two anti-craving agents (naltrexone, acamprosate) plus the aversive deterrent disulfiram, matched to mechanism and patient (Kaplan and Sadock 2024; New Oxford).

MNEMONIC

"DISULFIRAM DETERS, NALTREXONE de-REWARDS, ACAMPROSATE ANCHORS"

Disulfiram DETERS by punishment (ALDH block, acetaldehyde reaction); naltrexone de-REWARDS by blocking the opioid-mediated buzz (mu antagonist, the reward drinker); acamprosate ANCHORS abstinence by calming the hyperglutamatergic state (NMDA modulator, the relief drinker). Three verbs, three mechanisms, three patients.

37.2 Mechanism head-to-head: ALDH block versus mu-opioid antagonism versus glutamate modulation

Disulfiram. Disulfiram irreversibly inhibits aldehyde dehydrogenase, the enzyme that clears acetaldehyde (the first metabolite of ethanol). On drinking, acetaldehyde accumulates and produces the aversive disulfiram-ethanol reaction (flushing, throbbing headache, nausea and vomiting, tachycardia with hypotension). It touches neither craving nor the reward pathway; the block is irreversible, so the danger persists for up to two weeks after the last tablet (Stahl 2021).

Naltrexone. Naltrexone is a competitive, essentially pure mu-opioid antagonist. Alcohol releases endogenous opioids that drive dopamine into the nucleus accumbens, the felt reward of a drink; blocking the mu receptor blunts that reward, so heavy-drinking days and cue-induced craving fall (Stahl's Substance Use; Kaplan and Sadock 2024). It works in the still-drinking patient because it strips the reward rather than enforcing prior abstinence.

Acamprosate. Acamprosate is a glutamatergic neuromodulator, an NMDA partial co-agonist that also acts on metabotropic glutamate (mGluR5) receptors. Chronic alcohol up-regulates NMDA receptors; on withdrawal this leaves an unopposed hyperglutamatergic state driving craving and negative affect. Acamprosate damps that excitation and restores the excitatory-inhibitory balance, with no aversion and no reward blockade (Kaplan and Sadock 2024; New Oxford).

PEARL

Match the anti-craving agent to the type of drinker. Naltrexone suits the *reward drinker* who drinks for the buzz (it removes the reward); acamprosate suits the *relief drinker* who drinks to quell negative affect and stay functional (it calms the glutamate storm). Disulfiram suits neither craving type, it suits the motivated abstainer who wants an external barrier against impulse. This is why combining naltrexone and acamprosate adds no benefit, they act on different arms and there is no synergy (COMBINE study).

37.3 The dose and monitoring lines, side by side

The three doses. The examinable doses are worth carrying as a set: disulfiram **250 to 500 mg daily** (maintenance 250 mg daily, oral); naltrexone **50 mg daily** orally (started at 25 mg, plus a 380 mg monthly IM injectable form); and acamprosate **666 mg** three times daily, giving 1998 mg daily over 60 kg and 1332 mg daily under 60 kg (IPS 2014; NICE 2011; Maudsley 2021). Each is a maintenance-phase agent, begun after (or, for naltrexone, sometimes during) a cut-down, and each is paired with a structured psychosocial intervention.

The monitoring split. The monitoring maps onto the metabolism. Disulfiram and naltrexone are both hepatically handled, so both need baseline and periodic liver function tests; acamprosate is renally cleared, so it is the safe choice in liver disease but must be dose-reduced in renal impairment (Kaplan and Sadock 2024; NICE 2011). This is a favourite discriminator: acamprosate watches the kidney, disulfiram and naltrexone watch the liver.

PARAMETER	DISULFIRAM	NALTREXONE	ACAMPROSATE
Oral dose (mg daily)	250 to 500 (maint. 250)	50 (start 25)	1998 (over 60 kg); 1332 (under 60 kg)
Schedule	once daily (often nocte)	once daily; 380 IM monthly	666 three times daily
Metabolism / clearance	hepatic (hepatotoxic)	hepatic (dose-related)	renal (not metabolised)
Key monitoring	LFTs; U&E	LFTs; opioid-free status	renal function (U&E)
Safe in liver disease?	no (contraindicated)	caution; avoid acute hepatitis / failure	yes (Child-Pugh A/B)
Onset condition	at least 24 h after last drink	at least 7 to 10 opioid-free days	as soon as possible after withdrawal

Dose, metabolism and monitoring for the three agents; note acamprosate's renal clearance makes it the liver-disease choice, and each drug's onset condition (BAP 2026; IPS 2014; NICE 2011; Maudsley 2021).

37.4 The evidence head-to-head: what each agent actually delivers

Naltrexone and acamprosate have the meta-analytic base. Both are supported by large meta-analyses, each with a number-needed-to-treat of roughly **12** to prevent one return to drinking; naltrexone's most consistent signal is reducing the return to *heavy* drinking, while acamprosate's is maintaining complete abstinence (Kaplan and Sadock 2024; VA/DoD). The landmark head-to-head is the COMBINE study (Anton et al, JAMA 2006): naltrexone with medical management

beat placebo, acamprosate showed no significant benefit in that US trial, and combining the two added nothing over naltrexone alone. European trials have been more favourable to acamprosate, so the two are treated as parallel first-line options rather than one being clearly superior.

Disulfiram's evidence is adherence-dependent. Disulfiram works only when its intake is *supervised*: in open trials with observed dosing it outperforms placebo, but in blinded trials where patients self-administer it does not, because an unsupervised patient who wants to drink simply stops the tablet first (Kaplan and Sadock 2024; New Oxford). This is the whole reason it is reserved for the motivated patient with a reliable supervisor, and why guidelines rank it below the two anti-craving agents.

AGENT	SIGNATURE OUTCOME	EVIDENCE ANCHOR
Naltrexone	reduces return to heavy drinking; lowers craving (NNT ~12)	COMBINE (2006); large meta-analyses
Acamprosate	maintains complete abstinence (NNT ~12)	European RCTs; meta-analyses
Disulfiram	effective only under supervised administration	open (supervised) trials positive; blinded trials neutral

What the evidence says each agent does; disulfiram's benefit is real but contingent on observed dosing (Kaplan and Sadock 2024; Anton et al 2006).

37.5 The cautions head-to-head: the one contraindication that excludes each drug

One killer caution per drug. Each agent has a signature exclusion that a well-set question hinges on. Disulfiram must never be started in a patient who is still drinking or intoxicated (the first dose triggers the reaction) and is contraindicated in cardiac disease, where the tachycardia and hypotension of the disulfiram-ethanol reaction can precipitate a myocardial infarction or arrhythmia; it needs at least 24 hours of documented abstinence, consent and supervision (BAP 2026). Naltrexone must never be given to a current opioid user, even when prescribed for alcohol, because as a competitive antagonist it displaces the agonist and throws a dependent patient into precipitated withdrawal; it needs a 7-to-10-day opioid-free window (longer after methadone, and BAP avoids it for 12 months after long-acting buprenorphine). Acamprosate's limiting caution is renal, it is dose-reduced in moderate and contraindicated in severe renal impairment, though it is safe in liver disease (Kaplan and Sadock 2024; NICE 2011; BAP 2026).

AGENT	THE ONE CAUTION THAT EXCLUDES IT	PRACTICAL GUARD
Disulfiram	still-drinking / intoxicated; cardiac disease; hepatic impairment	24 h abstinent + consent + supervision + LFTs
Naltrexone	current opioid use (precipitated withdrawal); acute hepatitis / failure	7 to 10 opioid-free days + negative urine opioid screen
Acamprosate	severe renal impairment	check renal function; dose-reduce if under 60 kg / moderate impairment

The signature contraindication of each anti-craving comparison partner, the level the examiner tests (BAP 2026; NICE 2011; Kaplan and Sadock 2024).

TRAP **Do not reach for disulfiram first, and never give naltrexone to a drinker who also uses opioids.** Disulfiram is a second-choice, supervised, consented aversive agent, not a first-line anti-craving drug; and naltrexone into a current opioid user precipitates severe withdrawal within minutes even when it is being prescribed for alcohol, so confirm an opioid-free window first.

37.6 The guideline-anchored selection: BAP first, then IPS, NICE and WHO

BAP (lead position). The British Association for Psychopharmacology (BAP) is the anchor for **guideline-anchored selection**. BAP rates naltrexone strength A and recommends *preferring* naltrexone (oral daily or the monthly extended-release injection) for patients with high craving or who are still drinking; acamprosate is likewise strength A for maintaining abstinence after withdrawal; and disulfiram, though strength A for efficacy, is explicitly *reserved* for highly motivated, abstinence-goal patients with family or social support and supervised administration, started at least 24 hours after the last drink (BAP 2026). BAP also notes that combining acamprosate and naltrexone gives no added benefit, and that in comorbid bipolar disorder naltrexone is preferred first-line. So the verified first-line anti-craving agents are naltrexone and acamprosate, with disulfiram positioned below them.

The Indian Psychiatric Society. The Indian Psychiatric Society is explicit that naltrexone 50 mg daily orally (titrated from 25 mg) is first-line anti-craving pharmacotherapy after detoxification, with acamprosate 666 mg three times daily a parallel first-line option, particularly where opioid co-use is anticipated or hepatic enzymes are deranged; both are combined with a structured psychosocial intervention (IPS guidelines 2014). The IPS guidelines place disulfiram 250 mg daily as supervised aversive therapy only in motivated patients with a reliable family supervisor, after at least 24 hours of abstinence and informed consent, exactly the second-choice, family-supervised framing that fits Indian de-addiction practice.

NICE and WHO. NICE recommends acamprosate or oral naltrexone (each with an individual psychological intervention) as the relapse-prevention options after assisted withdrawal in moderate-to-severe dependence, and positions disulfiram for patients with an abstinence goal *when acamprosate and naltrexone are unsuitable or not preferred*, which again ranks disulfiram below the two anti-craving agents (NICE 2011). WHO mhGAP takes the pragmatic line that acamprosate, disulfiram or naltrexone may all be offered to reduce relapse to heavy drinking, choosing the agent by patient preference and availability (WHO mhGAP 2016). The convergent, verified message across all four: the two anti-craving agents are first-line, disulfiram is the supervised reserve.

RULE **After detox, offer a first-line anti-craving agent (naltrexone or acamprosate) plus a psychosocial intervention; keep disulfiram as the supervised reserve.** BAP, the Indian Psychiatric Society and NICE all make naltrexone and acamprosate first-line and position disulfiram for the motivated abstinence-goal patient with supervision, or when the anti-craving agents are unsuitable.

37.7 Selecting an agent for the patient in front of you

The selection logic. The **selection of anti-craving** agent follows from goal, drinking type, comorbidity and organ function. Goal: a patient who wants controlled reduction or is still drinking suits naltrexone (it works while drinking continues); a patient committed to total abstinence suits acamprosate or supervised disulfiram. Drinking type: reward drinkers to naltrexone, relief drinkers to acamprosate. Comorbidity: comorbid opioid use forbids naltrexone (use acamprosate or disulfiram); comorbid nicotine dependence favours varenicline alongside; comorbid bipolar favours naltrexone (BAP 2026). Organ function: liver disease pushes toward acamprosate (renally cleared, hepatically safe) and away from naltrexone and disulfiram; renal impairment pushes away from acamprosate.

The disulfiram-specific gate. Disulfiram is selected only when three things line up: a genuinely motivated patient with a firm abstinence goal, a reliable co-resident supervisor, and no cardiac or significant hepatic disease, with documented abstinence and informed consent (IPS 2014; BAP 2026). If any of those is missing, choose an anti-craving agent instead.

WORKED EXAMPLE

A 42-year-old man with moderate-to-severe alcohol dependence and early cirrhosis has completed inpatient withdrawal and wants to stay dry. Naltrexone is relatively contraindicated by his liver disease; disulfiram is contraindicated (hepatotoxic, and he has no supervisor). The guideline-anchored choice is acamprosate (Acamprol) 666 mg three times daily, renally cleared and safe in Child-Pugh A/B cirrhosis, paired with a psychosocial intervention and family support, with renal function checked at baseline. If instead he were a high-craving "reward drinker" with a healthy liver and no opioid use, naltrexone 50 mg daily (start 25) would be first choice; disulfiram would enter only if he were strongly abstinence-motivated with a reliable home supervisor and a normal heart and liver.

INDIA

In Indian de-addiction practice the selection is shaped by a very large treatment gap, the family-supervised model, and access. Disulfiram (Esperal, Dizone) remains widely used because a co-resident relative can supervise each dose, the classic family-based recovery-monitor model the Indian Psychiatric Society endorses. Naltrexone (Nodict, Naltima) and acamprosate (Acamprol) are non-scheduled and so sit outside the NDPS Act, 1985 constraints that bind agonist opioid-substitution prescribing, making them prescribable in any de-addiction or Drug De-addiction Programme (DDAP) setting without special licensing. Acamprosate's hepatic safety matters where alcohol-related liver disease is common, though its thrice-daily dosing is a real adherence obstacle, so it too is paired with a family supervisor and a structured psychosocial programme.

GOOD TO REMEMBER

- **Disulfiram (Indian brands Esperal, Dizone):** irreversible ALDH inhibitor and aversive deterrent (not anti-craving); oral **250 to 500 mg daily** (maintenance 250) supervised and consented, only in a motivated abstinence-goal patient started at least 24 hours after the last drink; second-choice line; never in a still-drinking, intoxicated, cardiac or hepatic patient; monitor LFTs.
- **Naltrexone (Indian brands Nodict, Naltima):** competitive mu-opioid antagonist reducing the reward of drinking; oral **50 mg daily** (start 25; 380 mg IM monthly); first-line anti-craving after detox, BAP-preferred for high craving / still drinking; never in a current opioid user (precipitated withdrawal, needs a 7-to-10-day opioid-free window); monitor LFTs.
- **Acamprosate (Indian brand Acamprol):** glutamate / NMDA modulator for abstinence maintenance in the detoxified patient; **666 mg** three times daily (1998 mg daily over 60 kg; 1332 under 60 kg); parallel first-line anti-craving; renally cleared, so safe in liver disease but dose-reduced in moderate and contraindicated in severe renal impairment.

HOLD THIS

Naltrexone and acamprosate are the two first-line anti-craving agents after detoxification and disulfiram is the supervised, consented aversive reserve, a ranking BAP leads and the Indian Psychiatric Society, NICE and WHO all echo; match by drinking type and organ function (naltrexone the reward-blunting mu-antagonist for the reward drinker but never in an opioid user; acamprosate the NMDA-modulating abstinence-stabiliser for the relief drinker and the choice in liver disease; disulfiram the ALDH-blocking deterrent only for the motivated, supervised, non-cardiac, non-hepatic abstainer started at least 24 hours dry).

38 · Emerging anti-craving agents

Only three anti-craving drugs are first-line and licensed for alcohol dependence, and they sit in their own notes: naltrexone, acamprosate and disulfiram. This topic is the **second tier** behind them, the **emerging anti-craving** and off-label agents a clinician reaches for when the licensed three fail, are contraindicated, or when a comorbidity steers the choice. Four names carry the marks: **baclofen**, **topiramate**, **gabapentin** and **nalmefene**. This is a management/drug topic, so the yield is in the one-line mechanism, the dose, the line and the single signature niche or caution of each, not in a long description.

Why it matters clinically. Exams like these because each has one clean discriminator: baclofen is the **GABA-B agonist for the cirrhotic drinker**, topiramate is the **carbonic-anhydrase inhibitor** that dulls cognition, gabapentin is the **gabapentinoid for withdrawal-linked negative affect and insomnia**, and nalmefene is the **as-needed opioid antagonist** that reduces drinking without demanding abstinence. All four are off-label or non-first-line for alcohol in most guidelines; the reward and mesolimbic-dopamine anatomy they act on is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and is not re-derived here.

30 to 80	300	18
BACLOFEN RELAPSE-PREVENTION DOSE (MG/DAY)	TOPIRAMATE TARGET CEILING (MG/DAY)	NALMEFENE AS-NEEDED DOSE (MG)

38.1 Baclofen: the GABA-B agonist for the drinker with liver disease

Mechanism and rationale. Baclofen is a selective GABA-B receptor agonist first marketed as a skeletal-muscle relaxant (Kaplan and Sadock 2024; Companion to Psychiatric Studies). Its off-label use in alcohol dependence rests on that GABA-B agonism alone; the guidelines state no craving mechanism for it (Maudsley Prescribing Guidelines). It carries no licence for this indication and the evidence is mixed, a recent meta-analysis failing to find a consistent positive effect on abstinence, so it stays a second-line off-label option (Maudsley Prescribing Guidelines).

The one niche. Baclofen's signature selling point is that it is *not hepatically metabolised*: it is renally cleared, so it can be given where alcohol-related liver disease makes naltrexone (hepatotoxic, contraindicated in acute hepatitis) unusable. It is a preferred anti-craving option in moderate-to-severe cirrhosis (BAP 2026; WFSBP rating it strength A specifically in cirrhotic liver disease). The dose is titrated slowly, starting **5 mg three times daily** and increasing by 5 to 10 mg/day every 3 days to a usual **30 to 80 mg/day** in divided doses (BAP 2026; IPS 2014).

The cautions. Sedation, confusion and affective instability are the monitoring flags, so BAP advises caution in comorbid mood disorder; and because abrupt cessation of a GABA-B agonist can precipitate a withdrawal state with seizures and delirium, it must never be stopped suddenly (BAP 2026).

GOOD TO REMEMBER

- **Baclofen (off-label, alcohol):** GABA-B receptor agonist that reduces craving; renally cleared, so the second-line anti-craving choice in the drinker with alcohol-related liver disease or cirrhosis where naltrexone is contraindicated; dose **30 to 80 mg/day** in divided doses (start 5 mg TDS, titrate every 3 days); watch sedation, confusion and affective instability and never stop abruptly (withdrawal seizures).

38.2 Topiramate: the anticonvulsant that raises GABA and blocks glutamate

Mechanism. Topiramate is an anticonvulsant with a dual action relevant to addiction: it *potentiates GABA-A* transmission and *antagonises the AMPA/kainate glutamate* receptor, and it is also a carbonic-anhydrase inhibitor (Kaplan and Sadock 2024). Damping down the hyperglutamatergic, GABA-deficient state that drives craving and heavy drinking is the rationale, and unlike the licensed three it can be started while a patient is still drinking (Kaplan and Sadock 2024; New Oxford Textbook).

Line and dose. Topiramate has the strongest evidence of the emerging agents; VA/DoD actually rates it strong-for and offers it first-line alongside naltrexone, while BAP, IPS and CANMAT keep it as an off-label second-line for moderate-to-severe alcohol use disorder (VA/DoD; BAP 2026). It is titrated slowly, target range **150 to 300 mg/day** to a ceiling of **300 mg/day** (New Oxford Textbook; Kaplan and Sadock 2024). Slow titration is not optional: it is what keeps the dose-limiting side effects tolerable.

The signature caution. Topiramate's memorable toxicity is *cognitive*, the so-called "dopey" or word-finding and memory impairment that patients dislike (its narrow therapeutic index for tolerability), plus paraesthesia, weight loss, metabolic acidosis and a raised risk of renal stones

and acute glaucoma from carbonic-anhydrase inhibition (Kaplan and Sadock 2024; BAP 2026). Monitor cognition and memory.

GOOD TO REMEMBER

- **Topiramate (off-label, alcohol):** anticonvulsant that potentiates GABA-A and blocks AMPA/kainate glutamate; second-line (first-line for VA/DoD) for moderate-to-severe alcohol use disorder, can start while still drinking; slow titration to **150 to 300 mg/day** (max 300); signature harm is cognitive impairment and word-finding difficulty, plus paraesthesia, weight loss and renal-stone/glaucoma risk, so monitor cognition and memory.

RULE **Match the emerging agent to the comorbidity.** Liver disease steers you to baclofen; craving with cognitive headroom to topiramate; alcohol-related insomnia or negative affect or a withdrawal history to gabapentin; a patient who will not commit to abstinence but wants to cut down to nalmefene.

38.3 Gabapentin: the gabapentinoid for withdrawal-linked craving and insomnia

Mechanism and niche. Off-label gabapentin binds the alpha-2-delta subunit of the voltage-gated calcium channel, reducing excitatory neurotransmitter release and calming the hyperexcitable, protracted post-withdrawal state (Kaplan and Sadock 2024). The whole case for **gabapentin for alcohol** is its niche: it is the pick for relapse prevention in patients with *alcohol-related insomnia, negative affect, or a documented history of alcohol withdrawal*, the group in whom the calming and sleep-restoring effect maps onto the symptom (BAP 2026).

Line and dose. Gabapentin is an off-label second-line agent for moderate-to-severe alcohol use disorder (BAP strength B; VA/DoD weak-for where first-line is contraindicated or ineffective); IPS also lists it, at **900 to 1800 mg/day** in divided doses, as an anticonvulsant adjunct where benzodiazepine monotherapy for withdrawal is inadequate or benzodiazepine misuse is a concern (IPS 2014; VA/DoD; BAP 2026).

The caution. Gabapentinoids carry their own *misuse and diversion* liability, so BAP explicitly weighs the risk of non-prescribed use, particularly in a population with substance use disorder; it is a reason to prefer it in a supervised or lower-risk patient (BAP 2026).

GOOD TO REMEMBER

- **Gabapentin (off-label, alcohol):** alpha-2-delta calcium-channel ligand; off-label second-line relapse-prevention agent whose niche is alcohol-related insomnia, negative affect or a history of alcohol withdrawal; dose **900 to 1800 mg/day** divided; signature caution is its own misuse and diversion liability in a substance-using population.

38.4 Nalmefene: the as-needed opioid antagonist to reduce drinking

Mechanism. Nalmefene is a 6-methylene analogue of naltrexone: a mu (MOR) and delta (DOR) opioid antagonist with partial agonist activity at the kappa (KOR) receptor, giving it a longer half-life and greater oral bioavailability than naltrexone (New Oxford Textbook; Goodman and Gilman). Like naltrexone it blocks the opioid-mediated reward of drinking (Stahl's Essential Psychopharmacology).

What makes it different, the "as-needed" model. Nalmefene's exam-defining feature is not its receptor profile but its *dosing paradigm*: it is taken **as-needed**, one **18 mg** tablet on each day drinking is anticipated (ideally 1 to 2 hours before the expected drinking), not as a daily maintenance drug (WFSBP; Maudsley Prescribing Guidelines). Its licensed goal is therefore *reduction of heavy drinking*, not abstinence, in alcohol-dependent patients who have a high drinking-risk level, no physical withdrawal, and who do not need immediate detoxification (WFSBP RG1; BAP 2026). NICE recommends it as an option for reducing alcohol consumption on this basis (Shorter Oxford Textbook; Maudsley Prescribing Guidelines).

The one shared contraindication. Being an opioid antagonist, nalmefene carries the same hard rule as naltrexone: it must be avoided in anyone using opioids, including opioid analgesics, because it will precipitate withdrawal and block analgesia (BAP 2026; Maudsley Prescribing Guidelines).

GOOD TO REMEMBER

- **Nalmefene (alcohol):** mu/delta antagonist and kappa partial agonist (a naltrexone analogue); taken **as-needed 18 mg** on anticipated drinking days (1 to 2 hours before), goal is *reduction of heavy drinking* not abstinence, for high-risk dependent drinkers without physical withdrawal; same opioid contraindication as naltrexone (avoid with any current opioid or analgesic-opioid use).

TRAP **Nalmefene is not naltrexone taken every day.** Its whole point is the as-needed, one-tablet-before-drinking model aimed at cutting down rather than abstaining; treating it as a daily maintenance antagonist, or missing that it shares naltrexone's opioid contraindication, both lose marks.

38.5 The four agents side by side

The discriminating table. The examinable content collapses to a mechanism, a dose, a line and a niche for each. Read the table down the "steer" column: that single clinical cue is what selects the agent in a vignette.

AGENT	MECHANISM	DOSE	LINE AND THE ONE STEER
Baclofen	GABA-B agonist	30 to 80 mg/day (start 5 mg TDS)	2nd-line off-label; the drinker with liver disease / cirrhosis (renally cleared)
Topiramate	GABA-A up, AMPA/kainate glutamate down; carbonic-anhydrase inhibitor	150 to 300 mg/day (max 300)	2nd-line off-label (1st-line VA/DoD); craving, can start while drinking; harms cognition
Gabapentin	alpha-2-delta calcium-channel ligand	900 to 1800 mg/day divided	2nd-line off-label; alcohol-related insomnia / negative affect / withdrawal history; misuse risk
Nalmefene	mu/delta antagonist, kappa partial agonist	18 mg as-needed on drinking days	reduce (not stop) drinking; high-risk, no withdrawal; avoid with opioids

The emerging anti-craving agents in one grid; the right-hand "steer" is the single cue that selects each in a vignette (BAP 2026; VA/DoD; WFSBP; IPS 2014).

INDIA

The emerging agents matter in India precisely because of the treatment gap and the licensing landscape. Alcohol-related liver disease is common in Indian de-addiction practice, and baclofen, being cheap, freely available and renally cleared, is a genuinely useful anti-craving choice where naltrexone's hepatotoxicity is a barrier; the IPS substance-use guideline lists it (30 to 80 mg/day) as a second-line option specifically for co-existing significant hepatic disease. Gabapentin is available and inexpensive and is used as an anticonvulsant adjunct in alcohol withdrawal, but its misuse liability is a real concern given the substance-using population and the broader diversion environment the Narcotic Drugs and Psychotropic Substances (NDPS) Act, 1985 tries to control. Topiramate is available generically. Nalmefene is *not* routinely available or established in Indian practice, so the licensed three plus baclofen carry most of the anti-craving work in the day care centre and de-addiction setting; the wider NDPS and medico-legal frame sits in the Mental health legislation and forensic psychiatry notes.

COMMON TRAP

Do not promote any of these four to first-line for alcohol out of the blue. In most guidelines (BAP, IPS, NICE) baclofen, topiramate and gabapentin are off-label second-line, reached only after or alongside the licensed three; the one defensible exception to name is VA/DoD, which offers topiramate first-line together with naltrexone. Nalmefene is licensed but for a different goal (reduced drinking, not abstinence), so it is not interchangeable with the abstinence-oriented three.

HOLD THIS

Behind the licensed three (naltrexone, acamprosate, disulfiram), the emerging anti-craving agents each own one cue: baclofen (GABA-B, 30 to 80 mg/day) for the cirrhotic drinker, topiramate (150 to 300 mg/day) for craving at the cost of cognition, gabapentin (900 to 1800 mg/day) for withdrawal-linked insomnia and negative affect, and nalmefene (18 mg as-needed) to cut down rather than quit.

Apply and consolidate

39 · Worked cases

This is the arc closer: four worked clinical cases that make you *reason* the substance-use material rather than recite it. Each one puts a decision in front of you that the earlier notes teach in the abstract, and forces the sequence, the drug, the dose and the safety step in the order an examiner (and a ward) demand. Work each case as a viva: state the recognition, name the discriminator, then commit to the first move with its number attached.

How to use these. The four cases map to the four commonest high-stakes decisions on this block: an escalating withdrawal that becomes **delirium tremens**; a **Wernicke** prophylaxis call in a drinker who came in for something else; an **opioid overdose** reversed with titrated naloxone and watched for re-narcotisation; and an **anti-craving** choice tailored to one patient. Every named syndrome closes with a criterion-anchored Good-to-remember and every named drug with a dose-anchored one, so the case teaches the fact it hangs on.

39.1 Case 1: escalating alcohol withdrawal that becomes delirium tremens

The vignette. A 44-year-old man with a decade of daily heavy drinking is admitted after a road-traffic injury and stops drinking abruptly. At hour 10 he is tremulous, sweating and anxious; by hour 60 he is disoriented in time and place, picking at insects he sees on the bedclothes, febrile, pulse 130, drenched. He does not know where he is. This is not anxiety and not "settling down after a drink": the clouded, fluctuating sensorium plus the autonomic storm makes it delirium tremens (Maudsley Prescribing Guidelines; Kaplan and Sadock 2024).

39.2 Case 1 reasoning: the CIWA-Ar guides the benzodiazepine while he can still report

Score first, dose to the score. While he was still orientable at hour 10 to 40, the right instrument was the CIWA-Ar: a symptom-triggered regimen medicates once the score crosses the trigger of about **8 to 10**, re-scores every one to two hours and gives a long-acting benzodiazepine (chlordiazepoxide, or diazepam) until the score settles, with **15 or more** mandating medication (the CIWA-Ar form is reproduced in the scales gallery). A score over **25** with fever or a fast pulse is the danger flag. Symptom-triggered dosing gives less total benzodiazepine and a shorter course than fixed-schedule dosing, and it is the assessment principle of alcohol withdrawal.

RULE **Score the withdrawal, then dose to the score.** Symptom-triggered CIWA-Ar-guided benzodiazepine (medicate at 8 to 10, treat hard at 15 or more) gives less drug and a shorter course than a fixed schedule, in the patient who can still report.

39.3 Case 1 reasoning: once he is delirious, titrate parenterally and abandon the score

The pivot at hour 60. A delirious patient cannot reliably report symptoms or take oral medication, so the CIWA-Ar becomes unreliable and dosing shifts to *clinical titration of a parenteral benzodiazepine* to a lightly sedated, arousable state. Escalate to intravenous lorazepam (about 1 to 2 mg per dose, repeated to effect) or intravenous diazepam, in a high-dependency or monitored bed (Maudsley Prescribing Guidelines; IPS 2014). Lorazepam is preferred where the liver is compromised, because it is glucuronidated with no active metabolite and does not accumulate. Alongside the benzodiazepine: correct potassium, magnesium and phosphate; monitor pulse, blood pressure and temperature; exclude infection, head injury and hepatic encephalopathy; and give parenteral thiamine before any glucose (Case 1 shares its supportive spine with Case 2). An antipsychotic is an adjunct for refractory agitation only, never monotherapy.

8 to 10	48 to 96 h	10 to 20
CIWA-AR TRIGGER TO START BENZODIAZEPINE	ONSET OF DELIRIUM TREMENS AFTER THE LAST DRINK	PER CENT MORTALITY OF DELIRIUM TREMENS UNTREATED

TRAP **Do not manage established delirium tremens by a score.** The CIWA-Ar depends on a patient who can report and orient; in the delirious patient it under-reads, so dose the parenteral benzodiazepine by clinical titration, not by the number.

GOOD TO REMEMBER

- **Delirium tremens (syndrome):** the criterion picture is clouded fluctuating consciousness plus disorientation plus a gross autonomic storm, with vivid visual and tactile hallucinations on top; onset 48 to 96 hours after the last drink; the discriminator from alcoholic hallucinosis is the *clouded* sensorium; the first move is to treat it as a medical emergency with generously titrated parenteral benzodiazepine and supportive care, and to give parenteral thiamine before any glucose.
- **Lorazepam (in delirium tremens):** the parenteral benzodiazepine of choice when the oral route is unreliable or the liver is compromised; glucuronidated, no active metabolite, so it does not accumulate; give IV/IM about 1 to 2 mg per dose repeated to a light arousable sedation; it controls the autonomic storm and prevents seizures.

39.4 Case 2: the Wernicke prophylaxis decision in a malnourished drinker admitted for something else

The vignette. A 51-year-old woman with long-standing alcohol dependence, visibly cachectic, is admitted with community-acquired pneumonia. She is not in florid withdrawal and has no eye signs. The intern writes up intravenous dextrose for her poor intake. The decision that matters here is not the pneumonia: it is whether, and in what order, she gets thiamine, because a carbohydrate load in a thiamine-depleted brain can precipitate acute Wernicke encephalopathy (NICE; WHO mhGAP 2016; IPS 2014).

39.5 Case 2 reasoning: parenteral thiamine before glucose, and treat on any one feature

The sequence and the doses. Give parenteral thiamine *before* the dextrose, always. For prophylaxis in a malnourished or withdrawing drinker, parenteral thiamine **100 mg** IM/IV daily for at least 3 to 5 days is standard (then oral). The reason to be aggressive is the exam trap: the

classic **Wernicke** triad of confusion, ophthalmoplegia (or nystagmus) and ataxia is complete in only about **10 per cent** of cases, so *any one* feature in a malnourished drinker mandates empirical high-dose treatment (Kaplan and Sadock 2024; NICE). If she develops any confusion, eye sign or ataxia, escalate at once to the emergency regimen, **500 mg IV three times daily** for 2 to 3 days then 250 mg daily for 5 days, before it hardens into the irreversible anterograde amnesia of Korsakoff syndrome (the amnestic mechanism sits in the Dementias and neurocognitive disorders notes and the Neuropsychiatry of systemic and neurological disease notes). Oral thiamine has poor, saturable absorption, so the acute treatment must be parenteral.

INDICATION	THIAMINE ROUTE AND REGIMEN
Prophylaxis (malnourished or withdrawing drinker)	**100 mg IM/IV daily for at least 3 to 5 days, then oral**
Before any IV glucose in a drinker	**Thiamine FIRST, glucose second (never the reverse)**
Suspected Wernicke (any one triad feature)	**500 mg IV three times daily for 2 to 3 days, then 250 mg daily for 5 days**

The thiamine decision tree for the malnourished drinker: parenteral, before glucose, and escalated on any single Wernicke feature (NICE; Kaplan and Sadock 2024).

TRAP **Never give IV glucose before thiamine in a drinker.** A glucose load in a thiamine-depleted patient can precipitate acute Wernicke encephalopathy; the order is thiamine first, always, and parenterally.

PEARL

The Wernicke prophylaxis decision is triggered by the *company the patient keeps*, not by eye signs. A cachectic drinker admitted for pneumonia, a fracture, hyperemesis or a GI bleed is a Wernicke risk the moment a drip goes up; the reason to prophylax is precisely that she is not yet showing the triad, and the ten-per-cent completeness figure means waiting for it is waiting too long.

GOOD TO REMEMBER

- **Wernicke encephalopathy (syndrome):** the criterion is the triad of confusion, ophthalmoplegia/nystagmus and ataxia, but the full triad is present in only about 10 per cent, so treat on any one feature; the discriminator from delirium tremens is eye signs and ataxia *without* the autonomic storm; the first step is high-dose IV thiamine (500 mg three times daily) at once, before it becomes irreversible Korsakoff.
- **Thiamine (vitamin B1):** give parenterally BEFORE any glucose in a malnourished or withdrawing drinker; withdrawal prophylaxis is 100 mg IM/IV daily for at least 3 to 5 days (then oral); suspected Wernicke is treated as an emergency with 500 mg IV three times daily for 2 to 3 days; oral absorption is poor and saturable, so acute treatment must be parenteral.

39.6 Case 3: opioid overdose reversed with titrated naloxone

The vignette. A 26-year-old man who uses heroin is brought in unresponsive, breathing four times a minute, cyanosed, with *pinpoint* pupils. This is the substance emergency that is genuinely time-critical: the triad of *coma, respiratory depression and miotic pupils* is opioid overdose, and the

immediate cause of death is respiratory failure (Kaplan and Sadock 2024). The first move is airway and ventilation, then the antidote.

39.7 Case 3 reasoning: titrate naloxone to breathing, not to full wakefulness, and watch for re-narcotisation

The antidote, titrated. Naloxone is a competitive opioid antagonist: give IM **0.4 to 2 mg**, repeated every 2 to 3 minutes up to about **10 mg**, or intranasal 4 mg per spray repeated after 2 to 3 minutes, alongside bag-mask ventilation (BAP 2026; WHO). Titrate to *adequate respiration*, not to a fully awake, sitting-up patient: over-reversal in a dependent user precipitates a violent, distressing acute withdrawal. The safety catch is **re-narcotisation**. Naloxone's half-life is shorter than that of heroin and much shorter than that of long-acting opioids like methadone, so as the naloxone wears off the patient can slide back into respiratory depression; observe for at least a few hours (longer for long-acting agents), and consider a naloxone infusion for methadone or sustained-release overdose.

0.4 to 2 mg	10 mg	4 mg
NALOXONE IM STARTING DOSE, REPEAT EVERY 2 TO 3 MIN	APPROXIMATE CEILING BEFORE DOUBTING THE OPIOID DIAGNOSIS	INTRANASAL NALOXONE PER SPRAY (TAKE-HOME KIT)

RULE **Titrate naloxone to breathing and expect it to wear off.** Aim for adequate respiration, not full wakefulness, and observe for re-narcotisation, because naloxone outlasts nobody, least of all a long-acting opioid.

TRAP **Opioid withdrawal is not an emergency; opioid overdose is.** Withdrawal is intensely unpleasant but rarely lethal, so do not treat it as an emergency; overdose is the pinpoint-pupil respiratory failure that naloxone reverses, and it kills within minutes.

GOOD TO REMEMBER

- **Opioid overdose (emergency):** the criterion triad is coma plus respiratory depression plus pinpoint (miotic) pupils; the first move is airway and ventilation, then titrated naloxone; the fallen-tolerance windows after detoxification or release from custody are the highest-risk period and the leading cause of death in opioid use disorder.
- **Naloxone (Indian brand Nexnal; the 0.4 mg/1 mL ampoule):** competitive opioid antagonist and the antidote to overdose; give IM 0.4 to 2 mg, repeat every 2 to 3 minutes to about 10 mg, or intranasal 4 mg per spray; titrate to respiration, not wakefulness; its short half-life means watch for re-narcotisation and re-dose or infuse; take-home kits with family rescue-breathing training are recommended for anyone with current or recent opioid use.

39.8 Case 4: choosing the anti-craving agent for a specific relapse-prevention plan

The vignette. A 38-year-old man has completed a medically assisted alcohol withdrawal and has been abstinent seven days. He is motivated, has compensated alcohol-related liver disease, lives with a supportive wife, and wants pharmacological help to stay dry. The task is not "prescribe an anti-craving drug"; it is to *match* the agent to this patient across naltrexone, acamprosate and disulfiram (IPS 2014; NICE 2011; Maudsley Prescribing Guidelines).

39.9 Case 4 reasoning: match mechanism and caution to the patient in front of you

Working the three agents. All three start only *after* withdrawal is complete, alongside a structured psychosocial intervention. Naltrexone (an opioid antagonist, oral 50 mg/day started at 25 mg, or the 380 mg monthly injection; Indian brands Nodict, Naltima) is the verified first-line, blunting the reward of drinking and reducing heavy-drinking days; but it is a poor fit if he is on any opioid analgesic, and its hepatic caution matters given his liver disease. Acamprosate (a glutamate/NMDA modulator, 666 mg three times daily = 1998 mg/day, reduced to 1332 mg/day if under 60 kg; Indian brand Acamprol) is renally cleared, so it is the cleaner choice in liver disease, works best to *maintain* an abstinence already achieved, and has the strongest evidence for holding total abstinence. Combining the two adds no benefit over either alone. Disulfiram (an aversive ALDH inhibitor, 250 to 500 mg/day; Indian brands Esperal, Dizone) works only when taken under supervision and is dangerous in significant hepatic or cardiac disease, so it is a supervised second-line here, not the drug to reach for first in a man with liver disease. For this motivated patient with compensated liver disease and a supervising spouse, the reasoned choice is *acamprosate* (renally safe, best abstinence-maintenance evidence), with a supervised disulfiram a considered second-line given his engaged wife.

AGENT (INDIAN BRAND)	MECHANISM	DOSE	BEST FIT / SIGNATURE CAUTION
Naltrexone (Nodict, Naltima)	Opioid (mu) antagonist; blunts reward of drinking	**Oral 50 mg/day (start 25 mg); or 380 mg IM monthly**	Verified first-line; reduces heavy-drinking days; avoid with opioid analgesics; hepatic caution
Acamprosate (Acamprol)	Glutamate/NMDA modulator; repairs withdrawal-driven hyperexcitability	**666 mg three times daily (1998 mg/day; 1332 if under 60 kg)**	Renally cleared, cleaner in liver disease; best evidence to *maintain* abstinence
Disulfiram (Esperal, Dizone)	Aldehyde-dehydrogenase inhibitor; aversive disulfiram-ethanol reaction	**250 to 500 mg/day (maintenance 250 mg/day)**	Needs supervision to work; contraindicated in significant hepatic or cardiac disease and in a still-drinking patient

The three anti-craving agents matched by mechanism, dose and caution; the choice is patient-specific, and in compensated liver disease acamprosate is the reasoned first move (IPS 2014; NICE 2011; Maudsley Prescribing Guidelines).

TRAP **Never start disulfiram in a still-drinking or cardiac patient, or naltrexone in a current opioid user.** Disulfiram plus alcohol is a deliberate toxic reaction, dangerous in cardiac disease; naltrexone in someone using opioids precipitates acute withdrawal.

GOOD TO REMEMBER

- **Naltrexone (Nodict, Naltima):** opioid antagonist, the verified first-line anti-craving agent in alcohol use disorder; oral 50 mg/day started at 25 mg, or 380 mg IM monthly; started after withdrawal is complete; reduces heavy-drinking days and cue-induced craving; avoid in current opioid users and use hepatic caution.
- **Acamprosate (Acamprol):** glutamate/NMDA modulator that repairs protracted withdrawal hyperexcitability; 666 mg three times daily (1998 mg/day, 1332 if under 60 kg); renally cleared, so the cleaner agent in liver disease; strongest evidence for *maintaining* an achieved abstinence; no punishment mechanism, so adherence-friendly.
- **Disulfiram (Esperal, Dizone):** aversive aldehyde-dehydrogenase inhibitor, 250 to 500 mg/day (maintenance 250 mg/day), producing the disulfiram-ethanol reaction; works only under supervision, so it fits a family-supervised model; contraindicated in significant hepatic or cardiac disease and in a patient who is still drinking.

INDIA

All four cases sit inside a heavy Indian treatment gap: most people with alcohol or opioid dependence never reach formal care, so delirium tremens and overdose reach general and emergency wards after an unsupervised, cost- or stigma-driven abrupt stop, exactly the patient who arrives at hour 60 in a full autonomic storm. Services concentrate in government de-addiction centres and the Drug De-addiction Programme units rather than general practice. The opioid emergencies run under the Narcotic Drugs and Psychotropic Substances (NDPS) Act, 1985 (developed in the Mental health legislation and forensic psychiatry notes). Naloxone is available as the 0.4 mg/1 mL ampoule and increasingly as take-home kits; buprenorphine (Indian brand Tidigesic; the buprenorphine-naloxone 4:1 combination as Suboxone or generics) is the workhorse of Indian opioid-agonist treatment precisely because methadone is restricted to licensed OST clinics, and the anti-craving agents are all cheaply available as Indian generics (Nodict, Acamprol, Esperal). The de-addiction context, not the abstract algorithm, is what these cases are really testing.

HOLD THIS

Recognise the syndrome, name the one discriminator, then commit to the numbered first move: parenteral benzodiazepine plus thiamine-before-glucose for delirium tremens, empirical high-dose thiamine on any one Wernicke feature, titrated naloxone to breathing for overdose, and an anti-craving agent matched to the patient (acamprosate when the liver is the constraint).

40 · Consolidation

This is the arc closer for the whole substance-use chapter, and its job is retrieval, not new teaching. Everything here has already been built earlier in the block; what this topic does is give you a small number of hooks that let you *pull the whole thing back* under exam pressure. The chapter opened on one distinction, harmful use versus the dependence syndrome, and seeded a master mnemonic there; here that mnemonic is paid off and stretched to cover the syndromes, the emergencies, the scales, the substitution agents and the anti-craving drugs. Use this topic the way a viva candidate uses the last ten minutes before the bell: cover the branches, name the number, commit to the first move.

How to work this closer. First rehearse the master mnemonic until the six dependence features fall out automatically, because that is the spine every stem hangs off. Then run the answer-free recall prompts cold, saying the answer aloud before you read on. Then walk the synthesis map branch by branch, covering each branch with your hand and reconstructing it. The four numbers that most often decide a mark, a scale cut-off, a thiamine dose and a withdrawal window, are gathered into one strip so you can drill them. The concept map that draws the whole chapter as one figure is flagged for central rendering (Fig 13.22).

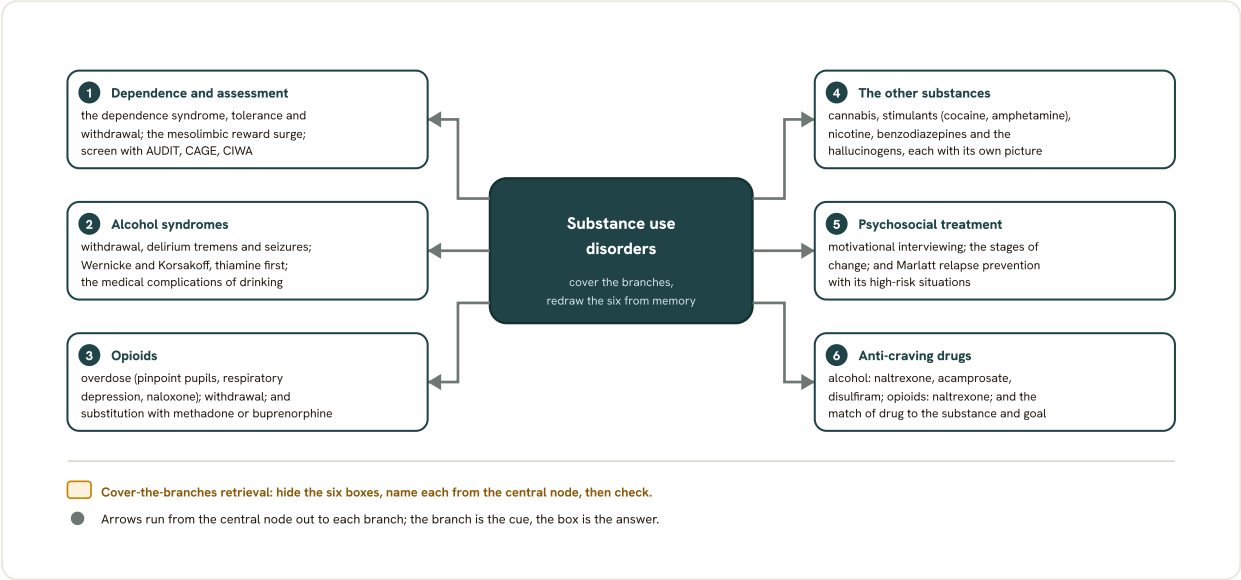

Fig 13.22 Chapter synthesis map: substance use disorders at a glance. Six branches radiate from the disorder at the centre: dependence and assessment with the reward neurobiology; the alcohol syndromes, emergencies and complications; opioid overdose, withdrawal and substitution; the other substances; the psychosocial treatments (motivational interviewing, the stages of change and Marlatt relapse prevention); and the anti-craving pharmacotherapy. Frame it for retrieval by covering the branches and redrawing all six from the central node.

40.1 The master mnemonic, paid off: the 3 C's + 3 unlocks the dependence syndrome

The payoff. The dependence-syndrome opener seeded the mnemonic **the 3 C's + 3**, and this is where it earns its keep as the single retrieval key for the chapter. The three C's are the behavioural core, compulsion (a strong desire to use), impaired *Control* over onset, level and termination, and *Continued* use despite clear harm. The plus-three are the reinforcing shell, tolerance, a physiological withdrawal state, and salience (primacy, the progressive neglect of other pleasures). That is the full six-feature ICD-10 dependence set; any **three** of the six clustering within **12 months** makes the diagnosis.

Why one mnemonic carries the chapter. The same six features regenerate the two nosologies and point at management. Collapse the three C's plus tolerance-and-withdrawal-as-one and salience, and you have the three central ICD-11 features (impaired control, increasing precedence, physiological features), of which **two** are needed. Recognise the "withdrawal" C and you are into the emergencies branch; recognise the "compulsion/craving" C and you are into the anti-craving branch. Count the units instead of the features and you have made the classic error the chapter warns against from the outset.

MNEMONIC

THE 3 C's + 3: Compulsion, impaired Control, Continued use despite harm; plus Tolerance, Withdrawal, Salience.

The three C's are the behavioural heart (compulsion, impaired control, persistence despite harm); the plus-three are the physiological-and-priority shell (tolerance, physiological withdrawal state, salience/primacy). Any three of the six, clustering within a 12-month period, are ICD-10 dependence. Fold them into three and you get the ICD-11 set (two of three needed).

RULE **Recall the mnemonic, then let it branch.** Start every substance stem by reciting the 3 C's + 3; the six features regenerate both nosologies, flag withdrawal risk, and route you to the right emergency, scale or drug.

TRAP **Reciting seven for ICD-10 dependence.** ICD-10 dependence has six features (threshold three); "seven criteria" is the DSM-IV dependence relic, and DSM-5 has eleven for a single substance use disorder (threshold two).

40.2 Active-recall prompt list: the syndromes (answer-free, say it before you read on)

Cover the answer column of your memory and answer each aloud. These prompts drill the recognition-and-discriminator layer that every clinical stem tests. The point is to force retrieval, not recognition, so do not peek at the topics; if you cannot answer one, that is exactly the branch to re-open.

Dependence vs harmful use

What single feature best discriminates dependence from harmful use, and do you count features or units?

ICD-10 vs ICD-11 dependence

How many of how many for each, and over what time frame?

Delirium tremens vs alcoholic hallucinosis

Which one clouds the sensorium, and which preserves clear consciousness?

Delirium tremens vs Wernicke encephalopathy

Which is an autonomic storm, and which is eye-signs-and-ataxia without the storm?

Wernicke vs Korsakoff

Which is the acute, reversible triad and which is the irreversible anterograde amnesia with confabulation?

Opioid vs sedative-hypnotic withdrawal

Which withdrawal is distressing but rarely fatal, and which can kill by seizures and delirium?

Tolerance and withdrawal vs the dependence syndrome

Why does physical dependence on a prescribed drug not by itself equal addiction?

40.3 Active-recall prompt list: the emergencies (name the recognition and the first move)

For each, state the recognition triad, the discriminator, and the very first management step with its number. These are the high-stakes, time-critical branches; the examiner wants the safety

step in the right order.

Delirium tremens
Onset window after the last drink? First move, and what guides the benzodiazepine once the patient is delirious?

Wernicke encephalopathy
What proportion show the full triad, so on how many features do you treat? Which comes first, thiamine or glucose?

Opioid overdose
The triad? The antidote, its starting dose, and what you titrate it to? What is re-narcotisation and how long do you watch?

Sedative-hypnotic (benzodiazepine) withdrawal
Why is a too-fast taper dangerous, and what is the safe substitution-and-taper principle?

Withdrawal seizure
In which withdrawals does it occur, and what is the class of drug that both treats and prevents it?

TRAP **Do not read opioid withdrawal as a medical emergency it is not.** Uncomplicated opioid withdrawal is intensely distressing but rarely life-threatening; sedative-hypnotic and severe alcohol withdrawal are the ones that kill by seizures and delirium.

40.4 Active-recall prompt list: the scales, the substitution and the anti-craving agents

The number branches. These prompts drill the cut-offs, induction doses and maintenance doses that are the pure-recall marks of the block. The scale *forms* live in the scales gallery; here you drill only what each is and its cut-off.

AUDIT, CAGE, DAST-10, ASSIST
State each screen's cut-off number and what it is for.

CIWA-Ar and COWS
The CIWA-Ar trigger to medicate, and the COWS threshold before a first buprenorphine dose?

SADQ and FTND
What does each grade (severity of what), and the score that flags severe/high?

Buprenorphine vs methadone induction
Which waits for objective withdrawal and why; which starts low and titrates slowly and why? Starting and maintenance doses of each?

Naltrexone, acamprosate, disulfiram
Mechanism, dose, and the one signature caution of each? Which needs an opioid-free window, and how long?

Nicotine replacement, varenicline, bupropion
First-line for the heavily dependent smoker, and the one contraindication of bupropion?

40.5 The whole-chapter synthesis map: cover a branch, reconstruct it

How to drill the map. The chapter is one tree with six branches growing off the master mnemonic. Read the branch heads, then cover the "reconstruct" column with your hand and

rebuild each branch from the head alone. When you can regenerate all six from the 3 C's + 3, the chapter is consolidated. The same six branches are drawn as a single concept figure for central rendering (Fig 13.22).

BRANCH (FROM THE 3 C'S + 3)	RECONSTRUCT: THE MUST-HOLD CONTENT
Diagnosis and nosology	Harmful use vs dependence; salience is the discriminator; ICD-10 three of six in 12 months; ICD-11 two of three central features; DSM-5 one disorder, eleven criteria (two or more), graded mild/moderate/severe.
Screening and assessment	AUDIT 8, CAGE 2, DAST-10 3, ASSIST 27 (alcohol high-risk); SADQ grades dependence severity (severe above 30); FTND grades nicotine dependence (high at 6 or more); the count-features-not-units rule.
Alcohol emergencies	Delirium tremens (clouded sensorium plus autonomic storm, 48 to 96 hours, symptom-triggered then titrated benzodiazepine); Wernicke (triad complete in about ten per cent, treat on any one feature, parenteral thiamine before glucose); Korsakoff (irreversible amnesia); alcoholic hallucinosis (clear sensorium).
Withdrawal management	Alcohol, score with CIWA-Ar and dose to the score with a long-acting benzodiazepine; sedative-hypnotic, substitute long-acting and taper slowly (never fast); opioid, distressing but rarely fatal, symptomatic relief plus a substitution decision.
Opioid substitution and overdose	Buprenorphine (partial agonist, wait for objective withdrawal, induct 2 to 8 mg, maintain 12 to 16 mg/day); methadone (full agonist, start low 20 mg, titrate slowly, maintain 60 to 120 mg/day); overdose reversed with titrated naloxone, watch for renarcotisation.
Anti-craving and psychosocial	Naltrexone 50 mg/day (opioid-free window first); acamprosate 666 mg three times daily (liver-safe); disulfiram 250 to 500 mg/day (aversive, supervised, after abstinence); nicotine replacement, varenicline, bupropion for tobacco; MI, brief intervention and relapse prevention wrap all of it.

The six chapter branches growing off the master mnemonic; cover the right column and rebuild each branch from its head (rendered centrally as Fig 13.22).

3 of 6 ICD-10 DEPENDENCE THRESHOLD, WITHIN 12 MONTHS	**8** AUDIT HAZARDOUS OR HARMFUL-USE CUT-OFF	**100 mg** PARENTERAL THIAMINE DAILY, WITHDRAWAL PROPHYLAXIS	**48 to 96 h** DELIRIUM TREMENS ONSET AFTER THE LAST DRINK

40.6 The four safety anchors that outrank everything else

If you hold nothing else, hold these. Four ordering-and-safety rules recur across the emergencies and the drugs, and getting any one of them wrong is the kind of error that loses

more than a mark. Parenteral thiamine goes in *before* glucose in any malnourished or withdrawing drinker, because a carbohydrate load in a thiamine-depleted brain can precipitate acute Wernicke. Naltrexone is never given to a current opioid user, because it precipitates withdrawal; you wait for a documented opioid-free window of **7 to 10 days**. Buprenorphine's first dose waits for objective withdrawal (a COWS of about **8 to 12**), because a partial agonist given too early precipitates withdrawal. And a benzodiazepine taper (or a sedative-hypnotic substitution taper) is never rushed, because a fast taper risks seizures and delirium.

The mirror-image traps. Each anchor has a classic wrong answer: giving glucose first, starting naltrexone in someone still using opioids, inducting buprenorphine before withdrawal appears, and tapering a benzodiazepine too fast. Reciting the anchor and its trap together is the most efficient way to make both stick.

COMMON TRAP

Two more high-yield errors to name and avoid: starting disulfiram in a still-drinking, intoxicated or cardiac patient (the disulfiram-ethanol reaction can be dangerous there), and managing established delirium tremens "by the score" (the CIWA-Ar under-reads in a patient who can no longer report, so you titrate a parenteral benzodiazepine clinically instead).

INDIA

The chapter's India thread ties into one strategic picture worth reconstructing whole. India carries a very large substance-use treatment gap: most people who meet dependence criteria never reach formal care, and services concentrate in government de-addiction centres and Drug De-addiction Programme (DDAP) units rather than in general practice, which is why the harmful-use end and non-specialist-delivered brief intervention carry so much weight (IPS 2014). The legal frame is the Narcotic Drugs and Psychotropic Substances Act, 1985 (the medico-legal detail sits in the Mental health legislation and forensic psychiatry notes), which is what makes agonist opioid-substitution prescribing licence-bound. Within that frame, buprenorphine, usually as the buprenorphine-naloxone 4:1 combination (Tidigesic for buprenorphine alone; Suboxone or Bunorph for the combination), is the accessible outpatient first-line for opioid maintenance because methadone is restricted to government OST clinics. The anti-craving agents that sit outside the NDPS scheduling, naltrexone (Naltima, Nodict), acamprosate (Acamprol) and disulfiram (Esperal, Dizone), are prescribable in any de-addiction setting, and disulfiram's family-supervised model fits Indian practice particularly well. Take-home naloxone (Nexnal) with family training is the highest-value overdose intervention against a heavy opioid burden.

PEARL

Every branch of this chapter routes back to one first question at the bedside: is this harmful use or dependence? That single call, made by counting the 3 C's + 3 rather than the units, decides whether the patient needs brief motivation-based intervention or the full apparatus of assisted withdrawal, relapse-prevention pharmacotherapy and long-term follow-up. Get the first question right and the rest of the tree is just retrieval.

HOLD THIS

The whole chapter grows off the 3 C's + 3 (Compulsion, impaired Control, Continued use despite harm, plus Tolerance, Withdrawal, Salience): count the features not the units, and the four safety anchors outrank everything, thiamine before glucose, no naltrexone in a current opioid user, no buprenorphine before objective withdrawal, and never a fast benzodiazepine taper.

GOOD TO REMEMBER

- **Dependence syndrome (the arc-closing criterion set):** three or more of the 3 C's + 3 (compulsion, impaired control, continued use despite harm, tolerance, withdrawal, salience) clustering within 12 months; the discriminator from harmful use is salience; the first move on recognising it is to assess withdrawal risk and the need for assisted withdrawal.
- **Delirium tremens (emergency recall anchor):** clouded, fluctuating sensorium plus an autonomic storm, 48 to 96 hours after the last drink; the discriminator from Wernicke is the autonomic storm, from alcoholic hallucinosis the clouded sensorium; first move is generously titrated parenteral benzodiazepine plus supportive care, thiamine before glucose.
- **Wernicke encephalopathy (emergency recall anchor):** the confusion-ophthalmoplegia-ataxia triad, complete in only about ten per cent, so treat on any one feature; parenteral thiamine before glucose, escalating to high-dose IV thiamine before it hardens into irreversible Korsakoff.
- **Thiamine (dose anchor):** 100 mg IM/IV daily for withdrawal prophylaxis, 500 mg IV three times daily for suspected Wernicke; always parenteral (oral absorption is saturable) and always before any glucose.
- **Buprenorphine (dose anchor):** partial mu agonist with a respiratory ceiling; first dose only once objective withdrawal appears (COWS about 8 to 12); induct 2 to 8 mg (usually 4 mg), maintain 12 to 16 mg/day; the Indian outpatient first-line as the 4:1 buprenorphine-naloxone combination.
- **Naloxone (dose anchor):** competitive opioid antagonist for overdose; 0.4 to 2 mg IM (4 mg intranasal), repeated every 2 to 3 minutes, titrated to adequate breathing not full arousal; watch for re-narcotisation because its half-life is shorter than the opioid it reverses.
- **Naltrexone (dose anchor):** mu-opioid antagonist, 50 mg/day orally (start 25); first-line anti-craving after alcohol detox; never in a current opioid user, and only after a 7 to 10 day opioid-free window (precipitated withdrawal).
- **Acamprosate (dose anchor):** glutamatergic NMDA-modulator, 666 mg three times daily (1998 mg/day over 60 kg, 1332 mg/day under); liver-safe, so the anti-craving agent of choice in alcohol-related liver disease; dose-reduce in moderate and avoid in severe renal impairment.
- **Disulfiram (dose anchor):** irreversible ALDH inhibitor and aversive deterrent, 250 to 500 mg/day, supervised and consented; started at least 24 hours after the last drink; never in a still-drinking, intoxicated, cardiac or significantly hepatically impaired patient.

Previously asked

Substance use is one of the most heavily examined territories in the paper, and it is tested at two levels at once: the individual substance (its intoxication, its withdrawal and its complications) and the treatment (the withdrawal protocol, the anti-craving or substitution agent, the psychosocial intervention and the relapse-prevention plan). The reliable pattern is that alcohol carries the most weight, that a single agent or a single scale can be asked as a standalone note, and that every long substance essay ends in a guideline-anchored management plan. The alcohol emergencies recur as diagnose-investigate-manage case questions, so the discrimination between delirium tremens, Wernicke encephalopathy and alcoholic hallucinosis must be exam-ready. The genuine

questions on record are grouped by band below. The reward-pathway anatomy and the dopamine circuit that these disorders act on are developed in the Neurochemistry, neuroendocrinology, neuroimaging and basic psychopharmacology notes; the motivational-interviewing and relapse-prevention technique is owned here but cross-referenced to the Psychotherapies, clinical assessment, MSE and nosology notes.

? HOW THIS TERRITORY IS ACTUALLY TESTED

Q **Alcohol withdrawal, the emergencies and the amnestic syndromes.** A "45 year old chronic alcoholic brought to casualty with fever, difficulty recognizing relatives and irrelevant speech" and a "30 year old alcoholic admitted following seizure with tremors, confusion, ataxia and next-day visual hallucinations" have both come as full 25-mark diagnose-investigate-manage case questions, and "Wernicke's-Korsakoff's psychosis", "Wernicke's encephalopathy" and "Korsakoff's Psychosis" recur as standalone 10-mark notes. Prepare the withdrawal spectrum and its benzodiazepine protocol, the delirium-tremens-versus-Wernicke-versus-alcoholic-hallucinosis differential, and the thiamine triad and doses (parenteral thiamine before glucose) in full. case question and short note, recurring

Q **Alcohol dependence, prognosis and the model of care.** "Discuss the model of care in management of Alcohol dependence syndrome", "Discuss alcohol dependence and its prognosis", "Enumerate various types of substance use and induced disorder and discuss management approaches in alcohol dependence syndrome" and "Discuss neuropsychiatric aspects of Alcoholism" (asked three times) have all come as essays. Prepare the dependence-syndrome concept, the assessment, the neuropsychiatric complications and the guideline-anchored management pathway, essay-length. essay, recurring

Q **The anti-craving and aversive agents.** "Antabuse (Disulfiram)", "Naltrexone" and "Acamprosate" have each been asked as standalone 10-mark notes, and "Relapse prevention in alcohol dependence" as a note that turns on agent selection. Prepare each agent with its mechanism, its indication, its dose and its signature caution (disulfiram in the still-drinking or cardiac patient, naltrexone in the opioid user), and the guideline-anchored comparison that chooses between them. short note, recurring

Q **Opioid, nicotine and the other-substance disorders.** "Management of Opioid Dependence", "Methadone", "Nicotine use disorder", "Management of Nicotine dependence", "Discuss Nicotine related psychiatric disorders and management in detail", "Discuss psychopathologies of cannabis use related disorders", "Cannabis dependence", "Cocaine dependence", "Benzodiazepine Dependence", "Mephedrone", "Caffeine induced disorders" and "Oral substitution therapy" are all on record. Prepare the by-substance intoxication and withdrawal picture and the treatment (opioid substitution and antagonist, the nicotine pharmacotherapy) for each named substance. essay and short note, recurring

Q **Psychosocial treatment, relapse prevention and the general frame.** "Alcoholics Anonymous" (asked three times), "Relapse prevention in alcohol dependence", "Discuss recent advances in management of substance use disorders", "Prevalence of substance abuse in adolescence", "Pathological Gambling" and the emergency-management case of a "23 year old male brought to psychiatric emergency after being arrested in a rave party" have all come. Prepare the twelve-step and self-help frame, the Marlatt relapse-prevention model, the stage-matched psychosocial interventions and the recent advances, and the acute substance emergency. essay and short note, recurring

Prepare this material to be assessed and treated, not just recited: the scale cut-offs (the CIWA-Ar and COWS thresholds, the AUDIT and CAGE), the dose-anchored good-to-remember boxes, the thiamine prophylaxis-versus-treatment figures, the substance-emergency differential and the guideline-anchored agent selection in these notes are built to the way the block is examined. The reward-pathway anatomy and the mesolimbic dopamine mechanics live in the Neurochemistry, neuroendocrinology, neuroimaging and basic psychopharmacology notes; the substance-induced psychotic disorder boundary lives in the Other psychotic disorders, delusional syndromes and catatonia notes; the wider delirium and emergency frame

lives in the Perinatal/women's mental health and emergency psychiatry notes; the NDPS and forensic frame lives in the Mental health legislation and forensic psychiatry notes; and the wider amnestic frame lives in the Dementias and neurocognitive disorders notes.

Quick review

THE WHOLE SUBJECT IN ONE TABLE: DEFINITIONS, SCREENS AND WITHDRAWAL SCALES	
HARMFUL USE VS DEPENDENCE	**Harmful use** (F1x.1) = demonstrable damage to physical/mental health; ICD-11 harmful pattern adds harm to others. **Dependence** (F1x.2) = capture, substance takes priority. Mutually exclusive in ICD-10. Discriminator: salience.
ICD-10 DEPENDENCE CRITERIA	Three or more of six within 12 months: desire/compulsion, impaired control, withdrawal, tolerance, salience, persistence despite harm. Threshold 3, six features. ("Seven" is the DSM-IV relic; DSM-5 = one SUD, eleven criteria, two or more.)
ICD-11 DEPENDENCE CRITERIA	Two or more of three: impaired control, precedence/salience, neuroadaptation (tolerance or withdrawal). Over 12 months, or if continuous use (daily) for at least 3 months. Hold: two of three.
SCREENING CUT-OFFS (FOUR NUMBERS)	**AUDIT** (10-item, 0-40): **8 or more** hazardous, refer above 15; AUDIT-C = first 3. **CAGE** (4-item): **2 or more**. **DAST-10**: **3 or more** (3-5 mod, 6-8 substantial, 9-10 severe). **ASSIST**: 0-3 / 4-26 / **27 or more** high (alcohol 0-10 / 11-26 / 27+). Positive screen triggers assessment, never diagnosis.
ALCOHOL WITHDRAWAL ON THE CLOCK	Tremor/autonomic overactivity at **6 to 12 hours**; hallucinosis (clear sensorium) 12 to 24 h; seizures ("rum fits") at **12 to 48 hours**, peak near the second day; delirium tremens at **48 to 72 hours** (up to 96). Early benzodiazepine cover prevents later seizures/delirium.
CIWA-AR (WITHDRAWAL SEVERITY)	Ten items (nine 0-7, orientation 0-4), max **67**. Under 10 mild, 8 to 15 moderate, **15 or more** needs pharmacotherapy; symptom-triggered dosing at about **8 to 10**. Do not use in established delirium tremens (titrate clinically).
SADQ (DEPENDENCE SEVERITY)	Twenty items, each 0-3, max **60**. 15 or less mild, 16 to 30 moderate, **above 30** severe (inpatient detox). SADQ before withdrawal sets starting dose/setting; CIWA-Ar during detox titrates each dose.
COWS (OPIOID WITHDRAWAL)	Eleven items. Bands: **5 to 12** mild, **13 to 24** moderate, **25 to 36** moderately severe, **above 36** severe; under 5 minimal. Buprenorphine induction threshold is COWS about **8 to 12**, not the mild band's 5.
THE EMERGENCIES, THEIR ONE DISCRIMINATOR, AND THE MAINTENANCE PHARMACOTHERAPY	
DELIRIUM TREMENS	Clouded fluctuating consciousness + disorientation + autonomic storm + vivid visual/tactile hallucinations; onset **48 to 96 hours**; about **5 per cent** of admissions; **10 to 20 per cent** mortality untreated. Discriminator: clouded sensorium. Parenteral benzodiazepine to light sedation, correct electrolytes; antipsychotic adjunct only.

THE EMERGENCIES, THEIR ONE DISCRIMINATOR, AND THE MAINTENANCE PHARMACOTHERAPY	
THE SUBSTANCE-EMERGENCY DIFFERENTIAL	One discriminator each. **DT**: clouded sensorium + autonomic storm. **Wernicke**: eye signs + ataxia, no storm; triad complete in only about **10 per cent**, treat on one feature (IV thiamine 500 mg three times daily). **Hallucinosis**: clear sensorium. **Opioid overdose**: pinpoint pupils + respiratory depression, naloxone. **Sedative withdrawal**: keyed to half-life (short-acting 12 to 24 h; long-acting peaks at 5 to 8 days).
THIAMINE AND NALOXONE	**Thiamine**: parenteral BEFORE glucose in a withdrawing drinker; prophylaxis **100 mg** daily 3 to 5 days, treatment **500 mg IV three times daily** 2 to 3 days if any Wernicke feature. **Naloxone**: opioid-overdose antidote, IM **0.4 to 2 mg** every 2 to 3 min up to about 10 mg (intranasal 4 mg); short half-life, watch re-narcotisation.
OST: BUPRENORPHINE	Partial mu-agonist, ceiling on respiratory depression (safer than methadone). Caution: precipitated withdrawal, so first dose waits for objective withdrawal (COWS about **8 to 12**). Induct **2 to 8 mg** (usually 4), maintenance **12 to 16 mg/day**. India first-line as buprenorphine-naloxone (4:1).
OST: METHADONE	Long-acting full mu-agonist, no ceiling. Cautions: overdose in first two weeks (accumulation) and QTc prolongation. Start **20 mg/day** (max 30), raise ~10 mg every few days; maintenance **60 to 120 mg/day** (below 60 raises dropout). India: licensed government/NACO clinics only.
NALTREXONE (ANTI-CRAVING)	Mu-antagonist, blunts reward (the reward drinker). Oral **50 mg/day** (start 25; 380 mg IM monthly); first-line after detox, BAP-preferred for high craving. Caution: never in current opioid use (precipitates withdrawal), needs a **7-to-10-day opioid-free window** + negative screen. Monitor LFTs.
ACAMPROSATE (ANTI-CRAVING)	Glutamate/NMDA modulator, stabilises abstinence (the relief drinker). **666 mg three times daily** (1998 mg/day over 60 kg; 1332 mg under 60 kg). Caution: renally cleared, so safe in liver disease but dose-reduced/contraindicated in renal impairment. Monitor renal function.
DISULFIRAM (AVERSIVE RESERVE)	Aldehyde-dehydrogenase inhibitor: acetaldehyde builds on drinking (flushing, headache, vomiting, tachycardia, hypotension). Not anti-craving; supervised consented deterrent. Oral **250 to 500 mg/day** (maintenance 250). Caution: never if still drinking (at least **24 hours** dry), never in cardiac/hepatic disease. Effect persists 7 to 14 days.

References

The substance-use content is grounded in the standard addiction-medicine and psychopharmacology sources (the source hierarchy below), with Kaplan and Sadock and the

Maudsley Prescribing Guidelines as the depth bar for the neurobiology, the withdrawal syndromes, the doses, the anti-craving and substitution pharmacology and the monitoring, and the management is guideline-first (the British Association for Psychopharmacology leading, with the Indian Psychiatric Society substance-use guidelines, NICE and WHO mhGAP). Every screening cut-off, withdrawal-scale threshold, detoxification regimen, anti-craving dose, first-line recommendation and medico-legal fact has been checked against these sources; anything that could not be confirmed was omitted and flagged rather than guessed. Each journal PMID here was verified against PubMed this build, matched on title, first author and year; identifiers that resolved to the wrong paper were corrected or dropped, and two candidate citations that could not be confidently resolved (a 1988 CIWA-Ar threshold co-citation and a 1993 SOCRATES paper) were dropped rather than listed. Books and guideline documents are cited by author, title and year without a PMID.

PAPER II

Anxiety, OCD and trauma-related disorders

Three sections . one complete notes document

This material gathers the anxiety, obsessive-compulsive and trauma-related disorders into one document, by syndrome and by treatment. The first band is **the anxiety disorders**: generalised anxiety disorder, panic disorder and Clark's cognitive model, agoraphobia, social anxiety disorder and the specific phobias, separation anxiety, the neurobiology of the fear circuit, the cognitive behaviour therapy of anxiety, and the differential diagnosis and medical mimics. The second band is **the obsessive-compulsive and related disorders**: obsessive-compulsive disorder and its symptom dimensions, the guideline-anchored management ladder, the Yale-Brown scale, the cortico-striato-thalamo-cortical circuit, clomipramine versus the serotonin reuptake inhibitors, exposure and response prevention, the treatment-resistant ladder to deep brain stimulation, and the related disorders from body dysmorphic disorder through hoarding, trichotillomania and excoriation to illness anxiety on the spectrum. The third band is **the trauma and stressor-related disorders**: post-traumatic stress disorder and its criteria, the evidence-based trauma-focused treatment, complex PTSD, the acute stress reaction and acute stress disorder, adjustment disorder, the neurobiology of fear conditioning, prolonged grief, and the attachment disorders of early neglect. The examinable skill is the safe, guideline-anchored diagnosis and treatment of each disorder: which disorder behind which fear, which scale and cut-off, which first-line agent for which anxiety disorder, the high-dose long-trial rule in obsessive-compulsive disorder, and the trauma-focused-psychotherapy-first algorithm in post-traumatic stress disorder.

HOW TO USE THESE NOTES

Read the three bands as one continuous account of how the anxiety, obsessive-compulsive and trauma-related disorders are diagnosed and treated. The **anxiety** band builds the frame: the individual anxiety disorders discriminated one from another, the fear-circuit neurobiology, the cognitive behaviour therapy owned here, and the medical mimics that must be excluded. The **obsessive-compulsive and related** band teaches obsessive-compulsive disorder in full, its cortico-striato-thalamo-cortical circuit, the Yale-Brown scale and the guideline-anchored management ladder (a high-dose serotonin reuptake inhibitor for a long trial, then clomipramine, then antipsychotic augmentation, then the refractory options), exposure and response prevention, and the related disorders across the spectrum. The **trauma and stressor** band teaches post-traumatic stress disorder and its trauma-focused treatment, complex PTSD and its distinction from a personality disorder, the acute stress and adjustment reactions, and the neurobiology of fear conditioning. Every management recommendation is guideline-anchored, led by the BAP guidelines with the Indian Psychiatric Society, NICE and CANMAT positions stated, on the where-to-treat, target-by-phase, modes-of-treatment spine; every named syndrome ends with a **Good to remember** box giving the criterion, the discriminator and the first step, and every named drug or psychotherapy ends with one giving the mechanism or principle, the signature caution and the one dose or first-line indication. Figures declare one axis and code it in colour: **petrol** marks structure and the neutral case, **coral** marks the trap or the danger, and **marigold** highlights the number to hold; the rating scales are reproduced as the actual instruments where the licence permits, credited to their sources, or typeset from their structure where it does not. Several boundaries are stated up front: the anxiolytic and hypnotic pharmacology is taught in the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes and cross-referenced here; the deep antidepressant pharmacology in the Mood disorders: pharmacotherapy notes; the fear-circuit anatomy and receptor systems in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; deep brain stimulation and neurosurgery in the ECT and neurostimulation notes; the somatic-symptom and illness-anxiety boundary in the Somatic-symptom, sexual, impulse-control disorders and suicide notes; and the wider cognitive behaviour therapy technique in the Psychotherapies, clinical assessment, MSE and nosology notes. Exposure and response prevention, trauma-focused cognitive behaviour therapy, eye movement desensitisation and Clark's cognitive model of panic are owned and fully taught here. This is doctor-facing revision, so the full technical vocabulary is used, brand names lead with the Indian brand, and every dose, scale cut-off, criterion and first-line recommendation is verified against a source or omitted and flagged.

Anxiety disorders

1 · Generalised anxiety disorder

Almost every anxious patient a psychiatrist sees carries the same engine under the bonnet: worry that will not switch off. **Generalised anxiety disorder** (GAD) is the disorder of chronic, **free-floating anxiety** and **excessive worry**, an **apprehensive expectation** spread across many domains of life rather than fixed to one object or situation, which the person finds hard to control and which drags a train of somatic and psychic symptoms behind it. Examiners like GAD because

it sits at the crossroads of the whole anxiety block: it is the free-floating baseline against which panic (episodic), phobia (cued) and obsessive-compulsive disorder (intrusive and ritualised) are contrasted, it carries the two scales you must know cold (the GAD-7 and the Hamilton Anxiety Rating Scale), and its management is the template first-line story, **SSRI first-line** with **pregabalin** and **buspirone** as options and the benzodiazepine held back, that repeats across the anxiety disorders.

Fig 14.1 Anxiety disorders organise threat differently: diffuse future danger in generalised anxiety, abrupt bodily alarm in panic, social evaluation, specific objects or situations, and fear of difficult escape or unavailable help in agoraphobia.

Why it matters, and the chapter mnemonic. This topic seeds the master mnemonic for the whole anxiety block, **"WORRIED FEARS"**, unpacked in the mnemonic box below and paid off at consolidation. The amygdala and fear-circuit anatomy that underlies the sustained arousal is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and is not re-derived here; the deep pharmacology of the SSRIs and SNRIs lives in the Mood disorders: pharmacotherapy notes, and the anxiolytic story of pregabalin, buspirone and the benzodiazepines (with dependence and withdrawal) in the

Dissociative, conversion and anxiolytic/hypnotic pharmacology notes. What this note owns is the diagnosis, the discrimination from normal worry and from the other anxiety disorders, the two scales and their cut-offs, and the guideline-anchored drug plan.

GENERALIZED ANXIETY DISORDER 7-ITEM SCALE (GAD-7)

Spitzer RL, Kroenke K, Williams JBW, Lowe B, 2006

Over the **last 2 weeks**, how often have you been bothered by the following problems? *(Use the scale to the right to indicate your answer.)*

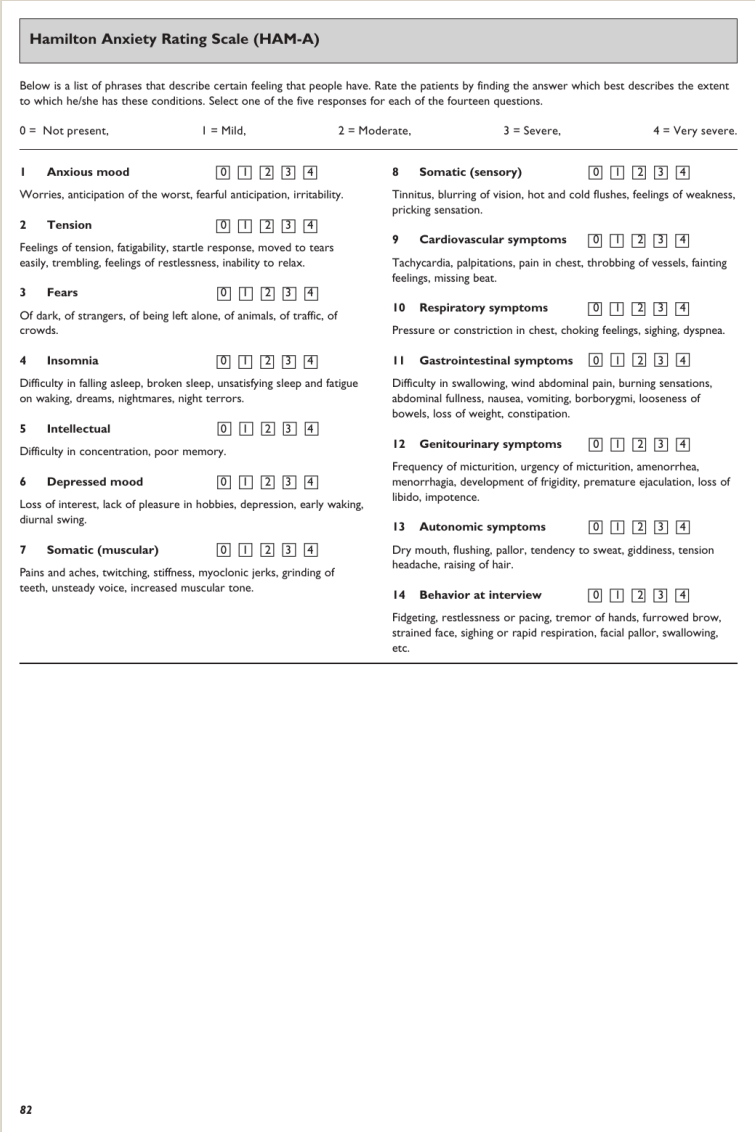
Question	Not at all	Several days	More than half the days	Nearly every day
1. Feeling nervous, anxious, or on edge	0	1	2	3
2. Not being able to stop or control worrying	0	1	2	3
3. Worrying too much about different things	0	1	2	3
4. Trouble relaxing	0	1	2	3
5. Being so restless that it is hard to sit still	0	1	2	3
6. Becoming easily annoyed or irritable	0	1	2	3
7. Feeling afraid, as if something awful might happen	0	1	2	3

Add columns (total): Column totals summed give a total score of 0 to 21.

Score interpretation: 0-4 minimal anxiety; 5-9 mild anxiety; 10-14 moderate anxiety; 15-21 severe anxiety.

Clinical threshold: A score of 10 or greater is the common cut-off for probable generalized anxiety disorder (a cut-off of 8 or greater maximizes sensitivity and specificity).

If you checked off any problems, how **difficult** have these made it for you to do your work, take care of things at home, or get along with other people?



Not difficult at all □ Somewhat difficult □ Very difficult □ Extremely difficult □

Hamilton Anxiety Rating Scale (HAM-A)

Below is a list of phrases that describe certain feeling that people have. Rate the patients by finding the answer which best describes the extent to which he/she has these conditions. Select one of the five responses for each of the fourteen questions.

0 = Not present, 1 = Mild, 2 = Moderate, 3 = Severe, 4 = Very severe.

1 **Anxious mood** [0] [1] [2] [3] [4]
Worries, anticipation of the worst, fearful anticipation, irritability.

2 **Tension** [0] [1] [2] [3] [4]
Feelings of tension, fatigability, startle response, moved to tears easily, trembling, feelings of restlessness, inability to relax.

3 **Fears** [0] [1] [2] [3] [4]
Of dark, of strangers, of being left alone, of animals, of traffic, of crowds.

4 **Insomnia** [0] [1] [2] [3] [4]
Difficulty in falling asleep, broken sleep, unsatisfying sleep and fatigue on waking, dreams, nightmares, night terrors.

5 **Intellectual** [0] [1] [2] [3] [4]
Difficulty in concentration, poor memory.

6 **Depressed mood** [0] [1] [2] [3] [4]
Loss of interest, lack of pleasure in hobbies, depression, early waking, diurnal swing.

7 **Somatic (muscular)** [0] [1] [2] [3] [4]
Pains and aches, twitching, stiffness, myoclonic jerks, grinding of teeth, unsteady voice, increased muscular tone.

8 **Somatic (sensory)** [0] [1] [2] [3] [4]
Tinnitus, blurring of vision, hot and cold flushes, feelings of weakness, pricking sensation.

9 **Cardiovascular symptoms** [0] [1] [2] [3] [4]
Tachycardia, palpitations, pain in chest, throbbing of vessels, fainting feelings, missing beat.

10 **Respiratory symptoms** [0] [1] [2] [3] [4]
Pressure or constriction in chest, choking feelings, sighing, dyspnea.

11 **Gastrointestinal symptoms** [0] [1] [2] [3] [4]
Difficulty in swallowing, wind abdominal pain, burning sensations, abdominal fullness, nausea, vomiting, borborygmi, looseness of bowels, loss of weight, constipation.

12 **Genitourinary symptoms** [0] [1] [2] [3] [4]
Frequency of micturition, urgency of micturition, amenorrhea, menorrhagia, development of frigidity, premature ejaculation, loss of libido, impotence.

13 **Autonomic symptoms** [0] [1] [2] [3] [4]
Dry mouth, flushing, pallor, tendency to sweat, giddiness, tension headache, raising of hair.

14 **Behavior at interview** [0] [1] [2] [3] [4]
Fidgeting, restlessness or pacing, tremor of hands, furrowed brow, strained face, sighing or rapid respiration, facial pallor, swallowing, etc.

82

The Hamilton Anxiety Rating Scale (HAM-A): 14 clinician-rated items covering psychic and somatic anxiety, each scored 0 to 4 (total 0 to 56); commonly below 17 is mild, 18 to 24 mild to moderate and 25 to 30 moderate to severe (the bands vary by source).

HAM-A (Hamilton, 1959); in the public domain.

Fig 14.2 The anxiety rating scales. The GAD-7 is the brief self-report screen for generalised anxiety, seven items each scored 0 to 3 for a total of 0 to 21, with 5, 10 and 15 marking mild, moderate and severe and a score of 10 or more the common threshold for probable generalised anxiety disorder. The Hamilton Anxiety Rating Scale is the clinician-rated severity measure, fourteen items spanning the psychic and the somatic symptoms of anxiety, each 0 to 4, for a total of 0 to 56. Both are shown here as their actual, freely reproducible forms; the GAD-7 keeps its original United States spelling.

1.1 The core concept: free-floating, excessive, hard-to-control worry

What "generalised" means. The defining quality is that the anxiety is *not tied to a specific trigger*. Unlike phobia (bound to a feared object) or panic disorder (episodic attacks), GAD is a persistent, diffuse free-floating anxiety, a general apprehensiveness "not restricted to any particular environmental circumstance" in the ICD-11 wording (ICD-11 CDDR). The cognitive core is excessive worry (apprehensive expectation) about multiple everyday domains, work, health, finances, the safety of family, minor chores, that is out of proportion to the actual likelihood or impact of the feared event.

The control criterion. The feature that separates GAD from the ordinary worry of a stressed but well person is that the patient *cannot control* the worry, cannot put it down to attend to the task in hand, and finds it pervasive, distressing and long-lasting. Everyday worry is manageable, focused and deferrable; GAD worry is uncontrollable, free-floating and self-perpetuating. This is the discriminator to lead with in any answer.

GOOD TO REMEMBER

- **Generalised anxiety disorder:** chronic, free-floating, excessive and uncontrollable worry (apprehensive expectation) spread across multiple life domains, not bound to a specific object or situation; the defining discriminator from normal worry is that it is excessive, pervasive and hard to control; the first diagnostic step is to exclude an organic mimic (hyperthyroidism, caffeine, substance withdrawal) before labelling it.

1.2 The symptom clusters: psychic worry plus a somatic tail

Psychic and somatic together. GAD is worry *with a body*. The psychic cluster is the apprehensive expectation itself, plus restlessness, feeling keyed up or on edge, difficulty concentrating or mind going blank, and irritability. The somatic cluster is dominated by **muscle tension** (with trembling, twitching, aches and soreness), fatigue and sleep disturbance, and a background of autonomic symptoms, sweating, nausea, gastrointestinal upset and an exaggerated startle. A teaching point examiners probe: overt autonomic hyperarousal (racing heart, breathlessness, dizziness) is *less* prominent in GAD than in panic disorder (Kaplan and Sadock 2024), because GAD is the sustained low-grade state rather than the acute surge.

Muscle tension is the signature somatic marker. Of the somatic features, muscle tension is the one most specific to GAD and the one most reliably present; it is the physical correlate of chronic vigilance and the symptom that best distinguishes GAD's body from the episodic autonomic storm of panic.

1.3 DSM-5-TR criteria: six months, three of six symptoms

The criteria to state cold. DSM-5-TR requires excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least **6 months**, about a number of events or activities; the person finds it difficult to control the worry; and the anxiety and worry are associated with **three or more of six** symptoms, more days than not for the past 6 months (DSM-5-TR 2022). The six are: restlessness or feeling keyed up or on edge; being easily fatigued; difficulty concentrating or mind going blank; irritability; muscle tension; and sleep disturbance. The disturbance must cause clinically significant distress or impairment, must not be attributable to a substance or another medical condition, and must not be better explained by another mental disorder.

The paediatric relaxation. A high-yield discriminator: in children, *only one* of the six associated symptoms is required, not three, reflecting that the worry-plus-body picture is thinner in a developing child.

CRITERION	DSM-5-TR REQUIREMENT
A. Worry	**Excessive anxiety and worry (apprehensive expectation), more days than not for at least 6 months, about multiple events/activities**
B. Control	The individual finds it difficult to control the worry
C. Symptoms	**3 or more of 6: restlessness/keyed up, easily fatigued, poor concentration, irritability, muscle tension, sleep disturbance (only 1 required in children)**
D. Impairment	Clinically significant distress or social/occupational impairment
E. Not organic	Not due to a substance or another medical condition (e.g. hyperthyroidism)
F. Not better explained	Not better accounted for by another mental disorder (panic, social anxiety, OCD, PTSD, illness anxiety and others)

DSM-5-TR criteria for generalised anxiety disorder; the two numbers to hold are the 6-month duration and 3-of-6 symptom threshold (only 1 in children) (DSM-5-TR 2022).

1.4 ICD-11 CDDR: free-floating anxiety and "at least several months"

Where ICD-11 differs. The ICD-11 CDDR frames GAD as either general apprehensiveness "not restricted to any particular environmental circumstance (free-floating anxiety)" or excessive worry (apprehensive expectation) about negative events across several domains of everyday life, accompanied by additional symptoms such as muscle tension, restlessness, difficulty relaxing, difficulty concentrating, irritability and sympathetic autonomic overactivity (ICD-11 CDDR). Crucially, ICD-11 does *not* impose the DSM's fixed 6-month clock: it requires the symptoms to be **not transient and to persist for at least several months, more days than not**. This softer, more clinically flexible duration is the classic ICD-11-versus-DSM-5 discriminator to name in a comparison answer.

Onset and course. ICD-11 notes the typical age of onset is the early-to-mid thirties (later than most anxiety disorders), that severity fluctuates between threshold and subthreshold forms, and that full remission is uncommon, GAD is chronic and relapsing, which is exactly why the guidelines argue for long continuation.

RULE **Duration is the ICD/DSM fork.** DSM-5-TR fixes GAD at 6 months more days than not with 3 of 6 symptoms; ICD-11 asks only for "at least several months" and does not set a hard 6-month threshold, so quote the framework you are asked about.

GOOD TO REMEMBER

- **ICD-11 GAD:** free-floating general apprehensiveness or excessive multi-domain worry plus muscle tension/autonomic and cognitive symptoms, not transient, persisting for at least several months more days than not; the defining contrast with DSM-5-TR is the absence of a fixed 6-month rule; typical onset is the early-to-mid thirties and full remission is uncommon.

1.5 The differential: excluding organic mimics and the other anxiety disorders

Rule out the body first. Before diagnosing GAD, exclude an organic cause of chronic anxiety: hyperthyroidism, phaeochromocytoma, hypoglycaemia, cardiac arrhythmia, and above all caffeine and substance withdrawal (alcohol and benzodiazepine withdrawal both produce a GAD-like picture). A first presentation of "anxiety" in an older patient, or one with prominent physical signs, warrants thyroid function and a substance history rather than a straight-to-SSRI reflex.

Then separate it from its neighbours. GAD is the free-floating baseline; the specific anxiety disorders are carved out by the *focus* of the fear, panic disorder (fear of the attacks themselves), social anxiety disorder (fear of negative evaluation), OCD (contamination or other obsessions), PTSD (trauma reminders), illness anxiety disorder (fear of serious illness), separation anxiety (separation from attachment figures). DSM criterion F requires that GAD not be better explained by any of these. Depression is the commonest comorbidity and can be hard to separate: in a depressive episode the worry is coloured by hopelessness and worthlessness, whereas GAD worry is future-oriented apprehension.

COMMON TRAP

Do not label chronic anxiety as GAD without excluding a medical mimic. Hyperthyroidism, a caffeine habit, and alcohol or benzodiazepine withdrawal each reproduce restlessness, tremor, poor sleep and autonomic arousal; missing them means treating the wrong disorder. Thyroid function, a substance and caffeine history, and attention to withdrawal timing come before the prescription.

1.6 The GAD-7: the screening and severity scale to know cold

What it is. The GAD-7 (Generalised Anxiety Disorder-7) is a seven-item self-report scale of general worry and fear symptoms over the last 2 weeks, each item scored 0 to 3 on a Likert scale (not at all, several days, more than half the days, nearly every day), giving a total range of **0 to 21** (Spitzer et al 2006; Kaplan and Sadock 2024). It is the workhorse instrument of primary-care anxiety screening and of tracking treatment response, and it is reproduced in full on the accompanying scale plate.

The cut-offs. The suggested severity bands are **5, 10 and 15** for mild, moderate and severe anxiety respectively. The single most useful clinical threshold to memorise is a score of **10**, the usual cut-off for probable GAD and the point at which further assessment is warranted. A two-item short form, the GAD-2, is used as a rapid case-finding question; NICE recommends being alert to GAD and considering the GAD-2 to ask about anxiety and the ability to control worry (NICE 2011). A caveat examiners like: the GAD-7 asks about the last 2 weeks, whereas the DSM diagnosis needs symptoms over 6 months, so a high GAD-7 supports but does not by itself make the diagnosis.

GOOD TO REMEMBER

- **GAD-7:** seven self-rated items over 2 weeks, each 0 to 3, total 0 to 21; severity bands at 5/10/15 for mild/moderate/severe; a score of 10 is the standard clinical cut-off for probable GAD; the 2-item GAD-2 is the rapid screen; it measures 2-week severity and screens, it does not replace the 6-month DSM diagnosis.

1.7 The Hamilton Anxiety Rating Scale (HAM-A): the clinician-rated outcome measure

What it is. The Hamilton Anxiety Rating Scale (HAM-A, also HARS) is a *clinician-rated* scale of 14 items, each scored 0 to 4, covering both the psychic and the somatic components of anxiety, for a maximum total of **56** (Maudsley Deprescribing Guidelines). It is the standard anxiety-severity and treatment-outcome measure in trials, the scale against which drug effects in GAD are reported, and it too is set out on the accompanying scale plate. Where the GAD-7 is a quick self-report screen, the HAM-A is the fuller clinician instrument used to quantify change.

Reading it. The 14 items split into a psychic-anxiety factor (anxious mood, tension, fears, insomnia, cognitive difficulty, depressed mood) and a somatic-anxiety factor (muscular, sensory, cardiovascular, respiratory, gastrointestinal, genitourinary, autonomic), so the profile shows which arm of the disorder dominates. Commonly used severity bands place mild anxiety below the high-teens and increasing severity above the mid-twenties, though the exact numeric cut-points vary by source and are not standardised the way the GAD-7 bands are, so quote the structure (14 items, max 56) with confidence and the precise band figures with appropriate caution.

GOOD TO REMEMBER

- **HAM-A (HARS):** a clinician-rated 14-item scale, each item 0 to 4, maximum 56, splitting into psychic-anxiety and somatic-anxiety factors; it is the standard outcome measure in GAD drug trials (drug effects are reported as points reduced on the HAM-A); contrast with the GAD-7, which is self-rated, 7 items and used to screen.

10 GAD-7 CLINICAL CUT-OFF FOR PROBABLE GAD (BANDS AT 5/10/15)	**0 to 21** GAD-7 TOTAL SCORE RANGE (7 ITEMS, EACH 0 TO 3)	**56** HAM-A MAXIMUM (14 ITEMS, EACH 0 TO 4)	**6 months** DSM-5-TR DURATION; 3 OF 6 SYMPTOMS

1.8 Management: SSRI or SNRI first-line, across the guidelines

The BAP position. Lead with the British Association for Psychopharmacology: an SSRI is the first-line pharmacological treatment for GAD, the efficacious agents named being citalopram, escitalopram, paroxetine and sertraline; if an SSRI is unsuitable, an SNRI (duloxetine or venlafaxine) or pregabalin is the alternative initial treatment, and higher pregabalin doses may achieve greater response (BAP 2014). This is the verified **SSRI first-line** anchor and must not be contradicted.

What the other guidelines say. The picture is strikingly consistent. The Indian Psychiatric Society CPG names cognitive behavioural therapy as the first-line psychological treatment (the Indian Psychiatric Society 2020), sitting alongside the same pharmacology. NICE offers an SSRI if drug treatment is chosen, considering sertraline first as the most cost-effective option, then an alternative SSRI or an SNRI, and pregabalin only if SSRIs and SNRIs cannot be tolerated (NICE 2011). CANMAT lists SSRIs (escitalopram, paroxetine, sertraline), SNRIs (duloxetine, venlafaxine XR), agomelatine and pregabalin as first-line, with CBT as a first-line psychological treatment of comparable magnitude (CANMAT 2014). The WFSBP likewise puts an SSRI or SNRI first-line with CBT as first-line psychotherapy (WFSBP 2022). The convergence is the exam point: *SSRI or SNRI first-line everywhere*.

GUIDELINE	FIRST-LINE PHARMACOLOGY	KEY NOTE
BAP 2014	**SSRI (citalopram, escitalopram, paroxetine, sertraline)**	SNRI or pregabalin if SSRI unsuitable
Indian Psychiatric Society 2020	SSRI/SNRI, with CBT first-line psychological	CBT named as first-line therapy
NICE 2011	**SSRI, consider sertraline first (most cost-effective)**	Pregabalin only if SSRI/SNRI not tolerated
CANMAT 2014	SSRI, SNRI, agomelatine or pregabalin	CBT equal first-line to drugs

First-line pharmacotherapy for GAD across the major guidelines; the shared message is SSRI or SNRI first, with pregabalin as an option and CBT a co-equal first-line psychological treatment.

RULE **SSRI or SNRI is first-line for GAD, full stop.** BAP, NICE, CANMAT, WFSBP and the Indian Psychiatric Society all put an SSRI (or SNRI) first, with pregabalin and buspirone as options; CBT is the co-equal first-line psychological treatment.

1.9 The options and the second line: pregabalin, buspirone and the trial rules

Pregabalin. Pregabalin (Indian brands Pregeb, Pregastar) is a calcium-channel alpha-2-delta ligand with a genuinely anxiolytic effect and a relatively rapid onset. It is an alternative initial treatment when SSRIs are unsuitable (BAP 2014) and an augmentation option after non-response to an SSRI or SNRI. Its advantages are that it is renally cleared (useful in hepatic impairment) and fast-acting; its cautions are weight gain in about a fifth of long-term users, discontinuation symptoms on abrupt withdrawal, and a real potential for misuse, which is why NICE requires a drug-abuse history to be evaluated before prescribing (NICE 2011).

Buspirone. Buspirone (Indian brand Buspin) is a 5-HT1A partial agonist, efficacious in the acute treatment of GAD, non-sedating and non-dependence-forming, which makes it a useful option, particularly where a benzodiazepine is being avoided. Its limitations are a slow onset (a couple of weeks, so no use as a rescue drug) and no evidence for relapse prevention.

The adequate trial. A shared rule: allow up to **12 weeks** to judge efficacy, but recognise that absence of any benefit by **4 weeks** signals that response to unchanged treatment is unlikely (BAP 2014). SSRIs and SNRIs are often started at half the usual dose in GAD and titrated up, because early activation is common. When a patient responds, continuation of at least a further 6 to 18 months (BAP: up to 18 further months; NICE: at least a year) reduces relapse.

GOOD TO REMEMBER

- **Pregabalin (Pregeb, Pregastar):** an alpha-2-delta calcium-channel ligand; alternative first-line or augmentation option in GAD, relatively rapid-acting and renally cleared; signature cautions are weight gain, discontinuation symptoms and misuse potential (check a drug-abuse history first).
- **Buspirone (Buspin):** a 5-HT1A partial agonist; non-sedating, non-dependence-forming option for acute GAD; signature caution is its slow onset (about 2 weeks, so not a rescue agent) and no relapse-prevention evidence.

1.10 The benzodiazepine: not first-line, and not for the long term

The hard rule. A benzodiazepine is explicitly *not* a first-line treatment for GAD and must not be used long-term. BAP reserves benzodiazepines only after non-response to an SSRI, SNRI, pregabalin and buspirone, for persistent, severe, distressing, impairing anxiety where other treatments have failed (BAP 2014). NICE is blunter: do not offer a benzodiazepine for GAD except as a short-term measure during a crisis, and no more than 2 to 4 weeks (NICE 2011). The reason is the class's tolerance, dependence and withdrawal liability, the full pharmacology of which is developed in the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes: a meta-analysis shows the HAM-A advantage of benzodiazepines over placebo shrinks from about 8 points at 1 week to almost nothing by 3 months (Maudsley Deprescribing Guidelines).

Propranolol. The beta-blocker propranolol (Indian brands Ciplar, Inderal) blunts the peripheral autonomic symptoms (tremor, palpitations) and is useful for *performance* anxiety, but it is not a treatment for GAD itself and is explicitly not recommended for its long-term management (MOH Singapore 2015).

TRAP **Never give a benzodiazepine as long-term monotherapy for GAD.** It is not first-line, is limited to short crisis use (2 to 4 weeks), and its apparent benefit fades within weeks as tolerance and dependence develop; the exam-fatal error is to write it up as the maintenance answer.

1.11 The India lens: the treatment gap and the benzodiazepine problem

Two genuine Indian realities. First, most people with GAD in India never reach formal care, part of the very large anxiety-disorder treatment gap; anxiety is under-recognised, somatised (patients present with physical complaints rather than "worry"), and under-treated. Second, and connected, is the entrenched over-prescription of benzodiazepines: in Indian general and primary care, a benzodiazepine (often alprazolam) is frequently the default and only "anxiety" prescription, given long-term against every guideline. The Indian Psychiatric Society CPGs exist precisely to correct this, an SSRI or SNRI first-line with CBT, the benzodiazepine reserved and time-limited, and the anxiolytic used only as a short bridge while the antidepressant takes effect (the Indian Psychiatric Society 2020).

Prescribing in Indian practice. The first-line agents are cheap and familiar as Indian brands: escitalopram (Nexito, Rexipra) and sertraline lead, with pregabalin (Pregeb, Pregastar) and buspirone (Buspin) as options and propranolol (Ciplar, Inderal) for the performance-anxiety niche. Starting the SSRI low and warning the patient about early activation, then holding the course to 12 weeks before judging failure, is the practical antidote to the "one alprazolam strip forever" pattern.

INDIA

The single highest-yield Indian point on this topic is the benzodiazepine over-prescription problem. Anxiety is common, somatised and under-recognised, and the treatment gap is wide; into that gap has flowed long-term benzodiazepine (typically alprazolam) prescribing that runs directly against the Indian Psychiatric Society CPG. The correct Indian answer mirrors the global one: an SSRI or SNRI first-line (Nexito or Rexipra escitalopram, sertraline) with CBT, pregabalin (Pregeb, Pregastar) or buspirone (Buspin) as options, and the benzodiazepine only as a short, time-limited bridge, never the maintenance treatment.

MNEMONIC

WORRIED FEARS

The chapter mnemonic, seeded here and paid off at consolidation. **WORRIED** holds the GAD picture: **W**orry (free-floating, uncontrollable), **O**n edge/restless, **R**umination and poor concentration, **R**elaxation impossible (muscle tension), **I**rritability, **E**asily fatigued, **D**isturbed sleep. **FEARS** holds the management: **F**irst-line SSRI/SNRI, **E**valuate for 12 weeks (4-week early-failure warning), **A**lternatives pregabalin and buspirone, **R**efer/CBT co-equal first-line, **S**hun the benzodiazepine as long-term monotherapy.

HOLD THIS

GAD is chronic, free-floating, uncontrollable worry across many domains, requiring 6 months and 3 of 6 symptoms in DSM-5-TR (only "several months" in ICD-11); the GAD-7 (self-rated, 0 to 21, cut-off 10) and HAM-A (clinician-rated, 14 items, max 56) are the scales; management is an SSRI or SNRI first-line (up to 12 weeks to judge), with pregabalin, buspirone and CBT as options, propranolol for performance anxiety, and the benzodiazepine never a long-term monotherapy.

2 · Panic disorder

Panic disorder is the disorder of the false alarm. A surge of autonomic terror arrives out of a calm sky, peaks in minutes, and the patient, feeling their heart pound and their breath shorten, concludes they are dying, suffocating or losing their mind. That misreading is the engine of the illness: the body's fear response is real, but the interpretation is catastrophic, and the fear of the next attack becomes a second illness layered on the first. Examiners test **panic disorder** on a tight set of exact points, the definition of a **panic attack** (an abrupt surge peaking within minutes, four or more of thirteen symptoms), the requirement of **recurrent** *unexpected* attacks plus a month of **anticipatory anxiety** or behaviour change, the medical mimics that must be excluded, and the management, where the one thing a wrong answer fails is starting an antidepressant without warning about early activation.

Why it matters clinically. This is a management/drug topic, so the marks sit in the drug, the dose, the line and the monitoring as much as in the phenomenology. Two facts anchor every answer. First, the diagnostic core is the *unexpected*, cued-by-nothing attack followed by persistent worry, which separates panic disorder from the situationally-bound attacks of the phobias. Second, the treatment core is that an SSRI is first-line but must be started low and slow with an

explicit warning, because these patients are exquisitely sensitive to the transient jitteriness of an antidepressant and will read it as another attack and stop the drug. The fear-circuit anatomy on which the alarm is built is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes, the wider CBT model in the Psychotherapies, clinical assessment, MSE and nosology notes, and the deep SSRI pharmacology in the Mood disorders: pharmacotherapy notes; they are not re-derived here.

2.1 What a panic attack is: an abrupt surge that peaks within minutes

The unit of the disorder. A panic attack is an abrupt surge of intense fear or intense discomfort that reaches a peak *within minutes*, during which four or more of a list of thirteen physical and cognitive symptoms occur (DSM-5-TR 2022). The word to hold is *abrupt*: the surge can rise from a calm state or an already-anxious state, and it crescendos fast rather than building over hours. Fewer than four symptoms is a **limited-symptom attack**, which still counts clinically but not as a full attack.

The thirteen symptoms. The list divides into autonomic and cognitive. The autonomic and somatic symptoms are palpitations or pounding heart, sweating, trembling, shortness of breath or smothering, feelings of choking, chest pain, nausea or abdominal distress, dizziness or faintness, chills or heat sensations, and paraesthesiae. The cognitive symptoms are the three that give panic its dread: derealisation or depersonalisation, fear of losing control or "going crazy", and fear of dying (DSM-5-TR 2022). It is the cognitive triad that turns a burst of arousal into terror.

WORKED EXAMPLE

A 28-year-old software engineer is brought to casualty at midnight convinced he is having a heart attack: chest tightness, a racing heart, tingling in both hands, a sense that the room is unreal and that he is about to die. It began abruptly while he was watching television and peaked in about five minutes. ECG, troponin and examination are normal. This is a full panic attack (well over four symptoms, including the cognitive fear-of-dying and derealisation), arising unexpectedly from a calm state. If this is his third such attack and he now avoids being alone at night for fear of another, the diagnosis is panic disorder, not cardiac disease.

2.2 Recurrent unexpected attacks: the diagnostic spine

Recurrent and unexpected. **Panic disorder** requires **recurrent** *unexpected* panic attacks (Criterion A) (DSM-5-TR 2022). *Recurrent* means more than one; *unexpected* means the attack comes with no obvious cue at the time it occurs, as when a person is relaxing or is woken from sleep by a **nocturnal panic attack**. This is the single discriminator that examiners protect: an attack triggered reliably by a feared situation is an *expected* attack and points to a phobia, not to panic disorder. Roughly half of patients with panic disorder also have expected attacks, so the presence of expected attacks does not rule the diagnosis out, but at least some attacks must come out of the blue.

The one-month tail. Criterion B requires that at least one attack has been followed by a month or more of one or both of: persistent concern or worry about further attacks or their consequences (the **anticipatory anxiety**), or a significant maladaptive change in behaviour

because of the attacks, such as avoiding exercise or unfamiliar places (DSM-5-TR 2022). Without this month-long tail there are panic attacks but not the disorder.

RULE **Unexpected attack plus a month of worry.** Panic disorder needs *recurrent unexpected* panic attacks (out of the blue, not situationally cued) plus at least one month of anticipatory worry or maladaptive avoidance; a situationally-triggered attack is a phobia's attack, not this diagnosis.

2.3 Anticipatory anxiety, catastrophic misinterpretation and the panic cycle

The cognitive engine. The dominant cognitive model, Clark's, holds that **panic disorder** arises from the **catastrophic misinterpretation** of benign bodily sensations: a normal palpitation is read as an impending heart attack, breathlessness as suffocation, dizziness as impending collapse or madness (Tasman Psychiatry; New Oxford Textbook of Psychiatry). The misinterpretation amplifies the very sensations it fears, which are then read as further proof of catastrophe, closing a vicious loop, the **panic cycle**, that drives the attack to its peak. This is why interoceptive exposure, deliberately inducing the feared sensations, is a core ingredient of panic-focused CBT: it disconfirms the catastrophic prediction.

Anticipatory anxiety and phobic avoidance. Between attacks the patient is left with **anticipatory anxiety**, a persistent apprehensive dread of the next attack, and often with *fear of the fear* itself. This can generalise into agoraphobia, avoidance of situations from which escape would be difficult or help unavailable if an attack struck, so that a third illness (avoidance) stacks on the anticipatory anxiety and the attacks. The three layers, the attack, the anticipatory anxiety, and the avoidance, are what a full answer names.

PEARL

Panic disorder is really three problems in a stack: the *panic attack* (the false autonomic alarm), the *anticipatory anxiety* (fear of the next alarm, the "fear of fear"), and the *phobic avoidance* that can crystallise into agoraphobia. The catastrophic misinterpretation of body sensations is the hinge that converts a burst of arousal into terror and keeps the cycle turning. Treatment must reach all three layers, which is why an SSRI (dampens the attacks) plus CBT (breaks the misinterpretation and the avoidance) is the fullest answer.

2.4 The mimics you must exclude before you diagnose

Panic is a diagnosis of exclusion of the organic. Criterion C requires that the disturbance is not due to a substance or another medical condition, and Criterion D that it is not better explained by another mental disorder (DSM-5-TR 2022). The medical mimics to actively exclude are **hyperthyroidism**, **hyperparathyroidism**, **phaeochromocytoma**, vestibular dysfunction, seizure disorders, and cardiopulmonary conditions such as arrhythmias, supraventricular tachycardia, asthma and COPD (DSM-5-TR 2022). Substance causes, intoxication with stimulants (cocaine, amphetamines, caffeine) or cannabis and withdrawal from alcohol or barbiturates, must also be considered.

The red flags that push you toward the organic. First onset after 45 years, or atypical features during the attack, vertigo, loss of consciousness, loss of bladder or bowel control, slurred speech

or amnesia, should make you suspect a medical or substance cause rather than primary panic disorder (DSM-5-TR 2022). A first "panic attack" in an older patient is a cardiac or endocrine event until proven otherwise.

TRAP **Missing the organic mimic.** A panic attack is a diagnosis of exclusion: hyperthyroidism, phaeochromocytoma, hypoglycaemia, an arrhythmia or supraventricular tachycardia, and stimulant or caffeine excess all mimic it. First onset after 45, or vertigo, syncope, incontinence, slurred speech or amnesia during the attack, are red flags for a medical cause, do not label them panic.

2.5 ICD-11 and the criterion-anchored discriminators

ICD-11 CDDR. ICD-11 places panic disorder (6B01) among the anxiety and fear-related disorders and, like DSM-5-TR, requires recurrent unexpected panic attacks that are not restricted to a particular stimulus or situation, together with persistent concern about their recurrence or their significance, or behaviours intended to avoid recurrence (ICD-11 CDDR). The systems align on the essentials: it is the *unexpected, uncued* attack plus the persistent apprehension that defines the disorder.

The discriminator to state. If panic attacks occur *only* in a specific context, in social situations (social anxiety disorder), before phobic objects (specific phobia or agoraphobia), triggered by obsessions (OCD), by trauma reminders (PTSD), or by separation (separation anxiety disorder), then only that disorder is diagnosed and not panic disorder (DSM-5-TR 2022). Panic disorder is the diagnosis when the attacks are, at least in part, cued by nothing at all.

GOOD TO REMEMBER

- **Panic disorder (the syndrome):** the defining criterion is *recurrent unexpected* panic attacks (an abrupt surge peaking within minutes, four or more of thirteen autonomic and cognitive symptoms) followed by at least one month of persistent anticipatory worry about further attacks or a maladaptive behaviour change; the discriminator from the phobias is that at least some attacks are *uncued*, and the first step before diagnosis is to exclude the organic mimics (hyperthyroidism, phaeochromocytoma, arrhythmia, stimulant/caffeine excess), especially with first onset after 45 or atypical neurological features.

2.6 Management overview: SSRI first-line, CBT, and where the guidelines converge

Lead with BAP. The British Association for Psychopharmacology (BAP) makes an **SSRI** the first-line pharmacological treatment for panic disorder (escitalopram, citalopram, fluoxetine, fluvoxamine, paroxetine or sertraline), and cognitive behaviour therapy the first-line psychological treatment, noting that drug and psychological approaches have broadly similar efficacy; for partial or non-response it recommends combining cognitive therapy with an antidepressant, which is more effective than drug treatment alone and may protect better against relapse (BAP 2014). This is the verified first-line position and anchors any answer: an SSRI or CBT, chosen by availability and patient preference, with the combination reserved for the incomplete responder.

Then the other bodies. The Indian Psychiatric Society clinical practice guideline makes SSRIs or SNRIs the first-line agents for the long-term management of panic disorder and recommends

CBT (psychoeducation, self-monitoring, systematic exposure to panic-inducing cues, countering anxious beliefs, relapse prevention), adding that a combination of CBT and medication gives the best outcomes; in the elderly it prefers SSRIs as safer, avoiding TCAs and benzodiazepines because of anticholinergic effects, orthostatic hypotension, ECG changes and paradoxical reactions (IPS 2017). NICE offers an SSRI licensed for panic (escitalopram, sertraline, citalopram, paroxetine) or venlafaxine as the first pharmacological option, offers CBT of 7 to 14 hours over four months as first-line, and explicitly says *do not* prescribe benzodiazepines, sedating antihistamines or antipsychotics for panic disorder (NICE 2011). CANMAT likewise places an SSRI or venlafaxine XR and CBT (with interoceptive and situational exposure) as first-line (CANMAT 2014). WFSBP grades the SSRIs and venlafaxine as first-line (Recommendation Grade 1) at **20 to 60 mg/day** (WFSBP 2008).

GUIDELINE	FIRST-LINE PHARMACOLOGY	PSYCHOTHERAPY	BENZODIAZEPINE STANCE
BAP 2014	SSRI (escitalopram, citalopram, fluoxetine, fluvoxamine, paroxetine, sertraline)	CBT first-line; combine with antidepressant for partial/non-response	Not first-line
Indian Psychiatric Society 2017	SSRI or SNRI first-line for long-term management	CBT; CBT plus medication gives best outcomes	Short-acting oral, only for the acute attack with reassurance
NICE 2011	SSRI licensed for panic (escitalopram, sertraline, citalopram, paroxetine) or venlafaxine	CBT 7 to 14 hours over 4 months, first-line	**Do not prescribe (worse long-term outcome)**
CANMAT 2014	SSRI or venlafaxine XR, first-line	CBT with interoceptive and situational exposure, first-line	Second-line only
WFSBP 2008	SSRI or venlafaxine, first-line, 20 to 60 mg/day	CBT alone or combined with medication	Reserve for treatment-resistant, no substance-use history

Guideline-level management of panic disorder; BAP-led, then the Indian Psychiatric Society, NICE, CANMAT and WFSBP, all converging on SSRI/SNRI plus CBT first-line and benzodiazepines out of the first line (verified from the drug-guideline supplement).

2.7 Starting the SSRI: start low, go slow, and warn about early activation

The single most examinable prescribing point. An **ssri panic** start must be at a *low* dose, lower than the usual antidepressant starting dose, and titrated slowly, because patients with panic disorder are unusually sensitive to the transient over-stimulation an antidepressant produces in the first days and weeks, the jitteriness syndrome of restlessness, insomnia, agitation and a paradoxical worsening of anxiety (Pohl et al., in Tasman Psychiatry; Maudsley Prescribing Guidelines; Stahl). Left unwarned, the patient reads this early activation as another panic attack, concludes the drug is harming them, and stops it. The instruction to memorise is therefore: *start low, go slow, and warn the patient in advance* that they may feel briefly more jittery before they feel better, that this is expected and self-limiting, and that it is not a sign of harm.

How this looks in practice. Begin, for example, sertraline at 25 mg/day rather than 50, or escitalopram at 5 mg/day, titrating upward after several days once early activation has settled; a short course of a benzodiazepine may be co-prescribed to cover the activation window in selected patients, then withdrawn (WFSBP 2008; MOH_SG 2015). The therapeutic effect is delayed, several weeks, so the patient must also be told the drug is not a rescue medication for an attack in progress but a preventive taken daily (NICE 2011).

TRAP **Starting the SSRI at a full dose with no warning.** Panic patients are hypersensitive to early SSRI activation (the jitteriness syndrome); a normal starting dose can trigger restlessness and a paradoxical surge of anxiety that the patient reads as another attack and stops the drug. Start at half the usual dose, titrate slowly, and warn in advance that a brief jittery phase is expected and self-limiting.

2.8 Dose, duration and stopping: the numbers to hold

Target dose and trial length. Once started low, the SSRI is titrated to the effective antidepressant range; WFSBP puts the first-line SSRI and venlafaxine range at **20 to 60 mg/day** (citalopram-equivalent), and panic disorder, like the other anxiety disorders, often needs the *upper* part of the range and an adequate trial before response is judged (WFSBP 2008; NICE 2011). NICE frames the antidepressant trial around a **12-week** course: if there is no improvement after a 12-week course of an SSRI, and only then, imipramine or clomipramine may be considered off-label as the next step (NICE 2011).

Continuation and the taper. After response, drug treatment is continued for *at least six months*, and when stopping the dose is reduced gradually over an extended period, a minimum of three months, to avoid discontinuation symptoms (BAP 2014). The relapse rate on abrupt withdrawal is high, so the slow taper is part of the treatment, not an afterthought. Patients should be told of both the delayed onset and the discontinuation risk from the outset, and monitored with a brief self-report panic-severity questionnaire (NICE 2011).

STEP	ACTION	SOURCE
Start	**SSRI at half the usual dose (e.g. sertraline 25 mg/day, escitalopram 5 mg/day); warn about early activation**	Maudsley; Stahl
Titrate	Up to the effective range, 20 to 60 mg/day, often the upper end	WFSBP 2008
Judge response	**Adequate trial; if no improvement after a 12-week course, consider imipramine or clomipramine (off-label)**	NICE 2011
Continue	At least six months after response	BAP 2014
Stop	**Taper gradually over a minimum of three months**	BAP 2014

The SSRI course in panic disorder: start low and warn, titrate to range, judge at 12 weeks, continue at least six months, taper over at least three (BAP 2014; NICE 2011; WFSBP 2008).

GOOD TO REMEMBER

- **SSRI in panic disorder (fluoxetine, sertraline, fluvoxamine, paroxetine, escitalopram; the antidepressant brand list applies):** the first-line agent across BAP, IPS, NICE, CANMAT and WFSBP; mechanism is serotonergic dampening of the fear circuit, the signature caution is early *activation* (the jitteriness syndrome), so *start at half the usual dose, titrate slowly and warn the patient in advance*; effective range 20 to 60 mg/day, judge response over a 12-week course, continue at least six months, and taper over a minimum of three months to avoid discontinuation.

2.9 CBT for panic: interoceptive exposure and the Clark model in practice

What panic-focused CBT does. CBT is first-line and, delivered as a structured 7-to-14-hour course over about four months, targets each layer of the disorder (NICE 2011; BAP 2014). Its ingredients are psychoeducation about the panic cycle, *interoceptive exposure* (deliberately inducing the feared bodily sensations, for example by hyperventilating or spinning, to disconfirm the catastrophic prediction), in-vivo exposure for any agoraphobic avoidance, and cognitive restructuring of the **catastrophic misinterpretation** at the heart of Clark's model (NICE 2011). Because it directly dismantles the misinterpretation and the avoidance, CBT tends to protect against relapse better than medication stopped early.

Where it sits against the drug. Drug and CBT have broadly similar acute efficacy; the fullest answer offers either as first-line and combines them for the partial responder (BAP 2014). The general CBT model and the wider exposure principle are developed in the Psychotherapies, clinical assessment, MSE and nosology notes.

GOOD TO REMEMBER

- **CBT for panic (the psychotherapy):** first-line, 7 to 14 hours over about four months; its defining active ingredient is *interoceptive exposure*, deliberately provoking the feared bodily sensations to disconfirm the catastrophic misinterpretation of Clark's model, plus cognitive restructuring and in-vivo exposure for agoraphobic avoidance; it has similar acute efficacy to an SSRI and better relapse protection, and combining CBT with an antidepressant is the recommended step for a partial responder.

2.10 The benzodiazepine: reserved, time-limited, never the first line

The reserved role. Every guideline pushes the benzodiazepine out of the first line. NICE says outright *do not* prescribe benzodiazepines for panic disorder, because they are associated with a worse long-term outcome (NICE 2011). CANMAT places them second-line, WFSBP reserves them for treatment-resistant cases with no substance-use history, and WHO permits them only for severe acute symptoms and only very short-term, 3 to 7 days (CANMAT 2014; WFSBP 2008; WHO mhGAP 2023). The Indian Psychiatric Society allows a short-acting, orally-dissolving benzodiazepine with reassurance for the *acute panic attack itself*, and MOH Singapore permits adding one to an antidepressant short-term to cover the early activation window, tapering it off within four weeks (IPS 2017; MOH_SG 2015). The through-line: a benzodiazepine is a bridge for the acute attack or the activation window, never the maintenance treatment and never a monotherapy.

Why the caution is genuine. The risks are dependence, tolerance, cognitive dulling, rebound anxiety and inter-dose panic, and a worse long-term course, which is why the drug is time-limited and tapered. The wider anxiolytic pharmacology, benzodiazepines, buspirone, pregabalin, the z-drugs, dependence and withdrawal, is developed in the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes.

INDIA

Panic disorder sits inside a large, mostly untreated Indian anxiety burden, most sufferers never reach formal care, and it collides with the country's benzodiazepine over-prescription problem: alprazolam and clonazepam are dispensed freely, often long-term, as a first move for "ghabrahat" and palpitations, which is exactly what every guideline warns against. The Indian Psychiatric Society CPG is unambiguous, an SSRI or SNRI is first-line for long-term management and the benzodiazepine is only a short-acting, orally-dissolving bridge for the acute attack. Indian brands are cheap and available, sertraline (Serta, Zosert, Daxid), escitalopram (Nexito, Cipralex), paroxetine (Paxidep) and fluoxetine (Fludac); the correct Indian answer is a low-started, well-explained SSRI plus CBT, not a chronic benzodiazepine. A neat exam pearl: the lactate provocation (sodium lactate infusion) test can precipitate an attack in about 70% of panic-disorder patients, a classic Indian-textbook association.

TRAP **The chronic benzodiazepine.** A benzodiazepine as ongoing monotherapy for panic disorder is the classic error: it worsens the long-term outcome, breeds dependence and inter-dose rebound panic. It is at most a short-acting bridge for the acute attack or the SSRI activation window, tapered within a few weeks, never the maintenance treatment.

4 of 13	1 month	12 weeks	6 months
SYMPTOMS NEEDED FOR A FULL PANIC ATTACK (FEWER IS A LIMITED-SYMPTOM ATTACK)	OF ANTICIPATORY WORRY OR BEHAVIOUR CHANGE REQUIRED (CRITERION B)	SSRI COURSE BEFORE JUDGING NON-RESPONSE AND CONSIDERING A TCA	MINIMUM CONTINUATION AFTER RESPONSE; TAPER OVER AT LEAST 3 MONTHS

HOLD THIS

Panic disorder is recurrent *unexpected* panic attacks (an abrupt surge peaking within minutes, four or more of thirteen symptoms) plus at least a month of anticipatory worry, driven by catastrophic misinterpretation of body sensations, and treated first-line with an SSRI started at half the usual dose with an explicit warning about early activation plus CBT with interoceptive exposure; the benzodiazepine is reserved, time-limited and never a monotherapy.

3 · Clark cognitive model of panic

David M. **Clark**'s **cognitive model of panic** (1986) is the single most examined psychological model in the anxiety chapter, because it does two things at once: it explains why a panic attack feels like a heart attack, and it hands the clinician the exact lever that **cognitive behaviour therapy** pulls to abolish it. The claim is deceptively simple. Panic disorder arises not from the bodily sensations of arousal themselves, which everyone gets, but from the **catastrophic misinterpretation** of those benign sensations as an imminent physical or mental disaster. A racing heart is read as *"I am having a heart attack"*, breathlessness as *"I am suffocating"*, dizziness as

"I am about to collapse or go mad". That misreading feeds a self-amplifying loop that Clark drew as a **vicious cycle** (shown in the accompanying figure), and it is the loop, not any one symptom, that the model asks you to memorise.

Why it matters. The model is the reason panic disorder is one of the most treatable conditions in psychiatry: break the misinterpretation and the cycle collapses. It supplies the discriminator examiners want (panic disorder is a disorder of *interpretation*, not of the autonomic nervous system) and it maps one-to-one onto the CBT protocol that BAP, NICE and CANMAT all place first-line. The wider CBT technique, the general cognitive model and the exposure principle belong to the Psychotherapies, clinical assessment, MSE and nosology notes; this topic owns Clark's disorder-specific loop, the safety behaviours that keep it turning, and how CBT dismantles each link.

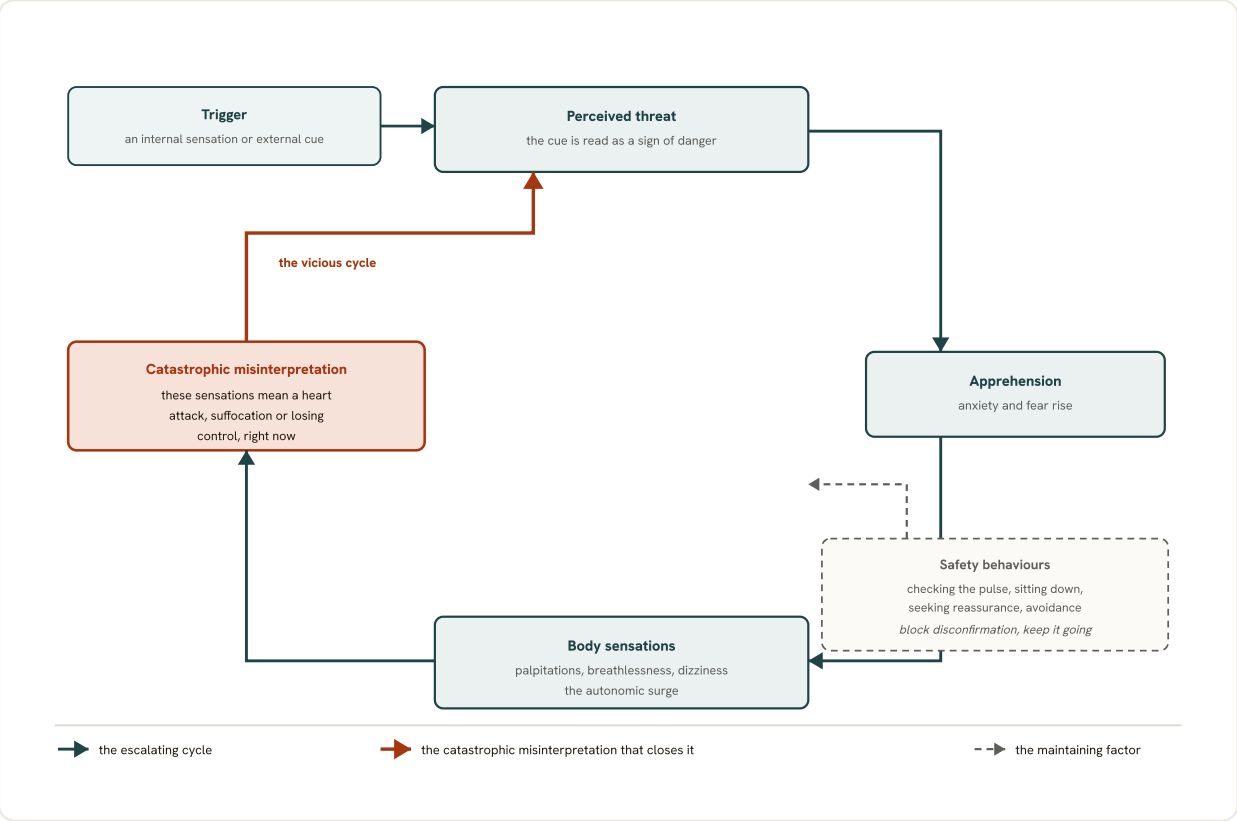

Fig 14.3 Clark's cognitive model of panic. A trigger, most often an ordinary bodily sensation, is read as a sign of threat; the apprehension that follows amplifies the autonomic body sensations, which are then catastrophically misinterpreted as an imminent heart attack, suffocation or loss of control, and that misinterpretation feeds straight back into the perceived threat, closing a vicious cycle that escalates to a full panic attack in minutes. Safety behaviours, checking the pulse, sitting down, seeking reassurance and avoidance, feel protective but block the disconfirmation that would break the cycle, so they maintain the disorder. Cognitive behaviour therapy works by targeting the misinterpretation and dropping the safety behaviours, and the wider technique is taught in the Psychotherapies, clinical assessment, MSE and nosology notes.

3.1 The core claim: catastrophic misinterpretation of benign bodily sensations

The single idea. According to Clark, a panic attack occurs when an individual interprets normal or benign **bodily sensations** as evidence of an immediate catastrophe (Clark 1986, 1988, 1996; Tasman Psychiatry). The sensations are ordinary products of arousal, exercise, caffeine, a missed meal, or a fleeting emotion; what is pathological is the meaning imposed on them. **The evidence that seals it.** When panic is provoked experimentally (for example by lactate infusion or carbon-

dioxide inhalation), panic-disorder patients and healthy controls report the *same* physical sensations, yet only the patients who make a catastrophic interpretation go on to a full attack (Sanderson and Rego; Tasman Psychiatry). The bodily signal is shared; the disorder lives in the appraisal. **Why "catastrophic".** The misinterpretation is not merely negative but specifically catastrophic and *imminent*, forecasting death, collapse, loss of control or insanity within seconds, which is what drives the terror out of proportion to the trigger.

RULE **The interpretation, not the sensation, is the disorder.** Everyone gets palpitations; only the person who reads them as "heart attack" panics. Treatment targets the appraisal.

3.2 The vicious cycle: the loop you must be able to draw

The five links. Clark's loop runs: a *trigger* (internal, such as a bodily sensation or intrusive thought, or external, such as a crowded shop) leads to the *perceived threat*, which produces *apprehension or fear*, which drives further *bodily sensations* of autonomic arousal, which are then subjected to *catastrophic misinterpretation*, which feeds straight back into perceived threat, tightening the spiral until a full attack crests (the accompanying figure lays out the loop). **Why it is self-amplifying.** Each turn recruits more arousal: the thought "I am dying" is itself a fresh threat, so the sympathetic surge grows, the sensations intensify, and the interpretation looks ever more confirmed. This positive-feedback quality is the reason a panic attack escalates from first flutter to peak terror within about **10 minutes** and then, once the loop can no longer amplify, spontaneously subsides. **The internal trigger point.** Crucially the trigger is often internal and invisible to bystanders, which is why panic attacks appear to come "out of the blue"; the patient has misread a benign internal cue, not responded to an external danger.

TRAP **Do not confuse the trigger with the cause.** The out-of-the-blue attack is not causeless; it is an internal bodily sensation, misread, that the patient did not consciously register as the trigger.

3.3 Safety behaviours: why the belief never disconfirms itself

What they are. Safety behaviours are actions the patient performs to avert the feared catastrophe: gripping the trolley or a companion's arm to avoid collapsing, sitting down and breathing deeply to avoid a "heart attack", carrying water or medication, scanning for exits, or avoiding exercise and caffeine (Anxiety and Panic Therapist Guide, Treatments that Work). **Why they are pathogenic.** They feel protective but are the engine of chronicity, because they prevent *disconfirmation*: the patient survives the attack, attributes the survival to the safety behaviour rather than to the harmlessness of the sensations, and so the catastrophic belief is never tested and never falsified ("I only survived because I sat down"). **The link to avoidance and agoraphobia.** The same logic scales up: avoiding the supermarket, the bus or being alone are macro-level safety behaviours that entrench agoraphobic avoidance, so that the belief "these sensations are dangerous" is protected across a widening range of situations (the phobic-avoidance detail sits with the panic disorder and agoraphobia topics).

PEARL

Safety behaviours are the reason reassurance and self-monitoring apps often make panic worse, not better. A pulse oximeter, a "check my heart" habit, or a benzodiazepine kept in the pocket "just in case" all become safety behaviours: they hand the patient a fresh reason the catastrophe was averted, so the belief is preserved rather than disproved. The therapeutic move is to *drop* the safety behaviour and let the sensation prove itself harmless.

3.4 How CBT breaks the cycle

The three levers. Cognitive behaviour therapy for panic maps exactly onto the loop and attacks it at three points (Clark; BAP, Baldwin et al.; NICE). *Cognitive restructuring* identifies and challenges the catastrophic misinterpretation, replacing "palpitations mean a heart attack" with an accurate, non-catastrophic account of arousal. *Interoceptive exposure* deliberately induces the feared sensations (hyperventilating to voluntary breathlessness and dizziness, spinning to induce vertigo, running on the spot to raise the heart rate) so the patient experiences the sensation, makes no misinterpretation, and learns experientially that it is harmless. *Dropping safety behaviours and situational (in-vivo) exposure* remove the props so the belief is finally tested and disconfirmed. **The behavioural experiment.** The pivotal technique is the behavioural experiment: the patient predicts the catastrophe ("if I don't sit down I will faint"), then hyperventilates without the safety behaviour, and observes that the catastrophe does not occur, which corrects the belief far more powerfully than argument. **Dose and place.** CBT for panic is first-line, delivered in the optimal range of **7 to 14 hours** total, typically weekly over about **4 months** (NICE; BAP). The general CBT and exposure technique is developed in the Psychotherapies, clinical assessment, MSE and nosology notes.

WORKED EXAMPLE

A 28-year-old woman has recurrent attacks that begin with a pounding heart she reads as "I'm having a heart attack." In the session the therapist has her hyperventilate for two minutes; her heart races and she feels dizzy, exactly her attack, but with the prediction "I will collapse" written down first. She does not collapse. Repeated across sessions, with her hand off the wall (a dropped safety behaviour), the sensation stops meaning catastrophe. The catastrophic misinterpretation is disconfirmed at its source, and the vicious cycle has nowhere to turn.

3.5 Where the model sits in management, and the benzodiazepine trap

First-line, and why. Because the model is so directly testable, CBT built on Clark's framework is a first-line treatment for panic disorder with or without agoraphobia, on a par with an SSRI (BAP; NICE; CANMAT places CBT first-line psychologically). Where medication is used, an SSRI licensed for panic (escitalopram, sertraline, paroxetine or citalopram) or venlafaxine is first-line; a patient starting an SSRI must be warned about early activation and a transient worsening of anxiety, because in Clark's terms the initial jitteriness supplies fresh bodily sensations to misinterpret. **The benzodiazepine trap.** NICE explicitly says *do not prescribe benzodiazepines* for panic disorder: they are associated with a worse long-term outcome, and, read through Clark's

model, they act as a chemical safety behaviour that blocks the disconfirming learning CBT depends on. This matters acutely in the Indian setting.

INDIA

Panic disorder in India is routinely met with a benzodiazepine, often alprazolam, prescribed long-term in primary care and by non-specialists, against every guideline. Clark's model gives the sharpest argument against the habit: the tablet-in-the-pocket becomes a safety behaviour that preserves the very belief driving the disorder, so symptomatic relief today buys chronicity tomorrow, on top of the well-documented dependence problem. The Indian Psychiatric Society clinical practice guidelines for anxiety disorders reserve benzodiazepines for short-term use and place SSRIs and CBT first; against the wide anxiety treatment gap, teaching the panic cycle to the patient is itself a low-cost, transferable intervention that does not require a psychologist on site.

TRAP **The prescribed benzodiazepine is a safety behaviour.** Giving alprazolam "to carry just in case" relieves the attack but preserves the catastrophic belief, blocking the disconfirmation CBT needs and inviting dependence.

7 to 14	4	1986
HOURS OF CBT FOR PANIC, THE FIRST-LINE DOSE (NICE, BAP)	MONTHS, THE TYPICAL CBT DELIVERY WINDOW	CLARK'S FOUNDATIONAL COGNITIVE-MODEL PAPER

GOOD TO REMEMBER

- **Clark cognitive model of panic:** panic disorder is the *catastrophic misinterpretation of benign bodily sensations* as imminent physical or mental catastrophe; the loop is trigger, perceived threat, apprehension, bodily sensations, catastrophic misinterpretation, back to perceived threat.
- **The maintaining mechanism:** safety behaviours (and avoidance) prevent disconfirmation, so the catastrophic belief is never tested and the disorder becomes chronic.
- **The discriminator:** the disorder is one of *interpretation*, not of the autonomic nervous system; provoked sensations are identical in patients and controls, only the misinterpretation predicts an attack.

GOOD TO REMEMBER

- **CBT for panic (Clark protocol):** first-line, 7 to 14 hours over about 4 months; three levers are cognitive restructuring of the misinterpretation, interoceptive exposure to the feared sensations, and dropping safety behaviours with in-vivo exposure, driven by behavioural experiments.
- **Signature caution:** a benzodiazepine (and any "just in case" prop) acts as a safety behaviour that blocks the disconfirming learning, so it is not first-line and NICE advises against it in panic disorder.

HOLD THIS

Panic disorder is the catastrophic misinterpretation of benign bodily sensations, sustained by safety behaviours that stop the belief being disconfirmed; CBT (7 to 14 hours) breaks the vicious cycle by restructuring the misinterpretation, exposing the patient to the sensations, and removing the safety behaviours so the catastrophe is finally proven not to happen.

4 · Agoraphobia

Agoraphobia is not, despite its name, a simple **fear of public places**. It is a fear of *being trapped*: of finding oneself in a situation from which escape would be difficult or embarrassing, or in which help would not be available, should a panic attack or some other incapacitating or humiliating bodily event strike. The Greek *agora* was the marketplace, and the marketplace still captures the clinical picture, the crowd, the queue, the bus, the open square, but the driving cognition is about escape and rescue, not about the place itself. The patient reorganises life around this fear until, at its most severe, they are completely homebound. Examiners test **agoraphobia** on a tight set of exact points: the two-or-more-of-five situations of Criterion A, the *escape/help-unavailable* cognition of Criterion B that separates it from a specific phobia, its modern status as a diagnosis in its own right independent of panic disorder, and the treatment, where the single load-bearing fact is that *graded in-vivo exposure* is the core of care.

Why it matters clinically. This is a hybrid topic, so the marks sit both in the criterion-anchored discrimination and in the exposure-based management. Two facts anchor every answer. First, the diagnostic core is the cluster of at least two of five feared situations plus the specific cognition that escape or help would be impossible, which is exactly what separates agoraphobia from the single-situation specific phobia and from the socially-evaluative fear of social anxiety disorder. Second, both ICD-11 and DSM-5-TR now diagnose **agoraphobia** as a stand-alone disorder, *irrespective of the presence of panic disorder*, a deliberate break from the older nesting of "panic disorder with agoraphobia". The fear-circuit anatomy on which the alarm is built is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes, and the general CBT model and the wider exposure principle in the Psychotherapies, clinical assessment, MSE and nosology notes; they are not re-derived here.

4.1 What agoraphobia actually is: fear of being trapped, not fear of the place

The core fear. The essential feature is marked fear or anxiety triggered by the real or anticipated exposure to a range of situations, feared *because the person believes that escape might be difficult or that help might be unavailable* if panic-like or other incapacitating or embarrassing symptoms were to occur (DSM-5-TR 2022; ICD-11 CDDR). The place is incidental; the dread is of being stuck in it. "Panic-like symptoms" means any of the thirteen panic-attack symptoms (dizziness, faintness, fear of dying and the rest), and "other incapacitating or embarrassing symptoms" covers vomiting, incontinence, and, in older adults, a fear of falling.

What the avoidance looks like. The behaviour that follows is avoidance: the person actively rearranges their life to prevent contact with the feared situations, takes a job near home to avoid the bus, has food delivered to avoid the shop, insists on a companion, or sits near the exit at the cinema as a *safety behaviour*. Avoidance can be behavioural or cognitive (using distraction to endure), and at its most severe the person becomes entirely housebound, dependent on others for basic needs (DSM-5-TR 2022).

WORKED EXAMPLE

A 34-year-old woman has, over eight months, stopped taking the bus, stopped going to the crowded weekly market, and will now enter a shop only if her sister comes with her; she has not left the house alone in weeks. She describes no fear of the bus or the market as such, but a dread that she will "feel faint and trapped with no way out and no one to help". There is no current panic disorder, though she had a handful of panic attacks a year ago. Two or more of the five agoraphobic situations are feared (public transport, crowds, being outside the home alone), the cognition is the escape/help-unavailable one, the avoidance is marked and companion-dependent, and it has lasted well beyond six months. This is agoraphobia, diagnosable in its own right, panic disorder or not.

4.2 Criterion A: two or more of the five situations

The five situations. The diagnosis requires marked fear or anxiety about *two or more* of five situation clusters (DSM-5-TR 2022): (1) using **public transportation** (buses, trains, ships, planes); (2) being in **open spaces** (car parks, marketplaces, bridges); (3) being in **enclosed places** (shops, theatres, cinemas); (4) **standing in line or being in a crowd**; and (5) **being outside of the home alone**. The examples are not exhaustive, and the "two or more" threshold is the number examiners protect, because it is precisely what lifts the picture out of specific phobia.

Consistency and proportion. The fear must be evoked *nearly every time* the person meets the situation (Criterion C), must be actively avoided or endured with intense distress or need a companion (Criterion D), and must be out of proportion to the actual danger and to the sociocultural context (Criterion E) (DSM-5-TR 2022). That last clause matters cross-culturally: where it is socioculturally expected that a woman does not leave the house alone, that avoidance is not, by itself, agoraphobia.

CRITERION	REQUIREMENT
A	Marked fear/anxiety about two or more of five situations (public transport, open spaces, enclosed places, crowds/queues, outside home alone)
B	**Feared because escape may be difficult or help unavailable if panic-like or incapacitating/embarrassing symptoms occur**
C	The situations almost always provoke fear or anxiety
D	Actively avoided, need a companion, or endured with intense fear
E	Out of proportion to actual danger and sociocultural context
F	**Persistent, typically six months or more**
G	Clinically significant distress or impairment

The DSM-5-TR criteria for agoraphobia; the two-of-five rule (A) and the escape/help-unavailable cognition (B) are the load-bearing discriminators (DSM-5-TR 2022).

4.3 Criterion B: the escape-or-help cognition that defines it

The discriminating thought. Criterion B is what makes agoraphobia agoraphobia: the situations are feared *because of thoughts that escape might be difficult or help might not be available* in the event of developing panic-like symptoms or other incapacitating or embarrassing symptoms (DSM-5-TR 2022; ICD-11 CDDR). This single cognition is the examiner's favourite discriminator. If the situation is feared for another reason, fear the plane will crash, fear the dog will bite, then it is a *specific phobia*, not agoraphobia. If it is feared because of negative social evaluation, it is *social anxiety disorder*. The **exposure agoraphobia** treatment that follows is built directly on disconfirming this escape-or-help prediction.

Where the fear centres. ICD-11 puts it crisply: fear or anxiety in agoraphobia centres on *imminent perceived dangerous outcomes*, panic attacks, symptoms of panic, incapacitation, or embarrassing physical symptoms, that are anticipated to occur in multiple situations where obtaining help or escaping might be difficult (ICD-11 CDDR). It is worth establishing the specific feared outcome (a panic attack versus incontinence versus falling), because that shapes the exposure plan.

RULE **Two of five, feared for escape not for the object.** Agoraphobia = fear/avoidance of two or more of the five situations, feared *because escape or rescue would be impossible* if something dreadful happened in the body; that Criterion-B cognition, not the place, is the diagnosis.

4.4 The nosological shift: agoraphobia as a stand-alone diagnosis

Independent of panic. The examinable modern point is that both classifications now diagnose agoraphobia *independent of panic disorder*. DSM-5-TR states it outright: agoraphobia is diagnosed irrespective of the presence of panic disorder, and if a presentation meets criteria for both, *both* diagnoses are assigned (DSM-5-TR 2022). ICD-11 (6B02) similarly lists agoraphobia as its own category within the anxiety and fear-related disorders, with a "with panic attacks" specifier rather than a subordination to panic disorder (ICD-11 CDDR). This retired the old DSM-IV construct of "panic disorder with agoraphobia" and the notion that agoraphobia could not exist without a panic history.

The panic relationship in numbers. The link is real but not obligatory: the proportion of agoraphobia cases with panic attacks or panic disorder preceding onset ranges from about 30% in community samples to more than 50% in clinical samples, and agoraphobia without any preceding panic runs a mean age at onset of 25 to 29 years (DSM-5-TR 2022). Many patients avoid so completely that they no longer have attacks at all, which is exactly why tying the diagnosis to current panic was untenable.

PEARL

The single most exam-worthy fact about agoraphobia in ICD-11 and DSM-5-TR is that it is now a *free-standing* diagnosis, no longer a mere appendage of panic disorder. Where a patient meets both sets of criteria, code *both* (panic disorder *and* agoraphobia), not the old composite "panic disorder with agoraphobia". Heritability is high (about 61%), the highest and most phobia-specific of the phobias, another favourite one-liner.

4.5 Differential diagnosis: the boundaries an answer must draw

Against specific phobia. If only *one* agoraphobic situation is feared, diagnose specific phobia, situational type; two or more warrant agoraphobia (DSM-5-TR 2022). And if the situation is feared because of direct harm from the object (the plane crashing) rather than the escape/help cognition, it is again specific phobia.

Against the others. In *social anxiety disorder* the fear is of negative evaluation, so a fear confined to social scrutiny is social anxiety, not agoraphobia. In *PTSD* the person deliberately avoids trauma reminders, whereas in agoraphobia situations are avoided for fear of imminent bodily catastrophe with no escape (ICD-11 CDDR). In *separation anxiety disorder* the fear is of being apart from an attachment figure. And the organic and depressive mimics that colour every anxiety presentation, thyroid disease, arrhythmia, and secondary depression, are excluded as for panic disorder.

GOOD TO REMEMBER

- **Agoraphobia (the syndrome):** the defining criterion is marked fear/avoidance of *two or more of five* situations (public transport, open spaces, enclosed places, crowds or queues, being outside the home alone), feared specifically *because escape would be difficult or help unavailable* should panic-like or incapacitating/embarrassing symptoms strike (Criterion B); it must be persistent (six months or more) and out of proportion to sociocultural context; the discriminators are one-situation-only or object-directed fear (specific phobia), evaluative fear (social anxiety), trauma-reminder avoidance (PTSD); and, in the exam-critical shift, it is now diagnosed *independent of panic disorder*, with both coded if both are present.

4.6 Management overview: exposure-based CBT is the core

The treatment principle. The management of agoraphobia is, first and above all, *psychological and exposure-based*. CANMAT recommends cognitive behavioural therapy that uses *combined strategies including situational exposure* as first-line, noting that combined techniques outperform single techniques on agoraphobia measures (CANMAT 2014). NICE frames agoraphobia within panic-focused CBT: offer CBT for panic disorder *with or without agoraphobia* as first-line, delivered over about 7 to 14 hours across four months, with *in-vivo exposure for agoraphobic avoidance* as an explicit ingredient (NICE 2011). Where formal face-to-face therapy is impractical, minimal-intervention formats (self-help books, telephone or video delivery, internet-based CBT) are effective and cost-effective alternatives (CANMAT 2014).

Where drugs sit. Because agoraphobia so often travels with panic, the pharmacological backbone is the panic backbone: an SSRI is the first-line agent for the anxiety/panic component (the antidepressant class shared across the anxiety disorders, fluoxetine, sertraline, fluvoxamine, paroxetine, escitalopram), started low and titrated, with the tricyclics clomipramine (Anafranil) or imipramine as second-line agents that have meta-analytic efficacy for both panic and agoraphobia (CANMAT 2014). Medication is combined with exposure where agoraphobia is severe or rapidly worsening, or where CBT alone is likely to be insufficient (comorbid moderate-to-severe depression, frequent severe panic, or suicidal ideation) (CANMAT 2014).

LINE	TREATMENT	SOURCE
First-line	CBT with combined situational (in-vivo) exposure and cognitive restructuring	CANMAT 2014; NICE 2011
First-line (drug)	SSRI for the panic/anxiety component (start low, titrate, warn about early activation)	NICE 2011; BAP 2014
Second-line (drug)	**Clomipramine or imipramine (efficacy for both panic and agoraphobia)**	CANMAT 2014
Access alternative	Low-intensity or internet-based CBT, guided self-help	CANMAT 2014
Severe/rapid	Combined pharmacotherapy plus psychotherapy	CANMAT 2014

Guideline-level management of agoraphobia; exposure-based CBT is first-line, the SSRI carries the panic component, and the tricyclics clomipramine and imipramine are second-line (CANMAT 2014; NICE 2011).

4.7 Graded in-vivo exposure: how the core treatment actually works

What exposure agoraphobia treatment does. Graded in-vivo exposure is the active ingredient. The patient and therapist build a hierarchy of feared situations from least to most distressing (standing at the front door, walking to the gate, a short bus ride, the crowded market) and the patient enters them *repeatedly and in a graded way*, remaining until the anxiety falls, so that the escape-or-help catastrophe (Criterion B) fails to materialise and is disconfirmed (CANMAT 2014; NICE 2011). The exposures must be *real and in-vivo*, prolonged, and repeated across settings; the safety behaviours (the companion, the exit seat, the water bottle) are progressively dropped, because it is only exposure *without* the safety crutch that fully extinguishes the fear.

For those who decline formal therapy. For patients with persistent agoraphobic distress or avoidance who fear or decline formal CBT, the guideline is still exposure: provide instruction and support to engage in *graded exposure exercises* on their own or with minimal facilitation (CANMAT 2014). Where in-vivo entry is genuinely impractical, virtual-reality or interoceptive exposure can substitute or supplement, and where panic drives the avoidance, interoceptive exposure (deliberately inducing the feared body sensations) is added, as in panic-focused CBT.

TRAP **Exposure with the safety behaviours left in.** Sending a patient into the feared situation while they keep the companion, the exit seat and the escape route intact teaches nothing, the catastrophe is never disconfirmed. Grade the hierarchy, keep exposures prolonged and repeated, and *systematically drop the safety behaviours*; and never let avoidance itself go unaddressed while only prescribing a drug.

4.8 The Indian frame: the treatment gap, the benzodiazepine problem, and the IPS line

Genuine Indian context. Agoraphobia sits inside a large, mostly untreated anxiety burden in India: the anxiety, OCD and PTSD treatment gap means most sufferers never reach formal psychological care, and structured exposure-based CBT, the very treatment that is first-line, is scarce outside a handful of centres. Into that gap falls India's **benzodiazepine over-prescription**

problem: alprazolam and clonazepam are dispensed freely and often long-term for "ghabrahat", panic and phobic avoidance, which is precisely the wrong move, a benzodiazepine suppresses the very anxiety the patient needs to feel and habituate to during exposure, and can actively blunt the therapeutic effect of exposure work. The Indian Psychiatric Society CPGs keep the line clean: an SSRI or SNRI for the panic/anxiety component and CBT with systematic exposure as the treatment, not a chronic anxiolytic (IPS 2017). Indian brands are cheap and available: sertraline (Serta, Zosert, Daxid), escitalopram (Nexito, Cipralex), paroxetine (Paxidep), fluoxetine (Fludac), and clomipramine (Anafranil) for the second line. The correct Indian answer is graded in-vivo exposure plus a low-started, well-explained SSRI, never a standing benzodiazepine.

GOOD TO REMEMBER

- **Graded in-vivo exposure (the psychotherapy):** the first-line, core treatment of agoraphobia; its mechanism is repeated, graded, prolonged entry into the feared situations so the escape-or-help catastrophe of Criterion B is disconfirmed and the fear extinguishes; the signature caution is that *safety behaviours must be dropped* and a concurrent benzodiazepine avoided (both prevent habituation); combined CBT (exposure plus cognitive restructuring) outperforms single techniques, with the SSRI carrying the panic component and clomipramine or imipramine as the second-line drug.

2 of 5	6 months	7 to 14 h	61%
SITUATIONS FEARED, REQUIRED FOR CRITERION A	MINIMUM DURATION FOR THE DIAGNOSIS (CRITERION F)	CBT WITH IN-VIVO EXPOSURE OVER ABOUT 4 MONTHS (NICE)	HERITABILITY, THE MOST PHOBIA-SPECIFIC OF THE PHOBIAS

HOLD THIS

Agoraphobia is fear and avoidance of two or more of five situations (public transport, open spaces, enclosed places, crowds or queues, being outside the home alone), feared *because escape would be difficult or help unavailable* if a panic-like or incapacitating symptom struck; it is now diagnosed independent of panic disorder (code both if both present), and its first-line treatment is graded in-vivo exposure within CBT, with an SSRI for the panic component and the benzodiazepine kept firmly out.

5 · Social anxiety disorder

Social anxiety disorder (still widely called **social phobia**) is the disorder of a marked, persistent **fear of scrutiny** and of negative evaluation in social situations. Where generalised anxiety disorder is free-floating and panic is episodic and cued-by-nothing, this fear is *bound to the social gaze*: the patient dreads acting in a way, or showing anxiety symptoms, that others will judge as humiliating, embarrassing or offensive, and so avoids or endures with dread the very situations, conversations, meetings, eating in front of others, public speaking, in which that scrutiny might fall on them. Examiners like it because it carries a clean, high-yield distinction, the **generalised** subtype versus the **performance-only** specifier, and because its management is the anxiety-block template with one signature twist: the beta-blocker for discrete **performance anxiety**.

Why it matters, and how this note is framed. This is a hybrid topic: it teaches the diagnosis and its discrimination, then the guideline-anchored drug and psychotherapy plan. The core

discriminator to lead with is the *object* of the fear, negative evaluation by others, which is what separates social anxiety disorder from specific phobia (feared object), agoraphobia (fear that escape is impossible or help unavailable) and separation anxiety (fear of separation from an attachment figure). The amygdala and fear-circuit substrate is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; the deep SSRI pharmacology in the Mood disorders: pharmacotherapy notes; the general CBT and exposure model in the Psychotherapies, clinical assessment, MSE and nosology notes; and the benzodiazepine, pregabalin and buspirone story in the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes. What this note owns is the phenomenology, the subtype split, the criteria, the LSAS, and the management.

5.1 The core concept: fear of scrutiny and of negative evaluation

The essential feature. The heart of the disorder is a marked, intense fear or anxiety about one or more social situations in which the individual is exposed to *possible scrutiny by others* (DSM-5-TR 2022). The dreaded outcome is not the situation itself but the judgement it invites: the person is concerned they will act in a way, or show visible anxiety, blushing, trembling, sweating, stumbling over words, that will be negatively evaluated as humiliating, embarrassing, or leading to rejection or offence. This fear of negative evaluation is the cognitive engine, and naming it is what earns the marks.

The three feared arenas. The scrutiny is dreaded across three kinds of situation: social *interactions* (having a conversation, meeting unfamiliar people), being *observed* (eating or drinking in front of others), and *performing* before others (giving a speech). Blushing is described as the hallmark physical response of the disorder (Kaplan and Sadock 2024). A useful clinical texture: some patients avoid public toilets when others are present (paruresis, "shy bladder"), and self-medication with alcohol before a social event is common.

GOOD TO REMEMBER

- **Social anxiety disorder (social phobia):** a marked, persistent fear of one or more social situations involving possible scrutiny, driven by the fear of negative evaluation (that one will be judged humiliating, embarrassing, weak or offensive); the defining discriminator from the other anxiety disorders is that the feared object is *the judgement of others*; blushing is the hallmark physical sign, and the first diagnostic step is to establish that the fear is of negative evaluation and out of proportion to the actual social threat.

5.2 Generalised versus performance-only: the subtype split to know cold

The one specifier DSM-5-TR keeps. DSM-5-TR replaced the old "generalised" subtype with a single specifier, *performance only*: the fear is **restricted to speaking or performing in public** (DSM-5-TR 2022). By default, without the specifier, the fear spans a broad range of social and interactional situations, the **generalised** picture, which is more chronic, more impairing and more comorbid. The **performance-only** group, by contrast, do not fear or avoid non-performance social situations; their impairment falls in professional lives that demand public performance, musicians, dancers, athletes, and in roles requiring regular public speaking.

Why the split drives treatment. The distinction is not cosmetic: it steers the prescription. Generalised social anxiety needs a serotonergic antidepressant and CBT. Discrete **performance anxiety** can be covered situationally, as needed, with a beta-blocker taken before the feared performance, an option that has no place in the generalised form. This is exactly why the subtype question is examinable.

FEATURE	GENERALISED (DEFAULT)	PERFORMANCE-ONLY SPECIFIER
Situations feared	**Broad: interactions, observation and performance**	Restricted to speaking/performing in public
Non-performance social situations	Feared and avoided	**Not feared or avoided**
Typical impairment	Pervasive; more chronic and comorbid	Focused on public-performance roles
First-line treatment	SSRI (or SNRI) plus CBT	**Situational beta-blocker for the discrete event**

The generalised picture versus the DSM-5-TR performance-only specifier; the split is high-yield because it changes the drug (serotonergic antidepressant versus as-needed beta-blocker).

RULE **Subtype sets the drug.** Generalised social anxiety disorder is treated with an SSRI (or SNRI) plus CBT; the discrete performance-only picture can be covered situationally with a beta-blocker before the event, which has no role in the generalised form.

5.3 DSM-5-TR criteria: marked fear, negative evaluation, six months

The criteria to state cleanly. DSM-5-TR requires (A) marked fear or anxiety about one or more social situations involving possible scrutiny; (B) the individual fears they will act, or show anxiety symptoms, that will be negatively evaluated; (C) the situations almost always provoke fear or anxiety; (D) they are avoided or endured with intense fear; (E) the fear is out of proportion to the actual threat and to the sociocultural context; (F) it is persistent, **typically lasting 6 months or more**; (G) it causes clinically significant distress or impairment; (H) it is not attributable to a substance or another medical condition; and (I) it is not better explained by another mental disorder (DSM-5-TR 2022). The specifier is *performance only*.

The paediatric qualifier. In children the anxiety must occur in *peer settings* and not only during interactions with adults, and the fear may be expressed by crying, tantrums, freezing, clinging or failing to speak. That "peer settings" caveat is a favourite discriminator.

CRITERION	DSM-5-TR REQUIREMENT
A. Fear	**Marked fear/anxiety about social situation(s) with possible scrutiny (interaction, observation, performance)**
B. Feared outcome	**Fear of acting or showing anxiety that will be negatively evaluated (humiliating, embarrassing, rejecting, offensive)**

CRITERION	DSM-5-TR REQUIREMENT
C. Consistency	The situations almost always provoke fear or anxiety (in children, may show as crying/tantrums/freezing)
D. Avoidance	Situations avoided or endured with intense fear or anxiety
E. Proportion	Out of proportion to the actual threat and to the sociocultural context
F. Duration	**Persistent, typically 6 months or more**
G. Impairment	Clinically significant distress or social/occupational impairment
H. Not organic	Not due to a substance or another medical condition
I. Not better explained	Not better explained by panic disorder, body dysmorphic disorder, autism spectrum disorder and others
Specifier	**Performance only: fear restricted to speaking or performing in public**

DSM-5-TR criteria for social anxiety disorder; the numbers to hold are the 6-month typical duration and the single performance-only specifier (DSM-5-TR 2022).

5.4 ICD-11 CDDR: marked and excessive fear, "at least several months"

Where ICD-11 frames it. ICD-11 (6B04) requires marked and excessive fear or anxiety that occurs *consistently* in one or more social situations, social interaction, being observed, or performing, with the concern that one will act, or show anxiety symptoms, that will be negatively evaluated (humiliating, embarrassing, leading to rejection or offence); the situations are consistently avoided or endured with intense fear; the symptoms are not transient and persist for **at least several months**; and they cause significant distress or impairment (ICD-11 CDDR). As across the anxiety block, ICD-11 does *not* impose the DSM's fixed 6-month clock, asking instead for "at least several months", the classic ICD-versus-DSM contrast to name.

The ICD-11 specifier. ICD-11 offers a "with panic attacks" qualifier rather than a performance-only one, so if you are asked about the performance-only distinction, that is a DSM-5-TR construct; ICD-11 codes the panic-attack overlay instead.

TRAP **Do not miss the medical and psychiatric mimics.** Blushing, tremor and palpitations before scrutiny can equally be hyperthyroidism, a phaeochromocytoma or excess caffeine; and fear of being looked at can be body dysmorphic disorder (fear centred on a perceived defect) or the social withdrawal of autism, not social anxiety, so exclude the organic mimic and check that the fear is genuinely of *negative evaluation*.

GOOD TO REMEMBER

- **ICD-11 social anxiety disorder (6B04):** marked, excessive, consistent fear of social situations with concern about negative evaluation, consistent avoidance, persisting at least several months, with distress or impairment; the defining contrast with DSM-5-TR is the absence of a fixed 6-month rule and a "with panic attacks" specifier in place of DSM's performance-only one.

5.5 The Liebowitz Social Anxiety Scale (LSAS): the severity instrument

What it is. The Liebowitz Social Anxiety Scale (**lsas**), developed by Michael Liebowitz in 1987, is the standard instrument for assessing social anxiety. It is a **24-item** scale that rates both *fear* and *avoidance* across 24 social and performance situations, each dimension scored **0 to 3**, splitting into a social-interaction subscale and a performance subscale (AIIMS Clinical Methods 2024; Kaplan and Sadock 2024). It exists in clinician-administered and self-rated forms; it is copyright-protected, so permission is needed to use it, and it is set out on the accompanying scale plate rather than reproduced here.

How it is used. The LSAS is the workhorse outcome measure in social anxiety trials, drug effects are reported as points reduced on the LSAS, and it is what tracks response over a treatment course. For quick case-finding, NICE instead recommends the 3-item Mini-Social Phobia Inventory (Mini-SPIN) or two screening questions, referring for full assessment if positive (NICE 2013). The through-line: Mini-SPIN to screen, LSAS to grade severity and follow response.

GOOD TO REMEMBER

- **LSAS (Liebowitz 1987):** a 24-item scale rating fear and avoidance across 24 situations, each 0 to 3, with social-interaction and performance subscales; it is the standard severity and outcome measure in social anxiety disorder (drug effects are reported as LSAS point reductions); contrast with the 3-item Mini-SPIN, which is the rapid screen.

5.6 Management: SSRI first-line and CBT, across the guidelines

Lead with BAP. The British Association for Psychopharmacology (BAP) makes an SSRI the first-line pharmacological treatment for social anxiety disorder, the efficacious agents named being escitalopram, fluoxetine, fluvoxamine, paroxetine and sertraline; it also offers cognitive behavioural therapy (cognitive therapy plus exposure) as an efficacious acute treatment of broadly similar efficacy to pharmacotherapy, and names the SNRI venlafaxine, the MAOI phenelzine and the RIMA moclobemide as alternative antidepressants (BAP 2014). This is the verified **SSRI first-line** anchor and must not be contradicted. BAP adds a pointed negative: *do not* prescribe atenolol or buspirone for generalised social anxiety disorder, as neither is efficacious (BAP 2014).

Then the other bodies. The convergence is striking. NICE puts individual CBT specifically developed for social anxiety disorder (the Clark and Wells or Heimberg model) as the *first-line* treatment for adults, and offers an SSRI (escitalopram or sertraline) if the adult declines psychological therapy and prefers medication, with an alternative SSRI (fluvoxamine or paroxetine) or the SNRI venlafaxine at the next step, and a MAOI (phenelzine or moclobemide) after that (NICE 2013). CANMAT lists first-line agents as escitalopram, fluvoxamine (including

CR), paroxetine (including CR), sertraline, venlafaxine XR or pregabalin, with CBT (cognitive restructuring plus exposure) as the gold-standard first-line psychotherapy (CANMAT 2014). The Indian Psychiatric Society does publish CPGs across the anxiety disorders and champions SSRI-plus-CBT for the anxiety block, but a dedicated social-anxiety-disorder recommendation could not be confirmed in the verified supplement, so its precise position is flagged under gaps rather than asserted here. The shared exam message: *SSRI first-line and CBT everywhere*.

GUIDELINE	FIRST-LINE	KEY NOTE
BAP 2014	**SSRI (escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline); CBT**	Do not use atenolol or buspirone for generalised SAD
NICE 2013	**Individual CBT (Clark & Wells / Heimberg); SSRI (escitalopram or sertraline) if medication preferred**	Do not routinely offer benzodiazepines/TCAs/antipsychotics
CANMAT 2014	SSRI/venlafaxine XR/pregabalin; CBT first-line	Beta-blockers not for generalised SAD; may help discrete performance
Indian Psychiatric Society	SSRI/SNRI with CBT (anxiety-block position)	Dedicated SAD recommendation unconfirmed (see gaps)

First-line treatment for social anxiety disorder; the shared message is an SSRI (or SNRI) plus CBT, with the beta-blocker reserved for discrete performance situations only.

RULE **SSRI plus CBT is first-line for social anxiety disorder.** BAP names an SSRI (escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline) first-line with CBT of similar efficacy; NICE puts disorder-specific CBT first and an SSRI if medication is preferred; CANMAT agrees. Venlafaxine, phenelzine and moclobemide are the antidepressant alternatives.

GOOD TO REMEMBER

- **SSRI in social anxiety disorder:** the mechanism is serotonergic (serotonin reuptake blockade with downstream receptor adaptation); it is first-line for the generalised disorder (escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline per BAP), needs an adequate trial before response is judged, and, once effective, is continued for at least a further 6 months because social anxiety disorder is chronic with high symptom re-emergence on stopping.

5.7 Propranolol for discrete performance anxiety, and what NOT to use

The one situational role. For discrete **performance anxiety**, a beta-blocker taken before the feared event is a recognised as-needed option. Propranolol (Indian brands Ciplar, Inderal), a non-selective beta-adrenergic blocker, is long-established as useful particularly for the performance situation, because it damps the peripheral autonomic symptoms, hand tremor and tachycardia, that the performer both feels and fears will be seen (Kaplan and Sadock 2024). The critical caveat: it has *no* effect on anticipatory anxiety or on the generalised disorder, so its use is strictly the discrete, foreseeable performance, taken before going on.

The important negatives. The beta-blocker is explicitly *not* a treatment for generalised social anxiety disorder: BAP says do not prescribe atenolol for it, and CANMAT lists propranolol and

atenolol among agents not recommended for the generalised disorder while conceding beta-blockers "may still help discrete performance situations" (BAP 2014; CANMAT 2014). Buspirone, too, is not efficacious as monotherapy for generalised social anxiety disorder (BAP 2014). And the benzodiazepine is not first-line and should not be a maintenance treatment: NICE says do not routinely offer benzodiazepines (alongside TCAs, anticonvulsants and antipsychotics) for social anxiety disorder in adults (NICE 2013).

WORKED EXAMPLE

A 24-year-old violinist has crippling tremor and a pounding heart only in the minutes before a solo recital; away from the stage she is socially at ease and has no other feared situations. This is the performance-only picture. The correct move is a beta-blocker, propranolol taken before the performance, to blunt the tremor and tachycardia she fears will be visible; it will not touch anticipatory dread and is not a daily treatment. Contrast a 30-year-old who avoids conversations, meetings, eating out and phone calls across his whole life, the generalised disorder, where the answer is an SSRI plus CBT, and a beta-blocker would be the wrong tool.

GOOD TO REMEMBER

- **Propranolol (Ciplar, Inderal) for performance anxiety:** a non-selective beta-blocker that damps the peripheral autonomic signs (tremor, tachycardia) of discrete performance anxiety when taken before the event; the signature caution is that it does nothing for anticipatory anxiety or for generalised social anxiety disorder, for which it is not recommended; check for asthma and bradycardia before prescribing.

5.8 CBT: the first-line psychotherapy and the partial-response rule

What disorder-specific CBT does. CBT is the first-line psychological treatment; NICE specifies *individual* CBT developed for social anxiety disorder, following the Clark and Wells or the Heimberg model, over group CBT, which it found less clinically and cost effective (NICE 2013). Its ingredients are cognitive restructuring of the fear of negative evaluation and the self-focused, distorted self-image, plus graded exposure to feared social situations, and it targets the safety behaviours (over-rehearsing, avoiding eye contact, gripping the glass) that maintain the belief that catastrophe was only just averted. Delivered well, it produces durable benefit that can outlast medication.

The partial-response rule. A clean examinable step: for an adult whose symptoms have only *partially* responded to an SSRI after **10 to 12 weeks**, NICE says add individual CBT to the SSRI; for a partial response to CBT, consider adding a pharmacological intervention (NICE 2013). So the initial trial length before judging partial response is 10 to 12 weeks, and the response to incomplete benefit is to combine, not to abandon.

GOOD TO REMEMBER

- **CBT for social anxiety disorder:** the principle is cognitive restructuring of the fear of negative evaluation plus graded exposure and the dropping of safety behaviours (Clark and Wells or Heimberg model); it is first-line and individual is preferred over group (NICE); the signature rule is that partial response to an SSRI at 10 to 12 weeks is managed by *adding* CBT, not switching away.

INDIA

Social anxiety disorder sits inside India's large, mostly untreated anxiety burden, most sufferers never reach formal care, and it is easily mistaken for "shyness" or a personality trait and left undiagnosed for years. It also collides with the country's benzodiazepine over-prescription problem: alprazolam and clonazepam are dispensed freely, often long-term, for "nervousness" before social or performance situations, which is exactly what NICE and BAP warn against, the benzodiazepine is not first-line and not a maintenance treatment. The correct Indian answer is a low-cost, widely available SSRI plus CBT for the generalised disorder, sertraline (Serta, Zosert, Daxid), escitalopram (Nexito, Cipralex), paroxetine (Paxidep) or fluoxetine (Fludac), with propranolol (Ciplar, Inderal) reserved for the discrete performer. The Indian Psychiatric Society CPGs anchor the SSRI-plus-CBT approach for the anxiety disorders; a dedicated social-anxiety-disorder recommendation could not be confirmed in the verified supplement and is flagged rather than invented.

24	6 months	10 to 12 weeks
LSAS ITEMS (FEAR + AVOIDANCE, EACH RATED 0 TO 3)	DSM-5-TR TYPICAL DURATION FOR SOCIAL ANXIETY DISORDER	SSRI TRIAL BEFORE ADDING CBT FOR PARTIAL RESPONSE (NICE)

HOLD THIS

Social anxiety disorder is fear of negative evaluation under scrutiny: SSRI (escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline) plus CBT first-line for the generalised disorder, propranolol before the event for discrete performance anxiety only, and never a benzodiazepine as maintenance.

6 · Specific phobias

The **specific phobia** is the purest of the anxiety disorders: a fear that is not free-floating, not episodic and not social, but bound tight to one circumscribed object or situation, so that the anxiety switches on the moment the thing is met and switches off the moment it is gone. It is also the commonest anxiety disorder in the community and the anxiety disorder examiners most like to test as a discrimination exercise, because the whole diagnosis turns on a single feature, the **circumscribed phobic stimulus**, and because it carries two facts that appear nowhere else in the anxiety block: the diphasic vasovagal response of the **blood-injection-injury** subtype, and the **applied-tension technique** that is its bespoke treatment.

Why it matters, and what this note owns. Specific phobia is the disorder against which the other anxiety disorders are carved, GAD is diffuse, panic is episodic and unexpected, social anxiety fears evaluation, agoraphobia fears escape being difficult, whereas specific phobia is cued and only cued. What this note owns is the subtype classification (with the fainting subtype and its coping skill), the DSM-5-TR and ICD-11 criteria, and the exposure-based treatment that is the treatment of choice. The general CBT model and the wider exposure principle behind all of this are developed in the Psychotherapies, clinical assessment, MSE and nosology notes and are not re-derived here; the amygdala and fear-circuit anatomy that lights up to a phobic stimulus lives in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes.

6.1 The core concept: a cued, circumscribed, out-of-proportion fear

The defining quality. The essence of a specific phobia is that the fear is *circumscribed* to a particular object or situation, the phobic stimulus, and is out of proportion to the actual danger it poses (DSM-5-TR 2022; ICD-11 CDDR). Unlike the other anxiety disorders, no specific dysfunctional cognition defines it: the person is simply and immediately afraid of the thing itself. The fear is evoked *nearly every time* the stimulus is met (it is reliable and cued, not "out of the blue"), it comes on immediately rather than being delayed, and it drives active avoidance, or, where the situation cannot be avoided, endurance with intense distress.

The old name. The specific phobia was called simple phobia in earlier classifications (DSM-III-R and ICD-10 "simple phobia"), and the terms are interchangeable in exam answers; "specific" replaced "simple" to signal the tie to a specific stimulus rather than any simplicity of the condition.

GOOD TO REMEMBER

- **Specific phobia (simple phobia):** a marked, out-of-proportion fear cued reliably and immediately by one circumscribed object or situation, leading to active avoidance or distressed endurance; the defining discriminator is that the fear is *bound to the stimulus* (cued and only cued), with no defining cognition, which separates it from the diffuse worry of GAD, the unexpected attacks of panic, and the evaluation fear of social anxiety.

6.2 The five subtypes: animal, natural environment, blood-injection-injury, situational, other

The DSM-5-TR specifiers. Specific phobia is coded by the type of phobic stimulus, and DSM-5-TR recognises five families (DSM-5-TR 2022): **animal** (spiders, insects, dogs), **natural environment** (heights, storms, water, darkness), **blood-injection-injury** (blood, needles, invasive medical or dental procedures, injury), **situational** (aeroplanes, lifts, enclosed places, driving), and **other** (situations that might lead to choking or vomiting; in children, loud sounds or costumed characters). When more than one stimulus is feared, each is coded separately, and this is the rule rather than the exception: the average patient with specific phobia fears three objects or situations, and roughly three-quarters fear more than one.

The classic eponyms. The Greek-derived names are worth recognising: acrophobia (heights), zoophobia (animals), claustrophobia (enclosed spaces), algophobia (pain), xenophobia (strangers), and, of the fainting subtype, the fear of blood, injection and injury. The list of named phobias is virtually endless, but the exam-relevant work is done by the five subtypes, not the eponyms.

SUBTYPE	TYPICAL STIMULI	AUTONOMIC SIGNATURE AND PEARL
Animal	Spiders, insects, dogs, snakes	Sympathetic arousal; earliest onset, more common in younger children and in females
Natural environment	Heights, storms, water, darkness	Sympathetic arousal; younger onset for water/weather
Blood-injection-injury	Blood, needles, injury, medical/dental procedures	**Diphasic vasovagal response with fainting; the only subtype with equal sex ratio and a familial pattern; treat with applied tension**
Situational	Aeroplanes, lifts, enclosed places, driving	Sympathetic arousal; older onset (flying, heights); overlaps with panic/agoraphobia
Other	Choking, vomiting; in children loud sounds, costumed figures	Heterogeneous residual category

The five DSM-5-TR specific-phobia subtypes; the one that carries all the special facts is blood-injection-injury (DSM-5-TR 2022). ICD-11 6B03 sets no subtype specifiers, its only specifier being "with panic attacks".

GOOD TO REMEMBER

- **Subtypes:** animal, natural environment, blood-injection-injury, situational and other; the average patient fears three stimuli and each is coded separately; the blood-injection-injury subtype is the exam favourite because it alone shows the diphasic vasovagal faint, has an equal sex ratio, runs in families, and is treated with applied tension rather than exposure alone.

6.3 The blood-injection-injury subtype: the diphasic vasovagal response

Why it is unique. Every other phobia produces plain sympathetic arousal, a racing heart and rising blood pressure that stay up until escape. The blood-injection-injury subtype does something different and diagnostic: it produces a **diphasic** (biphasic) autonomic response. There is a brief initial acceleration of heart rate and a rise in blood pressure, followed by an abrupt *deceleration* of heart rate and a *fall* in blood pressure, a vasovagal reflex that commonly ends in fainting (vasovagal syncope) at the sight of blood, a needle or an injury (DSM-5-TR 2022). This is the one anxiety presentation in which the patient does not run but falls: the fainting is the presenting feature and the reason the person avoids donating blood, having dental work, or attending for injections.

The other quirks. Two more facts hang off this subtype and are heavily tested. First, sex ratio: whereas specific phobias overall run about 2:1 female-to-male, the blood-injection-injury subtype affects men and women roughly equally (ICD-11 CDDR). Second, it has the strongest familial pattern of the phobias, a heritable tendency to the vasovagal faint. Recognising the diphasic pattern matters clinically because the ordinary phobia instruction, "relax", would lower blood pressure further and precipitate the faint the patient fears.

RULE **Blood-injection-injury faints; the rest run.** Only the blood-injection-injury subtype shows the diphasic vasovagal response (a brief pressor phase then a bradycardic hypotensive drop to syncope); every other subtype shows sustained sympathetic arousal, so recognising the faint identifies the subtype and dictates applied tension rather than relaxation.

GOOD TO REMEMBER

- **Blood-injection-injury phobia:** the criterion-defining feature is the diphasic vasovagal response, an initial brief rise in heart rate and blood pressure followed by a vagally mediated fall in both, ending in fainting at the sight of blood/needles/injury; it uniquely has an equal sex ratio and the strongest familial loading, and it is the one subtype where relaxation is contraindicated and applied tension is the treatment of choice.

6.4 Applied tension: the bespoke treatment for the fainting subtype

What it is. Applied tension is the coping skill developed by Lars-Goran Ost and colleagues specifically for the blood-injection-injury subtype (Ost, Sterner and Fellenius 1989). The patient is taught to repeatedly *tense* the large muscle groups of the arms, legs and trunk for about 10 to 15 seconds, release to normal (not to relaxation) for 20 to 30 seconds, and repeat five times, applying the technique at the first sign of the pressure drop when confronting the phobic stimulus. The tensing raises blood pressure, counteracts the vasovagal fall, and thereby prevents the faint that maintains the avoidance.

Why it beats plain exposure here. Ost concluded that applied tension should be the treatment of choice for blood phobia, and a dismantling study showed that tension alone was almost as effective as full applied tension (tension plus exposure), while exposure alone was considerably less effective (Craske, Antony and Barlow 2006). The teaching point is that in this one subtype the coping skill, keeping the blood pressure up, matters more than habituation, which is exactly why the generic "relax during exposure" instruction is wrong here.

COMMON TRAP

Do not teach relaxation to a blood-injection-injury phobic. Relaxation lowers blood pressure and, in a patient whose problem is a vasovagal pressure drop to syncope, it precipitates the very faint being treated. The correct skill is applied tension (repeated large-muscle tensing to raise blood pressure), not relaxation; confusing the two is the classic exam and clinical error for this subtype.

GOOD TO REMEMBER

- **Applied tension (Ost):** the treatment of choice for the blood-injection-injury subtype; repeated tensing of large muscle groups (about 10 to 15 seconds on, 20 to 30 seconds off, five cycles) raises blood pressure and aborts the vasovagal faint; the mechanism is counteracting the pressure drop, not habituation, so it is used *instead of* relaxation and is combined with graded exposure to the feared stimulus.

6.5 DSM-5-TR criteria: marked fear, immediate, avoided, out of proportion, six months

The criteria to state cold. DSM-5-TR requires a marked fear or anxiety about a specific object or situation (Criterion A); the phobic stimulus almost always provokes immediate fear or anxiety (B);

the stimulus is actively avoided or endured with intense fear (C); the fear is out of proportion to the actual danger and the sociocultural context (D); the fear, anxiety or avoidance is persistent, typically **6 months or more** (E); it causes clinically significant distress or impairment (F); and it is not better explained by another mental disorder (G) (DSM-5-TR 2022). In children the fear may present as crying, tantrums, freezing or clinging, and the child need not recognise the fear as excessive.

The two discriminators inside the criteria. Criterion B ("almost always" and "immediate") is what separates a true phobia from an occasional situational nerviness: the person who is anxious on only one flight in five does not qualify. Criterion D moves the judgement of "out of proportion" to the clinician, taking cultural context into account (a fear of the dark may be reasonable where night-time assault is common).

CRITERION	DSM-5-TR REQUIREMENT
A. Marked fear	**Marked fear/anxiety about a specific object or situation (in children: crying, tantrums, freezing, clinging)**
B. Immediate/reliable	**The phobic stimulus almost always provokes immediate fear or anxiety**
C. Avoidance	Actively avoided, or endured with intense fear or anxiety
D. Out of proportion	Fear out of proportion to actual danger and to sociocultural context (clinician judges)
E. Duration	**Persistent, typically 6 months or more**
F. Impairment	Clinically significant distress or functional impairment
G. Not better explained	Not better explained by another disorder (agoraphobia, OCD, PTSD, separation anxiety, social anxiety)

DSM-5-TR criteria for specific phobia; the numbers to hold are the 6-month duration and the "almost always / immediate" reliability of Criterion B (DSM-5-TR 2022).

GOOD TO REMEMBER

- **Specific phobia (DSM-5-TR):** marked fear of a circumscribed stimulus that almost always and immediately provokes anxiety (Criterion B), is avoided or endured with distress, is out of proportion to the real danger, persists 6 months or more, and impairs functioning; the first diagnostic step is to confirm the fear is *cued and reliable* and then to exclude that it is better explained by agoraphobia, OCD, PTSD, separation or social anxiety (Criterion G).

6.6 ICD-11 CDDR and the differential: what to exclude

Where ICD-11 sits. The ICD-11 CDDR essential features mirror DSM closely: marked and excessive fear or anxiety that consistently occurs on exposure or anticipated exposure to one or more specific objects or situations, out of proportion to the actual danger; the stimulus is actively avoided or endured with intense fear; the pattern is not transient, persisting for at least **several**

months; it is not better accounted for by another disorder; and it causes significant distress or impairment (ICD-11 CDDR). As across the anxiety block, ICD-11 uses the softer "at least several months" rather than DSM's fixed 6-month clock.

The differential. The work is in Criterion G. If the avoided situations are feared because escape would be difficult or help unavailable in a panic, it is agoraphobia. If the fear is of contamination or driven by an obsession, it is OCD, not a phobia (the hand-washer who avoids door handles has OCD). If the avoidance is of trauma reminders, it is PTSD. If it is fear of scrutiny and negative evaluation, it is social anxiety disorder. If it is fear of separation from an attachment figure, it is separation anxiety. And medical mimics of situational fear (for example genuine cardiac or vestibular disease presenting as fear of exertion or heights) are excluded first.

GOOD TO REMEMBER

- **ICD-11 specific phobia:** marked, excessive, out-of-proportion fear consistently cued by one or more specific stimuli, actively avoided or endured with intense fear, not transient (at least several months), with distress or impairment; the discriminator from its neighbours is the *reason* for the fear, of the stimulus itself in phobia, versus escape difficulty (agoraphobia), obsessions (OCD), trauma reminders (PTSD), evaluation (social anxiety) or separation (separation anxiety).

6.7 Epidemiology and course: the commonest anxiety disorder, earliest onset

The numbers. Specific phobia is the most prevalent anxiety disorder, with a 12-month community prevalence of about **8 to 12 per cent** in the United States (around 6 per cent in Europe, lower at 2 to 4 per cent in Asian, African and Latin American surveys) (DSM-5-TR 2022). It is roughly **twice as common in women** as in men across most subtypes, the exception being blood-injection-injury, which is equal. Onset is early, most commonly in childhood between 7 and 10 years of age, and specific phobias that persist from childhood rarely remit spontaneously.

Course and comorbidity. Animal and natural-environment phobias tend to the earliest onset; situational phobias such as flying and heights begin later. Patients report high lifetime rates of co-occurring depressive and other anxiety disorders, and in most cases the specific phobia comes *first* and precedes the other disorder, which is why it is a useful early marker.

12-MONTH US PREVALENCE, THE COMMONEST ANXIETY DISORDER	DSM-5-TR MINIMUM DURATION (ICD-11: SEVERAL MONTHS)	FEMALE-TO-MALE RATIO (EQUAL IN BLOOD-INJECTION-INJURY)	TYPICAL AGE OF ONSET

6.8 Treatment: graded in-vivo exposure is the treatment of choice

Behavioural first, not drugs. The treatment of choice for specific phobia is *exposure-based* behaviour therapy, not medication; meta-analyses show very large effect sizes that are stable for at least a year (Craske, Antony and Barlow 2006). The workhorse is graded in-vivo exposure: the patient builds an **exposure hierarchy** (feared tasks rated 0 to 100 for anxiety, ordered from least to most provoking) and then repeatedly, systematically confronts the real phobic stimulus, starting low and climbing the ladder, until the feared catastrophe fails to occur and new, non-fearful learning takes hold. Modern practice reframes the goal not as staying until fear declines

but as staying long enough to *learn* that the feared outcome does not happen and that anxiety can be tolerated (inhibitory-learning model).

How fast it works. Specific phobia is unusually treatable: animal and blood phobias often respond to a single, prolonged session of exposure lasting two to three hours (Ost). No routine drug is indicated; a short-acting benzodiazepine or beta-blocker is at most an occasional aid for a discrete one-off exposure (for example a single flight) and is never the treatment, because it undermines the corrective learning that exposure depends on.

TRAP **Do not reach for a drug (or a benzodiazepine) as the treatment for a specific phobia.** The evidence-based treatment is graded in-vivo exposure; medication is not first-line, and a benzodiazepine taken to get through exposure blunts the fear-extinction learning that makes exposure work, so it undermines the very treatment.

GOOD TO REMEMBER

- **Graded in-vivo exposure:** the treatment of choice for specific phobia; the principle is repeated, systematic confrontation with the real phobic stimulus up a rated exposure hierarchy until the feared outcome is disconfirmed and anxiety is tolerated (inhibitory learning); it can work in a single 2 to 3 hour session for animal and blood phobias, and drugs are not first-line.

6.9 Systematic desensitisation and flooding: the two ends of the exposure spectrum

Systematic desensitisation. Systematic desensitisation is Joseph Wolpe's original method (Psychotherapy by Reciprocal Inhibition, 1958): the patient is taught deep muscle relaxation, an anxiety hierarchy is constructed, and the phobic stimuli are then paired, one graded step at a time, with the incompatible relaxation response, usually imaginally at first. Wolpe's mechanism was **reciprocal inhibition** (counter-conditioning): the relaxation response inhibits the anxiety response so the stimulus can be faced without fear. It is *gradual* and pairs each step with relaxation. Note the practical implication for the fainting subtype: because desensitisation uses relaxation, blood-injection-injury phobia is instead paired with applied tension.

Flooding. Flooding is the opposite pole: the patient is exposed to the most feared stimulus at full intensity from the outset, with no hierarchy and no graded climb, and stays in the situation until the anxiety, which cannot be sustained indefinitely, extinguishes. It is faster but more distressing and less tolerable, so graded exposure and desensitisation are generally preferred. The three methods sit on one spectrum, gradual-with-relaxation (systematic desensitisation), gradual real-life (graded in-vivo exposure), and all-at-once (flooding), and share the single active ingredient of exposure with prevention of avoidance.

MNEMONIC

SAFE-D

The specific-phobia essentials. **S**pecific circumscribed stimulus (cued, immediate, Criterion B); **A**void or endure with distress; **F**ive subtypes (animal, natural environment, blood-injection-injury, situational, other); **E**xposure is the treatment (graded in-vivo, systematic desensitisation, flooding); **D**iphasic vasovagal faint marks blood-injection-injury, treated with applied tension.

GOOD TO REMEMBER

- **Systematic desensitisation (Wolpe):** graded exposure up an anxiety hierarchy paired with deep relaxation; mechanism is reciprocal inhibition (relaxation inhibits anxiety); signature caution is that its reliance on relaxation makes it unsuitable, as-is, for the blood-injection-injury subtype, where applied tension replaces relaxation.
- **Flooding:** ungraded exposure to the most feared stimulus at full intensity from the outset until anxiety extinguishes; faster than graded methods but poorly tolerated, so it is not first-choice; the active ingredient it shares with all exposure is sustained contact with prevention of avoidance.

6.10 The India lens: a common, treatable disorder lost in the treatment gap

The genuine Indian point. Specific phobia is common, it presents early, and it is one of the most treatable conditions in psychiatry, a few sessions of exposure can resolve a fear that has constrained a life for decades. Yet in India it sits squarely inside the anxiety treatment gap: most people with a phobia never reach care, the fear is normalised or somatised, and when they do present the reflex prescription in general and primary care is a benzodiazepine (typically alprazolam), which is neither first-line nor a treatment for phobia at all and only undermines the exposure learning that would actually help. The correct Indian answer mirrors the global one: graded in-vivo exposure is the treatment, applied tension for the fainting subtype, and the benzodiazepine is at most a rare, single-exposure aid, never the plan. Where a drug is genuinely considered a beta-blocker such as propranolol (Indian brands Ciplar, Inderal) can blunt peripheral autonomic symptoms for a discrete situational exposure, but it too is an adjunct, not the treatment.

INDIA

The highest-yield Indian point is that specific phobia is common, early-onset and highly treatable with a short course of exposure, yet it is routinely lost in the anxiety treatment gap and met, when it does present, with a long-term benzodiazepine (usually alprazolam) that runs against the Indian Psychiatric Society CPG stance on anxiety and actively undermines the exposure-based learning that cures phobia. The right answer stays behavioural: graded in-vivo exposure and systematic desensitisation, applied tension for the blood-injection-injury faint, propranolol (Ciplar, Inderal) at most as an autonomic adjunct for a one-off situational exposure, and the benzodiazepine reserved and time-limited if used at all.

HOLD THIS

Specific (simple) phobia is a cued, out-of-proportion fear of one circumscribed stimulus that almost always and immediately provokes anxiety (DSM-5-TR: 6 months; ICD-11: several months), classified in DSM-5-TR into five subtypes (animal, natural environment, blood-injection-injury, situational, other); its treatment is exposure-based behaviour therapy, graded in-vivo exposure first, with systematic desensitisation (Wolpe, reciprocal inhibition) and flooding on the same spectrum, and the blood-injection-injury subtype alone shows the diphasic vasovagal faint and is treated with applied tension, never relaxation.

7 · Separation anxiety disorder

A childhood diagnosis that grew up. **Separation anxiety disorder** is the excessive, developmentally inappropriate fear of separation from an **attachment figure**. The single highest-yield fact for the exam is a nosological one: both the ICD-11 and the DSM-5 now list it as a **lifespan anxiety** disorder inside the anxiety and fear-related grouping, no longer walled off in the childhood-onset chapter. Examiners test the placement change, the criterion-anchored definition, and the boundary with normal developmental separation anxiety.

Keep the discrimination sharp. The apprehension is focused specifically on **separation from an attachment figure** (a parent in a child; a spouse, partner or one's own child in an adult), which is what sets it apart from panic disorder, agoraphobia and generalised anxiety. Treatment mirrors the wider anxiety toolkit, so the management detail lives in the neighbouring topics; this note is deliberately brief and criterion-led.

7.1 Definition and the core fear

Attachment-focused, not situation-focused. The disorder is characterised by marked, excessive and developmentally inappropriate fear or anxiety about separation from those to whom the person is emotionally bonded, with catastrophic beliefs about what separation will bring (harm, illness, an untoward event, never being reunited). Attachment figures are usually parents in children and a spouse, romantic partner or one's own children in adults.

7.2 The ICD-11 placement change (the exam hook)

Out of the childhood chapter, into anxiety. In DSM-IV and ICD-10, separation anxiety sat among disorders first diagnosed in infancy, childhood or adolescence (ICD-10 F93.0, "separation anxiety disorder of childhood"). The **icd-11 placement** moves it to code 6B05 within anxiety and fear-related disorders, and DSM-5 places it among the anxiety disorders. The reclassification reflects that the disorder can begin, or persist, in adulthood.

7.3 Lifespan reframe: no upper age bar

Adults get the diagnosis too. Unlike earlier editions, DSM-5 dropped the requirement for onset before 18 years and recognises that some adults report onset after 18. This is the substantive change behind the "lifespan" framing: an adult with excessive fear of being apart from a spouse or child, meeting criteria, is diagnosed here rather than being forced into a residual category.

7.4 The symptom set and threshold

Three of eight. DSM-5-TR requires at least three of eight symptoms: recurrent excessive distress on anticipated or actual separation; worry about losing the attachment figure or about harm to them; worry that an untoward event will cause separation; reluctance or refusal to leave home, school or work; fear of being alone; reluctance or refusal to sleep away from the attachment figure; nightmares about separation; and physical complaints (nausea, stomach ache, headache) on separation.

AXIS	DSM-5-TR	ICD-11 (6B05)
Chapter	**Anxiety disorders (not childhood chapter)**	**Anxiety and fear-related disorders**
Age scope	No onset-before-18 rule; adults included	Lifespan; adult onset recognised
Symptom threshold	**At least 3 of 8**	Marked fear plus characteristic features
Duration, children/adolescents	At least 4 weeks	Not transient (at least several months)
Duration, adults	**At least 6 months (typically)**	At least several months
Impairment	Distress or functional impairment	Distress or functional impairment

The two systems agree on substance; DSM-5-TR carries the explicit symptom count and duration thresholds most often examined.

7.5 Duration criterion

Four weeks in the young, six months in adults. DSM-5-TR asks for symptoms lasting at least **4 weeks** in children and adolescents and typically at least **6 months** in adults, the longer adult window added to avoid over-diagnosing transient fears (for example after a bereavement or a move). ICD-11 phrases this as symptoms that are "not transient," persisting for at least several months.

7.6 Boundary with normal developmental separation anxiety

Normal is time-limited and age-expected. Developmentally normal separation anxiety appears around **6 months** and declines between two and three years of age; it is a healthy marker of attachment. The disorder is diagnosed only when the fear is out of proportion to the child's developmental level, persists across repeated separations, and produces genuine distress or impairment (school refusal, inability to sleep alone, somatic complaints on parting).

RULE **Focus of fear decides the diagnosis.** If the apprehension is specifically about separation from an attachment figure, it is separation anxiety disorder, whatever the patient's age.

TRAP **Do not treat it as childhood-only.** Reflexively excluding the diagnosis in an adult (or over-calling normal toddler clinginess as a disorder) are the two classic errors since the placement change.

WORKED EXAMPLE

A 34-year-old woman cannot let her husband travel for work; she rings him repeatedly, is convinced he will be harmed while apart, cannot fall asleep until he is home, and has skipped her own commitments to stay near him for the past eight months. The apprehension is separation-focused, adult-onset, and beyond six months with clear impairment. This is separation anxiety disorder, not generalised anxiety, whose worry would be diffuse rather than pinned to one attachment figure.

INDIA

Anxiety disorders carry a large untreated **treatment gap** in India, and much of what does reach treatment is met with benzodiazepines: the **benzodiazepine over-prescription** problem is well recognised, with clonazepam and alprazolam handed out as first-line and long-term anxiolytics against guidance. The **IPS Clinical Practice Guidelines** and the international consensus are unambiguous that an SSRI (available here under brands such as sertraline, escitalopram and fluoxetine), with CBT or exposure, is first-line for the anxiety disorders, and that a benzodiazepine is neither first-line nor for long-term use. Separation anxiety disorder, presenting through a clingy child brought for "school refusal" or an adult brought by an exasperated spouse, is easily missed or sedated rather than diagnosed.

3 of 8	4 wk	6 mo
DSM-5-TR SYMPTOM THRESHOLD	MINIMUM DURATION IN CHILDREN	TYPICAL MINIMUM DURATION IN ADULTS

MNEMONIC

A-P-A-R-T

Attachment-figure fear is the core; **P**lacement now under anxiety in ICD-11 and DSM-5; **A**dults included (lifespan, no age bar); **R**equires three of eight symptoms; **T**ime threshold four weeks in children, about six months in adults.

PEARL

School refusal is a presentation, not a diagnosis. Separation anxiety disorder is one of its commonest drivers in younger children; social anxiety disorder takes over as the leading cause into adolescence.

GOOD TO REMEMBER

- **Separation anxiety disorder:** defining criterion is excessive, developmentally inappropriate fear focused specifically on separation from an attachment figure, at least three of eight symptoms, four weeks in children and about six months in adults; first step is to check the fear is separation-focused and to place it, correctly, as a lifespan anxiety disorder in ICD-11 (6B05) and DSM-5, no longer a childhood-only diagnosis.

HOLD THIS

Separation anxiety disorder is now a lifespan anxiety disorder: ICD-11 and DSM-5 moved it out of the childhood chapter, dropped the onset-before-18 rule, and it is defined by attachment-figure-focused fear meeting three of eight symptoms.

For the shared anxiolytic pharmacology and the benzodiazepine dependence problem, see the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes; for SSRI dosing and adverse effects, the Mood disorders: pharmacotherapy notes; for the general CBT and exposure model, the Psychotherapies, clinical assessment, MSE and nosology notes; and for the childhood

attachment disorders that sit nearby, the Child behavioural, emotional and other disorders notes and the Child psychiatry: assessment, treatment, services and protection notes.

8 · The neurobiology of anxiety

The **neurobiology of anxiety** is the machinery of a survival system that has become a symptom. Fear is an adaptive, fast, hard-wired response to a present threat; anxiety is its slower, sustained, anticipatory cousin, aimed at a threat that is diffuse, future or imagined. Both run on the same core circuit, a threat-detection network built around the **amygdala**, wired to fire the body's alarm before the thinking cortex has finished deliberating, and normally reined back in by the prefrontal cortex and hippocampus. When the alarm fires too readily, extinguishes too poorly, or is regulated too weakly, the survival system becomes an anxiety disorder. Examiners test this topic as the anatomy of a loop and the chemistry that tunes it: know the amygdala-centred **fear circuit**, its two sensory roads, its outputs to the hypothalamus, the brainstem and the periaqueductal grey, its cortical and hippocampal brakes, and the three transmitter systems, GABA, serotonin and noradrenaline, that the anxiolytic drugs act on.

Why it matters clinically. Every drug that works in the anxiety disorders acts somewhere on this circuit, so the neurobiology is not decoration, it is the rationale for the treatment. A benzodiazepine calms anxiety because it potentiates **gaba** inhibition across the amygdala and its targets; an SSRI works because **serotonin anxiety** pathways from the raphe tune the fear circuit over weeks; propranolol blunts performance anxiety by blocking the peripheral noradrenergic surge that the **locus coeruleus** drives. Two ideas anchor the whole answer. First, the amygdala is the hub: it evaluates threat and organises the fear response, and it is normally held in check by the prefrontal cortex, so anxiety disorders are, in circuit terms, an over-active amygdala under-regulated by a weak cortical brake. Second, the circuit has a fast, crude, subcortical route and a slow, accurate, cortical route, so the alarm can fire before you consciously know why. The pathway anatomy and receptor systems are developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; this topic applies that anatomy to the **fear circuitry** of clinical anxiety and refers to the accompanying figure for the map.

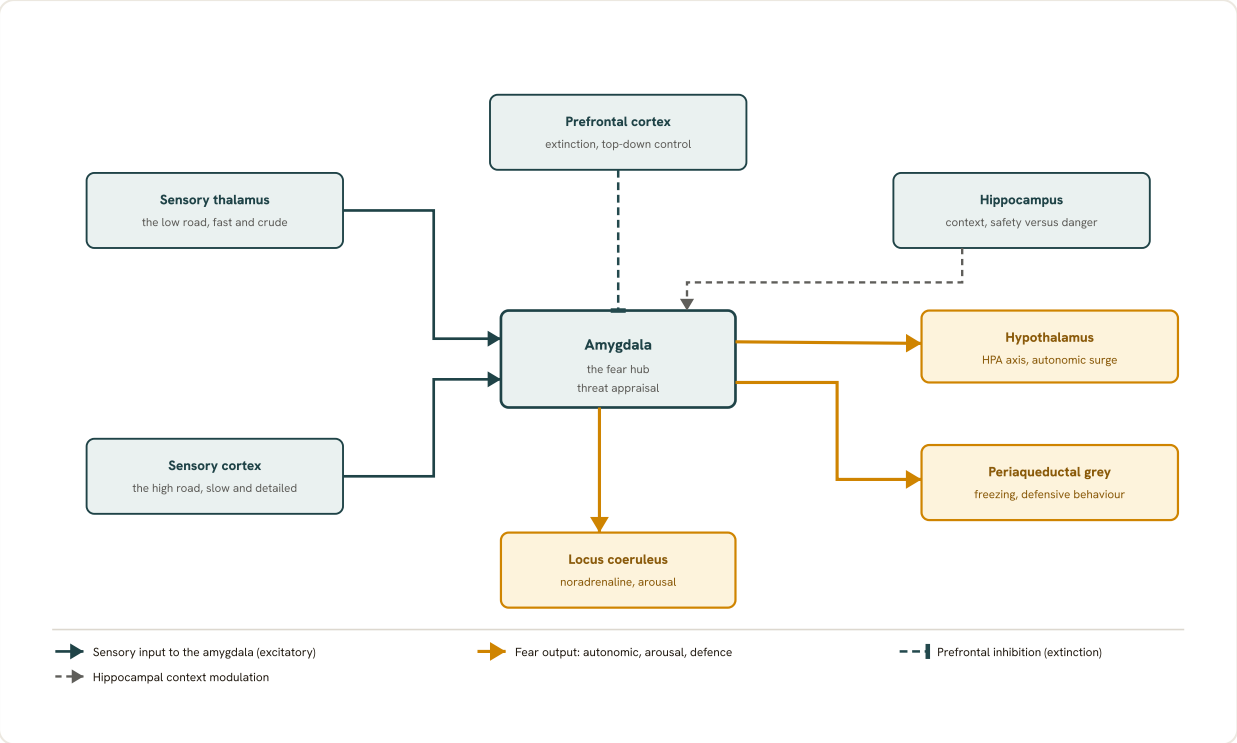

Fig 14.4 The fear circuit. The amygdala is the hub of the fear response: it receives a fast, crude input from the sensory thalamus (the low road) and a slower, detailed input from the sensory cortex (the high road), and it drives the fear state through the hypothalamus (the HPA axis and the autonomic surge), the periaqueductal grey (freezing and defensive behaviour) and the locus coeruleus (noradrenergic arousal). The prefrontal cortex exerts top-down inhibition, the basis of fear extinction, and the hippocampus supplies the context that separates safety from danger. A hyperresponsive amygdala with weak prefrontal control is the core lesion across the anxiety disorders. The receptor systems and the pathway anatomy are taught in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes.

8.1 Fear versus anxiety: the same circuit, two timescales

The distinction to open with. *Fear* is the response to a present, identifiable threat, phasic, fast, and organised largely by the central nucleus of the amygdala; *anxiety* is the response to a potential, diffuse or future threat, sustained, slower to build and slower to settle, and organised more by the bed nucleus of the stria terminalis (BNST), the amygdala's "extended" partner (Kaplan & Sadock CTP 2024). The BNST mediates the longer-duration apprehension elicited by less explicit or poorly-defined cues and contexts, which is why it is called the substrate of sustained anxiety rather than acute fear. Holding this apart matters because the clinical disorders are diseases of the anxiety end, a threat-detection system left switched on when no discrete threat is present.

One machine, one vulnerability. Because fear and anxiety share the amygdala hub, a system tuned to over-respond will produce both the acute false alarm (a panic attack) and the chronic apprehensive tension (generalised worry) in the same patient, which is why the anxiety disorders cluster and co-occur.

8.2 The amygdala as the hub: the lateral nucleus takes the input

The sensory gateway. The amygdala is an almond-shaped cluster of subnuclei (the amygdaloid complex) in the medial temporal lobe, and it is the pivot of the fear circuit. Its **lateral nucleus** (LA) is the primary sensory interface: it receives incoming sensory information from both the

sensory thalamus and the sensory cortex, and single LA neurons respond to auditory, visual and somatic stimuli, with the conditioned stimulus (the cue) and the unconditioned stimulus (the threat) converging there (Kaplan & Sadock CTP 2024). The LA is where a neutral cue first acquires threat value through **fear conditioning**, a form of synaptic plasticity (long-term potentiation) in the amygdala.

Distribution inside the complex. From the LA the signal is distributed to the basal and accessory basal nuclei and to the central nucleus (CE); the direct LA-to-CE projection can by itself drive conditioning to a simple cue, while the LA-to-basal projections build the longer-term fear memory (Kaplan & Sadock CTP 2024). The CE is the output nucleus, the amygdala's motor for the fear response.

PEARL

Think of the amygdala as a two-door hub. The *lateral nucleus* is the *in-door*, where thalamic and cortical sensory streams arrive and a cue is tagged as dangerous. The *central nucleus* is the *out-door*, from which the fear response is broadcast to the hypothalamus, brainstem and periaqueductal grey. Everything else, the fast road, the slow road, the cortical brake, is wiring around those two doors.

8.3 LeDoux's two roads: the low road and the high road

The fast, crude subcortical route. Joseph LeDoux mapped two parallel inputs to the amygdala. The *low road* runs from the sensory **thalamus** directly to the lateral amygdala, bypassing the cortex; it is fast and imprecise, a "quick and dirty" pathway that supports rapid conditioning to simple stimuli and permits an unconscious fear response before the stimulus is consciously identified (Kaplan & Sadock CTP 2024). Lesions of the auditory cortex do not prevent conditioning to a single tone, which is the experimental signature of the low road.

The slow, accurate cortical route. The *high road* runs from the sensory thalamus to the primary sensory and association **cortex** and then to the lateral amygdala; it is slower but detailed, and it is required for conditioned responding to more complex sensory stimuli and for the higher cognitive appraisal of the threat (Kaplan & Sadock CTP 2024). The two roads together explain the lived experience of fear: you flinch at the coiled shape on the path (low road) a fraction of a second before the cortex tells you it is a garden hose (high road).

WORKED EXAMPLE

A patient with a phobia of snakes freezes and gasps at a curved stick glimpsed in long grass, then within a second recognises it as a stick and feels foolish. The freeze-and-gasp is the low road, the sensory thalamus firing the amygdala directly and triggering the fear response before identification. The relief a moment later is the high road, cortical processing correcting the appraisal. In an anxiety disorder the low road is set too sensitive and the high-road correction is too weak or too slow to abort the alarm.

8.4 The output: central nucleus to hypothalamus, brainstem and periaqueductal grey

The three efferent targets to name. The central nucleus (CE) is the interface between the amygdala and the body's fear response, projecting to the medulla, midbrain and **hypothalamus** to drive the autonomic, endocrine and behavioural components (Kaplan & Sadock CTP 2024). Three CE outputs are the high-yield trio. To the *hypothalamus*, specifically the paraventricular nucleus (PVN), the amygdala drives release of corticotropin-releasing hormone and thereby the HPA-axis stress response; the projection is bisynaptic and GABAergic. To the **locus coeruleus** in the brainstem, the amygdala drives the noradrenergic surge that produces tachycardia, hypertension and hypervigilance. To the periaqueductal grey (PAG) in the midbrain, it drives the somatic and behavioural defence responses, freezing and avoidance (Gorman's neuroanatomical hypothesis, in Tasman Psychiatry).

Sustained anxiety takes the BNST branch. Both the CE and the BNST can directly activate the hypothalamus and brainstem; the BNST branch mediates the longer, context-driven anxiety states while the CE drives the phasic fear response (Kaplan & Sadock CTP 2024). Lesioning a specific CE efferent produces a selective deficit, PAG lesions blunt the somatobehavioural response, lateral hypothalamic lesions blunt the cardiovascular one, which is why the fear response is described as a set of parallel outputs from a single hub.

MNEMONIC

HELP the amygdala expresses fear: Hypothalamus, brainstem/LC, PAG

The central nucleus fires fear through its efferents: **H**ypothalamic PVN (CRH and the HPA stress axis), the brainstem **L**ocus coeruleus (noradrenaline, tachycardia, hypervigilance) and the **P**eriaqueductal grey (freezing and avoidance). Naming these three CE outputs is the fastest way to earn the "fear expression" marks.

8.5 The prefrontal brake and hippocampal context: how the alarm is switched off

The cortical brake. The medial and orbital prefrontal cortex (PFC) modulates the amygdala through extensive reciprocal projections and is the substrate of *fear regulation* and *extinction*, the learned reduction of a fear response once a cue is no longer dangerous (Kaplan & Sadock CTP 2024). The ventromedial PFC (the infralimbic region in the rat) drives extinction: it acts through the amygdala's GABAergic intercalated cells to inhibit central-nucleus output, so a strong vmPFC brake means a fear that can be extinguished. A weak vmPFC brake, or an over-driving dorsal anterior cingulate, means fear that persists, which is the circuit signature of the anxiety disorders and of PTSD.

Hippocampal context. The hippocampus supplies the *context* of the fear memory, whether the cue is dangerous *here and now* or only in the original setting, and it is central to contextual fear conditioning and to distinguishing a safe context from a dangerous one (Kaplan & Sadock CTP 2024). When hippocampal contextual gating fails, fear generalises to safe situations, the over-generalisation that characterises PTSD and generalised anxiety.

RULE **Over-active amygdala, under-active prefrontal brake.** The core circuit lesion of the anxiety disorders is an amygdala that fires too readily on threat and a ventromedial prefrontal cortex that regulates and extinguishes that fear too weakly; the hippocampus normally fixes the fear to its correct context, and when it fails, fear over-generalises to safe situations.

8.6 The GABA system: the brain's brake and the benzodiazepine target

Inhibition across the circuit. **gaba** (gamma-aminobutyric acid) is the principal inhibitory transmitter of the brain and the physiological brake on the fear circuit: GABAergic interneurons within the amygdala, the GABAergic intercalated cells through which the vmPFC inhibits CE output, and GABAergic tone throughout the limbic system all restrain the alarm (Kaplan & Sadock CTP 2024). A deficiency or reduced sensitivity of GABA-A signalling is a leading model of pathological anxiety.

Why the benzodiazepine works, and its ceiling. The benzodiazepine binds an allosteric site on the GABA-A receptor and potentiates GABA's action, increasing the frequency of chloride-channel opening, so it acutely amplifies the brake and calms anxiety within minutes. That immediacy is exactly why it is over-used and why it is *not* a first-line maintenance treatment: it does not correct the circuit, it only sedates it, and chronic use brings tolerance, dependence and rebound anxiety. The detailed anxiolytic pharmacology (benzodiazepines, buspirone, pregabalin, the z-drugs, dependence and withdrawal) is developed in the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes.

GOOD TO REMEMBER

- **GABA and the benzodiazepine (the transmitter and its drug):** GABA is the brain's chief inhibitory transmitter and the physiological brake on the amygdala and fear circuit; the benzodiazepine potentiates GABA at an allosteric GABA-A site (increasing chloride-channel opening frequency), giving a fast anxiolytic effect, the signature caution is that it sedates rather than corrects the circuit, so tolerance, dependence and rebound anxiety follow chronic use and it is never a first-line maintenance drug for an anxiety disorder.

8.7 The serotonin system: the slow tuner and the SSRI target

Raphe modulation of the fear circuit. **serotonin anxiety** pathways ascend from the dorsal raphe nucleus of the brainstem to the amygdala, prefrontal cortex, hippocampus and hypothalamus, where serotonin tonically modulates the excitability of the fear circuit (Kaplan & Sadock CTP 2024; New Oxford Textbook of Psychiatry). The relationship is complex rather than simply inhibitory, but the clinical fact is that enhancing serotonergic transmission dampens pathological anxiety over weeks, and the postsynaptic 5-HT1A receptor is a key mediator (the partial agonist buspirone acts here).

Why the SSRI is first-line and slow. The SSRI raises synaptic serotonin at once, but the anxiolytic benefit is delayed by several weeks, the lag reflecting adaptive receptor changes and a re-tuning of the circuit rather than acute inhibition. This delayed, circuit-remodelling action is precisely why the SSRI corrects where the benzodiazepine only sedates, and why the SSRI (and SNRI) is first-line across the anxiety disorders and PTSD. The deep antidepressant pharmacology

(the SSRIs, SNRIs, clomipramine, doses, adverse effects, interactions) is developed in the Mood disorders: pharmacotherapy notes.

TRAP **Expecting the SSRI to work like a benzodiazepine.** The serotonergic anxiolytic effect is delayed by weeks and can transiently *worsen* anxiety in the first days (early activation); reaching for a benzodiazepine because "the SSRI is not working yet", or stopping the SSRI too early, is the classic error, warn the patient about the lag and the early jitteriness from the outset.

GOOD TO REMEMBER

- **Serotonin and the SSRI (the transmitter and its drug):** serotonin ascends from the dorsal raphe to tune the amygdala, prefrontal cortex and hippocampus (the 5-HT1A receptor a key mediator); the SSRI raises synaptic serotonin at once but re-tunes the fear circuit only over several weeks, the signature caution is the delayed onset with early activation, and the principle is that it *corrects* the circuit where a benzodiazepine only sedates, which is why the SSRI/SNRI is first-line for the anxiety disorders and PTSD.

8.8 The noradrenaline system: the locus coeruleus and the alarm's amplifier

The brainstem alarm centre. The **locus coeruleus** (LC) is the principal noradrenergic nucleus of the brain, in the pons, and it is the amplifier of the fear response: activation of the LC raises noradrenaline throughout the forebrain and drives the peripheral autonomic surge, tachycardia, raised blood pressure, sweating and hyperarousal, that the patient feels as the physical face of anxiety (Kaplan & Sadock CTP 2024; Tasman Psychiatry). The amygdala's central nucleus projects to the LC, and the LC in turn feeds arousal back into the circuit, a positive loop that panic disorder in particular exploits.

The pharmacological proof. The noradrenergic model is not merely theoretical: yohimbine, an alpha-2 antagonist that increases LC firing and noradrenaline release, provokes panic in vulnerable patients, while clonidine, an alpha-2 agonist that suppresses the LC, reduces arousal (Tasman Psychiatry). Clinically the same physiology explains why propranolol (Ciplar, Inderal), a beta-blocker, blunts the peripheral tremor and tachycardia of *performance* anxiety, and why prazosin (Minipress, Prazopress), an alpha-1 antagonist, dampens the noradrenergic hyperarousal that drives the nightmares of PTSD.

GOOD TO REMEMBER

- **Noradrenaline and the locus coeruleus (the transmitter and its nucleus):** the LC is the pontine noradrenergic alarm centre that amplifies the amygdala's fear output into the peripheral autonomic surge (tachycardia, hypertension, hyperarousal); yohimbine (alpha-2 antagonist) provokes panic and clonidine (alpha-2 agonist) suppresses it, the clinical corollary is that propranolol blunts the peripheral surge of performance anxiety and prazosin dampens the noradrenergic hyperarousal behind PTSD nightmares.

8.9 Putting the circuit together: how the transmitters map onto the anatomy

One picture, three dials. The fear circuit is one anatomical loop with three chemical dials. GABA is the inhibitory brake wired through the amygdala and the prefrontal intercalated cells; serotonin is the slow tuner descending from the raphe onto the whole circuit; noradrenaline from

the locus coeruleus is the amplifier of the output. An anxiety disorder is, in this scheme, too little brake, mis-tuning of the serotonergic set-point, and too much amplifier, on a hub (the amygdala) that is over-reactive and a cortex (vmPFC) that regulates it too weakly. Every anxiolytic drug is best understood as adjusting one of these dials.

NODE / SYSTEM	ROLE IN THE FEAR CIRCUIT	CLINICAL / DRUG CORRELATE
Lateral nucleus of amygdala (LA)	Sensory in-door; thalamic + cortical input converge; site of fear conditioning (LTP)	Over-sensitive threat detection in anxiety disorders
Central nucleus of amygdala (CE)	**Out-door; organises the fear response via efferents**	Lesion abolishes conditioned fear expression
Low road (thalamo-amygdala)	Fast, crude, pre-conscious alarm; bypasses cortex (LeDoux)	Explains reflex fear before identification
High road (thalamo-cortico-amygdala)	Slow, accurate cortical appraisal of threat (LeDoux)	Weak or slow high-road correction sustains the alarm
Hypothalamus (PVN)	**CE efferent; CRH release, HPA stress axis**	Neuroendocrine stress response
Locus coeruleus	CE efferent; noradrenaline, autonomic surge, hyperarousal	**Yohimbine provokes, propranolol/prazosin blunt**
Periaqueductal grey (PAG)	CE efferent; freezing and defensive avoidance behaviour	Somatobehavioural fear output
Ventromedial PFC	**The brake; drives extinction via GABAergic intercalated cells**	Weak brake = fear that will not extinguish (PTSD)
Hippocampus	Supplies context of the fear memory	Failure = fear over-generalises to safe settings
GABA	Inhibitory brake across the circuit	Benzodiazepine target (fast, sedating)
Serotonin (raphe)	Slow tonic tuner of the whole circuit; 5-HT1A	SSRI target (slow, corrective, first-line)
Noradrenaline (LC)	Amplifier of the fear output	Beta-blocker / prazosin / clonidine target

The amygdala-centred fear circuit node by node, mapped to its transmitter systems and drug correlates; the accompanying figure draws the same loop as a map (input roads, amygdala hub, efferent targets, cortical and hippocampal brakes). Grounded in Kaplan & Sadock CTP 2024 and Tasman Psychiatry.

8.10 Definitions to fix the vocabulary

Amygdala

Almond-shaped medial-temporal complex of subnuclei; the hub that evaluates threat and organises the fear response.

Lateral nucleus (LA)

The amygdala's sensory in-door; thalamic and cortical input converge here and cues acquire threat value.

Central nucleus (CE)

The amygdala's output nucleus; its efferents to hypothalamus, LC and PAG express the fear response.

Low road

LeDoux's fast thalamo-amygdala route that bypasses the cortex; pre-conscious, crude, quick.

High road

LeDoux's slower thalamo-cortico-amygdala route; accurate cortical appraisal of the threat.

BNST

Bed nucleus of the stria terminalis; the "extended amygdala" that mediates sustained, context-driven anxiety rather than phasic fear.

Extinction

Learned reduction of a conditioned fear once the cue is no longer dangerous; driven by the ventromedial PFC.

INDIA

India carries a large, largely untreated anxiety burden: the great majority of people with an anxiety, OCD or PTSD disorder never reach formal care, a treatment gap widened by stigma, scarcity of psychiatrists and the framing of anxiety as physical "ghabrahat" or "gas". Into that gap steps the country's **benzodiazepine over-prescription** problem: alprazolam and clonazepam are dispensed freely, often long-term and as a first move, by general practitioners and over the counter, which is exactly the wrong dial to turn on this circuit, the sedating brake that breeds dependence rather than the corrective serotonergic re-tuning. The neurobiology gives the corrective the Indian Psychiatric Society CPG endorses: an SSRI or SNRI is first-line for the anxiety disorders because it re-tunes the fear circuit, with the benzodiazepine reserved as a short bridge only. The relevant Indian brands are cheap and available, escitalopram (Nexito, Cipralex), sertraline (Serta, Zosert, Daxid), fluoxetine (Fludac) and paroxetine (Paxidep) for the serotonergic drugs, propranolol (Ciplar, Inderal) for the noradrenergic blunting of performance anxiety, and prazosin (Minipress, Prazopress) for PTSD nightmares; the correct answer treats the circuit, not merely the symptom.

2	3	3
SENSORY ROADS TO THE AMYGDALA (LEDOUX'S FAST LOW ROAD, SLOW HIGH ROAD)	CENTRAL-NUCLEUS EFFERENT TARGETS TO NAME (HYPOTHALAMUS, LOCUS COERULEUS, PAG)	TRANSMITTER DIALS ON THE CIRCUIT (GABA BRAKE, SEROTONIN TUNER, NORADRENALINE AMPLIFIER)

HOLD THIS

The fear circuit is an amygdala hub fed by LeDoux's fast subcortical low road and slow cortical high road, expressing fear through the central nucleus onto the hypothalamus, locus coeruleus and periaqueductal grey, and normally braked by the ventromedial prefrontal cortex and contextualised by the hippocampus; anxiety is that circuit over-reactive and under-regulated, tuned by three dials, the GABA brake (benzodiazepine target), the serotonergic tuner (SSRI target, slow and corrective) and the noradrenergic amplifier from the locus coeruleus (beta-blocker and prazosin target).

9 · Cognitive behaviour therapy for anxiety

Cognitive behaviour therapy for anxiety is the psychological treatment that the whole anxiety block leans on: across generalised anxiety disorder, panic, social anxiety and the phobias, every major guideline names **cbt for anxiety** as a first-line option of broadly similar efficacy to drug treatment. This note owns the disorder-specific CBT model, the cognitive model of anxiety, **cognitive restructuring**, the **behavioural experiment**, and the three classes of exposure, including **interoceptive exposure**, with the safety-behaviour idea running through all of them; the wider CBT technique (the general cognitive model, the wider exposure principle) is cross-referenced to the Psychotherapies, clinical assessment, MSE and nosology notes.

Fig 14.5 Exposure therapy repeatedly approaches feared-but-safe cues while reducing avoidance and safety behaviours, allowing new inhibitory safety learning to compete with the older threat association.

Why it matters, and how this note is framed. Examiners reward the candidate who can do two things: state the *cognitive model* of anxiety (that it is the appraisal of a situation, not the situation itself, that drives the fear, and that avoidance and safety behaviours keep the belief alive by preventing disconfirmation), and name the *techniques* with their disorder-specific twist,

interoceptive exposure for the "fear of fear" in panic, dropping safety behaviours and shifting attention outward in social anxiety, exposure and response prevention for OCD (owned separately in the OCD notes). The single sharpest fact to hold is that CBT works by *disconfirming a catastrophic prediction* through direct experience, which is exactly what a behavioural experiment is engineered to do.

9.1 The cognitive model of anxiety: appraisal, not the event, drives the fear

The basic assumption. The cognitive model holds that people's beliefs and appraisals of events are at least as important as the events themselves in determining their emotional reactions; problematic anxiety is frequently the product of unrealistic, unhelpful beliefs about the world, the self and others (Kaplan and Sadock 2024). The classic sequence is *thoughts and beliefs lead to emotions and behaviours*, Aaron Beck's belief-disconfirmation model, so the therapeutic target is the faulty appraisal, not the feared object directly. In anxiety specifically, the appraisals share a family resemblance: probability overestimation (the feared outcome is far more likely than it is) and catastrophic thinking (its consequences would be unbearable), plus all-or-nothing thinking, overgeneralisation and selective attention to confirming evidence.

How maintenance works. The disorder is held in place by a vicious cycle: an ambiguous cue is appraised as threatening, which raises anxiety and arousal, which is itself read as further evidence of danger, and the person then *avoids* or deploys *safety behaviours* that abort the situation before the catastrophe can be shown not to happen. Because the feared outcome never gets a chance to be disconfirmed, the belief survives intact. CBT breaks this loop by getting the patient to stay in contact with the feared situation, or sensation, long enough to learn that the prediction was wrong.

GOOD TO REMEMBER

- **Cognitive behaviour therapy for anxiety:** the principle is that anxiety flows from a distorted *appraisal* (probability overestimation and catastrophic thinking) rather than the event itself, and is maintained by avoidance and safety behaviours that prevent the belief from being disconfirmed; the mechanism of change is disconfirmation of the catastrophic prediction through cognitive restructuring and exposure; it is first-line, of broadly similar efficacy to pharmacotherapy across the anxiety disorders.

9.2 The shape of a course: assessment, formulation, psychoeducation, homework

How a course of CBT is built. CBT begins with a structured assessment of the presenting complaint using validated measures (and disorder-relevant constructs such as worry-related metacognitions in GAD or anxiety sensitivity in panic), repeated over treatment to track outcome. The next step is psychoeducation: the patient is given a shared cognitive-behavioural formulation of their specific diagnosis and a treatment rationale, then therapist and patient collaboratively set targets, for example building the exposure hierarchy or eliciting the core fear (Kaplan and Sadock 2024). CBT is time-limited, structured and collaborative, and leans heavily on homework and self-monitoring between sessions so that skills generalise beyond the consulting room.

How long it takes. The course is short by psychotherapy standards. For panic disorder the optimal dose is **7 to 14 hours** of treatment, delivered weekly, typically over about four months (NICE). For GAD, a high-intensity individual CBT course is **12 to 15 weekly sessions** of one hour (NICE). This brevity is part of why guidelines can place CBT co-equal with drugs and why low-intensity and internet-delivered versions are pushed hard to widen access.

GOOD TO REMEMBER

- **Structure of CBT for anxiety:** assessment then shared cognitive-behavioural formulation and psychoeducation, collaborative goal-setting, and between-session homework and self-monitoring; it is brief and time-limited (panic 7 to 14 hours over about four months; GAD 12 to 15 weekly one-hour sessions per NICE), which is why it sits co-equal with pharmacotherapy as first-line.

9.3 Cognitive restructuring: Socratic dialogue, thought records, the downward arrow

What it is. Cognitive restructuring is the set of procedures for identifying and modifying the unhelpful appraisals. The three traditional techniques are (1) Socratic dialogue, a guided series of questions that helps the patient surface and challenge a fear-related belief and uncover disconfirming evidence; (2) the downward-arrow technique, repeatedly asking "and what would that mean?" to reach the deeper core belief; and (3) the thought record, in which the patient logs automatic thoughts, lists the evidence for and against, spots the cognitive error, and generates a more realistic, balanced alternative (Kaplan and Sadock 2024). The therapist does not simply reassure or argue; the patient is walked to the new conclusion so that they own it.

What it targets in anxiety. The restructuring is aimed squarely at the two anxiety appraisals, overestimating how likely the bad outcome is and catastrophising how bad it would be. In panic disorder that means challenging the catastrophic misinterpretation of a bodily sensation ("this pounding heart means I am having a heart attack"); in social anxiety it means challenging the prediction of humiliation and the distorted self-image seen "from the outside". Restructuring alone can reduce anxiety, but its power is greatest when it sets up a prediction that exposure can then test.

RULE **Restructure, then test.** Cognitive restructuring makes the catastrophic belief explicit and generates a specific prediction; exposure and behavioural experiments then supply the disconfirming experience, and it is the direct experience, not the argument, that shifts the belief.

GOOD TO REMEMBER

- **Cognitive restructuring:** identifying and modifying anxious appraisals (probability overestimation, catastrophising) via Socratic dialogue, thought records and the downward-arrow technique; the signature caution is that it is collaborative and guided, not reassurance or debate, and it works best when it produces a testable prediction that exposure can then disconfirm.

9.4 The behavioural experiment: testing a prediction against reality

The single most important technique. A behavioural experiment is the point where cognitive and behavioural methods fuse. Its goal is to test a belief about the nature and probability of a feared consequence under conditions that optimise exposure to, and encoding of, disconfirming

information (Kaplan and Sadock 2024). Before the experiment the patient makes a *detailed, specific prediction* of what they believe will happen, then carries out the relevant action and observes the actual result. Each time the catastrophe fails to occur, the patient is confronted with evidence against the belief. The worked panic example is canonical: a patient who fears they will "go crazy" if they feel dizzy is asked to spin in a chair, slowly then faster, and discovers that intense dizziness comes and goes without madness.

Why it beats reassurance. Homework assignments and behavioural experiments let the patient practise new behaviours and test the therapist's alternative explanations for themselves; even experiments that "fail" reveal more about the condition (Shorter Oxford Textbook). Because the learning is experiential and self-generated, it sticks in a way that being told "your heart is fine" never does, which is why the behavioural experiment is the engine of durable change in CBT for anxiety.

STEP	WHAT HAPPENS
Identify the belief	Elicit the specific catastrophic prediction (e.g. "if I feel dizzy I will collapse")
Make it testable	**Operationalise a concrete, falsifiable prediction with the patient**
Design the experiment	Choose an action that will expose the prediction to disconfirming evidence, drop safety behaviours
Run it	Carry out the action; the patient stays in contact and observes what actually happens
Review the evidence	**Compare prediction with outcome; update the belief from direct experience**

The anatomy of a behavioural experiment; the load-bearing steps are making the belief testable and then reviewing prediction against reality (Kaplan and Sadock 2024).

GOOD TO REMEMBER

- **Behavioural experiment:** a planned test in which the patient makes a specific prediction about a feared consequence, carries out an action (with safety behaviours dropped), and compares prediction with outcome; the principle is experiential disconfirmation of the catastrophic belief, and the signature caution is that the prediction must be concrete and falsifiable, and safety behaviours removed, or the experiment cannot disconfirm anything.

9.5 Exposure: the three classes, done without safety behaviours

What exposure is. Exposure therapy means intentionally confronting a feared but not actually dangerous object, situation, thought, memory or physical sensation, in order to reduce the fear and avoidance attached to it. Contemporary exposure divides into three classes: *in vivo*, *imaginal* and interoceptive, all conducted while encouraging the patient to *prevent safety behaviours*, the strategies that avert the feared outcome but, in doing so, block the new learning (Kaplan and Sadock 2024). Older systematic desensitisation paired graded imaginal or in vivo exposure with relaxation; that relaxation is now regarded as unnecessary and possibly counterproductive, and prolonged in vivo exposure has become the standard.

The three classes. *In vivo* exposure directly confronts feared objects, activities and situations, usually graded up a collaboratively agreed hierarchy (the snake photographed, then caged, then handled). *Imaginal* exposure has the patient vividly picture the feared scenario, thought or memory (its main use is confronting feared thoughts and traumatic memories, and it underpins imagery rescripting in PTSD). **Interoceptive exposure**, the most recent, deliberately induces the feared bodily sensations under control, hyperventilating for breathlessness and tingling, spinning for dizziness, straw-breathing for air-hunger, to teach that the sensations are not dangerous; it is the signature technique for panic disorder's "fear of fear".

CLASS	WHAT IS CONFRONTED	SIGNATURE USE
In vivo	Real feared objects, activities and situations, graded up a hierarchy	**Specific phobia, agoraphobic avoidance, social situations**
Imaginal	Feared thoughts, images and memories, vividly pictured	Traumatic memories (PTSD), feared consequences; imagery rescripting
Interoceptive	**Feared bodily sensations, induced on purpose (spin, hyperventilate, straw-breathe)**	**Panic disorder: the "fear of fear" / anxiety sensitivity**

The three classes of exposure; all are run while dropping safety behaviours, and interoceptive exposure is the panic-specific technique for anxiety sensitivity (Kaplan and Sadock 2024).

TRAP **Safety behaviours and reassurance sabotage exposure.** If the patient keeps a hidden crutch (clutching a water bottle, sitting near the exit, silent reassurance-seeking) or the exposure is too brief to let anxiety fall, the catastrophic belief is never disconfirmed, so the exposure looks like it "failed" when the design was at fault.

GOOD TO REMEMBER

- **Exposure (in vivo, imaginal, interoceptive):** graded confrontation of the feared stimulus without safety behaviours to allow new learning; in vivo for real situations and phobias, imaginal for feared thoughts and traumatic memories, interoceptive for the feared bodily sensations of panic; the signature caution is that safety behaviours, avoidance and reassurance-seeking must be dropped, and prolonged real (in vivo) exposure now replaces relaxation-paired systematic desensitisation.

9.6 Interoceptive exposure and the CBT model of panic

The panic cycle. The cognitive-behavioural model of panic (the Clark model) frames a panic attack as a vicious cycle: the person is hypervigilant for a bodily sensation, misinterprets it catastrophically ("this racing heart means a heart attack; this unreality means I am going mad"), which raises arousal and intensifies the sensation, spiralling into panic; agoraphobic avoidance then grows as an attempt to escape the situations where attacks might strike (Kaplan and Sadock 2024). The therapeutic implication is direct: break the catastrophic misinterpretation and the loop cannot close.

Where interoceptive exposure fits. CBT for panic has four components: psychoeducation about the panic cycle, cognitive restructuring of the catastrophic misinterpretation, **interoceptive**

exposure to the feared sensations to reduce the "fear of fear", and in vivo exposure to any avoided (agoraphobic) situations. Dismantling studies point to cognitive restructuring combined with in vivo or interoceptive exposure as the active ingredients, and adding interoceptive exposure is particularly helpful; in one meta-analysis the largest effect size was for cognitive therapy plus interoceptive exposure (**d = 0.88**), ahead of CBT without it and of medication alone. Between **41 and 87 per cent** of patients are panic-free after CBT, and CBT gains hold better than medication after treatment stops.

WORKED EXAMPLE

A 28-year-old with panic disorder is terrified that the dizziness and derealisation during an attack mean she is about to faint or lose her mind, so she sits down, grips a chair and sips water whenever they start (safety behaviours). Restructuring surfaces the prediction "if I let the dizziness build I will faint". The interoceptive exposure is to hyperventilate for a minute, then spin, deliberately bringing on the dizziness and unreality, without sitting, gripping or sipping. Over repeated trials she learns the sensations crest and pass without fainting or madness; the "fear of fear" falls, and in vivo exposure then returns her to the supermarket and the bus she had been avoiding.

GOOD TO REMEMBER

- **Interoceptive exposure in panic:** deliberate induction of feared bodily sensations (hyperventilation, spinning, straw-breathing) to break the catastrophic misinterpretation that drives the panic cycle and reduce the "fear of fear"; it is the panic-specific exposure class, one of the active ingredients of panic CBT, and the signature caution is that it fails if the patient keeps safety behaviours or the induced sensations are cut short.

9.7 Social anxiety CBT: dropping safety behaviours, shifting attention outward

The disorder-specific twist. In social anxiety disorder the Clark and Wells model adds two signature moves to the standard restructuring-plus-exposure package: a stronger emphasis on *identifying and eliminating safety behaviours* (over-rehearsing sentences, avoiding eye contact, gripping a glass to hide a tremor) and on *shifting attention outward* from the distorted, self-focused image the patient believes others can see (Kaplan and Sadock 2024). Exposures are integrated with cognitive challenge: the patient makes an explicit prediction, drops the safety behaviours, focuses attention on the other person rather than the self, and reviews the outcome afterwards, often with video feedback that contradicts the "I looked ridiculous" belief.

Why it works. Network meta-analysis puts individual CBT ahead of group CBT and of psychodynamic, supportive and mindfulness therapies for social anxiety, and the Clark and Wells version shows large effects against fluoxetine, exposure alone and group CBT. This is why NICE makes disorder-specific *individual* CBT the first-line treatment for social anxiety disorder, developed further in the Social anxiety disorder note.

PEARL

The two Clark-and-Wells refinements that lift social-anxiety CBT above generic exposure are *dropping safety behaviours* and *redirecting attention outward*. Self-focused attention manufactures the very "distorted self-image" the patient dreads others see; video feedback, showing the patient they did not visibly shake or blush as badly as they believed, is a behavioural experiment that disconfirms it directly.

GOOD TO REMEMBER

- **Social anxiety CBT (Clark and Wells):** cognitive restructuring of the fear of negative evaluation plus graded exposure, with two signature additions, systematically dropping safety behaviours and shifting attention outward from the self-focused image, tested with video-feedback experiments; individual CBT is first-line and outperforms group CBT for social anxiety disorder (NICE).

9.8 Evidence and place in the anxiety guidelines

What the guidelines say. The convergence is the exam point. NICE, BAP, CANMAT and the Indian Psychiatric Society all place **cbt for anxiety** as a first-line psychological treatment across generalised anxiety disorder, panic disorder and social anxiety disorder, of broadly similar efficacy to pharmacotherapy, with combination (CBT plus an SSRI or SNRI) reserved for partial or non-response. NICE makes CBT (or applied relaxation) one of two equivalent first-choice high-intensity options in GAD, first-line for panic (7 to 14 hours), and the first-line individual treatment for social anxiety disorder; BAP and CANMAT agree. For OCD the psychological arm is *exposure and response prevention*, taught in the OCD management notes; for PTSD it is trauma-focused CBT, taught in the PTSD notes.

The one durability advantage. A recurring finding is that CBT gains are more durable than medication gains once treatment stops (in panic, CBT alone held better than CBT plus imipramine after discontinuation), and cognitive therapy with exposure may reduce relapse better than drug treatment alone. That relapse-protection edge, plus lower dropout than medication, is why guidelines are keen to expand access through group, guided self-help and internet-delivered CBT.

DISORDER	CBT STATUS	DISORDER-SPECIFIC CBT INGREDIENT
Generalised anxiety disorder	**First-line (co-equal with drugs); 12 to 15 sessions**	Worry-focused restructuring; no standard in vivo target
Panic disorder	**First-line; 7 to 14 hours**	**Interoceptive exposure for the "fear of fear"**
Social anxiety disorder	First-line individual CBT (over group)	Drop safety behaviours, shift attention outward (Clark and Wells)
Specific phobia / agoraphobia	Exposure is treatment of choice	Graded in vivo exposure up a hierarchy
OCD	First-line psychotherapy (see OCD notes)	Exposure and response prevention

CBT across the anxiety block; the through-line is first-line status with a disorder-specific technique, and the durability edge over medication after stopping is the recurring evidence point.

INDIA

India has a wide anxiety, OCD and PTSD treatment gap, most sufferers never reach formal care, and where care is reached it too often means long-term benzodiazepine prescribing, alprazolam and clonazepam dispensed for "nervousness", which runs directly against the Indian Psychiatric Society CPGs. CBT is the evidence-based alternative that the gap most needs, yet trained CBT therapists are scarce outside metros. This is exactly where low-intensity and internet-delivered CBT, guided self-help and task-shifting to non-specialists matter: they are the realistic route to scaling a first-line psychological treatment in a low-resource setting, and they let the SSRI-plus-CBT model displace the benzodiazepine habit rather than reinforce it.

3	7 to 14 hours	0.88	10
CLASSES OF EXPOSURE (IN VIVO, IMAGINAL, INTEROCEPTIVE)	CBT DOSE FOR PANIC DISORDER (NICE)	EFFECT SIZE, COGNITIVE THERAPY PLUS INTEROCEPTIVE EXPOSURE IN PANIC	GAD-7 CLINICAL CUT-OFF (SCREEN THE DISORDER CBT TREATS)

HOLD THIS

CBT for anxiety works by disconfirming a catastrophic prediction through direct experience: cognitive restructuring makes the belief testable, the behavioural experiment and the three exposure classes (in vivo, imaginal, interoceptive, all with safety behaviours dropped) supply the disconfirming evidence, and it is first-line and co-equal with drugs across the anxiety disorders, with interoceptive exposure the signature technique for panic.

10 · Anxiety: differential diagnosis and medical mimics

Once the anxiety disorders have been learned one at a time, the examiner turns the question round: a patient walks in with palpitations, tremor, sweating and a racing sense of dread, and you must say *which* anxiety disorder this is, and first of all whether it is an anxiety disorder at all. This is the discrimination step. The **differential diagnosis of anxiety** has two limbs that must both be secured: separating the anxiety disorders from one another by the *focus of the fear*, and

separating a primary anxiety disorder from an organic cause, the **medical mimics**. The accompanying figure maps the anxiety disorders by the focus of the fear, and the figure alongside sorts the medical mimics by the feature that gives each away; this note is the text that unpacks both.

Why it matters, and the trap that fails candidates. The single discriminator that separates each anxiety disorder is a one-line fact the examiner expects you to produce instantly, and the classic error, the trap that turns a pass into a fail, is to reach for a psychiatric label while missing an organic mimic sitting in plain sight (**hyperthyroidism**, a **phaeochromocytoma**, an arrhythmia, hypoglycaemia, or a caffeine habit). The neurobiology of the fear circuit that these mimics hijack is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; the anxiolytic and withdrawal pharmacology that produces the substance-related pictures below lives in the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes; what this note owns is the discrimination itself.

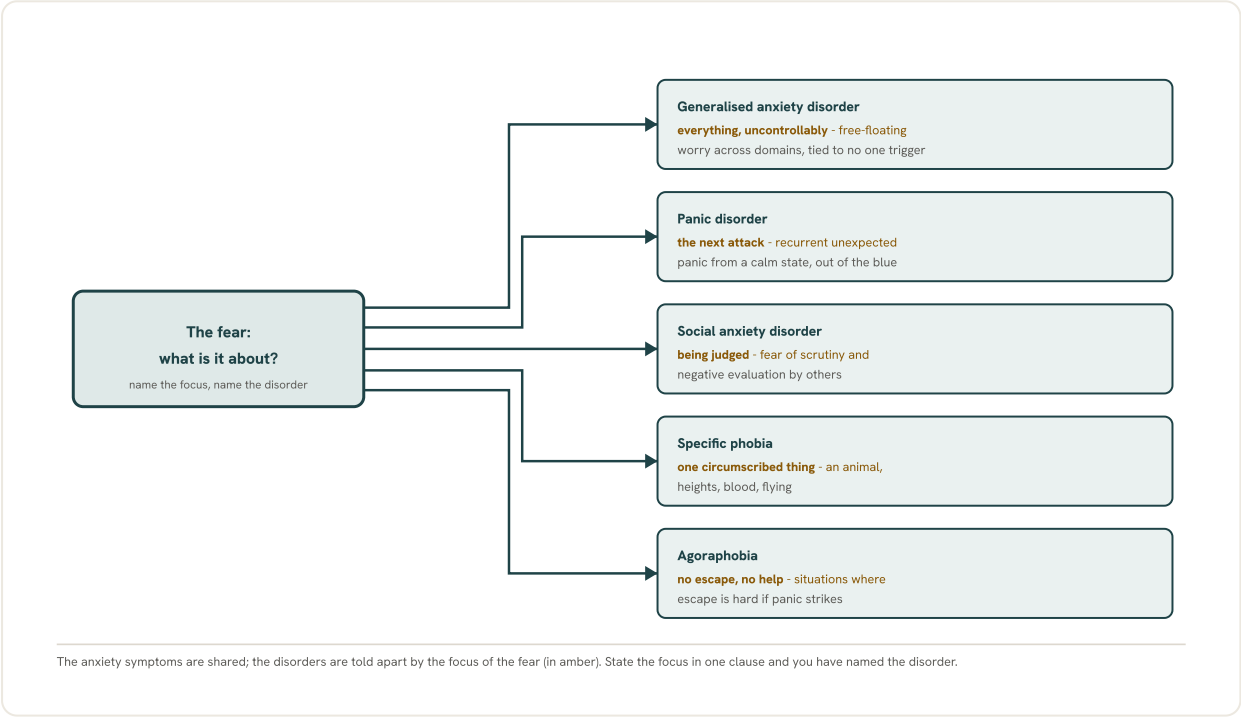

Fig 14.6 Discriminating the anxiety disorders by the focus of the fear. The somatic symptoms of anxiety are shared across all of these disorders, so they cannot separate them; what separates them is what the fear is about. Generalised anxiety fears everything and nothing in particular; panic fears the next attack; social anxiety fears being judged; specific phobia fears one circumscribed object or situation; agoraphobia fears being trapped where escape would be difficult or help unavailable. Name the focus and you have named the disorder.

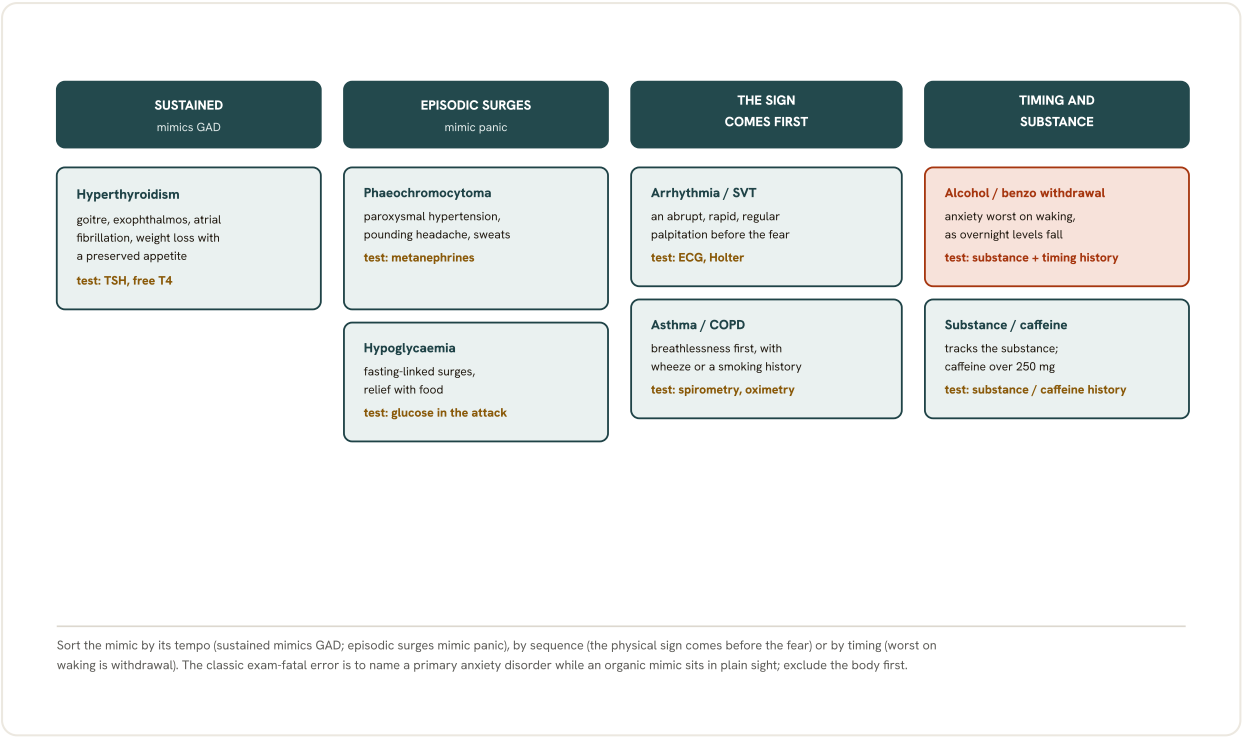

Fig 14.7 The medical mimics of anxiety, sorted by the feature that gives each away. Rather than a flat list, the mimics fall into four groups by their discriminating principle. A sustained driver (thyrotoxicosis) reproduces the steady picture of generalised anxiety; episodic paroxysmal surges (a phaeochromocytoma, hypoglycaemia) reproduce panic; where the physical sign comes first, an arrhythmia (a palpitation preceding the fear) or asthma and COPD (breathlessness first) is the answer; and anxiety that is worst on waking is alcohol or benzodiazepine withdrawal, while anxiety that tracks a substance or a heavy caffeine load is intoxication. Excluding the body, and choosing the test by the tempo, comes before any anxiety-disorder label.

10.1 The organising principle: one discriminator per disorder, the body ruled out first

Two questions, in order. Faced with an anxious patient, ask first "is this organic?" and only then "which anxiety disorder is it?". The order is deliberate: an SSRI started for what is actually thyrotoxicosis or a phaeochromocytoma is not merely useless but leaves a dangerous lesion untreated. The organic screen (thyroid function, a substance and caffeine history, attention to withdrawal timing, and where the story is episodic and physical, catecholamines and an ECG) comes before the psychiatric formulation, not after it.

Then the focus of the fear. Once the body is cleared, the anxiety disorders are told apart not by the *symptoms* of anxiety (which are shared) but by *what the fear is about*. GAD fears everything and nothing in particular; panic fears the next attack; social anxiety fears being judged; specific phobia fears one circumscribed thing; agoraphobia fears being trapped where escape is hard. Name the focus and you have named the disorder.

RULE **Exclude the body before you name the disorder.** Thyroid function, a caffeine and substance history, and (where symptoms are episodic and physical) an ECG and catecholamines precede any anxiety-disorder label; the focus of the fear then names the disorder.

10.2 Discriminating the anxiety disorders: the focus of the fear

The one-liner for each. The examiner wants the discriminating focus stated in a single clause. GAD is free-floating anxiety, chronic uncontrollable worry across many domains, not tied to any one trigger. Panic disorder is defined by *recurrent unexpected panic attacks* that come out of the

blue from a calm state, with the fear being of the attacks themselves (anticipatory anxiety about the next surge). Social anxiety disorder is a *fear of scrutiny and negative evaluation* in social or performance situations. Specific phobia is fear of a *circumscribed object or situation* (an animal, heights, blood, flying). Agoraphobia is fear of situations *where escape would be difficult or help unavailable* should a panic-like or incapacitating event strike, the fear is about escape and rescue, not the place itself.

DISORDER	THE ONE DISCRIMINATOR (FOCUS OF THE FEAR)	COURSE/CUE
Generalised anxiety disorder	**Free-floating, uncontrollable worry across many domains, not bound to any trigger**	Chronic, persistent
Panic disorder	**Fear of the attacks themselves; recurrent unexpected panic from a calm state**	Episodic, out of the blue
Social anxiety disorder	**Fear of scrutiny and negative evaluation by others**	Cued by social/performance settings
Specific phobia	Fear of one circumscribed object or situation	Cued by the single phobic stimulus
Agoraphobia	**Fear of situations where escape is difficult or help unavailable**	Cued by crowds, transport, open/enclosed spaces

The anxiety-disorders differentiation grid: each disorder is separated by the focus of the fear, not by the anxiety symptoms, which are shared (ICD-11 CDDR; DSM-5-TR 2022).

GOOD TO REMEMBER

- **Differential of the anxiety disorders:** the discriminator is the focus of the fear, GAD (everything, free-floating), panic (the next attack), social anxiety (negative evaluation), specific phobia (one circumscribed object), agoraphobia (being unable to escape or get help); state the focus in one clause and you have named the disorder.

10.3 Organic anxiety: the category and why episodic-versus-sustained matters

The concept. Organic anxiety disorder (organic anxiety disorder in ICD terms) is anxiety arising secondarily from a medical disorder, the fear-circuit output is real but the driver is bodily. The teaching pivot, drawn straight from the Shorter Oxford Textbook, is the *tempo* of the mimic. Sustained, low-grade organic drivers (thyrotoxicosis) reproduce the GAD picture; *episodic, paroxysmal* drivers (phaeochromocytoma, hypoglycaemia, paroxysmal arrhythmia) reproduce panic disorder or a phobic disorder, because they come in discrete surges (Shorter Oxford Textbook of Psychiatry). Matching the tempo of the mimic to the tempo of the psychiatric picture is how you decide which physical test to send.

The pointer to organicity. Features that should push you towards a physical cause rather than a primary anxiety disorder: a first presentation of anxiety in an older patient, prominent and disproportionate physical signs, anxiety without the cognitive content of worry or dread, a fluctuating episodic course with autonomic storms, and any hard sign on examination (goitre, exophthalmos, atrial fibrillation, sustained hypertension).

10.4 Hyperthyroidism: the sustained mimic of GAD

The picture. In hyperthyroidism (thyrotoxicosis) the patient is irritable and restless, with tremor and tachycardia, exactly the somatic tail of GAD, and it is the commonest and most examinable organic mimic (Shorter Oxford Textbook of Psychiatry). Because the thyroid drive is continuous, the resulting anxiety is *sustained*, so thyrotoxicosis is the classic mimic of generalised anxiety disorder rather than of panic.

The pointing feature, the test, the discriminator. The pointing features are the hard thyroid signs, an enlarged thyroid (goitre), atrial fibrillation, exophthalmos, heat intolerance and weight loss despite a good appetite. The screening test is thyroid function (a suppressed TSH with raised free T4). The discriminator from a primary anxiety disorder is that thyrotoxic patients lose weight while eating well and show the eye and gland signs, and their anxiety resolves when the thyroid is treated (Shorter Oxford Textbook of Psychiatry).

GOOD TO REMEMBER

- **Hyperthyroidism (thyrotoxicosis):** the sustained organic mimic of GAD (irritability, restlessness, tremor, tachycardia); pointing features are goitre, exophthalmos, atrial fibrillation and weight loss with preserved appetite; the screening test is thyroid function (suppressed TSH, raised free T4); the discriminator is the physical thyroid signs and resolution on treating the thyroid.

10.5 Phaeochromocytoma: the paroxysmal mimic of panic

The picture. A phaeochromocytoma is a catecholamine-secreting tumour that releases adrenaline and noradrenaline in bursts, producing paroxysmal episodes of palpitations, pounding headache, sweating and a surge of dread, indistinguishable at the bedside from a panic attack. Because the secretion is *episodic*, the phaeochromocytoma mimics panic disorder or a phobic disorder rather than GAD (Shorter Oxford Textbook of Psychiatry; New Oxford Textbook of Psychiatry).

The pointing feature, the test, the discriminator. The pointing feature is *paroxysmal hypertension*, blood pressure that spikes with each attack, together with the headache-palpitations-sweating triad. The screening tests are plasma or 24-hour urinary metanephrines and catecholamines. The discriminator from panic disorder is the objectively recorded hypertensive surge during an attack and the presence of the pounding headache, panic disorder does not raise the blood pressure to those levels or produce that headache. The classic exam pairing is that phaeochromocytoma and hypoglycaemia both cause *episodic* symptoms and therefore mimic panic or phobia (Shorter Oxford Textbook of Psychiatry).

GOOD TO REMEMBER

- **Phaeochromocytoma:** a catecholamine-secreting tumour producing paroxysmal palpitations, pounding headache and sweating that mimic panic; the pointing feature is paroxysmal hypertension; the screening test is plasma/urinary metanephrines and catecholamines; the discriminator is the recorded hypertensive surge and the headache during attacks.

10.6 Arrhythmia and supraventricular tachycardia, and hypoglycaemia

Cardiac: the palpitation that came first. A paroxysmal arrhythmia, above all a supraventricular tachycardia (SVT), produces sudden palpitations, breathlessness and a sense of doom that read as panic; paroxysmal tachycardia is on the standard organic-mimic list (New Oxford Textbook of Psychiatry). The pointing feature is a very rapid, regular, abruptly-starting-and-stopping palpitation that *precedes* the fear rather than following it, and, in panic disorder, mitral valve prolapse is a recognised association. The screening test is an ECG, and ideally a rhythm strip or ambulatory (Holter) monitor capturing an episode. The discriminator from panic is the temporal order and the rate: in SVT the tachycardia comes first and is faster and more regular than the sinus tachycardia of panic, which follows the psychological alarm.

Hypoglycaemia: the episodic autonomic surge. Recurrent hypoglycaemia produces episodic tremor, sweating, palpitations and anxiety and, like phaeochromocytoma, mimics panic or a phobic disorder because it is episodic (Shorter Oxford Textbook of Psychiatry; New Oxford Textbook of Psychiatry). The pointing feature is the relationship to fasting and the relief with food; the screening test is a paired capillary/venous glucose during an attack (Whipple's triad); the discriminator is the low glucose recorded during symptoms and their resolution with carbohydrate.

GOOD TO REMEMBER

- **SVT/arrhythmia:** abrupt rapid regular palpitations that come *before* the fear; test with ECG/Holter; discriminator is the tachycardia preceding the anxiety and being faster and more regular than panic's sinus tachycardia.
- **Hypoglycaemia:** episodic tremor, sweating and anxiety mimicking panic; test with glucose during symptoms; discriminator is the low glucose recorded in the attack and relief with food.

10.7 Asthma and COPD: the breathless mimic

The picture. Bronchospasm in asthma and hypoxia or hypercapnia in COPD produce breathlessness, chest tightness and a frightened, air-hungry arousal that is easily mislabelled panic, and the two genuinely co-occur and feed each other (breathlessness triggers panic, panic worsens breathlessness). The pointing feature is that the *breathlessness comes first* and is accompanied by wheeze, cough, a documented trigger (exertion, allergen, cold air) or a smoking history, rather than arising from a calm state. The screening test is peak expiratory flow or spirometry (and pulse oximetry in an acute episode). The discriminator from panic disorder is the demonstrable airflow obstruction and hypoxia, and the response to a bronchodilator, panic produces hyperventilation with a normal or low CO2, not true obstruction.

GOOD TO REMEMBER

- **Asthma/COPD:** breathlessness and chest tightness mimicking panic, with the dyspnoea coming first plus wheeze/cough/trigger or smoking history; test with peak flow/spirometry and oximetry; discriminator is demonstrable airflow obstruction and hypoxia responding to a bronchodilator, unlike the normocapnic hyperventilation of panic.

10.8 Substance and caffeine intoxication

Stimulant and substance-induced anxiety. Substance-induced anxiety is anxiety arising during intoxication with a stimulant, cocaine, amphetamine or other sympathomimetic, or from other agents, and it must be excluded before a primary diagnosis is made. The pointing feature is the temporal link to the substance and any intoxication signs (dilated pupils, tachycardia, hypertension, agitation); the screening test is a substance history and, where available, a urine drug screen; the discriminator is that the anxiety tracks the substance and clears as the drug is eliminated.

Caffeine, the ubiquitous and forgotten mimic. Caffeine anxiety (caffeinism, caffeine intoxication) is the mimic most often missed because it is legal and everyday. DSM defines caffeine intoxication as recent consumption usually in excess of **250 mg** of caffeine (about 2 to 3 cups of brewed coffee) with **five or more** of restlessness, nervousness, excitement, insomnia, flushed face, diuresis, gastrointestinal disturbance, muscle twitching, rambling thought, tachycardia, and psychomotor agitation (DSM-5-TR 2022). The pointing feature is a high daily caffeine load; the screening test is a careful dietary caffeine history (brewed coffee about 100 mg/cup, instant about 60 mg, tea about 45 mg, cola 25 to 50 mg per can); the discriminator is that the anxiety and insomnia settle on cutting caffeine down.

COMMON TRAP

The classic error is to diagnose a primary anxiety disorder and miss an organic mimic. Before labelling GAD or panic, exclude hyperthyroidism (goitre, exophthalmos, weight loss), a phaeochromocytoma and hypoglycaemia (episodic surges, paroxysmal hypertension in the phaeochromocytoma), an arrhythmia or SVT (palpitation preceding the fear), asthma or COPD (breathlessness first), and above all a caffeine habit or stimulant use, each reproduces the anxiety picture, and each is treated at its source, not with an SSRI.

GOOD TO REMEMBER

- **Substance-induced anxiety:** anxiety during stimulant/sympathomimetic intoxication; pointing feature is the temporal link plus intoxication signs; screen with substance history and urine drug screen; discriminator is clearance as the drug is eliminated.
- **Caffeine intoxication:** more than 250 mg caffeine plus 5 or more of restlessness, nervousness, insomnia, flushed face, diuresis, GI upset, twitching, tachycardia; screen with a caffeine dietary history; discriminator is resolution on reducing caffeine.

10.9 Alcohol and benzodiazepine withdrawal: the morning mimic

The picture. Withdrawal from alcohol or from a benzodiazepine reproduces GAD-like anxiety with tremor, sweating, tachycardia and insomnia, and it is a leading cause of "treatment-resistant anxiety" in a dependent patient who is really in daily micro-withdrawal (Shorter Oxford Textbook of Psychiatry). The pointing feature that Gelder emphasises is *timing*: anxiety that is worst on waking in the morning, when overnight alcohol and short-half-life benzodiazepine levels have fallen, points to withdrawal (and, separately, morning-worst anxiety also raises depressive disorder). The screening test is a detailed alcohol and sedative history with quantities

and timing; the discriminator from a primary anxiety disorder is the diurnal, dose-linked pattern of the anxiety and, on withdrawal from certain drug classes, hard signs such as pupillary changes.

GOOD TO REMEMBER

- **Alcohol/benzodiazepine withdrawal:** a GAD-like tremulous, sweaty, tachycardic anxiety that is worst on waking; the pointing feature is the morning timing as overnight levels fall; screen with a detailed substance-and-timing history; the discriminator is the diurnal, dose-linked pattern rather than the persistent free-floating worry of primary anxiety.

MIMIC	POINTING FEATURE	SCREENING TEST	DISCRIMINATOR FROM PRIMARY ANXIETY
Hyperthyroidism	**Goitre, exophthalmos, AF, weight loss with appetite**	Thyroid function (TSH, free T4)	Physical thyroid signs; sustained (mimics GAD); resolves on treating thyroid
Phaeochromocytoma	**Paroxysmal hypertension, pounding headache**	Plasma/urinary metanephrines, catecholamines	Recorded BP surge in attack; episodic (mimics panic)
Arrhythmia / SVT	Abrupt rapid regular palpitation before the fear	ECG, Holter/rhythm strip	Tachycardia precedes anxiety; faster, more regular than panic
Hypoglycaemia	Fasting-related surges, relief with food	Glucose during symptoms (Whipple's triad)	Low glucose recorded in attack; episodic (mimics panic)
Asthma / COPD	Breathlessness first, wheeze, smoking history	Peak flow/spirometry, oximetry	Airflow obstruction and hypoxia; responds to bronchodilator
Substance / caffeine intoxication	High stimulant or caffeine load, intoxication signs	Substance history, urine drug screen, caffeine history	Anxiety tracks the substance; clears on cessation
Alcohol / benzodiazepine withdrawal	**Anxiety worst on waking, dose-linked**	Detailed substance and timing history	Diurnal, dose-linked pattern; withdrawal signs

The anxiety-versus-medical-mimic grid: pointing feature, screening test and the discriminator from a primary anxiety disorder for each organic mimic (Shorter Oxford Textbook of Psychiatry; New Oxford Textbook of Psychiatry).

250 mg
CAFFEINE INTOXICATION THRESHOLD (PLUS 5 OR MORE SYMPTOMS)

5
DSM SYMPTOMS REQUIRED FOR CAFFEINE INTOXICATION

100 mg
CAFFEINE PER CUP OF BREWED COFFEE (INSTANT ABOUT 60)

TRAP **Missing an organic mimic is the exam-fatal error.** Episodic autonomic storms with paroxysmal hypertension are a phaeochromocytoma until proven otherwise; sustained tremor with weight loss is thyrotoxicosis; anxiety worst on waking is alcohol or benzodiazepine withdrawal, not "resistant GAD".

10.10 The India lens: the treatment gap and the benzodiazepine problem behind the differential

Two genuine Indian realities. First, the anxiety, OCD and PTSD treatment gap is wide, anxiety is under-recognised, heavily somatised (patients present with palpitations, tremor and "gas" rather than "worry"), and under-treated, so the organic mimics are precisely the physical complaints that get an anxious patient sent round the physicians for years without either an anxiety diagnosis or a thyroid test. Second, the entrenched over-prescription of benzodiazepines (typically alprazolam) means many "anxious" Indian patients are in chronic benzodiazepine dependence, so *benzodiazepine withdrawal* is itself a common, iatrogenic mimic of anxiety in Indian practice. The Indian Psychiatric Society CPGs exist to correct both, rule out the organic causes, treat the primary disorder with an SSRI or SNRI first-line, and reserve the benzodiazepine as a short, time-limited bridge rather than the standing prescription (the Indian Psychiatric Society 2020).

INDIA

The highest-yield Indian point on this discrimination topic is that the benzodiazepine over-prescription problem creates its own mimic: a large number of Indian patients labelled "anxiety" are actually in daily alprazolam micro-withdrawal, which reads as morning-worst anxiety. The correct Indian workup mirrors the global one, exclude hyperthyroidism (a cheap TSH), a phaeochromocytoma and hypoglycaemia where episodic, and a caffeine or substance load, then treat the primary disorder with an SSRI or SNRI (escitalopram Nexito or Rexipra, sertraline) rather than adding yet another benzodiazepine strip.

RULE **Tempo tells you which mimic.** Sustained anxiety with weight loss and tremor is thyrotoxicosis (mimics GAD); episodic autonomic surges are phaeochromocytoma or hypoglycaemia (mimic panic); a palpitation preceding the fear is an arrhythmia; morning-worst anxiety is withdrawal.

HOLD THIS

Before naming any anxiety disorder, exclude the organic mimics, thyrotoxicosis (sustained, mimics GAD), phaeochromocytoma and hypoglycaemia (episodic, mimic panic), arrhythmia/SVT (palpitation first), asthma/COPD (breathlessness first), caffeine and substance intoxication, and alcohol/benzodiazepine withdrawal (worst on waking); then separate the anxiety disorders by the focus of the fear, GAD (everything), panic (the next attack), social anxiety (negative evaluation), specific phobia (one object), agoraphobia (no escape).

Obsessive-compulsive and related disorders

11 · OCD: clinical features, dimensions and insight

Where anxiety disorders are about a feared object or a feared situation, **obsessive-compulsive disorder** is about a feared *thought* and the ritual built to undo it. **Obsessive-compulsive disorder** (**ocd**) is defined by **obsessions** (intrusive, unwanted, ego-dystonic thoughts, images or urges) and **compulsions** (repetitive behaviours or mental acts performed to neutralise the obsession or its dreaded consequence). It is the anchor diagnosis of the obsessive-compulsive and

related disorders grouping, which both DSM-5-TR and ICD-11 lifted out of the anxiety disorders into a spectrum of its own, and which the accompanying figure maps.

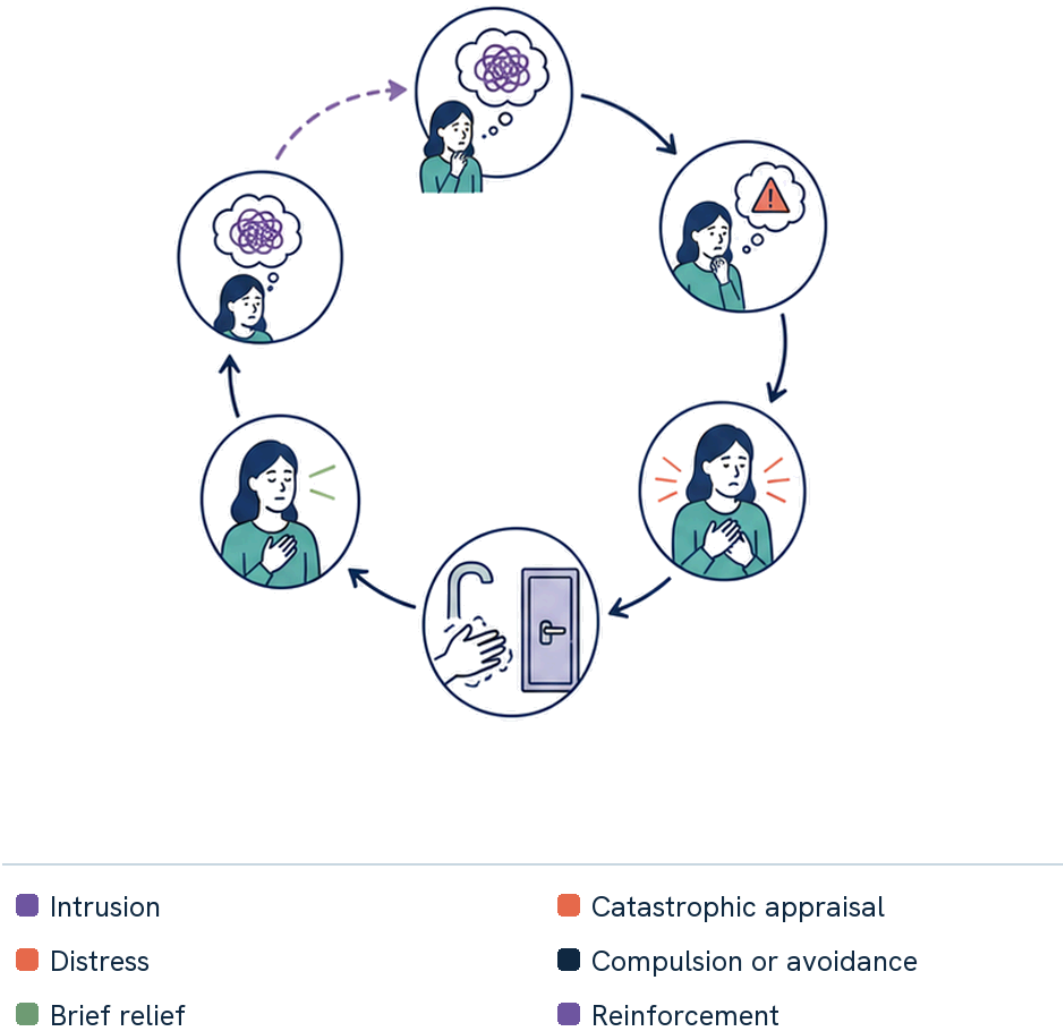

Fig 14.8 The OCD maintenance cycle: an intrusion is appraised as threatening, producing distress and a compulsion or avoidance response; brief relief negatively reinforces the response and strengthens the cycle.

Why it matters, and what this note owns. Examiners test three things on this topic and this note owns all three: the exact definitions of obsession and compulsion (the ego-dystonic, intrusive, resisted quality is the whole discriminator), the four **symptom dimensions** and how each obsession pairs to its compulsion, and the **insight specifier** that ranges from good insight to frankly delusional conviction, alongside the **tic-related ocd** specifier. The management story (a high-dose SSRI for a long trial, then clomipramine, then antipsychotic augmentation, with exposure and response prevention as the psychological spine) is developed in its own management note; the deep antidepressant pharmacology of the SSRIs and clomipramine lives in the Mood disorders: pharmacotherapy notes, and neurosurgery and deep brain stimulation for the refractory patient in the ECT and neurostimulation notes. What follows is the phenomenology, the dimensions, the insight and tic specifiers, and the epidemiology and course.

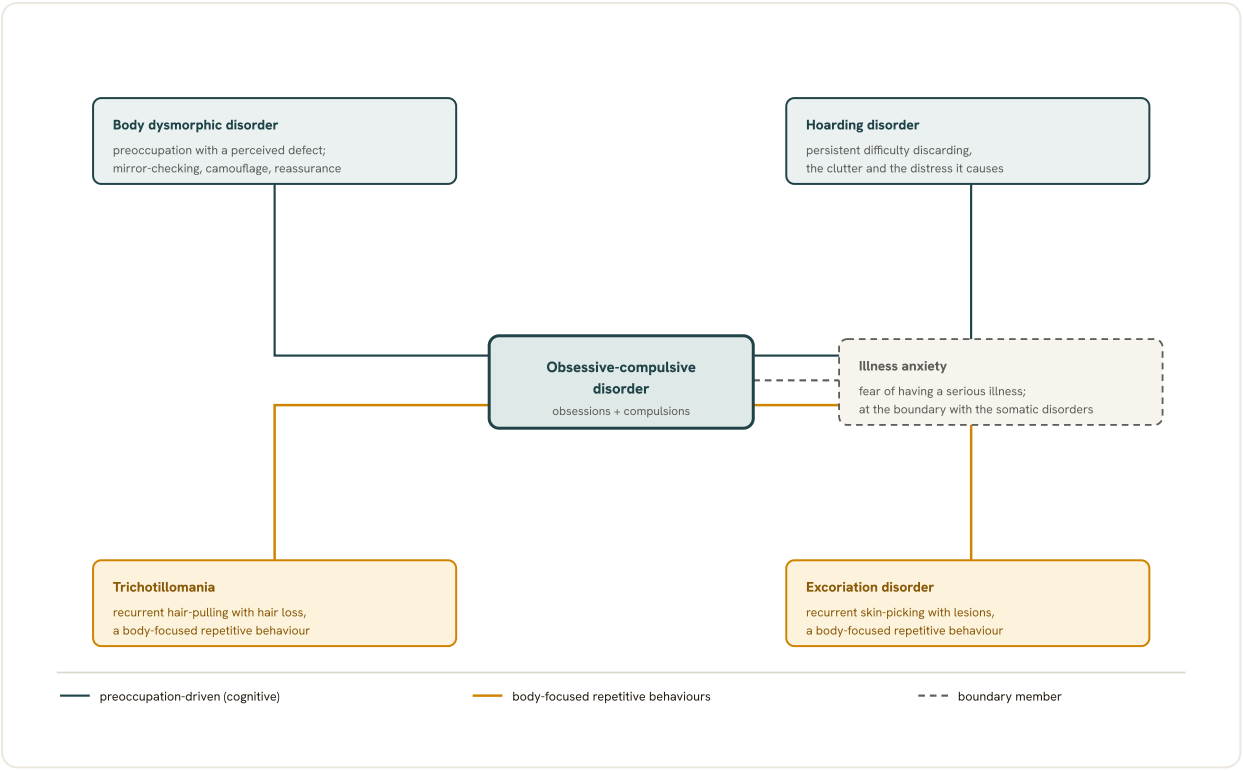

Fig 14.9 The obsessive-compulsive and related disorders spectrum. OCD sits at the centre; the related disorders share either a driving preoccupation or a repetitive behaviour. Body dysmorphic disorder (a preoccupation with a perceived defect), hoarding disorder (the difficulty discarding) and, at the boundary with the somatic-symptom disorders, illness anxiety are the preoccupation-driven members; trichotillomania (hair-pulling) and excoriation (skin-picking) are the body-focused repetitive behaviours. Grouping them as a spectrum is the pedagogic point: each is recognised by the shared thread of a repetitive act or a fixed preoccupation, and each responds, in part, to the serotonin reuptake inhibitors and to the behavioural therapies. The somatic-symptom boundary is taught in the Somatic-symptom, sexual, impulse-control disorders and suicide notes.

11.1 Obsessions: intrusive, unwanted, ego-dystonic mental events

The definition to state cold. Obsessions are recurrent and persistent thoughts (e.g. of contamination), images (e.g. of a violent or horrific scene) or urges/impulses (e.g. to stab someone) that are experienced as *intrusive and unwanted* and that, in most people, cause marked anxiety or distress (DSM-5-TR 2022; ICD-11 CDDR). Three qualities carry the diagnosis. They are **intrusive** (they force their way into awareness against the person's will), **unwanted** (not pleasurable, not experienced as voluntary), and **ego-dystonic** (felt as alien to the self and as senseless or repugnant, which is why the person tries to resist them). The individual attempts to ignore or suppress the obsession, or to neutralise it with another thought or action, that is, with a compulsion.

The ego-dystonic hinge. The ego-dystonic quality is the single most useful discriminator. A worry in generalised anxiety disorder is ego-syntonic (the person endorses it as a reasonable, if excessive, concern); a delusion is held as true; a ruminative depressive thought is congruent with low mood. An obsession, by contrast, is experienced as intrusive, senseless and one's own but unwanted, which is exactly why the patient fights it. That fight, and the distress it generates, is what makes it pathological rather than merely an odd thought.

GOOD TO REMEMBER

- **Obsession:** a recurrent, persistent thought, image or urge experienced as intrusive, unwanted and ego-dystonic, causing marked anxiety or distress; the person resists or tries to neutralise it (usually with a compulsion); the ego-dystonic, resisted quality is the defining discriminator from a GAD worry (ego-syntonic) and from a delusion (held as true).

11.2 Compulsions: repetitive acts that neutralise, not connected or clearly excessive

The definition to state cold. Compulsions are repetitive behaviours (e.g. hand washing, ordering, checking) or mental acts (e.g. praying, counting, repeating words silently) that the person feels *driven to perform* in response to an obsession or according to rules that must be applied rigidly (DSM-5-TR 2022). Their aim is to prevent or reduce anxiety or distress, or to prevent some dreaded event or situation, or to reach a sense of **completeness** or "just right" (ICD-11 CDDR). Two qualifiers are essential: the compulsion is either *not connected in a realistic way* to what it is meant to neutralise (arranging items symmetrically to stop harm coming to a relative), or is *clearly excessive* (showering for hours to prevent illness).

Mental compulsions are still compulsions. A high-yield trap is to equate compulsions with visible behaviours only. Mental acts, silent counting, praying to a formula, mentally reviewing a memory to be sure no harm was done, are compulsions too, and a patient with only intrusive thoughts and covert mental rituals ("pure O") can be mislabelled as having obsessions alone. Compulsions are not done for pleasure, though they may bring transient relief; that relief is what negatively reinforces and perpetuates the cycle.

WORKED EXAMPLE

A young man is plagued by intrusive images of harm coming to his mother whenever he leaves the house (obsession: intrusive, unwanted, ego-dystonic). To neutralise the image he touches the doorframe in sets of four and mentally recites a fixed phrase until it feels "just right" (compulsions: one overt, one mental, driven, rigidly ruled). The ritual is not realistically connected to his mother's safety and consumes over an hour a day. Obsession and compulsion are thematically paired (harm and checking/undoing), which is the typical structure.

GOOD TO REMEMBER

- **Compulsion:** a repetitive behaviour or mental act the person feels driven to perform in response to an obsession or by rigid rules, aimed at reducing distress or preventing a dreaded event or reaching a "just right" sense; it is either not realistically connected to what it neutralises or is clearly excessive; mental rituals (counting, praying, reviewing) count as compulsions.

11.3 Obsessions and compulsions are thematically paired

The pairing rule. Most people with OCD have both obsessions and compulsions, and the two are typically related in content or temporal sequence: contamination obsessions drive washing rituals, harm obsessions drive checking, symmetry obsessions drive ordering and repeating. Compulsions are usually performed *in response to* the obsession, but ICD-11 notes that early in the illness a compulsion may precede a clear obsession (a person checks the gas knob repeatedly

and only then concludes they must be afraid of fire). Understanding the obsession-compulsion link matters for treatment, because exposure and response prevention targets exactly that link.

Associated features that examiners like. Sensory phenomena, physical "just-right" sensations or a feeling of incompleteness that precede compulsions, are reported by up to **60%** of patients (DSM-5-TR 2022; Tasman). Avoidance of triggers is common, and the characteristic dysfunctional beliefs are an inflated sense of responsibility, overestimation of threat, perfectionism, intolerance of uncertainty and an overvaluation of the power of thoughts (believing that having a forbidden thought is as bad as acting on it). Family involvement in rituals, termed *accommodation*, maintains symptoms and is a treatment target, especially in children.

RULE **Obsession and compulsion are a matched pair.** The obsession is the intrusive, ego-dystonic thought; the compulsion is the driven, neutralising act; they are thematically linked (contamination and washing, harm and checking), and it is that link, not the behaviour alone, that defines and is treated in OCD.

11.4 The four symptom dimensions

The dimensional map. The content of obsessions and compulsions varies between individuals but clusters into recognised symptom dimensions that are consistent over time in adults, occur across cultures and may map onto partly different neural substrates (DSM-5-TR 2022; ICD-11 CDDR). DSM-5-TR names four: **contamination and washing** (contamination obsessions with cleaning/washing compulsions); **symmetry and ordering** (symmetry obsessions with repeating, ordering and counting compulsions, often with "just-right" sensory phenomena); **forbidden or taboo thoughts** (aggressive, sexual or religious/scrupulosity obsessions and related compulsions, often mental); and **harm and checking** (fears of harm to self or others with checking compulsions). ICD-11 CDDR groups the first three and treats **hoarding**-type accumulation arising from typical obsessions (e.g. fear of harming others) as a consequence rather than a dimension. Most patients have symptoms in more than one dimension.

The hoarding caveat. Accumulation driven by an obsession (keeping items for fear that discarding them will cause harm) sits within OCD, but it must be distinguished from primary *hoarding disorder*, now a separate diagnosis in the obsessive-compulsive and related grouping, in which the difficulty discarding is the primary problem and is driven by a perceived need to save and distress at discarding, not by a classic obsession. Naming that boundary is the examiner's expected nuance.

DIMENSION	TYPICAL OBSESSION	TYPICAL COMPULSION
Contamination and washing	**Fear of germs, dirt, illness, contamination**	Washing, cleaning, decontamination rituals, avoidance
Symmetry and ordering	Need for symmetry, exactness, "just right"	**Ordering, arranging, repeating, counting**
Forbidden or taboo thoughts	**Aggressive, sexual or religious (scrupulosity) intrusions**	Mental rituals, praying, confessing, reassurance-seeking
Harm and checking	Fear of harm to self or others	Checking locks, taps and gas; rechecking; reassurance-seeking

The four DSM-5-TR symptom dimensions of OCD; each obsession pairs to a characteristic compulsion, and most patients span more than one dimension (DSM-5-TR 2022; ICD-11 CDDR groups the first three).

GOOD TO REMEMBER

- **Symptom dimensions:** four DSM-5-TR clusters, contamination and washing; symmetry and ordering; forbidden or taboo thoughts (aggressive/sexual/religious); and harm with checking, ICD-11 grouping the first three; each obsession pairs to its compulsion, most patients span more than one dimension, and obsession-driven accumulation must be separated from primary hoarding disorder.

11.5 The insight specifier: good/fair, poor, absent/delusional

Insight is a spectrum, and it is specified. People with OCD vary in how far they recognise that their obsessive-compulsive beliefs are untrue or excessive, and DSM-5-TR captures this with a three-level insight specifier (DSM-5-TR 2022). *With good or fair insight*: the person recognises the OCD beliefs are definitely or probably not true, or may or may not be true. *With poor insight*: the person thinks the beliefs are probably true. *With absent insight/delusional beliefs*: the person is completely convinced the beliefs are true. Poorer insight is linked to worse long-term outcome, and insight can fluctuate within a person over the course of illness (and with the current anxiety level), which is why it should be judged over a period of a few days to a week rather than in a single anxious moment.

The ICD-11 two-level version. ICD-11 CDDR uses a two-level specifier, *with fair to good insight* and *with poor to absent insight*, collapsing the DSM's poor and absent categories; it applies the same insight logic across the cognitive obsessive-compulsive and related disorders (OCD, body dysmorphic disorder, olfactory reference disorder, hypochondriasis and hoarding disorder). The clinically vital point on both systems is that the delusional-conviction end of OCD is *not* reclassified as a psychotic disorder: an absent-insight/delusional OCD belief stays within OCD (with the specifier) and is treated as OCD, not as schizophrenia.

INSIGHT LEVEL (DSM-5-TR)	THE PERSON'S STANCE ON THE OCD BELIEF
Good or fair insight	Recognises beliefs are definitely/probably not true, or may or may not be true
Poor insight	**Thinks the beliefs are probably true**
Absent insight / delusional	**Completely convinced the beliefs are true (about 4% or fewer; still coded as OCD, not psychosis)**

The DSM-5-TR insight specifier; ICD-11 collapses the lower two into a single "poor to absent" level, and the delusional end stays within OCD rather than becoming a psychotic diagnosis (DSM-5-TR 2022; ICD-11 CDDR).

COMMON TRAP

Do not reclassify an absent-insight, delusionally-held OCD belief as a psychotic disorder. A small minority (around 4% or fewer) are completely convinced their obsessive belief is true; this is coded as OCD "with absent insight/delusional beliefs", not as schizophrenia or delusional disorder, and it is still treated with the OCD algorithm (SSRI, then augment), not primarily with an antipsychotic. Missing this leads to the wrong diagnosis and the wrong first-line drug.

GOOD TO REMEMBER

- **Insight specifier:** DSM-5-TR grades insight as good/fair, poor, or absent/delusional (about 4% or fewer are delusional); ICD-11 uses two levels (fair-to-good vs poor-to-absent); poorer insight predicts worse outcome; the delusional end stays coded as OCD, not a psychotic disorder, and keeps the OCD treatment algorithm.

11.6 The tic-related specifier

What it flags. DSM-5-TR adds a tic-related specifier: **tic-related ocd** is diagnosed when the individual has a current or past history of a tic disorder (DSM-5-TR 2022). It matters because up to **30%** of people with OCD have a lifetime tic disorder, most commonly males with childhood-onset OCD, and this subgroup differs in symptom themes (more symmetry, "just-right" and ordering), comorbidity (Tourette syndrome, ADHD), course and pattern of familial transmission. Tourette syndrome is cross-listed alongside OCD in ICD-11 precisely because of this high co-occurrence, the shared premonitory-urge phenomenology and the familial link.

The treatment relevance. The tic-related subtype is the one classic exception to the "antipsychotics do nothing on their own in OCD" rule: patients with comorbid tics tend to respond somewhat better to antipsychotic augmentation of an SSRI. So the specifier is not merely descriptive, it nudges the augmentation choice, which is why it is worth naming in an answer.

GOOD TO REMEMBER

- **Tic-related OCD:** the DSM-5-TR specifier for a current or past tic disorder; up to 30% of OCD patients have a lifetime tic disorder (mostly males, childhood onset); the subtype skews to symmetry/"just-right"/ordering symptoms with Tourette and ADHD comorbidity, and responds relatively better to antipsychotic augmentation of an SSRI.

11.7 Criteria in brief: the time-consuming threshold and the boundary with normality

The threshold. Beyond the presence of obsessions and/or compulsions, both systems require that they are *time-consuming* (a benchmark of more than **1 hour per day** is given) *or* cause clinically significant distress or functional impairment (DSM-5-TR 2022; ICD-11 CDDR). The symptoms must not be attributable to a substance or another medical condition, and must not be better explained by another mental disorder. ICD-11 lists a set of exclusions to work through, so a checking obsession is not GAD worry, a preoccupation with appearance is body dysmorphic disorder, difficulty discarding is hoarding disorder, hair-pulling is trichotillomania, and so on.

The boundary with normality. Intrusive thoughts and repetitive behaviours are common in the general population (a fleeting thought of harming a loved one, double-checking the front door). What converts them into OCD is the time-consuming, distressing, impairing quality; developmentally normative childhood rituals (avoiding pavement cracks) are transient, age-appropriate and not time-consuming, and should not be over-diagnosed. Sudden or unusually late onset should prompt a search for an organic cause, for example a basal ganglia lesion or, in children with abrupt onset, paediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS).

TRAP **Do not diagnose OCD from the content alone.** Intrusive thoughts and double-checking are near-universal; OCD needs the symptoms to be time-consuming (over an hour a day) or to cause significant distress or impairment, and a sudden or late-onset picture should trigger a hunt for an organic mimic (basal ganglia lesion, PANDAS) before the label is fixed.

11.8 The Yale-Brown Obsessive Compulsive Scale (Y-BOCS): the severity instrument

What it is. The Yale-Brown Obsessive Compulsive Scale (Y-BOCS) is the standard clinician-rated severity measure in OCD and the outcome instrument in virtually every drug trial (Kaplan and Sadock 2024). It has **10 items** rated from a semi-structured interview: the first five rate obsessions and the second five rate compulsions, across the same five parameters, time occupied, interference with functioning, distress caused, resistance, and degree of control. Each item scores **0 to 4**, so obsessions and compulsions each total 0 to 20 and the overall score runs **0 to 40**. It is preceded by a symptom checklist that captures the specific content across the dimensions, and it is reproduced on the accompanying scale plate rather than pasted here. The paediatric version is the CY-BOCS.

Reading the number. Higher scores mean greater severity, and typical scores for patients presenting with OCD fall in the **16 to 30** range; a threshold of **16** is the usual cut-off for entry into drug trials (Kaplan and Sadock 2024). The Y-BOCS is also how treatment "response" is defined in the literature, most often as a reduction of at least 25 to 35% from the baseline Y-BOCS score, which is why the scale, not just a clinical impression, anchors the decision on whether an adequate trial has failed.

GOOD TO REMEMBER

- **Y-BOCS:** clinician-rated, 10 items (5 obsessions + 5 compulsions across time, interference, distress, resistance, control), each 0 to 4, obsessions and compulsions each 0 to 20, total 0 to 40; typical OCD scores 16 to 30, with 16 the usual drug-trial entry threshold; it is the standard severity and outcome measure (response commonly defined as a 25 to 35% reduction). Paediatric form: CY-BOCS.

0 to 40	16	1 hour	30%
Y-BOCS TOTAL (10 ITEMS, EACH 0 TO 4)	Y-BOCS DRUG-TRIAL ENTRY THRESHOLD; TYPICAL OCD 16 TO 30	TIME-CONSUMING BENCHMARK (PER DAY) IN THE CRITERIA	LIFETIME TIC DISORDER IN OCD (TIC-RELATED SUBTYPE)

11.9 Epidemiology and course

The numbers. OCD has a lifetime prevalence of roughly **2 to 3%**, one of the more common serious psychiatric disorders; the classic Epidemiologic Catchment Area figures were about 2.9% in women and 2% in men, a modest female excess in adults (Tasman). The sex balance flips by age of onset: childhood-onset OCD, particularly before the age of 10, is commoner in males and carries greater genetic loading and poorer outcome, whereas adolescent-onset skews female. Around 30% of patients have a lifetime tic disorder, and only about 4% or fewer sit at the absent-insight/delusional end.

The course. Onset is typically in the late teens and early twenties, usually gradual; onset after 35 is uncommon and, like sudden onset, should prompt a search for an organic cause. Many adults (30 to 50%) report childhood onset. In adults OCD is generally a chronic condition with waxing and waning of symptoms; a minority run an episodic or a progressively worsening course. There is a more hopeful paediatric signal: of those with childhood or adolescent onset, roughly **40%** achieve full remission by early adulthood (ICD-11 CDDR). Depression is the commonest comorbidity, and untreated OCD is characteristically slow to reach care.

GOOD TO REMEMBER

- **OCD epidemiology and course:** lifetime prevalence about 2 to 3% (slight adult female excess; childhood onset before age 10 is male-predominant with worse prognosis); onset usually late teens to early twenties and gradual, with onset after 35 or sudden onset flagging an organic cause; adult course is chronic and waxing-waning, but around 40% of childhood-onset cases remit fully by early adulthood.

11.10 The India lens: a wide OCD treatment gap and a benzodiazepine reflex

Under-recognised and under-treated. OCD in India carries a wide treatment gap. Symptoms are hidden by shame (contamination, taboo sexual or religious/scrupulosity obsessions are rarely volunteered), long delays precede a first consultation, and the disorder is under-recognised in general practice. Culturally shaped content is genuine: scrupulosity and religious obsessions may be especially distressing where ritual exactitude matters, and contamination themes (concepts of ritual purity and pollution) are common; distinguishing a religious compulsion from devout normative practice sometimes needs a knowledgeable religious informant (ICD-11 CDDR). The

Indian Psychiatric Society CPGs frame the correct approach, an adequate high-dose SSRI trial with exposure and response prevention, developed in the management note.

The benzodiazepine problem. Into this gap flows the same reflex that dogs the anxiety disorders in Indian practice: a benzodiazepine (often alprazolam) prescribed as if it were treatment. It is not. Benzodiazepines do nothing for the core obsessions and compulsions, at best they blunt the accompanying anxiety, and long-term use brings tolerance and dependence. The first-line agents are cheap and familiar as Indian brands, escitalopram, sertraline, fluoxetine, fluvoxamine and paroxetine among the SSRIs, and clomipramine (Anafranil) as the tricyclic option, used at high dose for a long trial. Naming the ego-dystonic obsession and the neutralising compulsion, and reaching for an SSRI rather than an anxiolytic, is the practical correction.

INDIA

OCD is common (lifetime prevalence around 2 to 3%) but reaches Indian care late and often disguised, contamination and religious/scrupulosity themes are frequent and culturally shaped, and the treatment gap is wide. The recurring error is treating it with a benzodiazepine (typically alprazolam), which touches none of the obsessions or compulsions; the Indian Psychiatric Society line, and the correct answer, is a high-dose SSRI (escitalopram, sertraline, fluvoxamine, fluoxetine or paroxetine) or clomipramine (Anafranil) with exposure and response prevention, the benzodiazepine having no role in core OCD treatment.

MNEMONIC

CObRA-DIT

The features to reproduce. **CObRA** holds the definition and the four dimensions: **C**ontamination/washing, **O**rder/symmetry, **b**ad/forbidden taboo thoughts, **R**isk of harm with checking, all built from an **A**lien (ego-dystonic) obsession neutralised by a compulsion. **DIT** holds the specifiers and cut: **D**istress/time-consuming (over 1 hour a day), **I**nsight graded good-fair to absent/delusional, **T**ic-related subtype.

HOLD THIS

OCD is intrusive, unwanted, ego-dystonic obsessions neutralised by driven, rigidly-ruled compulsions (behavioural or mental) that are not realistically connected or clearly excessive and are time-consuming (over an hour a day) or impairing; it runs across four DSM-5-TR dimensions (contamination/washing, symmetry/ordering, forbidden thoughts, harm/checking), carries an insight specifier from good-or-fair through poor to absent/delusional (delusional OCD stays OCD, about 4% or fewer) and a tic-related specifier (up to 30% lifetime tics); severity is scored on the Y-BOCS (10 items, 0 to 40), lifetime prevalence is about 2 to 3%, and onset is usually the late teens to early twenties.

12 · The OCD management algorithm

OCD is one of the two topics that examiners use to test whether you actually understand psychiatric prescribing rather than reciting a first-line drug. The disorder responds to the same serotonergic agents as depression, but the *rules of engagement are different*: the dose runs higher,

the trial runs longer, and the response is judged on a scale rather than a gestalt. **ocd management** is therefore a small, tight algorithm with four rungs, and the whole thing turns on one idea you must be able to state in a single breath, a **high-dose ssri** given for a **long trial** alongside **erp**, then clomipramine, then antipsychotic augmentation, then the refractory options.

Why it matters, and what this note owns. This note owns the ladder and the numbers, the target doses, the trial durations, the Y-BOCS response and remission thresholds, and where each guideline sits. The deep pharmacology of the SSRIs and of clomipramine (kinetics, adverse effects, interactions) is developed in the Mood disorders: pharmacotherapy notes and is not re-derived here; the general CBT model and the wider exposure principle behind ERP live in the Psychotherapies, clinical assessment, MSE and nosology notes; and deep brain stimulation and ablative neurosurgery for the truly refractory patient are cross-referenced to the ECT and neurostimulation notes. The management algorithm itself is set out in the accompanying figure, and the Y-BOCS form on the accompanying scale plate.

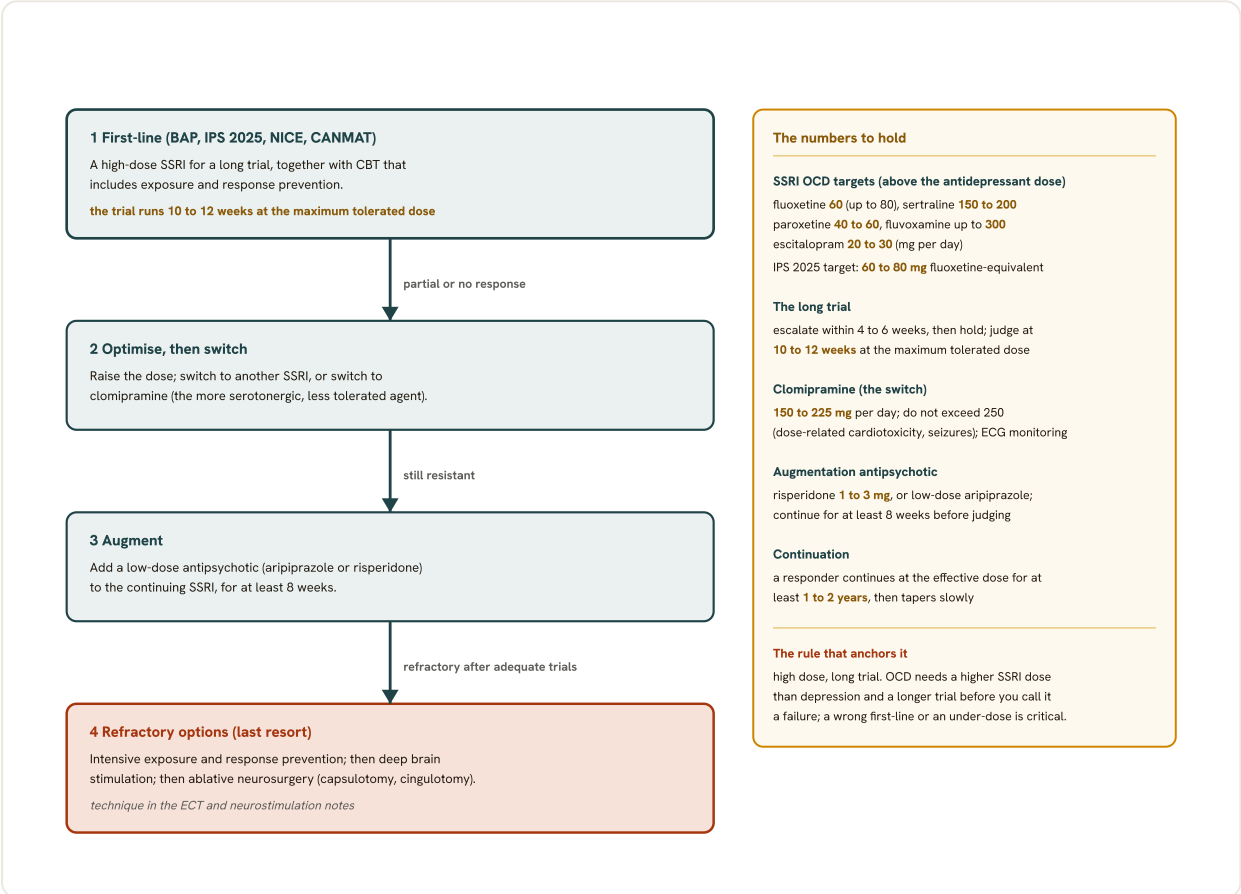

Fig 14.10 The OCD management algorithm. First-line, anchored on BAP, the IPS 2025 CPG, NICE and CANMAT, is a high-dose serotonin reuptake inhibitor given for a long trial of 10 to 12 weeks together with cognitive behaviour therapy that incorporates exposure and response prevention. On a partial or absent response the dose is optimised and the drug switched to another SSRI or to clomipramine (150 to 225 mg with ECG monitoring); a still-resistant illness is augmented with a low-dose antipsychotic (risperidone 1 to 3 mg or aripiprazole) for at least eight weeks; and the refractory case moves to intensive exposure and response prevention, then deep brain stimulation, then ablative neurosurgery. The anchoring rule is high dose, long trial: OCD needs a higher SSRI dose and a longer trial than depression, so under-dosing or stopping the trial early manufactures a false treatment failure. The deep antidepressant pharmacology is developed in the Mood disorders: pharmacotherapy notes, and the neurosurgical technique in the ECT and neurostimulation notes.

12.1 The shape of the ladder: four rungs and one governing principle

The four rungs. Every guideline collapses to the same staircase. *First-line* is a high-dose SSRI for a long trial *plus* CBT incorporating exposure and response prevention. *Partial or no response* means optimise the dose, then switch to another SSRI or to clomipramine. *Still resistant* means antipsychotic augmentation, low-dose aripiprazole or risperidone. *Refractory* means intensive ERP and, at a specialist centre, deep brain stimulation or ablative neurosurgery. Learn the staircase as a unit; the examiner wants the order, not a list.

The governing principle. The one line that runs through the whole ladder is that OCD is *under-treated by default*, because the doses are timid and the trials are cut short. Hold the principle first, then hang the drugs on it.

> **HOLD THIS**
> First-line OCD is a high-dose SSRI (target roughly fluoxetine 60 mg equivalent) for a long trial of about 10 to 12 weeks at the maximum tolerated dose, together with CBT incorporating exposure and response prevention; only then clomipramine, then aripiprazole or risperidone augmentation, then the refractory options.

12.2 First-line: a high-dose SSRI plus ERP, across every guideline

The BAP position. Lead with the British Association for Psychopharmacology: offer an SSRI as first-line pharmacological treatment for OCD, and consider higher daily SSRI doses, sometimes beyond standard formulary limits, because meta-analysis shows greater efficacy (though poorer tolerability) at higher dosages; offer exposure therapy or CBT as the evidence-based acute psychological treatment (BAP 2014). This is the verified **first-line ocd** anchor and must not be contradicted.

What the other guidelines say, and the IPS 2025 line to quote. The convergence is total. The Indian Psychiatric Society is explicit: offer an SSRI as the first-line pharmacological treatment and CBT with exposure and response prevention as first-line psychotherapy, treating OCD with *higher SSRI doses than those used for depression* and reducing to a low-to-medium dose only if the higher dose is not tolerated (the Indian Psychiatric Society 2025 / IPS 2025). NICE has adults choose an SSRI (fluoxetine, fluvoxamine, paroxetine, sertraline or citalopram) or more intensive CBT with ERP by degree of functional impairment, combining an SSRI with CBT for severe impairment (NICE 2005). CANMAT names an SSRI (escitalopram, fluoxetine, fluvoxamine, paroxetine or sertraline) and CBT with ERP as co-equal first-line, adding CBT to medication to enhance response and relapse prevention (CANMAT 2014). The WFSBP likewise puts an SSRI and CBT first-line across children, adolescents and adults (WFSBP 2023). Every source says the same thing: *SSRI plus ERP, and push the dose*.

GUIDELINE	FIRST-LINE PHARMACOLOGY	FIRST-LINE PSYCHOLOGY / KEY NOTE
BAP 2014	**SSRI, high dose (may exceed formulary limits)**	ERP / CBT; clomipramine equally efficacious but less tolerated
the Indian Psychiatric Society 2025	**SSRI, higher than depression doses**	CBT with ERP; monotherapy for mild-moderate, SSRI-combined for severe
NICE 2005	SSRI (fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram)	CBT with ERP matched to impairment; combined if severe
CANMAT 2014	SSRI (escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline)	CBT with ERP co-equal first-line

First-line OCD across the major guidelines; the shared message is a high-dose SSRI plus CBT incorporating exposure and response prevention, with the IPS 2025 CPG and BAP both stressing doses above the antidepressant range.

RULE **High dose, long trial, with ERP.** First-line OCD is an SSRI pushed to the maximum tolerated dose (above the depression range) for about 10 to 12 weeks, combined with CBT incorporating exposure and response prevention; this is unanimous across BAP, the Indian Psychiatric Society, NICE, CANMAT and WFSBP.

12.3 The high-dose rule: the SSRI target doses to quote

Higher than the antidepressant dose. The doses of SSRIs used in OCD run above those used in depression: fluoxetine to **60 mg** (sometimes 80), paroxetine **40 to 60 mg**, sertraline typically **150 to 200 mg** (the Maudsley notes sertraline has been pushed to 250 to 400 mg and even 650 mg without major safety problems), fluvoxamine to 300 mg, and escitalopram 20 to 30 mg (Maudsley Prescribing Guidelines; the Indian Psychiatric Society 2017/2025). The IPS 2025 target is pragmatic and worth quoting verbatim: aim for roughly the **60 to 80 mg** fluoxetine-equivalent, reducing to a tolerated dose only if the higher dose is not tolerated (IPS 2025). Escalate to the effective dose within about 4 to 6 weeks, then hold.

The one citalopram caution. The FDA cautions against citalopram above 40 mg/day because of dose-dependent QTc prolongation, so citalopram is the one SSRI whose OCD dose does *not* get pushed indefinitely (BAP 2014).

SSRI	INDIAN BRANDS (EXAMPLES)	OCD TARGET DOSE (MG/DAY)
Fluoxetine	Fludac, Prodep	**60 (up to 80)**
Sertraline	Daxid, Serta, Zosert	150 to 200 (higher tried)
Fluvoxamine	Fluvoxin	up to 300
Paroxetine	Paxidep, Xet	40 to 60
Escitalopram	Nexito, Stalopam	20 to 30

OCD SSRI target doses run above the antidepressant range; the exam anchor is fluoxetine 60 mg and the IPS 2025 target of 60 to 80 mg fluoxetine-equivalent (Maudsley; IPS 2025). Doses in cells are bare numbers; the unit is in the header.

GOOD TO REMEMBER

- **SSRI (first-line for OCD):** serotonin reuptake inhibitor; the OCD principle is a dose *higher* than the depression dose (fluoxetine 60 mg, target 60 to 80 mg fluoxetine-equivalent) held for a long trial; the signature caution is dose-dependent QTc prolongation limiting citalopram to 40 mg/day; the one first-line indication to state is high-dose SSRI plus ERP for all severities of OCD.

12.4 The long trial: judging response on the Y-BOCS at 10 to 12 weeks

Why the trial is long. Initial response in OCD emerges more slowly than in depression: it can take **10 to 12 weeks** at the maximum tolerated dose before you can call a trial failed (Maudsley; the Indian Psychiatric Society 2025). The IPS 2025 rule is precise: continue a maximally tolerated effective SSRI dose for at least **12 weeks** before judging efficacy, having escalated to the effective dose within 4 to 6 weeks (IPS 2025). The New Oxford Textbook frames the failure point the same way, under 25% reduction of the baseline Y-BOCS after 12 weeks of SRI treatment, of which at least 6 weeks should be at the maximal tolerated dose, counts as non-response.

The scale that governs the algorithm. The Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) is the clinician-rated, semi-structured instrument used at baseline and every 4 weeks to objectify response. It rates obsessions and compulsions separately on five aspects each (time, interference, distress, resistance, control), scored 0 to 4, for a total of **0 to 40**. The Goodman severity bands are worth memorising cold: 0 to 7 subclinical, 8 to 15 mild, 16 to 23 moderate, 24 to 31 severe, 32 to 40 extreme. A **25 to 35%** reduction is considered response; remission is a Y-BOCS of **12 or below** (the Indian Psychiatric Society 2017). In children the equivalent is the CY-BOCS (mild 16 to 19, moderate 20 to 29, severe 30 to 40) (the Indian Psychiatric Society 2019). The form itself is reproduced on the accompanying scale plate.

Y-BOCS TOTAL	SEVERITY BAND
0 to 7	Subclinical
8 to 15	Mild
16 to 23	**Moderate**
24 to 31	Severe
32 to 40	Extreme

Y-BOCS severity bands (Goodman et al 1989): 10 items each 0 to 4, total 0 to 40; response is a 25 to 35% reduction, remission a score of 12 or below.

GOOD TO REMEMBER

- **Y-BOCS:** clinician-rated 10-item scale, each 0 to 4, total 0 to 40; bands 0-7 subclinical, 8-15 mild, 16-23 moderate, 24-31 severe, 32-40 extreme; response = 25 to 35% reduction, remission = 12 or below; it is the instrument on which every rung of the OCD algorithm is judged, rated at baseline and every 4 weeks.

COMMON TRAP

The classic error is declaring an SSRI a failure too early or at too low a dose. An OCD trial is not adequate until the patient has had roughly 10 to 12 weeks at the maximum tolerated dose, with at least 6 of those weeks at the ceiling. Switching or augmenting before that, or judging on the depression-range dose, mislabels a slow-but-real responder as treatment-resistant and sends the ladder off prematurely.

12.5 CBT incorporating exposure and response prevention: the first-line psychotherapy

What it is. **cbt for ocd** (CBT tailored to obsessions and compulsions) is built around exposure and response prevention (erp): the patient is exposed, in a graded hierarchy, to the feared stimulus (the contaminated object, the intrusive thought) and then *prevented* from performing the neutralising ritual, so that anxiety habituates and the belief that the ritual averts catastrophe is disconfirmed. Foa's work established that exposure and ritual prevention must be delivered *together*, exposure alone or response prevention alone yields inferior outcomes. It is first-line psychotherapy in every guideline, monotherapy for mild-to-moderate illness and combined with an SSRI for severe illness (the Indian Psychiatric Society 2025; CANMAT 2014).

Where it sits on the ladder. ERP is not only a first-line treatment but also a first-line *augmentation* for partial or non-responders to an SSRI, where feasible (IPS 2025). Therapist-guided exposure is preferred to self-exposure (CANMAT 2014), and family accommodation should be assessed and reduced, since high accommodation predicts poor outcome (the Indian Psychiatric Society 2017).

GOOD TO REMEMBER

- **CBT with ERP (first-line psychotherapy for OCD):** graded exposure to the feared stimulus with prevention of the neutralising ritual, driving habituation and belief disconfirmation; the principle is that exposure and response prevention must be delivered together (either alone is inferior); the first-line indication is mild-to-moderate OCD as monotherapy and severe OCD combined with a high-dose SSRI.

12.6 Partial or no response: optimise, then switch SSRI or to clomipramine

Optimise first, then switch. When a first adequate SSRI trial fails, the sequence is optimise the dose (push to the maximum tolerated), then switch, either to a different SSRI or to clomipramine (BAP 2014; NICE 2005). Switching between treatments of proven efficacy helps some patients (BAP 2014). The IPS 2025 places clomipramine as a *second-line* agent, used when SSRIs are ineffective, given its poorer tolerability (IPS 2025).

The clomipramine-versus-SSRI point. This is the classic exam contrast. Clomipramine is the one tricyclic with genuine anti-obsessional efficacy (it is the most serotonergic TCA), and historically the first drug shown to work in OCD (1967). Its efficacy is at the margins of superiority over the SSRIs, but it is *less well tolerated* (anticholinergic burden, cardiac conduction effects, seizure risk in overdose), which is exactly why an SSRI is tried first and clomipramine held in reserve (BAP 2014). The OCD dose is **150 to 225 mg/day** (range 75 to 250), and ECG

monitoring is required (the Indian Psychiatric Society 2025 / 2017). Intravenous clomipramine is a specialist option after oral non-response.

TRAP **Clomipramine is not more effective enough to use first.** All SSRIs and clomipramine are efficacious in OCD; clomipramine sits at the margins of superiority but is less tolerated, so an adequate SSRI trial (high dose, long) comes first, with clomipramine as the switch on failure, under ECG monitoring.

GOOD TO REMEMBER

- **Clomipramine (Indian brand Anafranil):** the most serotonergic tricyclic and the original anti-obsessional drug; mechanism is potent serotonin (and noradrenaline) reuptake inhibition; second-line in OCD at 150 to 225 mg/day because it is less tolerated than an SSRI (anticholinergic, cardiac conduction, seizure in overdose), so it needs ECG monitoring and is used as the switch after an adequate SSRI trial fails.

12.7 Augmentation: low-dose aripiprazole or risperidone added to the SSRI

The third rung. For the patient who is a partial responder after an adequate SSRI or clomipramine trial, the next step is **augmentation** with a low-dose antipsychotic added to the continuing serotonergic drug. The IPS 2025 names low-dose aripiprazole or risperidone as the first-line pharmacological augmentation in treatment-resistant OCD, continued for at least 8 weeks; the doses are risperidone **1 to 3 mg/day** and aripiprazole in the low range (IPS 2025). BAP has the strongest augmentation evidence for risperidone, with aripiprazole also supported (BAP 2014), and CANMAT lists adjunctive aripiprazole or risperidone as the first-line adjuncts for treatment-resistant OCD (CANMAT 2014). The Maudsley agrees the usual second-line step is the addition of risperidone or aripiprazole.

The monotherapy caveat. Antipsychotics are for *augmentation only*: NICE is explicit that antipsychotics should not normally be used as monotherapy to treat OCD (NICE 2005). The augmentation target is often the patient with comorbid tic disorder or poorer insight.

GOOD TO REMEMBER

- **Antipsychotic augmentation (aripiprazole / risperidone):** low-dose dopamine blockade added to a continuing SSRI or clomipramine for treatment-resistant OCD (risperidone 1 to 3 mg/day, low-dose aripiprazole), for at least 8 weeks; strongest evidence is for risperidone; the signature caution is that antipsychotics are augmentation only and never monotherapy for OCD.

12.8 Refractory OCD: intensive ERP, then DBS and ablative neurosurgery

Define refractory first. **refractory ocd** means failure of at least two adequate SSRI trials, clomipramine, and CBT with ERP (with antipsychotic augmentation), each delivered at full dose and duration (the Indian Psychiatric Society 2017). Before escalating, the honest question is always whether the earlier trials were genuinely adequate, high dose, long enough, and with real ERP.

The refractory rung. For the genuinely refractory patient, intensify the psychological treatment (intensive, therapist-led ERP) and, at a specialist centre only, consider the somatic options:

intravenous clomipramine, then *deep brain stimulation*, and ablative neurosurgery (anterior capsulotomy or cingulotomy), reserved for treatment-refractory OCD after multidisciplinary review (BAP 2014; the Indian Psychiatric Society 2017; WFSBP 2023). In India this pathway runs through specialist centres such as NIMHANS. The neurostimulation and neurosurgical detail (DBS targets, capsulotomy) is developed in the ECT and neurostimulation notes. Neuromodulation such as rTMS or tDCS is an evolving, preliminary-evidence augmentation option (IPS 2025).

WORKED EXAMPLE

A 26-year-old man with contamination obsessions and washing rituals has a Y-BOCS of 28 (severe). He is started on fluoxetine, escalated to 60 mg over 5 weeks, and continued at 60 mg with weekly ERP. At 12 weeks his Y-BOCS is 25, under a 25% reduction, so this is non-response despite an adequate high-dose, long trial. The dose is optimised to 80 mg for a further period; still a partial responder, he is switched to a second SSRI, and on continued partial response low-dose risperidone (1 to 2 mg/day) is added for 8 weeks, with intensive ERP. Only after this whole sequence would clomipramine and, ultimately, specialist referral be considered.

12.9 Continuation and maintenance: at least 1 to 2 years at the effective dose

Do not stop early. OCD is chronic and relapsing, so a responder is continued on the effective SSRI (or clomipramine) at the *dose that produced improvement*. BAP and NICE say continue for at least 12 months; the IPS 2025 goes further, continue an effective SSRI or clomipramine for at least **1 to 2 years** after remission, at the dose that produced improvement (IPS 2025); CANMAT says at least 12 to 24 months (CANMAT 2014). The principle that motivates this: continuing an effective serotonin reuptake inhibitor markedly lowers the relapse rate compared with stopping after the initial response, so the effective dose is held rather than reduced. Taper slowly when eventually stopping, since anxiety-spectrum patients are sensitive to discontinuation.

60	10 to 12 weeks	32 to 40	1 to 2 years
FLUOXETINE OCD TARGET, MG (HIGHER THAN DEPRESSION)	ADEQUATE TRIAL AT MAXIMUM TOLERATED DOSE	Y-BOCS EXTREME BAND (RESPONSE = 25 TO 35% DROP)	IPS 2025 CONTINUATION AFTER REMISSION

INDIA

OCD sits inside India's wider anxiety-spectrum treatment gap: the disorder is common yet under-recognised, and the reflex of a benzodiazepine (still over-prescribed across Indian outpatient practice) does nothing for obsessions and risks dependence. The Indian Psychiatric Society CPGs, updated for OCD to 2025, anchor the same high-dose-SSRI-plus-ERP algorithm to Indian practice, and the tertiary pathway for refractory OCD (IV clomipramine, DBS, capsulotomy) runs through specialist centres such as NIMHANS. Indian brands are readily available, fluoxetine (Fludac, Prodep), sertraline (Daxid, Zosert), escitalopram (Nexito), fluvoxamine (Fluvoxin) and clomipramine (Anafranil), so the limiting factor is recognition and adequate dosing, not access.

MNEMONIC

SSRI → SWITCH → ADD → REFER

The four rungs in order: **SSRI** (high dose, long trial, with ERP) → **SWITCH** (optimise, then another SSRI or clomipramine) → **ADD** (aripiprazole or risperidone augmentation) → **REFER** (intensive ERP, then DBS / neurosurgery at a specialist centre).

PEARL

The single commonest reason "OCD does not respond to SSRIs" in the exam vignette is not true resistance but an inadequate trial, a depression-range dose stopped at 6 weeks. State the high-dose, long-trial rule and you have answered most OCD management questions before you reach the second rung.

13 · The Yale-Brown Obsessive Compulsive Scale

If a single instrument owns obsessive-compulsive disorder the way the HAM-D owns depression, it is this one. The **yale-brown obsessive compulsive scale** (**y-bocs**) is the standard clinician-rated severity measure for OCD and the outcome instrument in virtually every drug trial (Kaplan and Sadock 2024). Its design is deliberate and testable: it rates severity independently of symptom content, so a person whose only compulsion is silent counting and a person who washes for hours can be scored on the same scale and tracked over time. That content-blind design is exactly why examiners like it, and why it is the number that decides whether an adequate SSRI trial has actually failed.

Why it matters, and what this note owns. This is a scale note, so it teaches what the Y-BOCS is, how it is built, and, above all, its **severity bands**, the total-score ranges that convert a bare number into "mild", "moderate" or "extreme". The clinical phenomenology of obsessions and compulsions, the four symptom dimensions and the insight specifier live in the OCD clinical-features note; the high-dose SSRI, then clomipramine, then antipsychotic-augmentation algorithm lives in the OCD management note, and the deep antidepressant pharmacology in the Mood disorders: pharmacotherapy notes. What follows is the structure (a **ten-item** severity scale sitting on top of a symptom checklist), the scoring, the verified bands, and how the number is used to define response. The instrument is copyright Goodman and Rasmussen, so the accompanying scale plate typesets the structure and bands in our own words with a citation rather than reproducing the form; refer to that plate and do not expect the questionnaire pasted here.

Y-BOCS (TYPESET, NOT REPRODUCED)	VERIFIED STRUCTURE AND SEVERITY BANDS
Instrument	Yale-Brown Obsessive Compulsive Scale, clinician-rated, the reference severity measure for OCD (Goodman, Price, Rasmussen and colleagues, 1989)
Items	10 items: 5 rate the obsessions and 5 rate the compulsions, each across the same five parameters (time occupied, interference, distress, resistance and control); each item scored 0 to 4; total range 0 to 40
Companion	a symptom checklist precedes the severity scale, so the clinician first maps the symptom dimensions and then rates their severity
Severity bands	**0 to 7 subclinical, 8 to 15 mild, 16 to 23 moderate, 24 to 31 severe, 32 to 40 extreme**

Y-BOCS: typeset structure and verified bands only; the form is copyright Goodman and Rasmussen and its distribution is permission-required, so it is not reproduced (Goodman WK, Price LH, Rasmussen SA, et al. Arch Gen Psychiatry. 1989;46:1006-1011).

Fig 14.11 The Yale-Brown Obsessive Compulsive Scale (Y-BOCS). The reference severity measure for OCD: ten clinician-rated items, five for the obsessions and five for the compulsions, each rating time occupied, interference, distress, resistance and control on a 0 to 4 scale, for a total of 0 to 40, preceded by a symptom checklist. The severity bands run 0 to 7 subclinical, 8 to 15 mild, 16 to 23 moderate, 24 to 31 severe and 32 to 40 extreme. The form is copyright-restricted, so its structure and verified bands are given here in typeset form rather than reproduced.

13.1 What the Y-BOCS is, and who built it

The one-line definition. The Yale-Brown Obsessive Compulsive Scale is a semi-structured, clinician-administered interview that measures the *severity* of obsessive-compulsive symptoms, developed by Goodman, Rasmussen and colleagues in the late 1980s and published in 1989 (Kaplan and Sadock 2024; Goodman et al. 1989). It has become the standard instrument for assessing OCD severity and is used in virtually every drug trial, and it may also be used clinically to monitor treatment response. The paediatric adaptation is the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS), and a dimensional version (the DY-BOCS) also exists.

Severity, not diagnosis. The crucial framing point is that the Y-BOCS does not diagnose OCD; the diagnosis rests on the DSM-5-TR or ICD-11 criteria. The Y-BOCS presumes OCD is present and then quantifies how bad it is, which is why it is a severity and outcome measure rather than a screening or case-finding tool. It rates severity independently of the content or type of obsessions and compulsions, so the same score can be reached by very different symptom pictures.

GOOD TO REMEMBER

- **Y-BOCS:** a semi-structured, clinician-rated interview (Goodman, Rasmussen et al. 1989) that measures the *severity* of OCD, not the diagnosis; it is the standard OCD severity and outcome instrument used in virtually every drug trial; it rates severity independently of symptom content; paediatric version CY-BOCS.

13.2 Two parts: the symptom checklist, then the severity scale

The checklist comes first. The Y-BOCS is administered in two parts. Before the first use of the severity ratings, an associated symptom **checklist** is administered, a long menu (commonly cited as a 64-item checklist) covering the range of obsessions (aggressive, contamination, sexual, hoarding, religious/scrupulosity, symmetry, somatic) and compulsions (washing/cleaning, checking, repeating, counting, ordering/arranging, hoarding, mental rituals) organised by category (Kaplan and Sadock 2024; Foa et al.). Its job is to map *which* symptoms the patient has, which is invaluable for treatment planning and for anchoring the severity questions that follow.

The severity scale comes second. Once the clinician knows the range of symptoms the patient endorses, the **severity scale** proper is applied. This is the ten-item core that yields the 0 to 40 score, and its ratings are based on the range of symptoms the patient endorsed on the checklist. The distinction is a favourite exam point: the checklist tells you *what* the symptoms are; the severity scale tells you *how severe* they are and how they change with treatment. The severity scale is the more accurate tool for determining level of severity and tracking progress; the checklist is the better tool for understanding the range of a patient's symptoms.

RULE **Checklist maps content, severity scale measures severity.** Administer the symptom checklist first to establish *which* obsessions and compulsions are present; then apply the ten-item severity scale to those endorsed symptoms to produce the 0 to 40 severity score that is tracked over treatment.

13.3 The ten items: five obsessions, five compulsions, five parameters each

The architecture to state cold. The severity scale has **10 items**. The first five rate *obsessions* and the second five rate *compulsions*, and the two sets ask parallel questions across the same five parameters (Kaplan and Sadock 2024). The five parameters are: the **time** occupied by the symptoms, the **interference** they cause with functioning, the **distress** they cause, the patient's attempts to **resist** them, and the degree of **control** the patient has over them. Because the obsessions block and the compulsions block use the identical five parameters, learning the five parameters once gives you all ten items.

Why the parallel structure matters. The parallel obsessions-versus-compulsions design lets a clinician read an obsessions subtotal and a compulsions subtotal separately, which is useful when, for example, a "pure O" patient scores heavily on obsessions and lightly on compulsions. It also means treatment can be watched dimensionally: exposure and response prevention often moves the compulsions subscore first. The semi-structured interview and ratings can be completed in 15 minutes or less; a self-administered version takes about 10 to 15 minutes.

ITEM BLOCK	ITEMS	THE FIVE PARAMETERS RATED (EACH 0 TO 4)
Obsessions	**Items 1 to 5**	Time occupied; interference; distress; resistance; control
Compulsions	**Items 6 to 10**	Time occupied; interference; distress; resistance; control (parallel)

The ten-item severity scale: obsessions (items 1 to 5) and compulsions (items 6 to 10) rated across the identical five parameters, each item scored 0 to 4 (Kaplan and Sadock 2024).

COMMON TRAP

Do not confuse resistance with control, or read "high resistance" as a good sign. On the Y-BOCS a higher score is worse throughout, but the *resistance* item is scored counter-intuitively: making little or no effort to resist scores high (worse), while active resistance scores low. A patient who has "given up" fighting the compulsion scores worse on resistance, not better. Misreading the resistance item flips the interpretation of that item.

13.4 The scoring: 0 to 4 per item, subtotals 0 to 20, total 0 to 40

The arithmetic to memorise. Each of the ten items has item-specific anchors scored from **0 to 4** (Kaplan and Sadock 2024). The five obsessions items therefore sum to an obsessions subtotal of 0 to 20, the five compulsions items sum to a compulsions subtotal of 0 to 20, and the overall Y-BOCS total runs **0 to 40**. Higher scores mean greater severity. Typical scores for patients presenting with OCD fall in the **16 to 30** range, and a threshold of **16** is the value typically used for inclusion in drug trials, a number worth carrying because it recurs across the OCD trial literature.

The anchors, in words. Each 0 to 4 anchor is behaviourally defined, for example on the "time occupied by obsessions" item: 0 = none, 1 = mild (less than an hour a day), 2 = moderate (1 to 3 hours), 3 = severe (3 to 8 hours), 4 = extreme (more than 8 hours). That behavioural anchoring is what gives the scale its good inter-rater reliability. Reliability studies show good internal consistency, inter-rater reliability, and test-retest reliability over a one-week interval.

WORKED EXAMPLE

A patient rates 3 on obsession-time (3 to 8 hours of intrusive contamination thoughts), 3 on interference, 3 on distress, 2 on resistance and 2 on control: obsessions subtotal 13. On the compulsion side she rates 3, 3, 2, 2, 2 for washing rituals: compulsions subtotal 12. Y-BOCS total = 25, which places her in the *severe* band (24 to 31) and comfortably above the 16 trial-entry threshold. If a maximally tolerated, adequately long SSRI trial later brought her to 16, that is a 36% reduction, meeting the usual response definition.

13.5 The severity bands: subclinical, mild, moderate, severe, extreme

The five bands to know. The total score is conventionally read into five **severity bands** (Goodman et al. 1989; conventional Y-BOCS severity ranges). They are: **subclinical** 0 to 7, **mild** 8 to 15, **moderate** 16 to 23, **severe** 24 to 31, and **extreme** 32 to 40. The boundaries are worth over-learning because they are the exact numbers examiners ask for, and because they explain the trial-entry cut-off: a Y-BOCS of 16 is the floor of the *moderate* band, so trials enrolling at 16 and above are, by design, enrolling at least moderately ill patients. The bands are typeset (not reproduced) on the accompanying scale plate.

How the bands map to decisions. The bands are not merely descriptive. Mild-to-moderate OCD can reasonably be offered CBT with exposure and response prevention as monotherapy first-line; moderate-to-severe OCD warrants an SSRI, and severe illness warrants a combined SSRI plus

CBT/ERP from the outset (IPS 2025). At the extreme end, surgical candidates for neurosurgery or deep brain stimulation for refractory OCD typically carry Y-BOCS scores of a minimum of 26 to 30 of a possible 40 (Kaplan and Sadock 2024), which sits at the top of the severe band and into the extreme range.

BAND	Y-BOCS TOTAL (RANGE)	CLINICAL READING
Subclinical	0 to 7	Symptoms present but below clinical threshold
Mild	8 to 15	**Below the usual 16 trial-entry cut-off; CBT/ERP monotherapy reasonable**
Moderate	**16 to 23**	Floor is the 16 drug-trial threshold; SSRI indicated
Severe	24 to 31	Combined SSRI plus CBT/ERP from the outset
Extreme	32 to 40	**Top of scale; refractory-OCD neurosurgery/DBS candidates typically 26 to 30 minimum**

The five Y-BOCS severity bands and the total-score ranges that define them; note that 16, the usual drug-trial entry threshold, is the floor of the moderate band (Goodman et al. 1989; Kaplan and Sadock 2024).

GOOD TO REMEMBER

- **Severity bands:** subclinical 0 to 7; mild 8 to 15; moderate 16 to 23; severe 24 to 31; extreme 32 to 40. The 16 drug-trial cut-off is the floor of the moderate band; typical presenting OCD scores 16 to 30; neurosurgery/DBS candidates for refractory OCD usually score at least 26 to 30 out of a possible 40.

13.6 Using the number: defining response and an adequate trial

Response is a percentage fall on the Y-BOCS. The Y-BOCS is not only a snapshot; it is how "response" is operationalised in OCD. Across the trial literature, treatment response is most often defined as a reduction of at least **25 to 35%** from the baseline Y-BOCS total (New Oxford Textbook; Kaplan and Sadock 2024), and remission is often set at a low absolute score (for example a CY-BOCS below 11 in paediatric OCD). This is why the scale, rather than a clinical impression, is what tells you whether a trial has genuinely failed. A patient who "feels no better" but has moved from 28 to 19 has in fact responded (a 32% fall) and the SSRI should be continued, not abandoned.

The adequate-trial anchor. The single commonest error in OCD is calling a drug a failure too early. OCD needs a *high* SSRI dose held for a *long* trial: continue a maximally tolerated effective SSRI dose for at least **12 weeks** before judging efficacy, having escalated to the effective dose within the first 4 to 6 weeks (IPS 2025), and continue an effective agent for at least 1 to 2 years after remission. Only when the Y-BOCS has failed to fall by the response threshold after that full high-dose, long-duration trial is the patient a true non-responder who moves down the algorithm to clomipramine and then antipsychotic augmentation.

TRAP **Do not declare an SSRI failure before a full high-dose, long trial.** OCD demands a higher SSRI dose than depression, held for at least 12 weeks; judge failure by a less-than-25-to-35% fall on the Y-BOCS, not by the patient's subjective sense, before moving to clomipramine or augmentation.

INDIA

The highest-yield Indian point is that the Y-BOCS is the objective anchor the system most lacks. The OCD treatment gap in India is wide, OCD is frequently mislabelled (contamination fears dismissed as "habit", scrupulosity read as religiosity), and into that gap flows the same benzodiazepine over-prescription problem that dogs the anxiety disorders, with long-term alprazolam handed out where a high-dose SSRI and exposure and response prevention are indicated. A benzodiazepine has no place in OCD treatment (it does not treat obsessions or compulsions), and the Indian Psychiatric Society CPG (IPS 2025) is explicit: an SSRI at high dose first-line, escitalopram (Nexito, Rexipra), fluoxetine, sertraline or fluvoxamine, with CBT/ERP, then clomipramine (Anafranil) second-line, with the Y-BOCS tracked at baseline and through the trial so the "12 weeks at a high dose" rule is actually enforced rather than assumed.

0 to 40 Y-BOCS TOTAL, TEN-ITEM SCALE (EACH ITEM 0 TO 4)	**16** DRUG-TRIAL ENTRY CUT-OFF; FLOOR OF THE MODERATE BAND	**32 to 40** EXTREME SEVERITY BAND (TOP OF SCALE)	**12 weeks** MINIMUM HIGH-DOSE SSRI TRIAL BEFORE JUDGING FAILURE

MNEMONIC

TIDRC

The five parameters rated for both obsessions and compulsions: **T**ime occupied, **I**nterference with functioning, **D**istress, **R**esistance, and **C**ontrol. Rate these five for the obsessions (items 1 to 5) and the same five for the compulsions (items 6 to 10); each is 0 to 4, and the ten sum to the 0 to 40 total.

HOLD THIS

Ten items, each 0 to 4, total 0 to 40: subclinical 0 to 7, mild 8 to 15, moderate 16 to 23, severe 24 to 31, extreme 32 to 40, with 16 the drug-trial entry cut-off and the floor of the moderate band.

14 · The neurobiology of OCD: the CSTC circuit

Obsessive-compulsive disorder has the cleanest circuit story in psychiatry, and examiners love it precisely because it can be drawn as a loop. Where the anxiety disorders are diseases of an amygdala-centred fear circuit, OCD is a disease of a **cortico-striato-thalamic loop** that has lost its normal capacity to switch a thought or action off. The obsession is a message that will not stop repeating; the compulsion is the ritual the loop drives to try to discharge it. The anatomy to name is the **cortico-striato-thalamo-cortical** circuit, the **cstc** loop: from the **orbitofrontal** cortex and the anterior cingulate down to the striatum (the **caudate**), through the globus pallidus and substantia nigra, up to the **thalamus** and back to the cortex. Learn it as a loop with a brake, an

accelerator and a gate, and the imaging findings, the drug rationale and even the neurosurgical targets all fall into place.

Why it matters clinically. The imaging signature of OCD is a hyperactive orbitofronto-caudate-thalamic loop, and the two treatments that work, the high-dose serotonin reuptake inhibitor and exposure with response prevention, both turn that hyperactivity down; the neurobiology is therefore the rationale for the treatment, not decoration. Two ideas anchor the whole answer. First, the loop is normally self-limiting because the striatum gates and quietens cortical activity, so a healthy loop lets a thought arise, be checked, and be released. Second, OCD is modelled as an imbalance between a hyperactive *direct* (excitatory, "go") pathway and a relatively weak *indirect* (inhibitory, "stop") pathway through the **basal ganglia ocd**, so the loop reverberates and the thalamus over-drives the orbitofrontal cortex, and the patient cannot let the thought go. The direct and indirect pathway machinery and the receptor systems are developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; this topic applies that basal-ganglia anatomy to OCD and refers to the accompanying figure for the map.

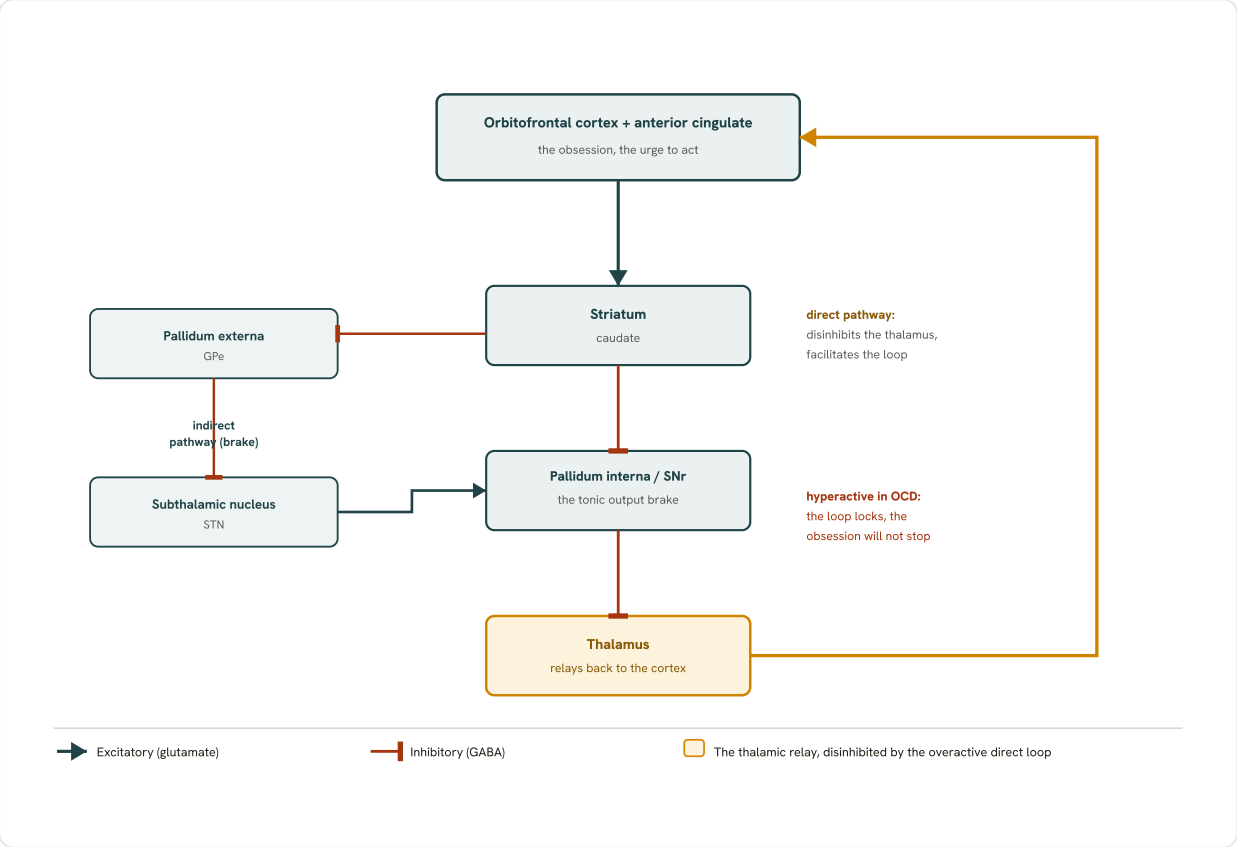

Fig 14.12 The cortico-striato-thalamo-cortical (CSTC) circuit in OCD. The orbitofrontal cortex and anterior cingulate drive the striatum (caudate); the direct pathway then runs striatum to pallidum interna and substantia nigra reticulata to thalamus, each step GABAergic and inhibitory, so the net effect is to lift the tonic brake on the thalamus and let the cortico-thalamic loop run; the indirect pathway, through the external pallidum and the subthalamic nucleus, is the opposing brake that normally damps it. In OCD the direct loop is overactive relative to the indirect brake, so the loop becomes hyperactive and self-sustaining, the neural correlate of an obsession and a compulsion that will not switch off, and the target that a serotonin reuptake inhibitor, exposure and response prevention, and in the last resort deep brain stimulation all act to quieten. The receptor systems and the wider pathway anatomy are taught in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes.

14.1 The loop in one sentence: cortex to striatum to pallidum to thalamus to cortex

The anatomy to draw first. The cortico-striato-thalamo-cortical circuit begins in the cortex, projects to the striatum (in OCD, chiefly the head of the caudate nucleus), which projects to the output nuclei of the basal ganglia (the globus pallidus interna and the substantia nigra pars reticulata), which project to the thalamus, which projects back up to the same region of cortex that started the loop (Kaplan & Sadock CTP 2024; Stahl's Essential Psychopharmacology). It is a closed re-entrant loop, and its job is to select and gate behaviour: to let a wanted action or thought proceed and to suppress the unwanted competitors.

Why the caudate is the pivot. The striatum is the entry gate of the loop and the caudate is the associative-territory striatum that receives the **orbitofrontal** and cingulate projections; it is the structure whose glutamatergic tone is raised in OCD and whose activity normalises when the patient responds to treatment (Kaplan & Sadock CTP 2024). Naming the caudate as the striatal node of the OCD loop is the single most examined anatomical fact of the topic.

14.2 The cortical origin: the orbitofrontal cortex and the anterior cingulate

The two cortical nodes to name. The OCD loop originates in two adjacent cortical regions. The **orbitofrontal** cortex (OFC) evaluates the affective and reward significance of stimuli and signals "something is wrong here, act on it"; the anterior cingulate cortex (ACC) is the error- and conflict-monitor that generates the nagging sense that an action is incomplete or a threat unaddressed (Kaplan & Sadock CTP 2024). In OCD both are over-active, so the loop is fed a continuous, false "error, not yet safe, do it again" signal, which is felt as the obsession and drives the checking or washing compulsion.

The clinical face of orbitofrontal over-activity. An over-active OFC is why the obsession carries a compelling sense of wrongness or danger that the patient cannot dismiss even when they know it is irrational; the ACC error-signal is why the compulsion never quite satisfies and must be repeated. The heightened error-monitoring is measurable as an exaggerated error-related negativity on EEG, a candidate endophenotype of OCD.

> **WORKED EXAMPLE**
>
> A patient leaves the house, then is gripped by the thought that the gas is on and the house will burn. The *orbitofrontal* cortex tags the situation as dangerous and salient; the anterior cingulate fires a persistent "this is not resolved" error-signal; the caudate fails to gate the signal, so it reverberates round the thalamus and back to the cortex. The patient returns and checks the stove. The check briefly quietens the loop, which negatively reinforces it, so the loop fires harder next time. That reverberating orbitofronto-caudate-thalamic circuit, not a real gas leak, is the disease.

14.3 The direct pathway: the excitatory "go" loop

How the accelerator works. Within the striatum two output pathways compete. The *direct pathway* runs from the striatum straight to the globus pallidus interna and substantia nigra pars reticulata (the basal-ganglia output nuclei); it is populated by excitatory D1 receptors and, by inhibiting those inhibitory output nuclei, it *releases* the thalamus, which then excites the cortex

(Stahl's Essential Psychopharmacology). The net effect is "go": the direct pathway is the accelerator that lets a cortical program, a thought or an action, proceed.

Why it is the villain in OCD. A relatively over-active direct pathway keeps the thalamus disinhibited, so it keeps driving the orbitofrontal cortex, and the loop cannot be switched off; the obsessional program runs on and on. The proposed core lesion of OCD is exactly this: an imbalance in which the excitatory direct loop dominates and the inhibitory indirect loop is too weak to counter it.

14.4 The indirect pathway: the inhibitory "stop" loop

How the brake works. The *indirect pathway* runs from the striatum to the globus pallidus *externa*, then to the subthalamic nucleus, then to the output nuclei; it is populated by inhibitory D2 receptors and its net effect is to *increase* inhibition of the thalamus, which reduces cortical excitation (Stahl's Essential Psychopharmacology). The indirect pathway is the brake that normally suppresses competing or unwanted programs, "stop".

The balance is the whole model. In the healthy loop the direct "go" and indirect "stop" pathways are balanced, so the striatum can select the wanted program and cancel the rest, a clean gate. In OCD the balance tips toward the direct pathway: too much "go", too little "stop", so unwanted intrusive programs are not cancelled and the thalamus is left over-driving the cortex. This direct-over-indirect imbalance is the mechanistic heart of the topic.

RULE **OCD is a hyperactive direct loop with a failing brake.** The imaging and modelling both point one way: an over-active excitatory direct pathway keeps the thalamus disinhibited and the orbitofronto-caudate-thalamic loop reverberating, while the inhibitory indirect pathway is too weak to gate the intrusive program, so the obsession cannot be switched off.

14.5 The output gate and the return to cortex: globus pallidus, substantia nigra and thalamus

The gate. The globus pallidus interna and the substantia nigra pars reticulata are the tonically active, inhibitory output gate of the basal ganglia; they normally clamp the thalamus down. The direct pathway *opens* the gate (disinhibits the thalamus) and the indirect pathway *closes* it (Stahl's Essential Psychopharmacology). Reduced globus pallidus volume is among the more replicated structural findings in OCD, consistent with a dysfunctional gate (Kaplan & Sadock CTP 2024).

The return limb. The **thalamus** is the relay that closes the loop, projecting back up to the orbitofrontal cortex and cingulate that started it. When the direct pathway holds the gate open, the thalamus over-excites the cortex, the cortex re-drives the striatum, and the circuit becomes a self-sustaining reverberation, which is the circuit-level description of an obsession that will not stop. Treatment-naive children with OCD show enlarged thalamic volumes, fitting an over-active return limb (Kaplan & Sadock CTP 2024).

MNEMONIC

CSTC = Cortex, Striatum (caudate), pallidum/nigra, Thalamus, back to Cortex

Trace the loop in order: **C**ortex (orbitofrontal + cingulate) to **S**triatum (the caudate gate) to the pallidum and substantia nigra (the output gate) to the **T**halamus (the relay) and back to **C**ortex. Then overlay the two pathways: *direct* = D1, "go", opens the gate; *indirect* = D2, "stop", closes the gate. OCD tips the balance toward "go".

14.6 The imaging signature: a hyperactive orbitofronto-caudate-thalamic loop

The finding to quote. Functional imaging in OCD shows increased resting glucose metabolism in the **orbitofrontal** cortex, the ventral striatum, the (right) **caudate** nucleus and the anterior cingulate, at rest and increasing further on symptom provocation (Kaplan & Sadock CTP 2024). Crucially, orbitofrontal and caudate metabolic rates are highly correlated, which is read as the interconnecting loops being "freed from their usual inhibitory influences and reverberating", the imaging translation of the failing brake.

The treatment proof. The same imaging validates the circuit as the target: both medication (a serotonin reuptake inhibitor) and behavioural therapy reduce orbitofrontal and caudate activity, and in children the raised caudate glutamate (Glx) falls to control levels after about **12 weeks** of an SSRI, tracking clinical response (Kaplan & Sadock CTP 2024). The circuit is not just correlated with OCD, it is where the treatments act, which is why the neurobiology carries the management rationale.

TRAP **Calling OCD an "amygdala" or "fear-circuit" disorder.** The anxiety disorders sit on the amygdala-centred fear circuit; OCD sits on the cortico-striato-thalamo-cortical loop through the *basal ganglia*, with the caudate, not the amygdala, as the pivot. Mixing the two circuits is the classic error, and it is why OCD is now classed apart from the anxiety disorders in DSM-5-TR and ICD-11.

14.7 The serotonin-glutamate chemistry that tunes the loop

Why serotonin, and why a high dose. The loop is tuned by serotonin: serotonergic projections from the raphe modulate the orbitofrontal-striatal circuit, and only the serotonergic antidepressants (the SSRIs and the serotonergic tricyclic clomipramine) work in OCD, which is the pharmacological argument for a serotonergic abnormality (Kaplan & Sadock CTP 2024). The clinical corollary is the OCD dosing rule: a *higher* SSRI dose than in depression, sustained for a *longer* trial of about **10 to 12 weeks** before judging response, because the circuit re-tunes slowly.

The glutamate layer. The excitatory transmitter of the cortico-striatal projection is glutamate, and raised caudate glutamate (Glx) in OCD is the neurochemical face of the over-active loop; it falls with successful SSRI treatment (Kaplan & Sadock CTP 2024). This glutamatergic model is why refractory OCD is a target for glutamate-modulating agents and, at the extreme, for neurosurgical or stimulation interruption of the loop. Deep brain stimulation and neurosurgery

for refractory OCD, which physically interrupt this circuit at the ventral capsule or cingulate, are developed in the ECT and neurostimulation notes.

GOOD TO REMEMBER

- **Serotonin reuptake inhibitor (mechanism and OCD rule):** only the serotonergic agents work in OCD (the SSRIs and clomipramine), the mechanism being a slow re-tuning of the hyperactive orbitofronto-caudate-thalamic loop; the signature principle is a *high* dose for a *long* trial of about **10 to 12 weeks** before declaring failure, and both drug and exposure therapy normalise the caudate hyperactivity on imaging.

14.8 Clomipramine, the serotonergic tricyclic that proved the loop

The historical anchor. Clomipramine (Anafranil), a non-selective serotonin reuptake-inhibiting tricyclic, was the first drug shown to work in OCD (used by Fernandez and Lopez-Ibor in the late 1960s) and remains the yardstick against which the SSRIs are compared. Its efficacy, tied to its serotonergic action, was the pharmacological evidence that fixed serotonin at the centre of the OCD circuit model.

Where it sits now. Clomipramine (75 to 300 mg/day) is at least as effective as the SSRIs and by some meta-analyses numerically more so, but its anticholinergic, cardiac and seizure burden means the better-tolerated SSRI is first-line and clomipramine is held for SSRI non-response; the response is better when depression coexists. The detailed antidepressant pharmacology, the SSRIs, SNRIs and clomipramine, their doses, adverse effects and interactions, is developed in the Mood disorders: pharmacotherapy notes.

GOOD TO REMEMBER

- **Clomipramine (mechanism and role):** a non-selective serotonin reuptake-inhibiting tricyclic, the *first* effective OCD drug and the proof that OCD is a serotonergic circuit disorder; the signature caution is its anticholinergic, cardiotoxic and seizure-lowering load, so despite efficacy equal to or better than the SSRIs it is second-line, reserved for SSRI non-response (typical range 75 to 300 mg/day).

14.9 Measuring the loop clinically: the Y-BOCS

What the scale is. The Y-BOCS (Yale-Brown Obsessive-Compulsive Scale), developed by Goodman and Charney in 1989, is the clinician-administered gold-standard severity measure for OCD; it rates obsessions and compulsions across five dimensions each (time, interference, distress, resistance and control), on a 0 to 4 anchor, for a total of **0 to 40** (Clinical Methods in Psychiatry, AIIMS; Tasman Psychiatry). It is the instrument used to define response (conventionally a 25 to 35 percent fall) and remission (a score of about **10 or less**) in the OCD trials. The instrument form itself is reproduced on the accompanying scale plate.

The severity bands to hold. The Goodman severity anchors are: 0 to 7 subclinical, 8 to 15 mild, 16 to 23 moderate, 24 to 31 severe, and 32 to 40 extreme; a total of 16 and above is the usual threshold for a clinical trial and for committing to pharmacotherapy. Anchoring "moderate OCD" to a Y-BOCS of 16 to 23 is the number examiners most often want.

0 to 40	16 to 23	10 to 12	75 to 300
Y-BOCS TOTAL RANGE (10 ITEMS)	Y-BOCS MODERATE BAND	WEEKS: ADEQUATE SSRI TRIAL IN OCD	CLOMIPRAMINE (MG/DAY)

INDIA

OCD in India carries a large treatment gap: the disorder is common, chronically under-recognised and, when it does present, often mislabelled and mistreated. A recurring Indian pattern is the reflex prescription of a *benzodiazepine* for the anxiety and distress of OCD, which sedates the patient but does nothing to the serotonergic loop and courts dependence; the benzodiazepine is not a treatment for OCD. The Indian Psychiatric Society Clinical Practice Guidelines for OCD frame the correct sequence, a high-dose serotonin reuptake inhibitor for an adequate trial, then clomipramine, then antipsychotic augmentation, with exposure and response prevention throughout, and the SSRIs and clomipramine (Anafranil) are all widely available as inexpensive Indian generics. The gap is not a drug-availability problem, it is a recognition-and-rational-prescribing problem.

HOLD THIS

OCD is a hyperactive cortico-striato-thalamo-cortical loop: an over-active orbitofrontal cortex and anterior cingulate drive a caudate that cannot gate them, so an excess of the excitatory direct ("go") pathway over the inhibitory indirect ("stop") pathway leaves the thalamus disinhibited and the loop reverberating, and the high-dose serotonin reuptake inhibitor and exposure therapy both work by turning that orbitofronto-caudate hyperactivity back down.

15 · Clomipramine versus SSRIs in OCD

This is the single most reliably examined drug comparison in the whole anxiety-spectrum syllabus, because it hides a trap in plain sight. The naive candidate reasons that if clomipramine is *marginally more efficacious* on meta-analysis it ought to be first-line; the examiner is testing whether you understand that a first-line recommendation is a decision about the *whole* risk-benefit balance, not about the point estimate of efficacy alone. The **clomipramine versus ssri** question turns on one sentence you should be able to deliver cold: the two are comparably effective (clomipramine perhaps a whisker ahead), but clomipramine is far less tolerable and more dangerous, so the SSRIs win first-line on tolerability and safety.

Why it matters, and what this note owns. This note owns the head-to-head: the serotonergic-specificity argument that explains why clomipramine (alone among tricyclics) works in OCD at all, the meta-analytic evidence on relative **efficacy in ocd**, the **tolerability ocd** reasons clomipramine loses first-line, and exactly where it sits on the ladder. The wider four-rung OCD algorithm (high-dose SSRI, long trial, then augmentation, then refractory options) is set out in the OCD management algorithm note and only referenced here; the deep antidepressant pharmacology of the SSRIs and clomipramine, their kinetics, adverse effects and interactions, is developed in the Mood disorders: pharmacotherapy notes. The comparison itself is laid out in the accompanying figure.

15.1 The serotonergic-specificity argument: why clomipramine works when other TCAs do not

The founding observation. Clomipramine was the *first* drug shown to work in OCD, in studies from the late 1960s onward, and this is not incidental trivia: it is the pharmacological clue that shaped the whole serotonin hypothesis of OCD. Clomipramine is the one tricyclic that is a *potent serotonin reuptake inhibitor*; the Companion notes it was the first drug to inhibit serotonergic uptake without primarily inhibiting noradrenergic reuptake (its active metabolite desmethylclomipramine is the noradrenergic one). Conventional tricyclics, with the exception of clomipramine, are *not* effective in OCD (Shorter Oxford). That single dissociation is the argument.

The desipramine experiment that clinches it. The clean demonstration is the head-to-head against a noradrenergic TCA: clomipramine (serotonergic) beats desipramine (noradrenergic) in OCD, and the same pattern of serotonergic-reuptake inhibitors outperforming non-serotonergic agents recurs across the obsessive-compulsive spectrum (New Oxford Textbook). The take-home is a mechanism rule, only drugs that potently block the serotonin transporter, whether the SSRIs or clomipramine, are anti-obsessional. The amygdala and cortico-striatal fear-circuit substrate behind this is in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes.

RULE **Serotonergic potency, not the tricyclic class, is what treats OCD.** Clomipramine works because it potently blocks the serotonin transporter; noradrenergic tricyclics such as desipramine do not, which is why clomipramine and the SSRIs are the only anti-obsessional agents.

15.2 The efficacy evidence: clomipramine marginally ahead, but not significantly

What the meta-analyses actually show. On placebo-referenced **meta-analysis ocd** data, both clomipramine and all SSRIs are efficacious; the SSRIs are roughly twice as likely as placebo to produce a clinical response (the Soomro meta-analysis, 17 adult studies, 3097 participants; New Oxford Textbook). The nuance the examiner wants is the *relative* comparison. The Companion states it plainly: in meta-analyses clomipramine is *marginally more efficacious* than the SSRIs, but the SSRIs are somewhat better tolerated. BAP frames the same finding as clomipramine sitting *at the margins of superiority* over SSRIs while being less well tolerated (BAP 2014).

The statistical caveat, and the confound. The apparent clomipramine edge is fragile. The Skapinakis network meta-analysis, combining direct and indirect evidence, found clomipramine had a larger effect size against placebo than the SSRIs, but *this difference was not statistically significant*, and individual SSRIs produced similar effect sizes with no single compound superior (New Oxford Textbook). The classic explanation for the apparent gap is a confound of era: the older clomipramine trials enrolled more severe, more treatment-naive samples and used indirect (cross-study) rather than head-to-head comparison, inflating its relative effect. When the evidence is pooled properly the two are, for practical purposes, equally effective.

DIMENSION	CLOMIPRAMINE	SSRIS (CLASS)
Serotonergic mechanism	Potent SERT block (most serotonergic TCA)	Selective, potent SERT block
Placebo-referenced efficacy	**Marginally higher effect size, not statistically significant**	Robustly efficacious, no single SSRI superior
Tolerability	**Poorer (anticholinergic, sedation, weight)**	Better tolerated
Safety in overdose	Cardiotoxic, seizure risk, dangerous	Relatively safe
Line of treatment	Second-line / switch after SSRI	**First-line**

The clomipramine-versus-SSRI head-to-head: comparable efficacy (clomipramine perhaps marginally ahead but not significantly), decisively worse tolerability and overdose safety, hence SSRIs first-line and clomipramine reserved (Companion; New Oxford; BAP 2014).

15.3 The tolerability and safety cost: why the marginal edge does not buy first-line

The three dangers. Clomipramine carries the full tricyclic liability that the SSRIs largely shed. First, the *anticholinergic* burden, dry mouth, constipation, urinary retention, blurred vision, sedation and weight gain, which drives dropout. Second, *cardiac* effects, QTc prolongation and slowed intracardiac conduction, so an ECG is checked before and during treatment and it is avoided after recent myocardial infarction or with uncorrected hypokalaemia (Stahl; NICE 2005). Third, the *seizure* risk, which is dose-dependent and the reason the ceiling is fixed: at 300 mg/day the seizure incidence approaches **7 per 1000**, a generally unacceptable risk, so the maximum is held at **250 mg/day** (Stahl; New Oxford Textbook). Clomipramine is also markedly more dangerous in overdose than any SSRI.

Why this decides the line. When two drugs are near-identical in efficacy, the tie is broken by tolerability and safety, and here the gap is not marginal at all. That is the entire logic of first-line: the SSRIs deliver essentially the same benefit at a fraction of the harm, so they are tried first and clomipramine is held in reserve for when an SSRI has failed or cannot be tolerated (BAP 2014; NICE 2005).

TRAP **"More efficacious, therefore first-line" is the wrong inference.** Clomipramine's meta-analytic efficacy edge is marginal and non-significant, and it is bought at a heavy tolerability and overdose-safety price, so an SSRI is first-line and clomipramine is the switch, never the opening move.

15.4 Where clomipramine sits on the ladder: the switch after an adequate SSRI trial

The BAP position, first. Lead with the British Association for Psychopharmacology: offer an SSRI as first-line pharmacological treatment for OCD, since all SSRIs and clomipramine have efficacy but SSRIs are generally better tolerated; clomipramine is an evidence-based acute treatment whose efficacy is at the margins of superiority over SSRIs but which is less well tolerated (BAP 2014). Clomipramine is therefore the drug you switch to, not the drug you start with, and the switch is made after an adequate first SSRI trial fails or is not tolerated.

What the other guidelines recommend, at guideline level. The convergence is total. The Indian Psychiatric Society places clomipramine explicitly as a *second-line* agent, used at 150 to 225 mg/day when SSRIs are ineffective, given its poorer tolerability (the Indian Psychiatric Society 2025). NICE recommends offering clomipramine after an adequate SSRI trial has been ineffective or poorly tolerated, or if the patient prefers it or previously responded, checking an ECG and blood pressure first where there is significant cardiovascular risk (NICE 2005, the CG31 OCD guideline). CANMAT lists clomipramine (with citalopram, mirtazapine or venlafaxine XR) as *second-line* pharmacotherapy for OCD (CANMAT 2014). The WFSBP likewise keeps an SSRI first-line and reserves clomipramine as second-line when first-line treatment is inadequate (WFSBP 2022). Every source says the same thing, SSRI first, clomipramine as the reserve.

GUIDELINE	CLOMIPRAMINE'S PLACE	DOSE (MG/DAY) / NOTE
BAP 2014	**Evidence-based, but second-line (less tolerated)**	marginal efficacy edge, offered as switch
the Indian Psychiatric Society 2025	**Second-line when SSRIs ineffective**	150 to 225
NICE 2005 (CG31)	After adequate SSRI ineffective / not tolerated	ECG + BP first if cardiovascular risk
CANMAT 2014	Second-line pharmacotherapy	with citalopram, mirtazapine, venlafaxine XR

Clomipramine is uniformly second-line for OCD across BAP, the Indian Psychiatric Society, NICE, CANMAT and WFSBP, reached as the switch after an adequate first-line SSRI trial fails; the OCD dose is 150 to 225 mg/day with ECG monitoring.

15.5 The dose and monitoring: 150 to 225 mg/day, ECG, and the 250 mg ceiling

The numbers to quote. The OCD dose of clomipramine is **150 to 225 mg/day** (starting from 75 mg and titrating), and the maximum recommended dose of **250 mg/day** should not usually be exceeded because of dose-related cardiotoxicity and seizures (the Indian Psychiatric Society 2025; New Oxford Textbook). Patients treated for OCD often need the high end of the wider dosing range, 200 to 250 mg/day, still under the 250 mg ceiling (Stahl). ECG monitoring is required before and during treatment, and blood pressure is checked (the Indian Psychiatric Society 2017; NICE 2005).

The interaction that catches people out. An SSRI switch to clomipramine is not always clean, because fluvoxamine (a CYP1A2 inhibitor) and fluoxetine/paroxetine (CYP2D6 inhibitors) raise clomipramine levels, so an unwary cross-taper can push a "standard" clomipramine dose into toxic, pro-convulsant, cardiotoxic territory (Stahl; the Indian Psychiatric Society 2019). Combining an SSRI with clomipramine also risks serotonin syndrome. The full interaction map is in the Mood disorders: pharmacotherapy notes.

150 to 225	250	7 per 1000
CLOMIPRAMINE OCD DOSE (MG PER DAY)	MAXIMUM DOSE CEILING, MG PER DAY (SEIZURE / CARDIAC RISK)	SEIZURE INCIDENCE AT 300 MG PER DAY (UNACCEPTABLE)

WORKED EXAMPLE

A 34-year-old woman with checking compulsions has failed an adequate trial of sertraline pushed to 200 mg/day for 12 weeks and a second adequate trial of fluoxetine 80 mg/day, both with real ERP, without response. Rather than reach for clomipramine first (its efficacy edge is marginal and non-significant), the switch is now justified precisely because two first-line SSRI trials have genuinely failed. She is started on clomipramine 75 mg, titrated toward 150 to 225 mg/day, with a baseline ECG and blood pressure and repeat ECG on dose increases. Because her prior fluoxetine is a CYP2D6 inhibitor with a long half-life, the clomipramine is introduced cautiously to avoid a levels spike into cardiotoxic or pro-convulsant range.

15.6 The whole comparison in one line, and the India lens

The one-line answer. If asked to compare in a sentence: clomipramine and the SSRIs are comparably effective anti-obsessional agents (clomipramine perhaps marginally more efficacious on meta-analysis, but not significantly so), and because clomipramine is less well tolerated and more dangerous in overdose, the SSRIs are first-line on the tolerability-and-safety balance, with clomipramine reserved as second-line for the patient in whom an adequate SSRI trial has failed. Everything above is scaffolding for that sentence.

INDIA

The comparison is not academic in India, where the anxiety and OCD treatment gap is wide, recognition is patchy, and the reflex prescription is too often a benzodiazepine, which does nothing for obsessions and risks dependence (the benzodiazepine over-prescription problem in Indian outpatient practice is discussed in the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes). Both drug classes are cheap and available: the SSRIs as fluoxetine (Indian brands Fludac, Prodep), sertraline (Daxid, Zosert) and escitalopram (Nexito), and clomipramine as Anafranil. The Indian Psychiatric Society CPGs, updated for OCD to 2025, anchor exactly the SSRI-first, clomipramine-second-line logic to Indian practice, so the practical barrier is under-recognition and timid dosing, not access.

HOLD THIS

Clomipramine (most serotonergic TCA) and the SSRIs are comparably effective in OCD, with clomipramine only marginally and non-significantly ahead on meta-analysis; because clomipramine is less tolerable (anticholinergic, cardiac, seizure-risk) and dangerous in overdose, the SSRIs are first-line and clomipramine is the second-line switch after an adequate SSRI trial fails, dosed 150 to 225 mg/day with ECG monitoring.

MNEMONIC

SAME PUNCH, WORSE SIDES

Clomipramine and the SSRIs land the **same anti-obsessional punch** (equal-ish efficacy, clomipramine a marginal, non-significant nudge ahead), but clomipramine has the **worse side effects and worse overdose safety**, so tolerability, not efficacy, decides the line and the SSRIs go first.

GOOD TO REMEMBER

- **Clomipramine (Indian brand Anafranil):** the most serotonergic tricyclic and the original anti-obsessional drug (its serotonergic potency, not its tricyclic class, is why it works); mechanism is potent serotonin reuptake inhibition; marginally, non-significantly more efficacious than SSRIs on meta-analysis yet second-line in OCD at 150 to 225 mg/day because it is less tolerable (anticholinergic, cardiac conduction, seizure above 250 mg/day) and dangerous in overdose, so it is the switch after an adequate SSRI trial fails, under ECG monitoring.
- **SSRIs (first-line for OCD):** selective potent serotonin reuptake inhibitors; robustly efficacious with no single SSRI superior; the signature reason they beat clomipramine to first-line is superior tolerability and overdose safety at comparable efficacy; the one first-line principle is a high-dose SSRI plus ERP before any switch to clomipramine.

PEARL

The whole topic is a worked example of a general prescribing principle: when two drugs are equally effective, the first-line choice is decided by tolerability and safety, not by a marginal, non-significant efficacy point estimate. State that principle and the clomipramine-versus-SSRI answer writes itself.

16 · Exposure and response prevention

Exposure and response prevention (**erp**) is the specific behavioural treatment for obsessive-compulsive disorder, and it is one of the highest-yield psychotherapy answers in the whole anxiety block. Where the wider exposure principle and the general CBT model belong to the Psychotherapies, clinical assessment, MSE and nosology notes, this note owns the disorder-specific machinery: how the graded **exposure hierarchy** is built, what the **response prevention** component actually forbids, why anxiety falls on repeated exposure without the ritual, and the evidence base and delivery. Every major guideline, BAP 2014, NICE 2005 and the Indian Psychiatric Society CPG updated to 2025, names CBT incorporating ERP as first-line psychotherapy for OCD, co-equal with a high-dose SSRI and superior at holding gains.

Why it matters, and how to answer it. ERP is not "exposure with some talking"; it is a precise procedure with two named halves and a named mechanism. The candidate who scores states the mechanism (**habituation** of anxiety on prolonged, repeated exposure to a feared cue while the neutralising ritual is blocked), names both components (graded exposure plus **ritual prevention**), and knows the line placement (first-line, roughly as effective as an SSRI acutely and better at preventing relapse). Hold one sentence above all others: ERP works because staying with the anxiety, and refusing the compulsion that would abort it, lets the patient learn by direct experience that the feared catastrophe does not occur and that the anxiety subsides on its own.

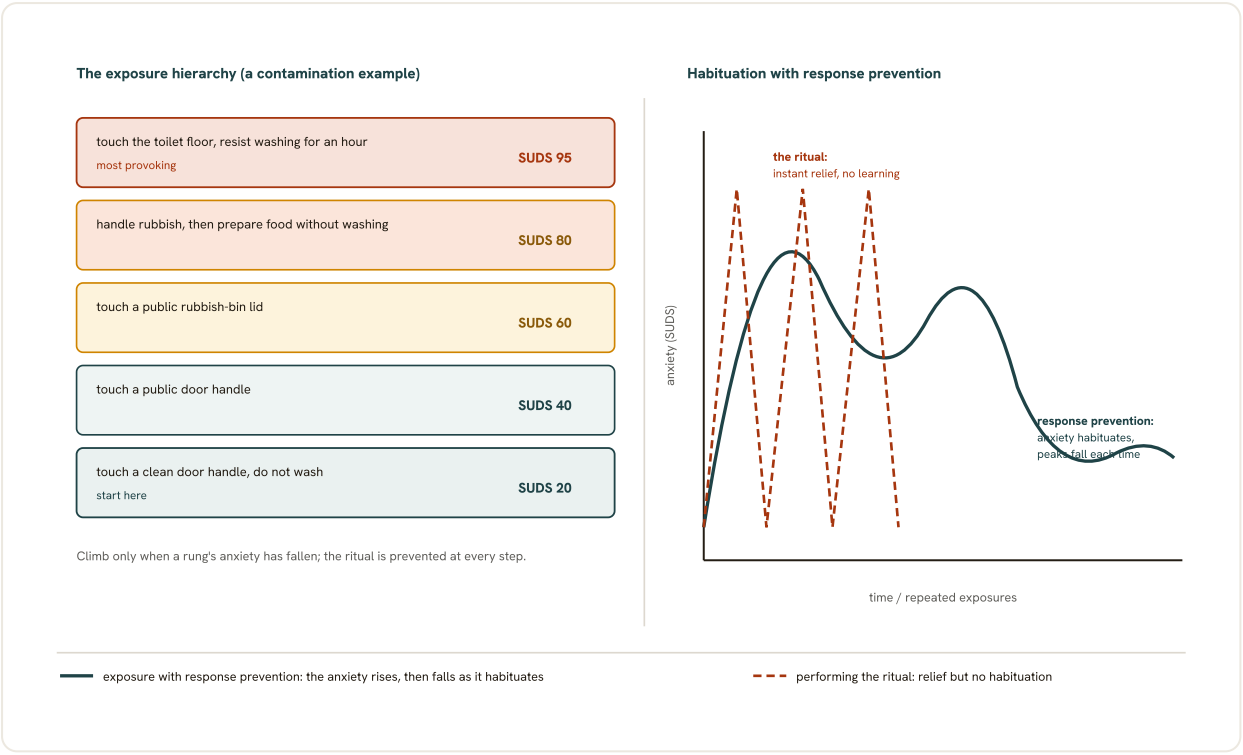

Fig 14.13 Exposure and response prevention (ERP). The patient and therapist build a hierarchy of feared situations, each rated for anxiety on a 0 to 100 subjective-units-of-distress scale, and work up it from the least to the most provoking. At each rung the patient stays in the situation and the compulsion is prevented; the anxiety rises, plateaus and then falls of its own accord as the body habituates, and the peak is lower on each repetition. Performing the ritual instead gives instant relief but teaches nothing, so the fear re-spikes to the same height every time. Preventing the response is therefore the active ingredient, and the wider exposure technique is taught in the Psychotherapies, clinical assessment, MSE and nosology notes.

16.1 What ERP is: two components with one mechanism

The definition. Exposure and response prevention is a manualised cognitive-behavioural treatment in which the patient is deliberately and repeatedly brought into contact with the situations, objects, thoughts or images that trigger obsessional distress (*exposure*), while refraining from the compulsion or avoidance that would normally relieve that distress (*response prevention*, also called ritual prevention) (Kaplan and Sadock 2024; Foa, Yadin and Lichner). Foa's canonical protocol, marketed as EX/RP, has five working parts: in-vivo exposure, imaginal exposure, ritual prevention, processing of the experience, and home practice. The exposure and the response prevention are not optional extras of each other; exposure without ritual prevention lets the patient neutralise and learn nothing, and ritual prevention without exposure gives the anxiety nothing to habituate to.

Exposure

Deliberate, planned contact with a feared cue (a situation, object, thought or image) sufficient to raise obsessional anxiety.

Response prevention

Blocking the compulsive ritual and the covert neutralising or avoidance that would otherwise discharge the anxiety.

Habituation

The automatic decline of an emotional response on repeated, prolonged exposure to the same stimulus once the ritual no longer aborts it.

16.2 The mechanism: habituation of anxiety when the ritual is blocked

The vicious cycle ERP breaks. In OCD an obsession provokes anxiety, the compulsion (or avoidance) discharges that anxiety, and the relief negatively reinforces the ritual, so the loop tightens with every repetition. Because the ritual is performed *before* the anxiety could fall by itself, the patient never learns that it would have fallen anyway, and never learns that the dreaded outcome would not have happened. Habituation is the principle that irrational fear and its behaviours fade on repeated and prolonged exposure to the source of the fear (Reddy, NIMHANS patient guide). ERP engineers exactly this: by exposing the patient to the trigger and forbidding the ritual, the anxiety is allowed to rise and then, if the patient stays with it, to subside on its own; with repetition the trigger progressively loses its power to provoke distress.

What the patient must not do. The habituation curve is fragile. Substituting one compulsion for another, using a distraction or relaxation trick to blunt the anxiety, or escaping the situation early all abort the exposure before habituation can occur, so the belief survives intact (Reddy). The instruction is to stay with the anxiety until it comes down substantially. Rituals and compulsions typically settle first; the obsessions themselves take longer to "wear out".

RULE **Block the ritual, or nothing changes.** Exposure only works if the neutralising response is prevented, because habituation and the disconfirmation of the feared outcome both require the patient to stay in the anxiety without the compulsion aborting it.

16.3 The exposure hierarchy: least to most anxiety-provoking

How it is built. Treatment begins by listing every situation, object, thought and image that triggers the patient's obsessions and rituals, plus everything the patient avoids to keep rituals at bay, and then arranging them in a graded hierarchy from the least to the most anxiety-provoking (Reddy; Kaplan and Sadock 2024). Each item is rated by the patient for the distress it provokes, conventionally on a subjective-units-of-distress scale, so the ladder is calibrated to that individual. The accompanying figure sets out this exposure-hierarchy ladder: low-distress rungs at the bottom, the most feared cue at the top, with the patient climbing only when the current rung has habituated. Exposure proceeds up the ladder, starting where anxiety is tolerable and moving to a harder item only once the easier one has stopped provoking much distress.

Graded, not flooding. The "graded" quality is deliberate and is what makes ERP tolerable enough to complete. Both in-vivo exposure (real contact, for example touching a "contaminated" surface and not washing) and imaginal exposure (vividly confronting the feared consequence, for example that harm will befall a loved one) are worked up the same hierarchy. This is the sense in which ERP is disorder-specific exposure: the ladder is composed of the patient's own obsessional cues and the response-prevention rule is attached to every rung.

16.4 Response (ritual) prevention: the discipline that makes exposure count

What is prevented. Ritual prevention bans the overt compulsion (the washing, checking, counting, reassurance-seeking) and, just as importantly, the covert neutralising and the mental rituals that patients substitute when the overt act is blocked. It also targets the avoidance that keeps triggers out of reach in the first place, for instance avoiding public toilets so as never to

have to wash extensively (Reddy). Where obsessions and compulsions occur only at home, treatment must become home-based, with the family briefed so they neither perform the ritual for the patient nor supply reassurance.

Family accommodation. A family that carries out rituals for the patient or endlessly reassures is accommodating the OCD and directly undermining response prevention; high family accommodation predicts poorer outcome, and reducing it through structured psychoeducation is part of the work (IPS 2025). A willing family member can be trained as a co-therapist to support graded exposure and ritual prevention at home.

TRAP **The hidden ritual.** A patient who stops washing but silently counts, prays or seeks reassurance instead has substituted a covert ritual for an overt one; habituation will not occur, and the therapist who misses it wrongly concludes ERP has failed.

16.5 Evidence base and effectiveness

How well it works. ERP is the most effective and most widely used behaviour therapy for OCD, effective in roughly **60 to 70%** of patients who engage with it (Reddy, NIMHANS). Guideline-level evidence places CBT with ERP as first-line psychotherapy, of broadly similar acute efficacy to an SSRI for mild-to-moderate OCD and superior in maintaining gains over time (BAP 2014; IPS 2025). A rigorous adult trial found that ERP augmentation of an ongoing SSRI outperformed risperidone augmentation, which is a favourite exam point: when an SSRI response is partial, adding ERP is a first-line augmentation strategy, ahead of an antipsychotic (Kaplan and Sadock 2024; IPS 2025). Combined ERP plus a high-dose SSRI is the recommended package for moderate-to-severe OCD, while ERP monotherapy suffices for milder illness.

Its limits. ERP demands motivation and the willingness to tolerate deliberate distress, and there can be significant resistance to undertaking it; a skilled therapist is needed where self-help does not suffice (Kaplan and Sadock 2024). Poor insight, entrenched family accommodation and comorbid depression all blunt response. Adequate "dose and duration" of exposure matter exactly as they do for a drug: too little exposure, like too low an SSRI dose, is a common reason for apparent failure.

60 to 70	10 to 12	1 to 2
PERCENT RESPOND TO ERP (NIMHANS)	HOURS OF ERP FOR MOST TO RESPOND	HOURS A SINGLE PROLONGED EXPOSURE MAY NEED

16.6 Delivery: dose, duration and format

How much is enough. Habituation takes time within a session and across the course. A single exposure may need to run long enough for anxiety to fall, sometimes only **30 minutes** but often a prolonged **1 to 2 hours** in more resistant fears; most patients show response between **10 to 12 hours** of exposure and response prevention overall (Reddy). Foa's protocol delivers this across roughly 17 to 20 sessions combining therapist-supervised and self-directed home practice. Daily home practice is the engine of change: ERP done only in the clinic, without between-session exposure, tends to stall.

Formats and access. ERP can be delivered face-to-face, in low-intensity or guided-self-help form for milder OCD (up to about 10 therapist hours per NICE 2005), by group or telephone CBT, and increasingly through internet-delivered programmes, though therapist-led ERP outperforms computerised CBT. Response is objectified by tracking OCD symptom severity on the Yale-Brown Obsessive-Compulsive Scale, whose severity bands and trial-entry threshold are taught, and the instrument reproduced, on the accompanying scale plate in the Y-BOCS note.

WORKED EXAMPLE

A young man with contamination obsessions washes for hours and avoids all public surfaces. Therapist and patient list his triggers and rank them from least to most distressing: touching his own front door (low), a shared office keyboard (mid), a hospital door handle (high), a public-toilet flush (top). Starting at the bottom, he touches the door and, under response prevention, does not wash; his anxiety climbs, then falls over the next hour as he stays with it. After several repetitions the door provokes almost nothing, and he climbs to the next rung. The covert urge to "wash later" is named early and blocked, so habituation, not a delayed ritual, is doing the work.

COMMON TRAP

Calling ERP off too soon. Like an under-dosed SSRI trial, an ERP course that is too short, too shallow up the hierarchy, or done only in sessions without daily home practice will look like non-response. Before concluding ERP has failed, confirm the exposures were adequate in intensity and duration, that no covert ritual or reassurance was smuggled in, and that family accommodation was addressed.

INDIA

Some of the most usable ERP material for Indian patients is Indian: the NIMHANS OCD patient guide (Reddy) lays out the hierarchy, the habituation rationale and the 60-to-70% figure in plain language, and the IPS CPG (updated for OCD to 2025) anchors CBT-with-ERP as first-line psychotherapy for Indian practice. This matters because OCD sits inside India's wide anxiety-spectrum treatment gap, and the reflex prescription of a benzodiazepine, still over-prescribed across Indian outpatient care, does nothing for obsessions: it neither provides exposure nor allows habituation, and it can blunt the very anxiety ERP needs the patient to feel. Where medication is combined with ERP the Indian-brand SSRIs are freely available, fluoxetine (Fludac, Prodep), sertraline (Daxid, Zosert), fluvoxamine (Fluvoxin) and escitalopram (Nexito), so the limiting factor is trained delivery of ERP, not drug access.

MNEMONIC

EXPOSE → PREVENT → STAY → HABITUATE

EXPOSE to the feared cue, up a graded hierarchy → **PREVENT** the ritual and the covert neutralising → **STAY** with the anxiety instead of escaping → **HABITUATE**, as the anxiety falls on its own and the trigger loses its power.

HOLD THIS

ERP works by blocking the ritual so the patient stays in the anxiety long enough to habituate and to learn the feared catastrophe never comes: two components (graded exposure plus response prevention), one mechanism (habituation), first-line for OCD.

GOOD TO REMEMBER

- **Exposure and response prevention:** the disorder-specific behaviour therapy for OCD, combining graded exposure up a patient-built hierarchy (in-vivo and imaginal) with response (ritual) prevention that blocks both overt and covert neutralising; the mechanism is habituation of anxiety once the ritual can no longer abort it, with disconfirmation of the feared outcome; first-line psychotherapy, roughly as effective as a high-dose SSRI acutely and better at maintaining gains, effective in about 60 to 70% of engaged patients, and the preferred first-line augmentation (ahead of an antipsychotic) for a partial SSRI response; the signature caution is that a hidden covert ritual, too-short exposure, or family accommodation will abort habituation and mimic non-response.

17 · Treatment-resistant OCD

Roughly a third to a half of OCD patients fail to respond adequately to a first serotonergic drug, and the examiner uses this fact to test one thing: can you tell a genuinely refractory patient from an *under-treated* one. The commonest cause of apparent non-response is not biology but an inadequate first trial, a depression-range dose stopped too soon and delivered without exposure and response prevention. **treatment-resistant ocd** is therefore a diagnosis of exclusion that you earn only after confirming an adequate trial, and its ladder then runs through **antipsychotic augmentation**, combined ERP, and finally the somatic options of neuromodulation and **neurosurgery ocd**.

Why it matters, and what this note owns. This note owns the resistance ladder above first-line: what counts as an adequate trial, how augmentation is sequenced, and where the neuromodulation and ablative options sit. The full first-line algorithm (the high-dose SSRI, the long trial, the Y-BOCS thresholds, clomipramine as the switch) is developed in the OCD management notes and is not re-derived here; the SSRI and clomipramine pharmacology lives in the Mood disorders: pharmacotherapy notes; the general exposure principle behind ERP lives in the Psychotherapies, clinical assessment, MSE and nosology notes; and the technical detail of **deep brain stimulation** and ablative neurosurgery (electrode targets, capsulotomy, cingulotomy technique) is cross-referenced to the ECT and neurostimulation notes. The refractory ladder is set out in the accompanying figure.

17.1 Confirm an adequate trial before you call it resistant

Adequate means high dose, long duration, real adherence. Before anything is added or switched, confirm the failed trial was genuinely adequate on three axes. A *high dose*, pushed to the maximum tolerated (SSRI target roughly **60 to 80 mg** fluoxetine-equivalent, above the depression range). A *long duration*, at least **10 to 12 weeks** at that ceiling before the trial is judged failed, with escalation to the effective dose within about 4 to 6 weeks (IPS 2025). And *adherence*, that the patient actually took the drug and, critically, received exposure and response prevention rather than a drug alone. The New Oxford Textbook frames the failure point as under

a 25% reduction of baseline Y-BOCS after 12 weeks of SRI treatment, of which at least 6 weeks are at the maximal tolerated dose.

The formal definition. True resistance is failure of at least two adequate SSRI trials, an adequate clomipramine trial, and CBT with ERP, each at full dose and duration (the Indian Psychiatric Society 2017). The honest first question at every rung is whether the earlier steps were real.

HOLD THIS

Do not call OCD treatment-resistant until you have confirmed an adequate trial on all three axes: a high dose (60 to 80 mg fluoxetine-equivalent), a long duration (10 to 12 weeks at the maximum tolerated dose), and genuine adherence including ERP; most apparent non-response is an under-treated first trial, not true resistance.

RULE **Adequate trial first, ladder second.** The first move in a "non-responder" is to re-audit the failed trial for dose, duration and adherence, not to reach for the next drug.

17.2 Optimise and switch: the steps that precede augmentation

Optimise, then switch. Once the trial is confirmed adequate but the response is partial or absent, the sequence before augmentation is to optimise the dose to the maximum tolerated, then switch, either to a different SSRI or to clomipramine (BAP 2014; NICE 2005). Switching between treatments of proven efficacy helps some patients (BAP 2014). Clomipramine is the second-line agent, at **150 to 225 mg/day** under ECG monitoring, used because it is the most serotonergic tricyclic but less well tolerated than an SSRI (the Indian Psychiatric Society 2025). The clomipramine-versus-SSRI contrast is developed in the clomipramine notes; here it is simply the switch on the way up the ladder.

COMMON TRAP

Jumping to augmentation or neurosurgery while the earlier rungs were sub-therapeutic. A patient who "failed" fluoxetine 20 mg for 6 weeks without ERP has not failed OCD treatment at all; augmenting that with an antipsychotic exposes them to metabolic risk for no reason and mislabels a slow-but-real responder as refractory.

17.3 Antipsychotic augmentation: the best-evidenced next rung

What it is and the doses. For the confirmed partial responder to an adequate SSRI or clomipramine trial, **antipsychotic augmentation** means adding a low-dose antipsychotic to the continuing serotonergic drug. BAP has the strongest augmentation evidence for risperidone, with aripiprazole also supported (BAP 2014). The Indian Psychiatric Society names low-dose aripiprazole or risperidone as the first-line pharmacological augmentation in treatment-resistant OCD, continued for at least **8 weeks**, at risperidone **1 to 3 mg/day** and aripiprazole in the low range (the Indian Psychiatric Society 2025). CANMAT lists adjunctive aripiprazole or risperidone as the first-line adjuncts, reserved for inadequate SSRI response given tolerability concerns (CANMAT 2014). WFSBP likewise puts antipsychotic augmentation first among the pharmacological options for resistant OCD (WFSBP 2023).

The monotherapy caveat and the serotonergic alternatives. Antipsychotics are for augmentation only: NICE is explicit that they should not normally be used as monotherapy for OCD, and reserves augmentation for after failed SSRI, combined SSRI-plus-CBT and clomipramine trials, under multidisciplinary review (NICE 2005). Beyond dopamine blockade, the guidelines note serotonergic augmentation with the 5-HT3 antagonists ondansetron or granisetron, and glutamatergic options (topiramate, lamotrigine, riluzole, memantine) that BAP regards as weaker or unproven (BAP 2014). The augmentation target is often the patient with comorbid tics or poorer insight.

AUGMENTATION OPTION	GUIDELINE STANDING	DOSE / NOTE
Risperidone (Sizodon, Risdone)	**First-line augmentation; strongest evidence (BAP, IPS, CANMAT)**	1 to 3 mg/day, at least 8 weeks
Aripiprazole (Arpizol, Asprito)	First-line augmentation, co-equal with risperidone	low range, at least 8 weeks
Ondansetron / granisetron	Serotonergic (5-HT3) augmentation option	added to fluoxetine or fluvoxamine
Topiramate / lamotrigine	Weaker glutamatergic augmentation	SSRI add-on, limited evidence

Augmentation in treatment-resistant OCD; low-dose risperidone or aripiprazole added to a continuing SSRI or clomipramine is the best-evidenced next rung, never monotherapy (BAP 2014; IPS 2025; CANMAT 2014). Doses are bare numbers in the cells; the unit is in the header line.

GOOD TO REMEMBER

- **Antipsychotic augmentation (risperidone / aripiprazole):** low-dose dopamine blockade *added* to a continuing SSRI or clomipramine for the confirmed partial responder in treatment-resistant OCD (risperidone 1 to 3 mg/day, low-dose aripiprazole) for at least 8 weeks; strongest evidence is for risperidone; the signature caution is that antipsychotics are augmentation only and never monotherapy for OCD.

17.4 Combining and intensifying ERP

ERP is a first-line augmentation, not just a first-line treatment. Where the failed pharmacological trial did not include structured exposure, adding or intensifying exposure and response prevention is itself a first-line augmentation strategy for the partial or non-responder to an SSRI, wherever feasible (the Indian Psychiatric Society 2025). BAP frames combining an SSRI or clomipramine with ERP as the step when efficacy needs to be maximised (BAP 2014), and for the refractory patient the psychological arm is intensified to therapist-led, high-frequency ERP. Family accommodation should be assessed and reduced, since high accommodation predicts poor outcome (the Indian Psychiatric Society 2017). The general exposure principle sits in the Psychotherapies, clinical assessment, MSE and nosology notes.

GOOD TO REMEMBER

- **Combining and intensifying ERP:** graded exposure with prevention of the neutralising ritual, added to pharmacotherapy as a first-line augmentation for partial responders; the principle is that a drug trial without ERP is an incomplete trial, so intensifying therapist-led exposure is a legitimate rung before escalating to somatic options; the first-line indication is the SSRI partial responder in whom real exposure has not yet been delivered.

17.5 Neuromodulation and the neurosurgical threshold

Non-invasive neuromodulation. Before the invasive options, rTMS and tDCS augmenting an SSRI are an evolving, preliminary-evidence option in partial or treatment-resistant OCD (the Indian Psychiatric Society 2025), and WFSBP lists rTMS among the non-pharmacological choices for resistant illness (WFSBP 2023). These sit below the ablative and stimulation options in invasiveness and are detailed in the ECT and neurostimulation notes.

Who crosses the neurosurgical threshold. The invasive options are reserved for severe, incapacitating OCD that has exhausted conventional drug and behavioural therapy. The practical selection criteria worth carrying: a chronic, severe, disabling illness (typically over 5 years), a surgical-candidate Y-BOCS of at least **26 to 30** out of a possible 40, and documented failure of an exhaustive array of adequate trials (each medication trial no less than 2 months), all confirmed by a multidisciplinary committee with formal informed consent (Kaplan and Sadock 2024). Fewer than 1% of treatment-seeking OCD patients meet current surgical criteria. In India this pathway runs through specialist tertiary centres such as NIMHANS; intravenous clomipramine is a further specialist option before device or lesion procedures (the Indian Psychiatric Society 2017).

TRAP **Neurosurgery is for the exhausted ladder, not the difficult patient.** The bar is a Y-BOCS of 26 to 40, years of failed adequate trials, and multidisciplinary consent; a distressing but incompletely treated case does not qualify.

17.6 Deep brain stimulation: reversible modulation of the CSTC circuit

What DBS is. **dbs** (deep brain stimulation) delivers high-frequency electrical stimulation through bilateral electrodes implanted stereotactically, connected to a subcutaneous pulse generator in the chest wall. Unlike a lesion it is *reversible and adjustable*: it can be switched off or reprogrammed if it causes adverse effects or is ineffective, though it commits the patient to indefinite specialist follow-up (Kaplan and Sadock 2024). It received FDA humanitarian device exemption for intractable OCD in 2009 and is an approved treatment in the European Union; other psychiatric uses remain investigational.

The targets and the numbers. The most frequent DBS target for OCD is the ventral capsule/ventral striatum (VC/VS), evolved from the anterior limb of the internal capsule and now extending posteriorly to include the ventral internal capsule, caudate and nucleus accumbens; other reported OCD targets are the nucleus accumbens directly, the subthalamic nucleus, the inferior thalamic peduncle and the medial forebrain bundle (New Oxford Textbook). A cohort of 34 patients at the VC/VS target on high-frequency stimulation for 36 months showed a **62%**

response rate, response being at least a **35%** Y-BOCS reduction; full effects typically take about 3 months to evolve. The rationale is modulation of the hyperactive cortico-striato-thalamo-cortical (CSTC) circuit; the fear-circuit anatomy sits in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes. Transient stimulation-related hypomania affects a substantial minority and resolves with parameter changes.

GOOD TO REMEMBER

- **Deep brain stimulation (DBS) for OCD:** reversible, adjustable high-frequency stimulation via bilateral implanted electrodes; the mechanism is modulation of the hyperactive CSTC circuit; the commonest target is the ventral capsule/ventral striatum (VC/VS), with roughly a 62% response rate (at least 35% Y-BOCS reduction) at 36 months; the signature point is FDA humanitarian device exemption for intractable OCD (2009), reserved for the fully exhausted ladder with a surgical Y-BOCS of 26 to 40.

17.7 Ablative neurosurgery: capsulotomy and cingulotomy

The two lesion procedures in use. Where DBS modulates, ablative **neurosurgery ocd** makes a permanent stereotactic lesion. Four bilateral lesion procedures were historically used; two remain current, anterior capsulotomy and anterior cingulotomy (Kaplan and Sadock 2024). *Anterior capsulotomy* (Leksell, Sweden) lesions the ventral part of the anterior limb of the internal capsule, impinging on the adjacent ventral striatum (the modern "ventral capsulotomy"), interrupting fibres between ventral prefrontal cortex and subcortical nuclei; a large review found about **64%** of cases substantially benefited. *Anterior cingulotomy* (Ballantine, Massachusetts General Hospital) places small thermocoagulation lesions in the anterior cingulate cortex (Brodmann areas 24 and 32) at the margin of the cingulum bundle; recent reviews show about 38 to 47% of OCD patients are full responders, with non-responders sometimes responding to a repeat procedure.

The trade-off with DBS. Ablation is a permanent, non-adjustable lesion and its outcome cannot be fairly judged for up to 2 years, but once done it needs no device team; DBS is reversible and acts within months but commits the patient to indefinite specialist programming. Both are last-rung options at specialist centres after the whole ladder has genuinely failed. The technical detail lives in the ECT and neurostimulation notes.

WORKED EXAMPLE

A 34-year-old woman has had incapacitating contamination OCD for 9 years, Y-BOCS 34 (extreme). Records confirm two adequate high-dose SSRI trials (fluoxetine 80 mg and sertraline 250 mg, each over 12 weeks with therapist-led ERP), an adequate clomipramine trial at 225 mg/day, and 8-week augmentation trials of risperidone then aripiprazole, all failed. After multidisciplinary review and formal consent at a tertiary centre, she is offered a reversible option first: VC/VS deep brain stimulation, with intensive ERP resumed within the first month post-implant. Only if that fails would an ablative capsulotomy be weighed. The point the examiner wants is that the whole ladder was audited as adequate before the somatic threshold was crossed.

10 to 12 weeks	1 to 3	26 to 30	62
ADEQUATE SSRI TRIAL AT MAXIMUM TOLERATED DOSE	RISPERIDONE AUGMENTATION, MG/DAY, AT LEAST 8 WEEKS	MINIMUM SURGICAL-CANDIDATE Y-BOCS (0 TO 40 SCALE)	VC/VS DBS RESPONSE RATE, PER CENT, AT 36 MONTHS

INDIA

Treatment-resistant OCD sits inside India's wider anxiety-spectrum treatment gap: the disorder is common yet under-recognised, and much "resistance" in Indian outpatient practice is really under-dosing plus the reflex of a benzodiazepine, still over-prescribed, that does nothing for obsessions and risks dependence. The Indian Psychiatric Society CPGs, updated for OCD to 2025, anchor the same audit-the-trial-then-augment ladder, and reserve the tertiary pathway (intravenous clomipramine, DBS, capsulotomy) for the genuinely refractory patient managed through specialist centres such as NIMHANS. Indian brands for the augmentation and switch drugs are readily available, risperidone (Sizodon, Risdone), aripiprazole (Arpizol, Asprito) and clomipramine (Anafranil), so the true limiting factor is confirming an adequate trial, not access.

MNEMONIC

AUDIT → SWITCH → AUGMENT → MODULATE → LESION

The resistance ladder in order: **AUDIT** the failed trial (high dose, long duration, adherence, ERP) → **SWITCH** (optimise, then another SSRI or clomipramine) → **AUGMENT** (low-dose risperidone or aripiprazole, plus intensified ERP) → **MODULATE** (rTMS/tDCS, then reversible DBS at the VC/VS) → **LESION** (ablative capsulotomy or cingulotomy at a specialist centre).

PEARL

In the resistant-OCD vignette the marks are almost never in the neurosurgery; they are in proving the earlier ladder was adequate. Name the three axes of an adequate trial (high dose, 10 to 12 weeks, adherence with ERP) and place DBS and capsulotomy only after two SSRIs, clomipramine, augmentation and ERP have genuinely failed, and you have answered the question before you reach the operating theatre.

18 · Body dysmorphic disorder

The exam sells body dysmorphic disorder (**bdd**) as the "ugliness" disorder, but that framing hides the point: the defect is not there, or is so slight that no one else can see it, and the whole clinical picture is built out of an intrusive preoccupation plus repetitive behaviours done to check or fix it. That architecture, a distressing appearance-related thought that will not leave and a compulsive ritual done in response, is why the DSM-5-TR and ICD-11 moved **bdd** out of the somatoform group and into the **obsessive-compulsive and related disorders**, sitting alongside OCD, hoarding and the body-focused repetitive behaviours (Kaplan and Sadock 2024; ICD-11 CDDR). Read it as OCD wearing a mirror: the same obsession-then-compulsion loop, but the content is fixed on how the person looks.

Why it matters, and what this note owns. Two things make BDD disproportionately examinable and clinically dangerous. First, it is *under-recognised*, patients present to dermatology and

cosmetic surgery, not psychiatry, and hide the concern from shame, so the diagnosis is missed unless you ask. Second, it carries one of the highest suicide burdens in psychiatry, higher rates of suicidal ideation and attempts than most disorders it is confused with. This note teaches the diagnosis and its discriminations (the **imagined defect**, the repetitive behaviours, the muscle-dysmorphia variant, the poor-insight and delusional forms), then the guideline-anchored treatment: a serotonin reuptake inhibitor at high dose and BDD-tailored CBT, first-line for every insight level including the delusional one. The general OCD algorithm and deep antidepressant dosing live elsewhere and are cross-referenced.

18.1 The core: preoccupation with an imagined or slight defect

The defining criterion. BDD is a **preoccupation** with one or more perceived defects or flaws in physical appearance that are *not observable or appear only slight to others* (DSM-5-TR 2022; ICD-11 CDDR). That last clause is the whole diagnosis: the concern is out of all proportion to any objective finding. The preoccupation is time-consuming (typically occupying at least an hour a day and often far more), intrusive, distressing and hard to resist, exactly the phenomenology of an obsession. Concerns most often focus on the skin, hair and nose but can involve any body area, and most patients are preoccupied with several areas over the course of the illness.

Not a normal appearance concern. Everyone dislikes something about how they look; BDD is separated from that by the distress, the time consumed, the functional wreckage and the repetitive behaviours. Insight is characteristically poor, the belief that one is disfigured feels true, which is why simple reassurance and even a mirror showing an ordinary face do not shift it.

GOOD TO REMEMBER

- **Body dysmorphic disorder (defining criterion):** preoccupation with one or more perceived defects in appearance that are *not observable or appear only slight to others*, plus repetitive behaviours or mental acts performed in response, causing clinically significant distress or impairment; classified with the obsessive-compulsive and related disorders (DSM-5-TR 2022; ICD-11 CDDR).

18.2 The second pillar: repetitive behaviours and mental acts

The compulsive half is required. A DSM-5-TR diagnosis needs the person, at some point, to have performed *repetitive behaviours or mental acts* in response to the appearance concern (DSM-5-TR 2022). These are the BDD compulsions: mirror checking (repeated checking of mirrors and other reflective surfaces such as windows), excessive grooming (hair styling, make-up), camouflaging (a hat over "balding", sunglasses over "asymmetrical" eyes, heavy make-up), reassurance seeking, skin picking to "fix" the skin, and repeatedly comparing one's appearance with other people's (New Oxford Textbook; Kaplan and Sadock 2024). They average a striking **3 to 8 hours a day**, are distressing and hard to resist, and, like OCD compulsions, do not relieve the distress and often worsen it.

Medical risks live here. Some behaviours are physically dangerous: compulsive skin picking (done by roughly 27 to 45% of BDD patients) can cause serious skin damage occasionally needing emergency surgery, and compulsive tanning raises cancer risk. Camouflaging doubles as a *safety*

behaviour, motivated by avoiding a feared outcome, which is why it is a target in CBT rather than something to accommodate.

RULE **Obsession plus compulsion, aimed at appearance.** BDD is diagnosed only when the appearance preoccupation is accompanied by repetitive behaviours or mental acts (mirror checking, grooming, camouflaging, reassurance seeking, comparing) done in response to it, the OCD loop with appearance as its content.

18.3 Muscle dysmorphia: the specifier that runs the other way

Too small, not too flawed. Muscle dysmorphia is a DSM-5-TR specifier of BDD in which the person is preoccupied with the idea that their body build is *too small or insufficiently muscular* (DSM-5-TR 2022). It occurs nearly always in men, who describe themselves as "puny", "tiny" or "too small" while in reality looking normal or unusually muscular from excessive weightlifting or steroid use (Kaplan and Sadock 2024; ICD-11 CDDR). The specifier applies even if the person is also preoccupied with other body areas.

Why it is the severe variant. Muscle dysmorphia carries *poorer* quality of life and *higher* rates of suicidality and substance use than other forms of BDD, in particular anabolic-androgenic steroid abuse, with the attendant medical harms (New Oxford Textbook; Kaplan and Sadock 2024). Practical trap: it is easily missed because gym culture normalises the behaviour, and it must be separated from an eating disorder, if the preoccupation is with body fat or weight in someone meeting eating-disorder criteria, that diagnosis takes precedence and BDD is not coded.

GOOD TO REMEMBER

- **Muscle dysmorphia:** a DSM-5-TR specifier of BDD, preoccupation that one's body build is too small or insufficiently muscular; nearly always in men; associated with anabolic-androgenic steroid abuse and higher suicidality; excluded when the focus is body fat/weight in an eating disorder (DSM-5-TR 2022; Kaplan and Sadock 2024).

18.4 Insight, referential thinking and the delusional variant

Insight is a specifier, not a separate disorder. Both DSM-5-TR and ICD-11 grade insight rather than splitting off a "delusional" diagnosis. DSM-5-TR specifies *with good or fair insight*, *with poor insight*, and *with absent insight / delusional beliefs*; ICD-11 collapses these to **fair to good insight** versus **poor to absent insight** (DSM-5-TR 2022; ICD-11 CDDR). Insight is characteristically poor, most patients hold their belief with over-valued-idea or delusional conviction.

The delusional form is still BDD. The old label "delusional dysmorphophobia" is gone: when the appearance belief reaches delusional intensity it is coded as BDD with absent insight, *not* as a delusional disorder, provided the belief stays within the appearance theme (ICD-11 CDDR; Companion to Psychiatric Studies). This matters for treatment (18.6): delusional BDD responds to the SRI, not to an antipsychotic alone. Add to this a strong streak of *referential thinking*, most patients believe others take special notice of the "defect", stare or mock, and an interpretive bias that reads neutral faces as contemptuous, which fuels social withdrawal.

TRAP **Do not rediagnose delusional BDD as a psychotic disorder.** A delusional-intensity appearance belief confined to the appearance theme is BDD with absent insight; treat it with a serotonin reuptake inhibitor, because dopamine-antagonist monotherapy is usually ineffective for delusional BDD.

18.5 The discriminations that get tested

Four boundaries own the marks. BDD sits at the crossroads of several disorders, and the exam lives on the seams. Hold the discriminators as a table rather than prose.

CONFUSED WITH	SHARED SURFACE	THE DISCRIMINATOR
Social anxiety disorder	Fear of being looked at, social avoidance	**In BDD the fear is specifically about others judging a *perceived appearance defect*; in social anxiety the fear spans behaviour and evaluation across social contexts, not one defect (ICD-11 CDDR)**
Eating disorder (anorexia/bulimia)	Distorted body image, appearance preoccupation	**If the preoccupation is with body fat or weight in someone meeting eating-disorder criteria, diagnose the eating disorder; BDD covers non-weight defects (DSM-5-TR 2022)**
Obsessive-compulsive disorder	Obsessions plus compulsions, poor-insight spectrum	**Content: BDD obsessions/compulsions are confined to *appearance*; if wider obsessional themes are present code OCD too (Kaplan and Sadock 2024)**
Normal appearance concern	Disliking a feature	**BDD adds an hour-plus daily preoccupation, repetitive behaviours, marked distress and functional impairment (DSM-5-TR 2022)**
Delusional disorder (somatic)	Fixed false belief about the body	**If the belief stays within the appearance theme it is BDD with absent insight, not delusional disorder (ICD-11 CDDR)**

The five boundary calls for body dysmorphic disorder; in each, the discriminator is the *content and breadth* of the concern, not its intensity (DSM-5-TR 2022; ICD-11 CDDR).

GOOD TO REMEMBER

- **BDD discriminators:** vs social anxiety, the fear is about a *specific perceived defect*; vs eating disorders, the focus is *not* body fat/weight; vs OCD, the obsessions/compulsions are confined to *appearance*; a delusional-intensity appearance belief is still BDD (absent insight), not delusional disorder (DSM-5-TR 2022; ICD-11 CDDR).

18.6 The high suicide risk, and the cosmetic-surgery trap

This is the number that matters most. BDD carries one of the highest suicide burdens in psychiatry. In clinical samples, lifetime rates of suicidal ideation run **78 to 81%** and suicide attempts **24 to 28%** (New Oxford Textbook). Population studies show appearance-specific suicidal ideation and attempts many-fold higher than in non-BDD groups, and the completed-suicide rate, though preliminary, appears markedly elevated. Mental-health quality-of-life scores in BDD are *poorer* than in depression, OCD, schizophrenia or bipolar disorder, and hospitalisation and unemployment rates are high. Muscle dysmorphia and adolescent BDD carry even higher suicidality.

Cosmetic treatment does not work and can harm. A majority of BDD patients seek and receive costly cosmetic, dermatologic or dental treatment; it is essentially *ineffective* for BDD and can worsen the picture, with some patients performing dangerous self-surgery (New Oxford Textbook). The first clinical move on suspecting BDD is therefore to *redirect away* from the surgeon and toward psychiatric treatment, screening suicide risk from the outset.

> **PEARL**
>
> The patient in front of the dermatologist or cosmetic surgeon who returns again and again dissatisfied, or who fixates on a barely visible "flaw", is the classic undetected BDD. Because they hide the concern from shame and rarely volunteer it, you must ask directly, and once you suspect it, screen suicide risk before anything else. Cosmetic intervention rarely satisfies and can precipitate crisis.

18.7 First-line treatment: a high-dose SRI

SRIs are first-line for every insight level. Serotonin reuptake inhibitors (SSRIs, and clomipramine as the SRI-class TCA) are, with BDD-tailored CBT, the recommended first-line pharmacotherapy, endorsed by the NICE OCD/BDD guideline (New Oxford Textbook; NICE 2005). The evidence base includes a placebo-controlled fluoxetine trial and a blinded crossover showing the SRI clomipramine (Anafranil) beating the non-SRI desipramine, the direct parallel to the clomipramine-versus-SSRI point in OCD: it is the *serotonergic* action that matters, not the tricyclic structure. Crucially, delusional (absent-insight) patients respond to the SRI alone; antipsychotic monotherapy is usually ineffective for delusional BDD, so the SRI is given regardless of insight.

Dose high, choose escitalopram or fluoxetine. BDD, like OCD, needs *higher SRI doses than depression* (New Oxford Textbook). Escitalopram (Nexito, Rexipra) and fluoxetine are the best-studied and usual first choices, escitalopram having few drug interactions; a relapse-prevention trial used escitalopram at a mean of about **26 mg/day**. Citalopram is least preferred because its dosing ceiling sits below the dose usually needed. The brand names to lead with in India are the escitalopram, fluoxetine, sertraline and fluvoxamine antidepressant brands; clomipramine is Anafranil.

AGENT	ROLE IN BDD	ANCHOR / DOSE NOTE (MG/DAY WHERE GIVEN)
Escitalopram (Nexito, Rexipra)	**Preferred first-line SRI**	Best-studied with fluoxetine; few interactions; relapse-prevention trial mean about 26
Fluoxetine	First-line SRI	Placebo-controlled trial positive; dose higher than for depression
Sertraline / fluvoxamine	Alternative first-line SRIs	Open-label support; high-dose principle applies
Clomipramine (Anafranil)	**Reserved: SRI-class TCA after SSRI non-response**	Beat desipramine in a crossover; TCA cautions; kept behind SSRIs on tolerability
Antipsychotic alone	Not for delusional BDD as monotherapy	Dopamine-antagonist monotherapy usually ineffective; give the SRI

Pharmacotherapy of BDD: a high-dose SRI first-line for every insight level, with clomipramine reserved for SSRI non-response (New Oxford Textbook; NICE 2005). Doses in the header; bare figures in the cells.

WORKED EXAMPLE

A man is fixated that his nose is grossly deformed; it looks normal, he checks mirrors and windows for hours, cancels social plans and has begun asking about rhinoplasty. Screen suicide risk (elevated in BDD), redirect from the surgeon, and start escitalopram, titrating toward a *high* dose and holding it for a full 12 to 16 weeks, at the highest tolerated dose for at least 3 to 4 of those weeks, before judging response. Add BDD-tailored CBT. Even if his conviction is delusional, the SRI, not an antipsychotic alone, is the treatment.

GOOD TO REMEMBER

- **SRI in BDD:** first-line pharmacotherapy at *high dose* (higher than for depression), escitalopram or fluoxetine preferred, clomipramine reserved for SSRI non-response; given for *all* insight levels because delusional BDD responds to the SRI while antipsychotic monotherapy usually does not; adequate trial 12 to 16 weeks at maximal tolerated dose (New Oxford Textbook; NICE 2005).

18.8 First-line treatment: BDD-tailored CBT

Generic CBT is not enough. The recommended psychotherapy is *cognitive behavioural therapy specifically tailored to BDD*, not off-the-shelf CBT (New Oxford Textbook; NICE 2005). It targets the appearance-related core beliefs ("I am defective", "I am unlovable"), uses **exposure and response prevention** against the rituals and safety/camouflaging behaviours, perceptual and mirror-retraining to break the zoomed-in scrutiny, and cognitive restructuring of the referential and threat-interpretation biases. The wider CBT model and the exposure principle are developed in the Psychotherapies, clinical assessment, MSE and nosology notes.

How the two combine. A high-dose SRI and BDD-tailored CBT are the two first-line pillars; combining them is standard for more severe or treatment-resistant cases, and psychiatric treatment (not cosmetic intervention) is what actually improves BDD symptoms and functioning.

GOOD TO REMEMBER

- **BDD-tailored CBT:** first-line psychotherapy; core = exposure and response prevention against checking/camouflaging plus cognitive restructuring of appearance beliefs and mirror-retraining; must be BDD-specific, not generic CBT; combined with a high-dose SRI in severe or resistant cases (New Oxford Textbook; NICE 2005).

18.9 Definitions to hold cold

Imagined defect

The appearance flaw central to BDD is not observable, or appears only slight, to others; the concern is disproportionate to any objective finding.

Mirror checking

The signature BDD compulsion: repeated checking of mirrors and reflective surfaces (also windows) to inspect the perceived defect; averages hours a day and does not relieve distress.

Camouflaging

Hiding the disliked area (hats, sunglasses, make-up, posture); both a compulsion and a safety behaviour, a CBT target.

Muscle dysmorphia

BDD specifier: preoccupation that the body is too small/insufficiently muscular; nearly always male; linked to anabolic steroid use and higher suicidality.

Absent insight / delusional

Highest-conviction insight specifier; the appearance belief is held with delusional certainty yet remains BDD, responsive to the SRI.

INDIA

BDD is a textbook casualty of the Indian treatment gap for the anxiety, OCD and related disorders: it presents to dermatology, cosmetic and "fairness"-focused services, not psychiatry, and is rarely named, so a high-suicide-risk disorder goes untreated while the cosmetic industry profits from an intervention that does not work. The same benzodiazepine over-prescription reflex that plagues Indian anxiety practice is misplaced here too, an alprazolam script does nothing for the appearance preoccupation and delays the treatment that helps. The Indian Psychiatric Society CPGs anchor the obsessive-compulsive-spectrum standard: a high-dose SSRI first-line, escitalopram (Nexito, Rexipra) or fluoxetine, then clomipramine (Anafranil), with BDD-tailored CBT, and no place for a benzodiazepine as treatment. The genuinely high-yield Indian move is recognition and suicide screening: ask about hidden appearance preoccupation, and refer away from the surgeon.

78 to 81%	24 to 28%	3 to 8	12 to 16
LIFETIME SUICIDAL IDEATION IN CLINICAL BDD SAMPLES	LIFETIME SUICIDE ATTEMPTS IN CLINICAL BDD SAMPLES	HOURS A DAY OCCUPIED BY BDD COMPULSIVE BEHAVIOURS	WEEKS: ADEQUATE HIGH-DOSE SRI TRIAL BEFORE JUDGING RESPONSE

MNEMONIC

MIRROR

Muscle-dysmorphia specifier (too small, male, steroids); **I**magined or slight defect, not observable to others; **R**epetitive behaviours required (mirror checking, camouflaging, comparing); **R**eferential thinking and poor insight (delusional variant is still BDD); **O**CD-spectrum classification; **R**isk of suicide very high, and cosmetic surgery does not help. Treatment: high-dose SRI plus BDD-tailored CBT for every insight level.

HOLD THIS

BDD = preoccupation with a perceived defect that is unobservable or slight to others, *plus* repetitive behaviours (mirror checking, camouflaging, comparing), in the OCD spectrum; very high suicide risk; treat with a *high-dose* SRI (escitalopram or fluoxetine, clomipramine reserved) and BDD-tailored CBT for all insight levels, because delusional BDD responds to the SRI and cosmetic surgery does not.

19 · Hoarding, trichotillomania and excoriation

The exam packs three disorders into one short block, and the reason to learn them together is that all three are new arrivals in the **obsessive-compulsive and related disorders** chapter, sitting beside OCD and body dysmorphic disorder in both DSM-5-TR and ICD-11 (DSM-5-TR 2022; ICD-11 CDDR). Hoarding disorder was a subtype of OCD and is now a separable syndrome; trichotillomania moved out of the old impulse-control chapter; and excoriation disorder is brand new. Trichotillomania and excoriation are the two **body-focused repetitive** behaviour disorders, and the phrase you must be able to say is exactly that: recurrent, self-directed grooming behaviours (hair-pulling, skin-picking) that produce a physical lesion and that the person keeps trying, and failing, to stop.

Why it matters, and what this note owns. This is a low-yield block by volume but a high-yield one for keywords: each entity is a one-line viva answer built around a single defining criterion. The traps are all discriminations, hoarding versus normal collecting, trichotillomania versus alopecia, skin-picking versus an OCD compulsion, so the note teaches the criterion first and the discriminator second. On treatment, one behavioural technique carries the whole block: habit reversal training. The deep antidepressant dosing that these SSRIs share with OCD lives in the Mood disorders: pharmacotherapy notes and is cross-referenced, not repeated.

19.1 Hoarding disorder: the defining criterion is difficulty discarding

Persistent difficulty discarding, not the clutter. The essential feature of hoarding disorder is a *persistent* **difficulty discarding** or parting with possessions, regardless of their actual value (DSM-5-TR Criterion A). The examinable point is that the diagnosis is anchored on the *discarding difficulty*, not on the mess: the clutter is a downstream consequence. The difficulty is driven by a perceived need to save the items and by distress at the thought of discarding them (Criterion B), which is what makes the saving *purposeful* and separates it from passive accumulation.

Clutter, distress and the third-party clause. The retained possessions congest and clutter *active living areas* so their intended use is compromised, the person cannot cook in the kitchen or sleep in the bed (Criterion C), and this causes clinically significant distress or impairment, including an unsafe home (Criterion D). A neat examiner's hook sits in Criterion C: if the living areas are uncluttered *only because a third party* (family, cleaners, authorities) cleared them, the person still has the disorder. The *with excessive acquisition* specifier applies to the 80 to 90% who also over-buy or over-collect, and insight is graded good/fair, poor, or absent/delusional.

GOOD TO REMEMBER

- **Hoarding disorder (defining criterion):** persistent *difficulty discarding* possessions regardless of value, driven by a perceived need to save and distress at discarding (Criteria A to B), producing clutter that compromises active living areas (C) and significant distress/impairment (D); coded with the obsessive-compulsive and related disorders; specify *with excessive acquisition* (DSM-5-TR 2022; ICD-11 6B24).

19.2 Hoarding versus normal collecting, and versus the OCD it left

Collecting is organised; hoarding is not. The first discrimination is against **normative collecting**, which is organised, selective and a source of pleasure, and does *not* produce the clutter, distress or functional impairment of the disorder (DSM-5-TR 2022). Even when the sheer quantity is similar, the collector's items are curated and the living space stays usable; the hoarder's are piled in disorganised heaps in spaces meant for other purposes.

Why it is no longer an OCD subtype. In OCD, accumulation would be driven by an *obsession* (for example not discarding papers because they might contain harm-preventing information) and the saving feels ego-dystonic and unwanted. In hoarding disorder the saving is *not* triggered by an intrusive obsession; the person genuinely wants to keep the items and feels distress only when made to discard (New Oxford Textbook; DSM-5-TR 2022). Criterion F also forces you to exclude the medical and other-disorder mimics, brain injury and cerebrovascular disease, the low energy of depression, psychotic delusions, and the accumulation seen in major neurocognitive disorder, which is why new-onset hoarding in an older adult demands a cognitive and neurological work-up first.

TRAP **New-onset hoarding in an older adult is a red flag, not a diagnosis.** Before coding hoarding disorder, exclude brain injury, cerebrovascular disease and a major neurocognitive disorder (Criterion F); late-onset accumulation is disproportionately organic.

19.3 Hoarding: what actually helps

Disorder-specific CBT is the mainstay; drugs are weak. Hoarding disorder responds *poorly* to the SSRI-plus-ERP algorithm that works for OCD, part of the evidence that it is a distinct condition (New Oxford Textbook). The best-supported treatment is a *hoarding-specific* cognitive behavioural therapy that targets the discarding difficulty directly, sorting-and-discarding practice, cognitive work on saving beliefs and decision-making, motivational enhancement for the characteristically limited insight, and skills training for the organising and planning deficits. It is

delivered over many months and gains are partial; there is no quick pharmacological fix, so the framing to hold is behavioural-first.

GOOD TO REMEMBER

- **Hoarding-specific CBT:** the first-line treatment for hoarding disorder; targets the difficulty discarding, saving beliefs, decision-making, motivation and organising skills; the disorder responds *poorly* to the standard OCD SSRI regimen, so behaviour therapy, not a drug, leads (New Oxford Textbook).

19.4 Trichotillomania: recurrent hair-pulling with hair loss

The five-part criterion. Trichotillomania (hair-pulling disorder) is recurrent pulling out of one's own **hair-pulling** resulting in *hair loss* (Criterion A), with repeated attempts to decrease or stop (B), clinically significant distress or impairment (C), not attributable to another medical/dermatological condition (D), and not better explained by another mental disorder such as body dysmorphic disorder (E) (DSM-5-TR 2022). The commonest sites are scalp, eyebrows and eyelashes; pulling may be a focused ritual (with mounting tension then relief) or automatic (outside full awareness), and the person may examine, manipulate or swallow the pulled hair.

Two clinical hooks worth marks. It is a **body-focused repetitive** behaviour: crucially, it is *not* triggered by an obsession, which is exactly how it separates from OCD. And *trichophagia* (swallowing hair) can build a trichobezoar, a gastric hairball causing obstruction, anaemia or perforation, the classic surgical complication and a favourite viva twist. Onset typically coincides with puberty and the course is chronic with waxing and waning.

GOOD TO REMEMBER

- **Trichotillomania (defining criterion):** recurrent *hair-pulling resulting in hair loss* with repeated attempts to stop (Criteria A to B), distress/impairment (C), not due to a dermatological condition (D) and not explained by BDD (E); a body-focused repetitive behaviour *not* driven by an obsession; watch for trichophagia and trichobezoar (DSM-5-TR 2022).

19.5 Excoriation (skin-picking) disorder: the parallel entity

The same architecture, on skin. Excoriation (skin-picking) disorder is recurrent **skin-picking** resulting in *skin lesions* (Criterion A), with repeated attempts to decrease or stop (B), significant distress or impairment (C), not attributable to a substance (for example cocaine) or another medical condition such as scabies (D), and not better explained by another mental disorder (E) (DSM-5-TR 2022). Read it as the dermatological twin of trichotillomania: the second **body-focused repetitive** behaviour disorder, most often targeting the face, arms and hands, and, like hair-pulling, running from focused to automatic and not obsession-driven.

The exclusions carry the traps. Criterion D is the examiner's ground: skin-picking in amphetamine or cocaine intoxication ("meth mites", the delusion of infestation) is coded as a substance-induced obsessive-compulsive and related disorder, not excoriation disorder; and picking to correct a perceived appearance flaw is *body dysmorphic disorder*, not excoriation. Onset is often around puberty and the female preponderance is marked in clinical samples.

GOOD TO REMEMBER

- **Excoriation (skin-picking) disorder (defining criterion):** recurrent *skin-picking resulting in skin lesions* with repeated attempts to stop (Criteria A to B), distress/impairment (C), not due to a substance (cocaine) or medical condition (scabies) (D) and not explained by another disorder such as BDD (E); the second body-focused repetitive behaviour disorder (DSM-5-TR 2022).

RULE **Body-focused repetitive behaviours are not compulsions.** Hair-pulling and skin-picking produce a lesion and are *not* triggered by an obsession; that missing obsession is what separates trichotillomania and excoriation from OCD.

19.6 The four entities at a glance

One table fixes the criterion and the discriminator. The block is easiest to hold as a grid of "defining act" against "the thing it is *not*".

DISORDER (ICD-11)	DEFINING CRITERION	KEY DISCRIMINATOR
Hoarding disorder (6B24)	Persistent difficulty discarding possessions, driven by need to save + distress	**Not normal collecting (that is organised, no distress); not obsession-driven as in OCD; exclude organic/neurocognitive causes**
Trichotillomania (6B25.0)	Recurrent hair-pulling with hair loss, repeated attempts to stop	**A body-focused repetitive behaviour, *no* obsession; not dermatological alopecia; not BDD hair removal; beware trichobezoar**
Excoriation / skin-picking (6B25.1)	Recurrent skin-picking with skin lesions, repeated attempts to stop	**Body-focused repetitive behaviour, *no* obsession; not stimulant-induced picking; not BDD skin-picking to fix a flaw**
OCD (6B20, for contrast)	Obsessions and/or compulsions; compulsions relieve obsession-driven distress	**The presence of an *obsession* driving the behaviour is what the three OCRDs above lack**

The compact OCRD block: each entity is anchored on its defining act, and every discrimination turns on whether an *obsession* drives the behaviour (DSM-5-TR 2022; ICD-11 CDDR).

2.5	1 to 2	10:1	1200 to 2400
HOARDING DISORDER POINT PREVALENCE, %	TRICHOTILLOMANIA 12-MONTH PREVALENCE, %	FEMALE-TO-MALE RATIO, TRICHOTILLOMANIA CLINICAL SAMPLES	N-ACETYLCYSTEINE (MG/DAY) TRIALLED IN TRICHOTILLOMANIA

19.7 Habit reversal training: the shared first-line psychotherapy

The one behavioural technique for the block. Habit reversal training (HRT), developed by Azrin, is the first-line treatment for the body-focused repetitive behaviours (Kaplan and Sadock 2024). Its three core elements are the answer to any viva: *awareness training* (self-monitoring, to catch the urge and the moments that precede pulling or picking); *stimulus control* (changing the environment so the behaviour is less likely to start, for example gloves, plasters or a barrier); and *competing response training*, the core, engaging at the first sign of the urge in a motor behaviour

physically *incompatible* with the habit (classically clenching a fist for a minute) until the urge passes. Relaxation and social/contingency reinforcement support the package.

Where drugs sit. Pharmacotherapy is adjunctive and the evidence is thin. SSRIs are the usual first-line drug for the body-focused repetitive behaviours on tolerability grounds, and clomipramine (Anafranil) has the best trichotillomania trial data among the antidepressants; the glutamate modulator N-acetylcysteine reduced hair-pulling in a placebo-controlled trial and reads as comparable to behaviour therapy (Kaplan and Sadock 2024). Combining HRT with medication may beat either alone.

GOOD TO REMEMBER

- **Habit reversal training (principle and structure):** Azrin's first-line behavioural treatment for trichotillomania and excoriation; three elements, *awareness training*, *stimulus control*, and *competing response training* (a motor act incompatible with the habit); drugs (SSRIs, clomipramine, N-acetylcysteine) are adjunctive with a thin evidence base (Kaplan and Sadock 2024).

INDIA

This block magnifies the Indian treatment gap for the anxiety, OCD and related disorders, because these are the disorders patients hide hardest. Trichotillomania and excoriation present to dermatology and cosmetic services as "alopecia" or "acne", and hoarding is dismissed as untidiness or eccentricity, so the psychiatric diagnosis is rarely named. The reflex prescription of a benzodiazepine, still over-prescribed across Indian outpatient practice, does nothing for a body-focused repetitive behaviour and delays the behaviour therapy that helps. The Indian Psychiatric Society CPGs anchor the obsessive-compulsive-spectrum standard for the SSRI half, and Indian brands are readily available, fluoxetine (Fludac, Prodep), sertraline (Daxid, Zosert), escitalopram (Nexito), fluvoxamine (Fluvoxin) and clomipramine (Anafranil), so the limiting factor is recognition, not access. The genuinely high-yield Indian move is to ask directly about hair-pulling, skin-picking and discarding difficulty, and to refer to habit reversal training rather than reach for an anxiolytic.

PEARL

All four OCRDs in this block separate on one axis. OCD has an *obsession* driving a compulsion that relieves it. Hoarding, trichotillomania and excoriation have no obsession: the person *wants* to keep the objects, or the pulling/picking simply discharges tension. If you can find the obsession, you are in OCD; if you cannot, you are in one of the three new neighbours.

HOLD THIS

Hoarding is anchored on *difficulty discarding*; trichotillomania and excoriation are the two *body-focused repetitive* behaviours (hair-pulling with hair loss, skin-picking with skin lesions), none of them obsession-driven, and habit reversal training is the shared first-line treatment for the two body-focused ones.

20 · Illness anxiety and the OCRD spectrum

This is the short topic that fixes a favourite exam trap: where does illness anxiety actually live, and what is the **ocrd spectrum** that keeps trying to claim it? The clinical picture is old, the patient preoccupied with the fear of having a serious disease, checking the body and seeking or avoiding doctors, on a scale out of all proportion to any finding. The classical name was hypochondriasis; the stigma attached to that word is why DSM-5 renamed it (Kaplan and Sadock 2024). The examinable point is that the two manuals split it in opposite directions, and understanding why turns on the **obsessive-compulsive spectrum** idea.

Why it matters, and what this note owns. The whole disorder is built from an intrusive preoccupation plus repetitive behaviours (checking, reassurance-seeking) done in response, the same obsession-then-compulsion architecture as OCD, which is exactly why ICD-11 files **health anxiety** disorder inside the obsessive-compulsive and related disorders while DSM-5-TR files illness anxiety among the somatic-symptom disorders. This note teaches that placement, the criterion-anchored diagnosis of illness anxiety, the concept of the OCRD spectrum that binds OCD, BDD, hoarding, the body-focused behaviours and health anxiety by their shared repetitive-behaviour feature, and the first-line treatment. The illness-anxiety-versus-somatic-symptom-disorder boundary (how much bodily symptom is present) is worked out in the Somatic-symptom, sexual, impulse-control disorders and suicide notes; here we own the OCRD-facing side.

20.1 Illness anxiety disorder: the criterion and the two subtypes

The defining criterion. Illness anxiety disorder is a **preoccupation** with having or acquiring a serious illness, in which somatic symptoms are absent or, if present, only mild, and the preoccupation persists despite appropriate medical evaluation and reassurance (DSM-5-TR 2022; Kaplan and Sadock 2024). It is not held with delusional intensity and is not restricted to a concern about appearance (that would be body dysmorphic disorder). The person has a high level of health anxiety and performs excessive health-related behaviours, or shows maladaptive avoidance, and the duration must be at least **6 months** (though the specific feared illness may change over that time).

Two subtypes, opposite behaviours. DSM-5-TR specifies a *care-seeking type*, in which medical care including physician visits, tests and procedures is used frequently, and a *care-avoidant type*, in which medical care is rarely used (DSM-5-TR 2022). The care-avoidant patient is easy to miss precisely because they stay away from clinics; the fear is so intense that they avoid the very reassurance they crave. Core phenomenology, in the older language, is disease conviction, disease fear and bodily preoccupation.

GOOD TO REMEMBER

- **Illness anxiety disorder (defining criterion):** preoccupation with having or acquiring a serious illness with somatic symptoms absent or only mild, persisting *despite* appropriate evaluation and reassurance, for at least **6 months**; not delusional, not confined to appearance; specify *care-seeking* vs *care-avoidant* type (DSM-5-TR 2022).

20.2 The DSM-versus-ICD split: same patient, two chapters

DSM-5-TR: renamed and split across the somatic group. DSM-5 removed the term hypochondriasis for its pejorative connotation. About two-thirds to three-quarters of former hypochondriasis cases, those with prominent somatic symptoms, are recoded as *somatic symptom disorder*; the remaining minority (around **20%**), whose symptoms are minor and whose focus is the fear of illness itself, become *illness anxiety disorder* (Kaplan and Sadock 2024; DSM-5-TR 2022). Both sit in the somatic-symptom-and-related-disorders chapter. The dividing line is the amount of somatic symptom present.

ICD-11: kept the name, moved it into the OCRD grouping. ICD-11 retained the label *hypochondriasis (health anxiety disorder)* and placed it, as code 6B23, inside the **obsessive-compulsive or related disorders** grouping, not the somatic block (ICD-11 CDDR). Its stated rationale is shared phenomenology, repetitive intrusive thoughts about having an illness and repetitive or excessive health-related behaviours driven by that preoccupation, plus a similar treatment response. In ICD-11 the presence of somatic symptoms is explicitly *not* an essential feature, so the label turns on the anxious preoccupation and the checking, not on bodily complaints.

FEATURE	DSM-5-TR	ICD-11 CDDR
Name	Illness anxiety disorder	**Hypochondriasis (health anxiety disorder)**
Chapter	Somatic symptom and related disorders	**Obsessive-compulsive and related disorders (6B23)**
Somatic symptoms	Absent or mild; if prominent, code somatic symptom disorder instead	**Not an essential feature**
Rationale for placement	Health-focused somatic preoccupation	**Repetitive intrusive thoughts + checking, like OCD; shared treatment response**
Insight	Not of delusional intensity	**Insight specifier applies (fair-to-good vs poor-to-absent)**

The single most tested fact on this topic: the same clinical picture is an OCRD in ICD-11 but a somatic-symptom disorder in DSM-5-TR (ICD-11 CDDR; DSM-5-TR 2022).

RULE **Two manuals, opposite files.** Hypochondriasis / illness anxiety is an *obsessive-compulsive related disorder* in ICD-11 (6B23) but a *somatic-symptom disorder* in DSM-5-TR, split off by how much bodily symptom is present.

20.2b The OCRD spectrum: what binds the group

The unifying feature. The **ocrd spectrum** (the obsessive-compulsive related, or obsessive-compulsive spectrum, disorders) is the family of conditions linked by a shared core: an intrusive, repetitive *preoccupation* and the repetitive *behaviours* performed in response to it (New Oxford Textbook; ICD-11 CDDR). In ICD-11 the grouping contains obsessive-compulsive disorder (6B20), body dysmorphic disorder (6B21), olfactory reference disorder (6B22), hypochondriasis /

health anxiety disorder (6B23), hoarding disorder (6B24) and the body-focused repetitive behaviour disorders (6B25, trichotillomania and excoriation/skin-picking); Tourette syndrome is cross-listed for its analogous premonitory-urge-and-repetitive-behaviour phenomenology. The historical idea, proposed by Hollander, arranged these on a compulsivity-to-impulsivity dimension, harm-avoidant checking at one pole, reward-driven grooming behaviours at the other.

What earns a place, and what does not. Membership is defined by the repetitive-behaviour-or-preoccupation feature and by serotonergic treatment response, which is why illness anxiety, whose sufferers check the body and seek reassurance, fits so naturally that ICD-11 moved it in. The spectrum is a *conceptual* bridge: it explains why these disorders cluster, co-occur and respond to serotonin reuptake inhibitors, but it does not collapse them into one diagnosis. The insight specifier (fair-to-good vs poor-to-absent) applies across OCD, BDD, olfactory reference disorder, hypochondriasis and hoarding, another shared thread (ICD-11 CDDR).

Obsessive-compulsive spectrum
disorders linked by intrusive repetitive preoccupation, repetitive behaviours in response, and serotonergic treatment response

OCD (6B20)
obsessions and compulsions across varied content

Body dysmorphic disorder (6B21)
the loop fixed on a perceived appearance defect

Hoarding disorder (6B24)
difficulty discarding, driven by perceived need to save

Body-focused repetitive behaviours (6B25)
trichotillomania (hair-pulling), excoriation (skin-picking)

Hypochondriasis / health anxiety (6B23)
the loop fixed on the fear of serious illness

GOOD TO REMEMBER

- **OCRD spectrum (unifying feature):** conditions bound by an intrusive repetitive *preoccupation* plus repetitive *behaviours* done in response, and by serotonergic treatment response; ICD-11 grouping = OCD, BDD, olfactory reference disorder, hypochondriasis, hoarding, body-focused repetitive behaviours, with Tourette cross-listed (ICD-11 CDDR).

20.3 The discriminations: what illness anxiety is not

Four boundaries carry the marks. Illness anxiety sits between the somatic, anxious, obsessional and psychotic groups, and each seam is testable. Hold them as a table.

CONFUSED WITH	SHARED SURFACE	THE DISCRIMINATOR
Somatic symptom disorder	Health preoccupation, doctor-shopping	**In SSD there are prominent, distressing *somatic symptoms*; in illness anxiety somatic symptoms are absent or mild and the focus is the *fear of illness* (DSM-5-TR 2022)**
Generalised anxiety disorder	Worry about health	**GAD worry spans many domains (finances, family, work); illness anxiety worry is *specifically and persistently* about having a serious disease (New Oxford Textbook)**
Obsessive-compulsive disorder	Intrusive illness thoughts, checking	**OCD illness thoughts are usually experienced as intrusive and senseless with wider obsessional content; illness anxiety fear is a sustained, ego-syntonic disease conviction (Kaplan and Sadock 2024)**
Delusional disorder, somatic type	Fixed belief about having a disease	**Illness anxiety belief is *not* of delusional intensity and yields, at least briefly, to evidence; a truly unshakeable somatic delusion is delusional disorder (Kaplan and Sadock 2024)**

The four boundary calls for illness anxiety; the discriminator is the *somatic load, the breadth of worry, and the fixity of belief*, not the health theme itself (DSM-5-TR 2022; Kaplan and Sadock 2024).

TRAP **Do not upgrade illness anxiety to a somatic delusion.** The illness-anxiety belief is over-valued, not delusional; it softens with evidence even if it returns. A fixed, evidence-proof conviction of disease is delusional disorder (somatic type), a different diagnosis and a different treatment.

20.4 First-line treatment: the SSRI and CBT

An SSRI, at an adequate trial. The serotonin reuptake inhibitors are the first-line pharmacotherapy for health anxiety, consistent with its OCRD placement and serotonergic response (Kaplan and Sadock 2024). The pivotal evidence is Fallon and colleagues' placebo-controlled trial of fluoxetine (Fludac, Prodep) at **20 to 80 mg/day**: responders separated from placebo by around 8 weeks and the gain held to 24 weeks, so the trial must run long enough (about **12 weeks**) before it is judged a failure. As across the OCRD group, doses tend to the higher end, and any of the SSRIs, escitalopram (Nexito, Rexipra), sertraline (Daxid, Zosert), fluvoxamine (Fluvoxin) or fluoxetine, is reasonable; deep dosing lives in the Mood disorders: pharmacotherapy notes. Reassurance, though part of every intervention, is not a treatment on its own and, given repeatedly, feeds the checking loop.

CBT is the prototype psychotherapy. Cognitive behavioural therapy is the first-line, best-evidenced psychological treatment for health anxiety; controlled trials, including Barsky and

Ahern's brief six-session individual CBT, show durable falls in hypochondriacal beliefs and health anxiety at one-year follow-up (Kaplan and Sadock 2024). CBT targets the misinterpretation of benign bodily sensations, the catastrophic disease beliefs, and the safety behaviours (body-checking, reassurance-seeking, symptom-Googling) that maintain the fear, exactly the exposure-and-response-prevention logic of the wider OCRD group; the general CBT model lives in the Psychotherapies, clinical assessment, MSE and nosology notes.

GOOD TO REMEMBER

- **SSRI (in health anxiety):** first-line drug, serotonergic response mirroring the OCRD group; Fallon's RCT used fluoxetine at **20 to 80 mg/day** with response by ~8 weeks, so give an adequate (~**12-week**) trial before calling it a failure (Kaplan and Sadock 2024).
- **CBT (in health anxiety):** first-line, best-evidenced psychotherapy; targets misinterpretation of bodily sensations and the reassurance-seeking / checking safety behaviours, with durable one-year gains (Barsky and Ahern; Kaplan and Sadock 2024).

6 months	20 to 80	~20%	6B23
MINIMUM DURATION FOR ILLNESS ANXIETY DISORDER	FLUOXETINE TRIAL DOSE IN HEALTH ANXIETY (MG/DAY)	OF FORMER HYPOCHONDRIASIS BECOMES ILLNESS ANXIETY (REST = SSD)	ICD-11 CODE, INSIDE THE OCRD GROUPING

INDIA

Health anxiety is common in Indian general practice yet reaches psychiatry late, part of the wider anxiety and OCD treatment gap, and it is a prime setting for the country's benzodiazepine over-prescription problem: a worried, somatising patient is handed alprazolam or clonazepam for the anxiety rather than started on the SSRI and CBT that actually treat the disorder. The Indian Psychiatric Society clinical practice guidelines keep an SSRI (with CBT) as first-line for the anxiety and obsessive-compulsive disorders and reserve benzodiazepines for short-term crisis use only; the anxiolytic dependence story is in the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes. The SSRIs are widely and cheaply available under Indian brands, escitalopram as Nexito or Rexipra, fluoxetine as Fludac or Prodep, sertraline as Daxid or Zosert, so cost is rarely the barrier; recognition is.

PEARL

Read illness anxiety as OCD wearing a stethoscope: the intrusive thought is *"I have a serious disease"*, the compulsions are body-checking, symptom-Googling and reassurance-seeking, and the relief is momentary before the doubt returns. That framing tells you why ICD-11 put it in the OCRD grouping and why the treatment is the OCRD treatment, an SSRI at an adequate dose plus CBT with response prevention, not endless investigation and not a benzodiazepine.

HOLD THIS

Illness anxiety (hypochondriasis) is a somatic-symptom disorder in DSM-5-TR but an obsessive-compulsive related disorder (6B23) in ICD-11; first-line treatment is an SSRI plus CBT, never a benzodiazepine.

Trauma and stressor-related disorders

21 · PTSD: clinical features and criteria

Post-traumatic stress disorder is the disorder in which a terrifying event does not become a memory. In health, a horrific experience is filed away as something that happened *there* and *then*; in **ptsd** it is relived *here* and *now*, forcing itself back into the present through intrusive images, flashbacks and nightmares, so that the person is driven to avoid every reminder and lives permanently braced for the next catastrophe. Examiners test this on a tight lattice of exact points, the definition of the qualifying trauma, the symptom clusters (four in DSM-5, three in ICD-11), the greater-than-one-month duration, the delayed-onset and dissociative subtypes, the epidemiology, and the **pcl-5** with its provisional cut-off, and the classic trap is to accept a personality-disorder label, or a benzodiazepine, where the answer is trauma.

Why it matters clinically. Trauma exposure is near-universal but **ptsd** follows in only a minority, which makes the diagnosis about a *specific* post-exposure syndrome rather than distress alone. Two facts anchor every answer. First, the phenomenological signature is re-experiencing *in the present* plus a persistent sense of current threat, which separates true **post-traumatic stress disorder** from ordinary painful recollection. Second, the two classifications no longer align neatly, so a full answer must hold both the DSM-5 four-cluster and the **icd-11 ptsd** three-cluster architecture side by side, and know that a patient can meet one and miss the other. The amygdala and fear-circuit anatomy on which the alarm is built is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes, and the treatment (trauma-focused psychotherapy first, then the SSRIs/SNRI, prazosin for nightmares, no benzodiazepine) sits in a separate management note; it is not re-derived here.

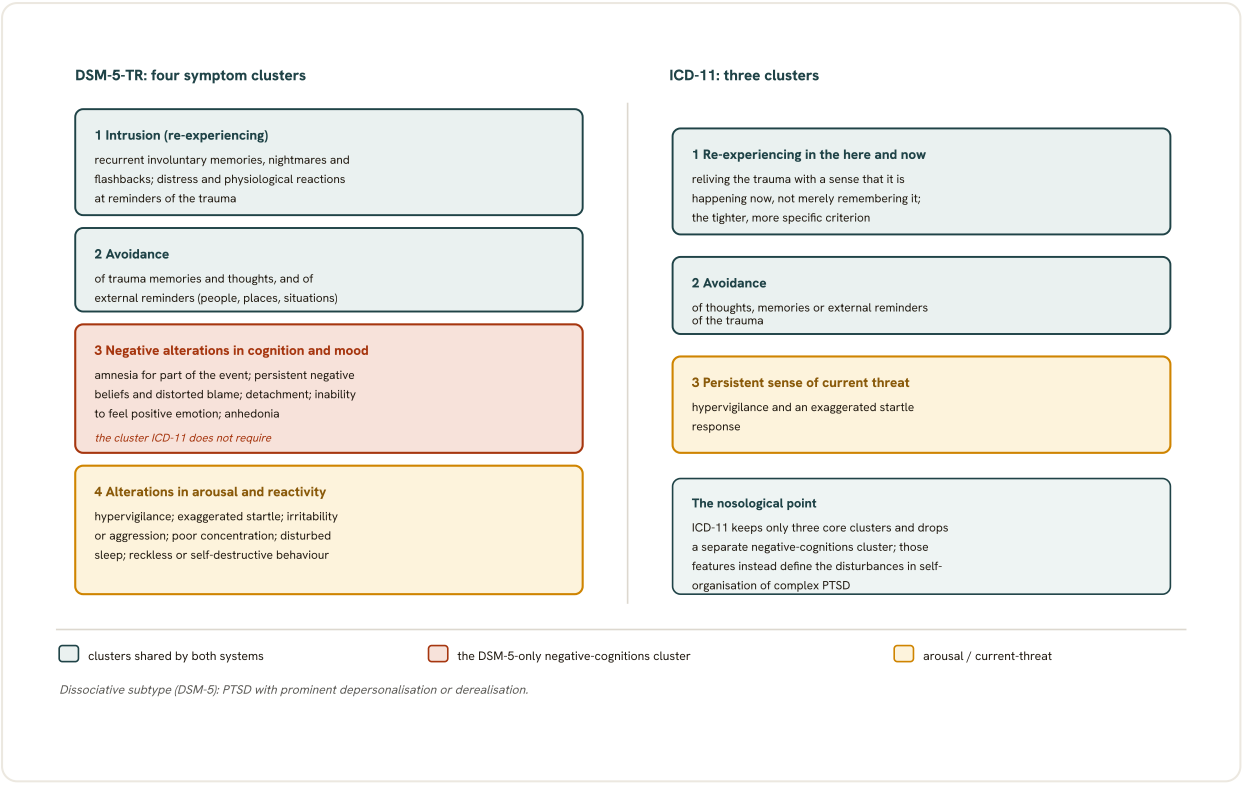

Fig 14.14 The PTSD symptom clusters, DSM-5-TR against ICD-11. DSM-5-TR requires all four clusters: intrusion, avoidance, negative alterations in cognition and mood, and alterations in arousal and reactivity. ICD-11 keeps a tighter three: re-experiencing in the here and now (a sense that the trauma is happening now, not just being remembered), avoidance, and a persistent sense of current threat; it deliberately drops the separate negative-cognitions cluster, whose features instead define the disturbances in self-organisation of complex PTSD. DSM-5 also recognises a dissociative subtype with prominent depersonalisation or derealisation.

PCL-5

Instructions: Below is a list of problems that people sometimes have in response to a very stressful experience. Keeping your worst event in mind, please read each problem carefully and then select one of the numbers to the right to indicate how much you have been bothered by that problem in the past month.

Your worst event: _____

In the past month, how much were you bothered by:	Not at all	A little bit	Moderately	Quite a bit	Extremely
1. Repeated, disturbing, and unwanted memories of the stressful experience?	0 ○	1 ○	2 ○	3 ○	4 ○
2. Repeated, disturbing dreams of the stressful experience?	0 ○	1 ○	2 ○	3 ○	4 ○
3. Suddenly feeling or acting as if the stressful experience were actually happening again (as if you were actually back there reliving it)?	0 ○	1 ○	2 ○	3 ○	4 ○
4. Feeling very upset when something reminded you of the stressful experience?	0 ○	1 ○	2 ○	3 ○	4 ○
5. Having strong physical reactions when something reminded you of the stressful experience (for example, heart pounding, trouble breathing, sweating)?	0 ○	1 ○	2 ○	3 ○	4 ○
6. Avoiding memories, thoughts, or feelings related to the stressful experience?	0 ○	1 ○	2 ○	3 ○	4 ○
7. Avoiding external reminders of the stressful experience (for example, people, places, conversations, activities, objects, or situations)?	0 ○	1 ○	2 ○	3 ○	4 ○
8. Trouble remembering important parts of the stressful experience?	0 ○	1 ○	2 ○	3 ○	4 ○
9. Having strong negative beliefs about yourself, other people, or the world (for example, having thoughts such as: I am bad, there is something seriously wrong with me, no one can be trusted, the world is completely dangerous)?	0 ○	1 ○	2 ○	3 ○	4 ○
10. Blaming yourself or someone else for the stressful experience or what happened after it?	0 ○	1 ○	2 ○	3 ○	4 ○
11. Having strong negative feelings such as fear, horror, anger, guilt, or shame?	0 ○	1 ○	2 ○	3 ○	4 ○
12. Loss of interest in activities that you used to enjoy?	0 ○	1 ○	2 ○	3 ○	4 ○
13. Feeling distant or cut off from other people?	0 ○	1 ○	2 ○	3 ○	4 ○
14. Trouble experiencing positive feelings (for example, being unable to feel happiness or have loving feelings for people close to you)?	0 ○	1 ○	2 ○	3 ○	4 ○
15. Irritable behavior, angry outbursts, or acting aggressively?	0 ○	1 ○	2 ○	3 ○	4 ○
16. Taking too many risks or doing things that could cause you harm?	0 ○	1 ○	2 ○	3 ○	4 ○
17. Being "superalert" or watchful or on guard?	0 ○	1 ○	2 ○	3 ○	4 ○
18. Feeling jumpy or easily startled?	0 ○	1 ○	2 ○	3 ○	4 ○
19. Having difficulty concentrating?	0 ○	1 ○	2 ○	3 ○	4 ○
20. Trouble falling or staying asleep?	0 ○	1 ○	2 ○	3 ○	4 ○

PCL-5 (18 August 2023) National Center for PTSD Page 3 of 3

The PCL-5: 20 self-report items mapped to the four DSM-5 clusters, each rated 0 to 4 over the past month (total 0 to 80); a provisional cut-off of about 31 to 33 suggests probable PTSD, but the National Center for PTSD states the cut-off as provisional and under review, so it is used to flag, not to diagnose.

PCL-5 (Weathers et al.); US National Center for PTSD, in the public domain (a work of the United States federal government).

Fig 14.15 The PTSD Checklist for DSM-5 (PCL-5). The standard self-report measure for PTSD symptom severity and monitoring: twenty items, one per DSM-5 symptom, each rated 0 (not at all) to 4 (extremely) over the past month, for a total of 0 to 80. A provisional cut-off of about 31 to 33 flags probable PTSD, but the National Center for PTSD holds the cut-off as provisional, so the score screens and tracks rather than diagnoses. Shown as the actual public-domain Veterans Affairs form.

21.1 The traumatic-stressor criterion: what counts as Criterion A

The gateway. PTSD is one of the few diagnoses that requires a specified *cause*. DSM-5-TR Criterion A demands exposure to actual or threatened death, serious injury or sexual violence in one of four ways: *directly experiencing* the event; *witnessing* it in person as it happened to others; *learning* that it happened to a close family member or friend (where the event was violent or accidental); or *repeated or extreme exposure to aversive details* of traumatic events, as in first responders or those handling human remains (DSM-5-TR 2022; Kaplan & Sadock CTP 2024). The fourth route does *not* apply to exposure through electronic media, television, films or pictures unless that exposure is work-related.

How the systems frame it. ICD-11 requires exposure to an event or situation of an *extremely threatening or horrific* nature, listing disasters, combat, serious accidents, torture, sexual violence, terrorism, assault or acute life-threatening illness, and includes witnessing the sudden violent injury or death of others and learning of the sudden violent death of a loved one (ICD-11 CDDR). A historically examinable point: DSM-5 *removed* the old DSM-IV Criterion A2 requirement that the person felt intense fear, helplessness or horror at the time, because many who later develop full PTSD (combat personnel, first responders) show muted emotion at the moment of trauma (Kaplan & Sadock CTP 2024).

WORKED EXAMPLE

A 34-year-old woman survives a bus accident in which two fellow passengers die. Over the following weeks she is ambushed by vivid images of the crushed vehicle that arrive unbidden and feel as if it is happening again; she cannot take a bus, detours around the accident road, sleeps two hours a night, startles violently at horns, and believes the world is now lethally dangerous and that she should have saved the others. This is Criterion A (directly experiencing a life-threatening accident) followed by re-experiencing, avoidance, negative cognitions and hyperarousal persisting beyond a month: post-traumatic stress disorder, not an understandable transient reaction.

21.2 The DSM-5 four symptom clusters (B, C, D, E)

Four groups, minimum counts. DSM-5-TR parses PTSD into four symptom clusters, each with a required minimum, all beginning or worsening after the trauma (DSM-5-TR 2022; Kaplan & Sadock CTP 2024). **Cluster B, intrusion** (one or more of five): intrusive distressing memories, traumatic nightmares, dissociative flashbacks, intense distress at reminders, and marked physiological reactivity to reminders. **Cluster C, avoidance** (one or more of two): avoidance of trauma-related thoughts or feelings, and avoidance of external reminders (people, places, activities). **Cluster D, negative alterations in cognitions and mood** (two or more of seven): dissociative amnesia for the event, persistent negative beliefs about self or the world, distorted blame, persistent negative emotional state, markedly diminished interest, detachment or estrangement, and an inability to feel positive emotions. **Cluster E, alterations in arousal and reactivity** (two or more of six): irritability or aggression, reckless or self-destructive behaviour, hypervigilance, exaggerated startle, concentration problems, and sleep disturbance.

The threshold criteria. On top of the four clusters, the full picture must last *more than one month* (Criterion F), cause clinically significant distress or functional impairment (Criterion G), and not be attributable to a substance or another medical condition (Criterion H) (DSM-5-TR 2022). The negative-cognitions cluster (D) is the one that was *new* in DSM-5, absent from DSM-IV, and it widens PTSD from a fear-based reaction into a disorder of altered worldview, mood and self-belief.

MNEMONIC

TRAUMA → IANA (1·1·2·2)

The four DSM-5 clusters and their minimum counts, in order B-C-D-E. **I**ntrusion / re-experiencing (need **1** of 5), **A**voidance (need **1** of 2), **N**egative alterations in cognitions and mood (need **2** of 7), **A**rousal and reactivity (need **2** of 6). Then the three threshold gates: over one month, distress/impairment, not substance or medical.

21.3 Cluster B in depth: re-experiencing in the here and now

The pathognomonic feature. What makes an intrusion a PTSD symptom rather than an ordinary bad memory is that it is lived **re-experiencing** in the present, not retrospective recall. The intrusive memory carries the emotional and physiological charge of the original event and is experienced as recurring and current, even while the person knows intellectually that the trauma is in the past (Kaplan & Sadock CTP 2024). At the extreme, a *dissociative flashback* (Criterion B3) transports the person back so completely that they lose awareness of present surroundings. Nightmares thematically related to the trauma and marked distress or bodily reactivity on encountering reminders complete the cluster.

Not sufficient. The reciprocal point, which discriminates PTSD from rumination and grief, is that merely reflecting on, ruminating about, or remembering the feelings of the event is *not* enough to meet the re-experiencing requirement; the event must be experienced as occurring again in the here and now (ICD-11 CDDR). This is the exact line that separates PTSD re-experiencing from the preoccupied recollection of prolonged grief disorder.

RULE **Present-tense, not past-tense.** The single discriminating feature of PTSD is that the trauma is re-experienced in the here and now (intrusive images, flashbacks, nightmares that feel current), not simply remembered as belonging to the past; ordinary distressing recall or rumination does not meet the re-experiencing criterion.

21.4 Clusters C, D and E: avoidance, negative cognitions, hyperarousal

Avoidance. Because the re-experiencing is so intolerable, the person makes effortful attempts to avoid its triggers, both external (people, places, conversations, activities) and internal (thoughts, feelings, bodily sensations tied to the event). This **avoidance** tends to *generalise* over time, new objects and situations progressively drawn into the avoided set, which can confine severely affected patients to a shrinking, no-surprises world (Kaplan & Sadock CTP 2024).

Negative cognitions. The Cluster D **negative cognitions** and mood run beyond the event itself into fixed, permanent-feeling beliefs, the world is *always* dangerous, other people are untrustworthy, the self is irreversibly damaged or to blame, alongside anhedonia, detachment, a persistent negative emotional state and, in some, dissociative amnesia for part of the event. These overlap with depression and mark how far PTSD reshapes the whole disposition, not just the trauma response.

Hyperarousal. Cluster E, the alterations in arousal and reactivity, is the state of a threat-detection system stuck on: **hyperarousal** with hypervigilance (unrelenting scanning for danger),

exaggerated startle, irritability and angry outbursts, poor concentration, sleep disturbance, and reckless or self-destructive behaviour (DSM-5-TR 2022; Kaplan & Sadock CTP 2024). The irritability and aggression are frequently aimed at family and close relationships, deepening the person's isolation.

PEARL

The four clusters have an inner logic worth stating in a viva. The trauma stays intolerably alive (*intrusion*); because it is intolerable it is walled off (*avoidance*); the effort to make sense of it corrodes belief about self, others and the world (*negative cognitions*); and a system that failed to keep the person safe once now never stands down (*hyperarousal*). Naming that chain shows you understand PTSD as a coherent post-exposure trap, not a checklist.

21.5 The ICD-11 three-cluster model and the DSM-5 divergence

ICD-11 6B40. Icd-11 ptsd deliberately narrows the picture to three core elements, all developing after the trauma and lasting *at least several weeks* (ICD-11 CDDR). First, *re-experiencing* the traumatic event in the present (vivid intrusive memories, flashbacks or nightmares experienced as occurring again in the here and now). Second, *deliberate avoidance* of reminders, whether internal (thoughts, memories) or external (people, situations). Third, *persistent perceptions of heightened current threat*, indicated for example by hypervigilance or an enhanced startle reaction. Function must be significantly impaired, or maintained only through significant extra effort.

Why the divergence is examinable. ICD-11 collapses DSM-5's negative-cognitions cluster and much of avoidance out of the core criteria, keeping only three tighter **symptom clusters**, and reserves the wider disturbances of affect regulation, self-concept and relationships for the separate diagnosis of complex PTSD. The consequence, repeatedly demonstrated in military and international samples, is that many people who meet DSM-5 PTSD do *not* meet ICD-11 PTSD and vice versa (Kaplan & Sadock CTP 2024). Neither system should therefore be used to exclude a distressed, impaired trauma survivor from care.

FEATURE	DSM-5-TR (309.81 / F43.10)	ICD-11 (6B40)
Number of clusters	**Four (B intrusion, C avoidance, D negative cognitions/mood, E arousal)**	**Three (re-experiencing in the present, avoidance, persistent sense of current threat)**
Re-experiencing	Intrusive memories, nightmares, flashbacks, cued distress, cued physiological reactivity (need 1 of 5)	Re-experienced in the here and now (not mere recall); required core element
Avoidance	Internal and/or external reminders (need 1 of 2)	Deliberate avoidance of reminders; required core element
Negative cognitions and mood	Separate required cluster D (need 2 of 7)	Not a core criterion; features moved to complex PTSD

FEATURE	DSM-5-TR (309.81 / F43.10)	ICD-11 (6B40)
Arousal / current threat	Cluster E arousal and reactivity (need 2 of 6)	Expressed as persistent perceptions of heightened current threat (e.g. hypervigilance, startle)
Duration threshold	More than 1 month	At least several weeks
Complex presentations	Handled within PTSD plus dissociative subtype	Separate diagnosis: complex PTSD (6B41)

The DSM-5-TR four-cluster and ICD-11 three-cluster architectures of PTSD side by side; the key divergence is that ICD-11 drops the negative-cognitions cluster from the core and spins complex reactions into complex PTSD, so a patient can meet one system and not the other (criteria verified against DSM-5-TR 2022 and the ICD-11 CDDR).

GOOD TO REMEMBER

- **Post-traumatic stress disorder (the syndrome):** the defining criterion is a qualifying trauma (Criterion A, actual or threatened death, serious injury or sexual violence, experienced, witnessed, learned of, or through repeated occupational exposure) followed by a characteristic syndrome lasting *more than one month* (DSM-5) or *at least several weeks* (ICD-11); the discriminator from ordinary distress is re-experiencing *in the here and now* plus a persistent sense of current threat, and the first step is to confirm the stressor and then map the clusters (DSM-5 four: intrusion, avoidance, negative cognitions, arousal; ICD-11 three: re-experiencing, avoidance, current threat).

21.6 The dissociative subtype and delayed-onset (delayed expression)

Dissociative subtype. DSM-5 recognises a **dissociative subtype** of PTSD: full PTSD criteria are met and, in addition, there are persistent or recurrent symptoms of *depersonalisation* (feeling detached from, or an outside observer of, one's own mind or body) or *derealisation* (a sense that surroundings are unreal, dreamlike or distorted) (DSM-5-TR 2022; Kaplan & Sadock CTP 2024). It marks a subgroup who respond to reminders not with hyperarousal but with dissociation, characterised biologically by *over*modulation of the amygdala; the World Mental Health Surveys estimated it at about **14.4%** of those with PTSD.

Delayed expression. The *with delayed expression* specifier applies when the full diagnostic criteria are not met until *at least 6 months* after the event, even though some symptoms may have appeared immediately (DSM-5-TR 2022). The examinable subtlety is that genuine delayed *onset* from a truly asymptomatic state is rare; most apparent delayed-onset cases are worsening of pre-existing subsyndromal symptoms or delayed help-seeking, often re-triggered by a reminder or new stressor (Kaplan & Sadock CTP 2024).

GOOD TO REMEMBER

- **Dissociative subtype:** full PTSD *plus* persistent depersonalisation or derealisation; the signature caution is that these patients dissociate rather than hyperarouse to reminders (amygdala overmodulation), and it accounts for about 14.4% of PTSD.
- **Delayed expression specifier:** full criteria first met at least 6 months after the trauma; true asymptomatic delayed onset is rare, so look for pre-existing subsyndromal symptoms rekindled by a reminder or fresh stressor.

21.7 Epidemiology and course

Common trauma, selective disorder. Lifetime trauma exposure is near-universal (roughly 50 to 89% in United States samples; about 70% in a 69,000-adult worldwide study), yet only a minority exposed develop PTSD (Kaplan & Sadock CTP 2024). The National Comorbidity Survey Replication put the *lifetime* prevalence of PTSD in United States adults at **6.8%** and past-year prevalence at 3.5%. The disorder is roughly twice to three times as common in women (lifetime 9.7% in women versus 3.6% in men), partly reflecting the very high conditional risk after sexual assault.

Course. Conditional risk after trauma varies sharply by trauma type (highest after sexual assault, lower after accidents). Symptoms in most trauma-exposed people wane over the first months; nearly half of those who develop PTSD recover within 3 months, but roughly a third run a *chronic* course persisting for months to years, with survivors of interpersonal violence taking longest to remit (DSM-5-TR 2022; ICD-11 CDDR; Kaplan & Sadock CTP 2024). Symptom severity can fluctuate, patients crossing in and out of formal diagnostic threshold in the early years.

21.8 The PCL-5: what it is and its verified provisional cut-off

What it is. The **pcl-5** (the PTSD Checklist for DSM-5, Weathers et al. 2013) is a 20-item self-report questionnaire, one item for each of the 20 DSM-5 PTSD symptoms, each rated 0 to 4 over the past month and summed to a total score of **0 to 80** (Kaplan & Sadock CTP 2024). It takes about 5 to 10 minutes, is free from the United States National Center for PTSD, and its items are ordered by DSM-5 cluster (items 1 to 5 = Cluster B, 6 to 7 = Cluster C, and so on), so it can also support a provisional cluster-based diagnosis by counting endorsed symptoms per domain.

The cut-off to memorise. The PCL-5 is a screen and severity monitor, *not* a diagnosis (the CAPS-5 or SCID structured interview remains the gold standard). A total-score cut of **31 to 33** has been suggested as indicative of *probable* PTSD, with the CAPS-5 or SCID structured interview remaining the diagnostic gold standard (Kaplan & Sadock CTP 2024). Refer to the accompanying scale plate for the reproduced instrument; the number to carry is the provisional cut-off of 31 to 33 on a 0 to 80 range, and the concept map of the clusters is set out in the figure alongside.

TRAP **Treating a PCL-5 score as a diagnosis.** A PCL-5 of 33 or more is *probable* PTSD and a prompt to assess, not a diagnosis; the diagnosis needs a clinical interview confirming Criterion A and the cluster pattern. Equally, do not miss complex PTSD hiding behind a borderline personality-disorder label, chronic interpersonal trauma with affect dysregulation, disturbed self-concept and relational difficulty on top of the core PTSD triad is complex PTSD (ICD-11 6B41), and mislabelling it forfeits trauma-focused treatment.

31 to 33	0 to 80	1 month	6.8%
PCL-5 PROVISIONAL CUT-OFF FOR PROBABLE PTSD	PCL-5 TOTAL RANGE (20 ITEMS, EACH 0 TO 4)	DSM-5 MINIMUM DURATION (OVER ONE MONTH)	LIFETIME PTSD PREVALENCE (NCS-R, DSM-IV)

21.9 The India device: the treatment gap, benzodiazepines, and the IPS line

Where PTSD lands in Indian practice. India carries a very wide anxiety/OCD/PTSD treatment gap: trauma is common (road-traffic and industrial accidents, interpersonal and domestic violence, disasters), but PTSD is under-recognised, frequently somatised, and reaches formal care late, with most sufferers never seeing a mental-health professional (echoing the international finding that over half of people with PTSD do not seek treatment). Into that gap has flowed the benzodiazepine over-prescription problem: distress after trauma is met with a long-term benzodiazepine (typically alprazolam), which touches none of the core clusters and is explicitly *not* a PTSD treatment. The Indian Psychiatric Society CPGs and every major guideline put trauma-focused psychotherapy first, then an SSRI or the SNRI venlafaxine, with prazosin (Minipress, Prazopress) for trauma nightmares and propranolol (Ciplar, Inderal) in the peri-trauma setting; the benzodiazepine has no role. Indian brands of the anchor drugs are named where they arise, escitalopram as Nexito or Rexipra, clomipramine as Anafranil, in the accompanying management note.

INDIA

The single highest-yield Indian point is that a benzodiazepine is the wrong answer for PTSD twice over: it is not a treatment for any PTSD cluster, and early post-trauma benzodiazepine use may actually *increase* the risk of developing PTSD (CANMAT 2014). Against India's wide trauma treatment gap and its benzodiazepine over-prescription problem, the IPS-aligned answer is trauma-focused psychotherapy first, then paroxetine, sertraline or venlafaxine, with prazosin (Minipress, Prazopress) reserved for nightmares, never alprazolam as maintenance.

HOLD THIS

PTSD needs a Criterion-A trauma followed, for more than one month (DSM-5) or at least several weeks (ICD-11), by the cluster pattern: DSM-5 has FOUR clusters (intrusion 1/5, avoidance 1/2, negative cognitions and mood 2/7, arousal and reactivity 2/6) while ICD-11 has THREE (re-experiencing in the here and now, deliberate avoidance, a persistent sense of current threat); the pathognomonic feature is re-experiencing *in the present* not mere recall; specifiers are the dissociative subtype (depersonalisation/derealisation, ~14.4%) and delayed expression (full criteria first met at least 6 months on); lifetime prevalence is 6.8% (women ~2 to 3x men); and the PCL-5 is a 20-item, 0 to 80 self-report screen with a probable-PTSD provisional cut of 31 to 33, never a substitute for the CAPS-5/SCID interview.

22 · The evidence-based treatment of PTSD

The **evidence-based treatment of ptsd** is one of the cleanest algorithms in the anxiety and trauma syllabus, and examiners reward the candidate who states its two hard rules in the first sentence: *trauma-focused psychotherapy is first-line, and a benzodiazepine is never used*. Everything else, the choice of SSRI, the role of venlafaxine, prazosin for nightmares, antipsychotic augmentation for the refractory case, hangs off that spine. This is a management topic, so the marks are in the lines of treatment, the licensed agents, the doses, the monitoring and the sequence, not in re-describing the clusters (those sit in the separate PTSD clinical-features note).

Why it matters clinically. Every major guideline converges: BAP (BAP 2014), NICE (NICE 2018), CANMAT (CANMAT 2014), the WFSBP (WFSBP 2022) and the United States VA/DoD (VA/DoD 2023) all place a manualised **trauma-focused psychotherapy** ahead of any drug, and reserve pharmacotherapy for the patient who declines, cannot access, or does not respond to that psychotherapy. The **first-line ptsd** drugs are a tight list, sertraline and paroxetine (both licensed for PTSD), and venlafaxine, with **prazosin** added specifically for trauma-related nightmares. The deep antidepressant pharmacology of these agents, their doses, adverse effects and interactions, is developed in the Mood disorders: pharmacotherapy notes, and the general exposure/CBT model in the Psychotherapies, clinical assessment, MSE and nosology notes; this note assembles them into the PTSD algorithm and keeps to what the guidelines actually say.

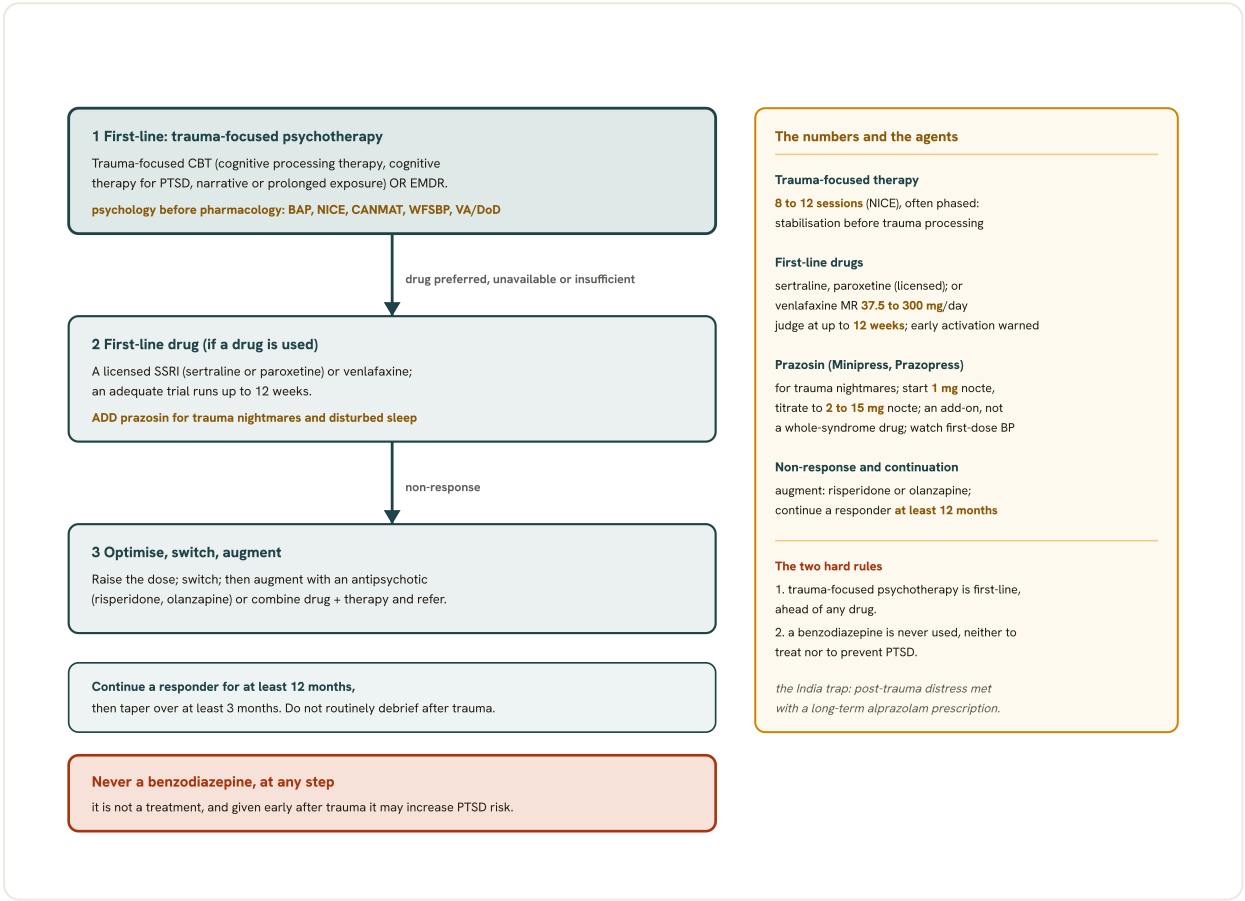

Fig 14.16 The PTSD treatment algorithm. Its two hard rules open every answer: trauma-focused psychotherapy is first-line, and a benzodiazepine is never used. First-line is a manualised trauma-focused therapy, trauma-focused CBT or EMDR over 8 to 12 sessions, placed ahead of any drug by BAP, NICE, CANMAT, WFSBP and VA/DoD. Where a drug is used because the patient prefers it or therapy is unavailable or insufficient, the first-line agents are a licensed SSRI (sertraline or paroxetine) or venlafaxine (37.5 to 300 mg modified release), trialled up to 12 weeks, with prazosin (Minipress or Prazopress) added at 1 mg nocte and titrated to 2 to 15 mg for trauma nightmares. The non-responder has the dose raised, then a switch, then antipsychotic augmentation (risperidone, olanzapine) or a drug-plus-therapy combination with referral, and a responder continues for at least twelve months. The benzodiazepine is excluded throughout, a rule that collides directly with the Indian habit of meeting post-trauma distress with long-term alprazolam.

22.1 The governing principle: trauma-focused psychotherapy is first-line

Psychology before pharmacology. The single most examinable statement in PTSD management is that a trauma-focused psychological therapy, not a drug, is the first-line treatment. BAP instructs the clinician to "choose an evidence-based acute psychological treatment for chronic

PTSD: trauma-focused individual CBT or EMDR" (strength A) (BAP 2014). NICE goes further and makes it a *strong* recommendation to offer individual **trauma-focused cbt** or **emdr** in preference to drug treatment (NICE 2018), and the VA/DoD guideline states the point most explicitly of all: "recommend specific manualized trauma-focused psychotherapies over pharmacotherapy as first-line treatment for PTSD" (strong recommendation) (VA/DoD 2023). Drug treatment is offered where psychotherapy is declined, unavailable, or insufficient, not as an equal first option.

What "trauma-focused" means. The therapies that carry this recommendation are the ones that process the traumatic memory directly, cognitive processing therapy, cognitive therapy for PTSD, narrative exposure therapy and prolonged exposure therapy (the **tf-cbt** family), and eye movement desensitisation and reprocessing (**emdr**) (NICE 2018; VA/DoD 2023). Generic supportive counselling or non-trauma-focused CBT does not qualify. The WFSBP names CBT as "the psychotherapy with the best evidence for PTSD" (WFSBP 2022), and WHO mhGAP, the guideline that matters most for low-resource Indian settings, likewise puts individual or group trauma-focused CBT or EMDR first for adults and for children and adolescents (WHO mhGAP 2023).

RULE **Trauma-focused therapy first.** In PTSD the first-line treatment is a manualised trauma-focused psychotherapy, trauma-focused CBT (cognitive processing therapy, cognitive therapy for PTSD, narrative exposure, prolonged exposure) or EMDR; pharmacotherapy is second, offered only when psychotherapy is declined, unavailable or insufficient.

GOOD TO REMEMBER

- **Trauma-focused CBT / TF-CBT (the psychotherapy):** the mechanism is deliberate processing of the traumatic memory (cognitive processing, cognitive therapy for PTSD, narrative exposure, prolonged exposure) so the event is refiled as past rather than relived as present; it is FIRST-LINE for PTSD (offered before drugs), typically delivered over 8 to 12 sessions, more where there are multiple traumas, comorbid depression or dissociation (NICE 2018).
- **EMDR / eye movement desensitisation and reprocessing (the psychotherapy):** structured recall of the trauma paired with bilateral (eye-movement) stimulation to reprocess the memory; it is a first-line trauma-focused therapy alongside TF-CBT, and NICE offers it for PTSD presenting more than three months after a non-combat trauma over 8 to 12 sessions (NICE 2018; CANMAT 2014).

22.2 When to reach for drugs, and the two licensed SSRIs

The indication for pharmacotherapy. A drug is offered when the patient has a preference for medication over therapy, when a trauma-focused psychotherapy is not available or not acceptable, or when psychotherapy alone has been insufficient (NICE 2018; BAP 2014). NICE frames it precisely: "consider venlafaxine or an SSRI such as sertraline for adults with a diagnosis of PTSD if the person has a preference for drug treatment" (NICE 2018). Note the strength, this is a *weak* ("consider") recommendation, whereas the trauma-focused therapy is a *strong* ("offer") one.

The ssri ptsd answer. Of the SSRIs, two are licensed specifically for PTSD and are the drugs to name: sertraline and paroxetine. BAP identifies "paroxetine, sertraline or venlafaxine" as the first-

line pharmacological choice for chronic PTSD (strength A) (BAP 2014); CANMAT lists fluoxetine, paroxetine, sertraline and venlafaxine XR as first-line pharmacotherapy for core PTSD symptoms (CANMAT 2014); and VA/DoD, when a drug is used, offers "paroxetine, sertraline or venlafaxine" (strong) (VA/DoD 2023). The Maudsley concurs, an SSRI (paroxetine, sertraline or fluoxetine preferred) up to the maximum licensed dose is first-line drug treatment, and it repeats the rider that psychological approaches should be used before drugs (Maudsley 2021). The generic is primary in the note; the shared antidepressant brand list (fluoxetine, sertraline, fluvoxamine, paroxetine, escitalopram) is developed in the Mood disorders: pharmacotherapy notes.

WORKED EXAMPLE

A 40-year-old lorry driver, six months after a fatal highway collision, has nightly nightmares, cannot drive past the accident stretch and is hypervigilant and irritable. He declines "talking therapy" and asks for tablets. The evidence-based response is not a benzodiazepine and not reassurance. It is to explain that a trauma-focused psychotherapy would be the first choice, but that since he prefers medication, sertraline (starting low, titrating to the maximum tolerated licensed dose over several weeks) or paroxetine is appropriate; because trauma nightmares are prominent, prazosin can be added at night; and he is warned that a therapeutic effect may take up to 12 weeks to assess.

22.3 Venlafaxine: the SNRI first-line alternative

Equal footing with the SSRIs. The SNRI venlafaxine sits alongside the two licensed SSRIs as a first-line pharmacological option. BAP names it in the same breath as paroxetine and sertraline, noting that on meta-analysis "only paroxetine, sertraline and venlafaxine were superior to placebo" (strength A) (BAP 2014); the WFSBP recommends "SSRIs or the SNRI venlafaxine as first-line pharmacological treatment for PTSD" (WFSBP 2022); and NICE lists venlafaxine as the drug alternative to an SSRI (NICE 2018). On non-response to an SSRI, BAP's first step is to raise the dose (venlafaxine has post-hoc efficacy across trauma types), and only then to switch to another evidence-based treatment (BAP 2014).

The dose to carry. The Maudsley gives venlafaxine modified release **37.5 to 300 mg** daily for PTSD, recommended by NICE (Maudsley 2021). As with all these agents, an adequate trial is needed before declaring failure, guidelines advise that up to **12 weeks** may be required to assess pharmacological efficacy in PTSD (BAP 2014).

GOOD TO REMEMBER

- **Sertraline / paroxetine (SSRI, PTSD):** the two SSRIs licensed for PTSD and the first-line drug answer once psychotherapy is set aside; mechanism is serotonin re-uptake inhibition, the signature caution is that a full trial takes up to 12 weeks and early SSRI activation can transiently worsen symptoms, and continuation after response is for at least 12 months (BAP 2014; NICE 2018).
- **Venlafaxine (SNRI, PTSD):** the first-line SNRI alternative to the SSRIs, dosed as modified release 37.5 to 300 mg/day; the mechanism is dual serotonin-noradrenaline re-uptake inhibition, the caution is dose-related blood-pressure rise so monitor BP at higher doses, and on SSRI non-response raising the dose or switching to venlafaxine is the BAP-endorsed next step (BAP 2014; Maudsley 2021).

22.4 Prazosin: the targeted add-on for trauma nightmares

What it treats and how. Prazosin (Minipress, also marketed in India as Prazopress and Minipress XL) is a selective alpha-1 adrenergic blocker used *specifically* for trauma-related nightmares and sleep disturbance in PTSD, not for the disorder as a whole. It reduces central noradrenergic tone, damping the sympathetic surge that drives nightmares and the hyperaroused sleep of PTSD. CANMAT states it plainly: "for PTSD-associated trauma nightmares and poor sleep quality, use prazosin" (CANMAT 2014), and BAP notes that "prazosin augmentation reduces nightmares and other PTSD symptoms" (strength A) (BAP 2014). It is an *add-on* to a first-line SSRI or SNRI (or to psychotherapy), targeting one symptom cluster.

The dose and the caution. The Maudsley dose is **2 to 15 mg nocte**: initiate at 1 mg at night and titrate the dose gradually to reduce the risk of first-dose hypotension (Maudsley 2021). Because it is an antihypertensive, blood pressure and dizziness must be monitored (BAP 2014). Lead the drug with the Indian brand: prazosin is *Minipress* (and Prazopress) in Indian practice.

TRAP **Prazosin is not a PTSD cure-all.** Prazosin treats trauma nightmares and disturbed sleep, one symptom domain, and is an add-on, not a first-line agent for the whole disorder; do not offer it as monotherapy for core PTSD in place of a trauma-focused psychotherapy or a licensed SSRI/SNRI, and always start at 1 mg nocte to avoid first-dose hypotension.

GOOD TO REMEMBER

- **Prazosin (Minipress / Prazopress, alpha-1 blocker):** the targeted add-on for PTSD trauma nightmares and sleep disturbance; mechanism is alpha-1 adrenergic blockade lowering central noradrenergic tone, the signature caution is first-dose hypotension so start at 1 mg nocte and titrate to 2 to 15 mg nocte, and it augments (never replaces) first-line psychotherapy or an SSRI/SNRI (CANMAT 2014; Maudsley 2021).

22.5 The hard rule: no benzodiazepine in PTSD

Not a treatment, and possibly harmful. The most heavily tested negative rule in the whole topic is that a benzodiazepine is *not* used for PTSD, neither as treatment nor as prophylaxis. The VA/DoD makes it a strong recommendation "against the use of benzodiazepines for the treatment of PTSD" (VA/DoD 2023). CANMAT is equally firm and adds the mechanism of harm: "do not use benzodiazepines early after trauma to prevent PTSD; early benzodiazepine use may *increase* PTSD risk" (CANMAT 2014). NICE states that no drug treatment, "including

benzodiazepines", should be offered to prevent PTSD (NICE 2018), and BAP's do-not-use list for PTSD includes alprazolam (with citalopram, tiagabine and divalproex), which were not efficacious in placebo-controlled trials (BAP 2014).

Why the error is so common. Benzodiazepines touch none of the PTSD symptom clusters, they do not process the traumatic memory, do not reduce re-experiencing or avoidance, and blunt the emotional engagement that trauma-focused therapy depends on. Their apparent early calming effect is what makes the trap seductive, and their risk of dependence in a chronically distressed, often substance-comorbid population makes the error costly.

INDIA

This rule collides directly with Indian prescribing reality. Against a very wide anxiety/OCD/PTSD treatment gap, post-trauma distress is routinely met with a long-term benzodiazepine (typically alprazolam), the benzodiazepine over-prescription problem in Indian practice in one line. The guideline-anchored, IPS-aligned answer is the opposite: trauma-focused psychotherapy first, then sertraline, paroxetine or venlafaxine, with prazosin (Minipress, Prazopress) for nightmares, and no benzodiazepine, which is not merely ineffective but may raise the risk of PTSD when given acutely after trauma (CANMAT 2014). WHO mhGAP, designed for exactly these low-resource settings, keeps trauma-focused CBT or EMDR first (WHO mhGAP 2023).

22.6 The guideline-by-guideline algorithm

Convergence across five guidelines. The value of holding the guidelines side by side is that their agreement is the exam answer. Leading with BAP and NICE: first-line is trauma-focused psychotherapy (TF-CBT or EMDR); first-line drug, where a drug is used, is a licensed SSRI (sertraline or paroxetine) or venlafaxine; prazosin is added for nightmares; and the benzodiazepine is excluded. CANMAT, the WFSBP and VA/DoD add nothing that contradicts this and reinforce every element. The table alongside sets out the primary recommendations verbatim in structure so the concordance is visible.

GUIDELINE (YEAR)	FIRST-LINE TREATMENT	FIRST-LINE DRUG (IF USED)	KEY ADD-ON / NOT-USED
BAP (2014)	Trauma-focused individual CBT or EMDR (strength A)	**Paroxetine, sertraline or venlafaxine (strength A)**	Prazosin for nightmares; do NOT use alprazolam, citalopram
NICE (2018)	Individual trauma-focused CBT or EMDR (strong "offer")	**Venlafaxine or an SSRI such as sertraline (weak "consider")**	Risperidone add-on if refractory; do NOT offer benzodiazepines, even to prevent PTSD
CANMAT (2014)	Individual trauma-focused CBT or EMDR (first-line)	**Fluoxetine, paroxetine, sertraline or venlafaxine XR (first-line)**	Prazosin for nightmares/sleep; do NOT use benzodiazepines (may increase risk)

GUIDELINE (YEAR)	FIRST-LINE TREATMENT	FIRST-LINE DRUG (IF USED)	KEY ADD-ON / NOT-USED
WFSBP (2022)	CBT (best-evidenced psychotherapy)	**SSRIs or the SNRI venlafaxine (first-line)**	Antipsychotic augmentation of an SSRI if unresponsive
VA/DoD (2023)	Manualised trauma-focused psychotherapy over pharmacotherapy (strong); PE / CPT / EMDR	**Paroxetine, sertraline or venlafaxine (strong)**	Recommend AGAINST benzodiazepines and against cannabis

The evidence-based PTSD treatment algorithm across five guidelines: trauma-focused psychotherapy first everywhere, a licensed SSRI (sertraline/paroxetine) or venlafaxine as the first-line drug, prazosin added for nightmares, and the benzodiazepine excluded (recommendations verified against BAP 2014, NICE 2018, CANMAT 2014, WFSBP 2022 and VA/DoD 2023). The complete stepped algorithm is drawn in the accompanying figure.

22.7 The non-responder: augmentation and second-line agents

Optimise, then switch, then augment. When a first-line drug fails at an adequately tolerated dose, the BAP sequence is: first raise the dose, then switch to another evidence-based treatment (pharmacological or psychological), and only then, for the treatment-refractory case after dose optimisation and switching, combine an evidence-based drug with a trauma-focused psychotherapy and refer to specialist services (BAP 2014). The Maudsley second-line list (no fixed order, weaker evidence) is mirtazapine, phenelzine, amitriptyline, and the antipsychotics (Maudsley 2021).

Antipsychotic augmentation. For the disabling, unresponsive case, NICE says to "consider an antipsychotic such as risperidone in addition to psychological therapy" where symptoms have not responded and there is severe hyperarousal or psychotic symptoms (NICE 2018); the WFSBP endorses augmenting an SSRI with an antipsychotic for treatment-unresponsive PTSD (WFSBP 2022); and BAP notes RCT efficacy for risperidone and olanzapine as alternatives, with olanzapine or risperidone (or prazosin) as antidepressant-augmentation options in refractory PTSD (BAP 2014). Antipsychotics tend to help the intrusion symptoms (flashbacks, nightmares) more than avoidance or hyperarousal (Maudsley 2021).

PEARL

State the ladder as a single ordered line and you own the management viva: trauma-focused psychotherapy (TF-CBT or EMDR) first; if a drug is used, a licensed SSRI (sertraline, paroxetine) or venlafaxine, given an adequate trial of up to 12 weeks; add prazosin for nightmares; on non-response raise the dose, then switch, then augment with an antipsychotic (risperidone, olanzapine) or combine drug plus psychotherapy and refer; continue a responding drug for at least 12 months; and never a benzodiazepine at any step.

22.8 Prevention, early intervention and continuation

Do not debrief. A classic negative point: routine single-session or multiple-session psychological debriefing is *not* recommended to prevent PTSD after trauma, it does not help and may harm (BAP 2014; NICE 2018). For subthreshold symptoms within a month of the trauma, NICE advises active monitoring with follow-up within a month rather than immediate treatment (NICE

2018). Where preventive action is warranted after major trauma, BAP notes that propranolol (Ciplar, Inderal in India) or sertraline, or trauma-focused CBT, may be considered to reduce the emergence of post-traumatic symptoms (BAP 2014).

How long to continue. A drug that produces a response should be continued for at least **12 months** using a relapse-prevention approach (BAP 2014), with fluoxetine and sertraline having RCT evidence for longer-term relapse prevention. When stopping, taper gradually over an extended period (BAP suggests a minimum three-month taper) to avoid discontinuation and rebound symptoms (BAP 2014).

12 weeks	12 months	1 to 15	8 to 12
TIME UP TO WHICH A PTSD DRUG TRIAL MAY BE NEEDED TO ASSESS EFFICACY (BAP)	MINIMUM CONTINUATION OF A RESPONDING DRUG	PRAZOSIN NOCTE RANGE, MG (START 1, TITRATE)	SESSIONS OF TRAUMA-FOCUSED CBT OR EMDR (NICE)

22.9 The India device and the treatment gap

Where the algorithm meets Indian practice. Trauma is common in India (road-traffic and industrial accidents, interpersonal and domestic violence, disasters), yet PTSD is under-recognised, frequently somatised, and reaches formal care late. Trauma-focused psychotherapy, the first-line treatment everywhere, is scarce outside tertiary centres, which is precisely why the WHO mhGAP framing matters: it keeps trauma-focused CBT or EMDR first even in low-resource settings (WHO mhGAP 2023). The Indian Psychiatric Society clinical practice guidelines for the anxiety and stress-related disorders align with the international consensus, an SSRI as the first-line pharmacotherapy and a structured psychotherapy as the first-line psychological treatment, and the benzodiazepine reserved out of the PTSD pathway. Indian brands of the anchor drugs are named where they arise: prazosin as Minipress or Prazopress, propranolol as Ciplar or Inderal, with the shared SSRI antidepressant brand list carried in the Mood disorders: pharmacotherapy notes.

TRAP **Under-dosing and stopping too early.** A PTSD SSRI/SNRI trial must run to an adequate dose for long enough, up to 12 weeks may be needed before judging efficacy; abandoning the trial at three or four weeks, or never titrating past a token starting dose, manufactures a false "treatment failure" and pushes the prescriber toward the wrong answer (a benzodiazepine).

HOLD THIS

The evidence-based treatment of PTSD, in one line: trauma-focused psychotherapy FIRST (trauma-focused CBT, that is cognitive processing therapy / cognitive therapy for PTSD / narrative exposure / prolonged exposure, or EMDR), across BAP, NICE, CANMAT, WFSBP and VA/DoD; where a drug is used, a licensed SSRI (sertraline or paroxetine) or venlafaxine, trialled up to 12 weeks and continued at least 12 months if it responds; prazosin (Minipress/Prazopress) 1 mg nocte titrated to 2 to 15 mg for trauma nightmares; antipsychotic augmentation (risperidone, olanzapine) for the refractory case; and NEVER a benzodiazepine, which is not a treatment and may increase PTSD risk if given early after trauma.

23 · Complex PTSD

Complex PTSD is the diagnosis ICD-11 created for the survivor of trauma that was not a single event but a captivity: prolonged, repeated, inescapable harm, most damagingly in childhood. On top of the ordinary post-traumatic triad it adds a deeper wound, to the way the person regulates emotion, holds themselves in their own mind, and relates to other people. The examiner's target here is almost never the whole criterion list; it is one discrimination done cleanly. cptsd is the disorder most often mislabelled as a personality disorder, above all emotionally unstable (borderline) personality disorder, and the person who can hold the **distinction from personality disorder** in a viva is the person who will not forfeit a trauma survivor's access to trauma-focused treatment.

Fig 14.17 ICD-11 complex PTSD contains the core PTSD triad, re-experiencing, avoidance and persistent current threat, plus affect dysregulation, negative self-concept and relational disturbance.

Why it matters clinically. **icd-11 complex** PTSD (6B41) is a *new* category, absent from DSM-5, built on Judith Herman's 1992 description of a syndrome in survivors of prolonged and repeated trauma. Its architecture is deliberately simple to state: the three core elements of PTSD *plus* three

disturbances in self-organisation (often abbreviated DSO), namely **affect dysregulation**, a persistent negative self-concept, and interpersonal difficulties. Two facts anchor every answer. First, you cannot have complex PTSD without first meeting PTSD; the DSO clusters sit on top of, never instead of, re-experiencing, avoidance and a sense of current threat. Second, the differential that examiners want is not PTSD versus complex PTSD (that is a severity-and-breadth step) but complex PTSD versus a personality disorder, because that is where real patients are misrouted. The core PTSD phenomenology is developed in the PTSD notes; the amygdala and fear-circuit substrate in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; the general exposure principle in the Psychotherapies, clinical assessment, MSE and nosology notes; the reactive attachment and disinhibited engagement disorders that can co-occur in maltreated under-5s in the Child behavioural, emotional and other disorders notes and the Child psychiatry: assessment, treatment, services and protection notes.

Shared: affective dysregulation
the emotional instability both show, which is exactly why complex PTSD gets mislabelled as a personality disorder

The four splits read each row across	Complex PTSD ICD-11 6B41	Borderline personality disorder the emotionally unstable pattern
Trauma avoidance and current threat the deciding line	**Core diagnostic features** the trauma fingerprint: present by definition	**Not diagnostic features** not part of the personality-disorder picture
Sense of self	**Stable but negative** a settled, chronically low self-view	**Unstable identity** an oscillating, disturbed sense of self
Relationships	**Avoidance, disconnection** pulls away, keeps others at a distance	**Fear of abandonment** frantic push-pull, clings and lashes
Suicidality	**Less frequent, less impulsive** but of higher lethality	**Frequent and impulsive** recurrent self-harm and attempts

Both share affective dysregulation (top). The shaded row is the deciding one: the trauma fingerprint is present in complex PTSD and absent in the personality disorder.

Fig 14.18 Complex PTSD against borderline personality disorder. The two share their most visible symptom, affective dysregulation (the banner), which is exactly why a trauma survivor is so often mislabelled as borderline and the trauma missed. ICD-11 gives four lines that separate them. The deciding one, shaded, is the trauma fingerprint: trauma-reminder avoidance and a persistent sense of current threat are core to complex PTSD and are not diagnostic features of a personality disorder. Beneath it, the self-view is stable but negative in complex PTSD versus an unstable identity in the personality disorder; relationships are marked by avoidance and disconnection versus a fear of abandonment and push-pull instability; and suicidality is less frequent and less impulsive but of higher lethality, against the frequent, impulsive self-harm of the borderline pattern. Getting the label right unlocks trauma-focused treatment.

23.1 The definition: PTSD core plus three disturbances in self-organisation

The whole diagnosis in one sentence. Following the traumatic exposure, the person develops, for *at least several weeks*, all three core elements of PTSD *and* all three disturbances in self-organisation, with significant functional impairment (ICD-11 CDDR 6B41). The complex PTSD label is earned only when both halves are present; meet the PTSD triad alone and the diagnosis is PTSD (6B40), not complex PTSD.

The two halves. The *PTSD half* is the familiar triad: re-experiencing the event in the here and now (not mere recall), deliberate avoidance of reminders, and persistent perceptions of heightened current threat. The *self-organisation half* is the added signature of chronic entrapment: **affect dysregulation**, a persistent negative self-concept, and persistent difficulties in relationships. A single verbal-recall handle for the three DSO clusters is that the person cannot regulate feeling, cannot hold a workable view of the self, and cannot sustain closeness to others.

MNEMONIC

PTSD + A S R

Complex PTSD = the PTSD triad PLUS three disturbances in self-organisation. **A** = **A**ffect dysregulation (heightened reactivity, outbursts, reckless or self-destructive behaviour, dissociation under stress, emotional numbing). **S** = negative **S**elf-concept (persistent beliefs of being diminished, defeated or worthless, with pervasive shame, guilt or failure). **R** = **R**elationship difficulties (persistent trouble feeling close to or sustaining relationships with others). All three DSO clusters, on top of all three PTSD clusters.

23.2 The traumatic exposure: prolonged, repeated, inescapable

The typical stressor. Complex PTSD is generally a function of trauma that is *chronic, repeated and difficult or impossible to escape*, continuing over months or years: childhood physical, sexual or emotional abuse and severe neglect, domestic violence, torture, being trafficked, prolonged captivity or being a child soldier (ICD-11 CDDR; Herman 1992; Kaplan & Sadock CTP 2024). Exposure in early development carries a greater risk of complex PTSD (rather than PTSD) than does adult-onset trauma. Kaplan & Sadock frame simple PTSD as arising from a single or circumscribed event and complex PTSD from prolonged, inescapable stress, particularly in early childhood, complex precisely because of its extensive impact on all areas of development and functioning.

The threshold caution. Exposure to an extreme, prolonged or repetitive stressor from which escape is difficult does *not* in itself indicate complex PTSD; many people endure such stressors without developing any disorder (ICD-11 CDDR, boundary with normality). The presentation must meet all the diagnostic requirements. The stressor is the setting, not the diagnosis.

RULE **Two halves, both required.** Complex PTSD = the full PTSD triad PLUS all three disturbances in self-organisation (affect dysregulation, negative self-concept, interpersonal difficulty); no PTSD core, no complex PTSD, and DSO clusters without the PTSD triad point elsewhere.

23.3 Disturbance one: affect dysregulation

What it looks like. The presentation is characterised by severe and pervasive problems in **affect dysregulation** (ICD-11 CDDR). This runs in both directions on the arousal dial: *hyper*-regulation failure, showing as heightened emotional reactivity to minor stressors, violent outbursts, and reckless or self-destructive behaviour; and *hypo*-regulation, showing as emotional numbing, an inability to feel pleasure or positive emotion, and dissociative symptoms when under stress. A

telling ICD-11 detail is that, unlike in PTSD, the startle reaction in complex PTSD may be *diminished* rather than enhanced, the system shuts down rather than fires.

Where affect dysregulation misleads. This is the cluster that most resembles the affective instability of borderline personality disorder, and the overlap is genuine: affective dysregulation is a feature of both (ICD-11 CDDR). It is therefore the single cluster you must *not* read in isolation, because it is the shared ground on which the misdiagnosis is built. The discrimination lives in the accompanying figure, the complex-PTSD discriminator grid, and is unpacked in 23.6.

23.4 Disturbance two: a persistent negative self-concept

What it looks like. There are persistent beliefs about oneself as *diminished, defeated or worthless*, accompanied by deep and pervasive feelings of shame, guilt or failure related to the stressor (ICD-11 CDDR). The survivor of prolonged abuse may feel guilty for not having escaped, for having succumbed, or for not having prevented the suffering of others. The key adjective is *persistent*: this is a settled, stable, chronically low self-view, not a mood that swings across an afternoon.

The discriminating quality. Contrast this with the *unstable* sense of self of borderline personality disorder, where identity itself oscillates. In complex PTSD the self-view is bad but *steady*; in borderline PD it is bad and *unstable*. Stability of a negative self-concept is one of the cleanest single discriminators from a personality disorder (ICD-11 CDDR, boundary with personality disorder), and worth saying in exactly those words.

23.5 Disturbance three: interpersonal difficulties

What it looks like. There are persistent difficulties in sustaining relationships and in feeling close to others (ICD-11 CDDR). The characteristic pattern is *withdrawal*: the person consistently avoids, derides, or has little interest in relationships and social engagement. Where relationships do form they may be occasionally intense but hard to sustain. The organising theme is disconnection and avoidance of closeness.

The discriminating quality. This is the interpersonal cluster's crucial split from borderline PD. In complex PTSD, relationships are dominated by *avoidance and a general sense of disconnection*; they are *less* likely to be driven by fear of abandonment and the frantic, unstable, push-pull attachment that defines the borderline pattern (ICD-11 CDDR). Complex PTSD pulls away; borderline PD clings and lashes. That contrast (disconnection versus abandonment-driven instability) is the second clean discriminator.

GOOD TO REMEMBER

- **Complex PTSD (the syndrome, ICD-11 6B41):** the defining requirement is the full PTSD triad (re-experiencing in the here and now, deliberate avoidance, persistent sense of current threat) PLUS all three disturbances in self-organisation, affect dysregulation, a persistent negative self-concept, and interpersonal difficulties, lasting at least several weeks after prolonged/repeated/inescapable trauma, with functional impairment; the discriminator from PTSD is the added DSO clusters, and the first step is to confirm the PTSD core is present before adding the complex label.

23.6 The critical distinction: complex PTSD versus personality disorder

Why the confusion is real. Many people with a personality disorder have a history of childhood trauma, and affective dysregulation is a feature of both complex PTSD and personality disorder, particularly the borderline pattern (ICD-11 CDDR). The two therefore share their most visible symptom, emotional instability, which is exactly why the borderline label gets reached for and the trauma gets missed. ICD-11 lists four specific ways the profiles diverge, and these are the examinable discriminators.

The four discriminators. First, *avoidance of trauma reminders and a heightened sense of current threat* are core to complex PTSD and are *not* diagnostic features of a personality disorder, they are the trauma-specific fingerprint. Second, the *self-view*: complex PTSD shows a stable but persistently negative self-view, whereas an *unstable* sense of self is more typical of personality disorder. Third, *relationships*: complex PTSD is marked by avoidance and disconnection, personality disorder (borderline) by fear of abandonment and relationship instability. Fourth, *suicidality*: in personality disorder it tends to be frequent and impulsive, whereas in complex PTSD it tends to be less frequent, less impulsive, and of *higher lethality* (ICD-11 CDDR).

FEATURE	COMPLEX PTSD (ICD-11 6B41)	PERSONALITY DISORDER, BORDERLINE PATTERN
Trauma-reminder avoidance and heightened current threat	**Core diagnostic features (the PTSD fingerprint)**	**Not diagnostic features**
Sense of self	**Stable but persistently negative self-view**	**Unstable sense of self / identity disturbance**
Relationships	Avoidance and general disconnection	Fear of abandonment, relationship instability (push-pull)
Suicidality	Less frequent, less impulsive, higher lethality	Frequent, often impulsive
Affective dysregulation	Present (shared feature)	Present (shared feature)
Origin required for diagnosis	Prolonged/repeated/inescapable trauma is typical, but the syndrome must be met	Enduring personality pattern; trauma frequent but not required

The complex-PTSD-versus-borderline-personality-disorder discriminator grid; affective dysregulation is the shared feature that drives the misdiagnosis, and the four rows above it (trauma avoidance/current threat, stable-negative versus unstable self, disconnection versus abandonment, lethality pattern) are the ICD-11 lines that separate them (verified against ICD-11 CDDR 6B41, boundary with personality disorder). The concept map is set out in the figure alongside.

TRAP **Complex PTSD mislabelled as a personality disorder.** A childhood-abuse survivor with affective instability, low self-worth and stormy relationships is reflexively called borderline; the trauma-reminder avoidance, the persistent sense of current threat, the *stable* negative self-view and the disconnection (not abandonment-driven) pattern are the ICD-11 lines that make it complex PTSD, and the label change unlocks trauma-focused treatment.

WORKED EXAMPLE

A 27-year-old woman with a documented history of chronic childhood sexual abuse presents with intrusive flashbacks of the abuse that feel as if it is happening now, avoidance of anything that reminds her of it, and constant hypervigilance. On top of this she has explosive anger at trivial provocations alternating with numb emptiness, a fixed conviction that she is worthless and to blame, and a pattern of keeping everyone at arm's length. A previous clinician had labelled her borderline personality disorder on the emotional instability alone. The re-experiencing, the trauma-specific avoidance, the persistent current threat, the *stable* (not oscillating) negative self-view and the *avoidant* (not abandonment-driven) relational style make this complex PTSD (ICD-11 6B41), not a personality disorder, and reframe the whole treatment plan around the trauma.

GOOD TO REMEMBER

- **Complex PTSD versus personality disorder (the discrimination):** both share affective dysregulation, but complex PTSD is marked by trauma-reminder avoidance and a persistent sense of current threat (absent in PD), a *stable* negative self-view (versus an unstable sense of self), relationships dominated by avoidance/disconnection (versus fear of abandonment), and suicidality that is less frequent, less impulsive but of higher lethality; the trauma fingerprint is the deciding feature.

23.7 Management: trauma-focused psychotherapy first, guideline-anchored

The management principle. As for PTSD, the first-line treatment for complex PTSD is *trauma-focused psychotherapy*, not a drug (NICE 2018; BAP 2014). NICE 2018 covers complex presentations explicitly and directs an *urgent referral for specialist trauma assessment* when PTSD presents with severe dissociation or complex-PTSD features (pervasive affect dysregulation, severely disturbed self-concept, profound interpersonal difficulties), or when first-line trauma-focused therapy has failed or worsened symptoms. The evidence-based psychological treatments are individual trauma-focused CBT (cognitive processing therapy, cognitive therapy for PTSD, narrative exposure therapy or prolonged exposure) and EMDR (eye-movement desensitisation and reprocessing), each delivered over about **8 to 12 sessions**, extended where there are multiple traumas, comorbid depression or significant dissociation (NICE 2018). Clinically, complex PTSD often needs a *phased* approach: stabilisation and affect-regulation skills before trauma processing, because a poorly timed exposure can destabilise a dysregulated survivor.

Where drugs sit. Pharmacotherapy is an adjunct, not the spine. Where a drug is used, the first-line agents are the same evidence-based antidepressants as in PTSD: sertraline, paroxetine or the SNRI venlafaxine (BAP 2014; NICE 2018; CANMAT 2014). Adequate response can take up to **12 weeks** to judge, and responders should continue for at least **12 months** (BAP 2014). For trauma nightmares and disturbed sleep, prazosin (Minipress, Prazopress) is the targeted agent, an alpha-1 antagonist added for the nightmare symptom, not a whole-syndrome treatment (CANMAT 2014; BAP 2014). Where disabling hyperarousal or psychotic-level symptoms resist first-line care, NICE allows adjunctive risperidone alongside psychological therapy. The detailed SSRI/SNRI pharmacology (doses, adverse effects, interactions) sits in the Mood disorders: pharmacotherapy notes and is not re-derived here.

GOOD TO REMEMBER

- **Trauma-focused psychotherapy (the first-line treatment):** the principle is that complex PTSD, like PTSD, is treated *psychologically first*, with trauma-focused CBT or EMDR (about 8 to 12 sessions, often phased with stabilisation before processing); the signature caution is that a drug is an adjunct, and NICE 2018 directs urgent specialist referral for complex-PTSD features or when first-line therapy has failed or worsened.
- **Prazosin (Minipress, Prazopress):** an alpha-1 adrenergic antagonist; the one indication to anchor is trauma-related *nightmares* and sleep disturbance, added on to a first-line antidepressant, with blood pressure and dizziness the signature cautions, never a stand-alone PTSD treatment.

23.8 The India device: the trauma treatment gap, benzodiazepines, and the IPS line

Where complex PTSD lands in Indian practice. India carries a very wide anxiety, OCD and PTSD treatment gap, and complex PTSD sits at its blindest point. The precipitating traumas, chronic childhood abuse and neglect, prolonged domestic and interpersonal violence, are precisely those that are under-reported, stigmatised and reach formal care late, and the presentation, emotional instability with self-loathing and stormy relationships, is the one most readily misfiled as a personality disorder or dismissed. Into that gap flows the benzodiazepine over-prescription problem: a long-term benzodiazepine (typically alprazolam) is handed to a distressed survivor, touching none of the six clusters and, given early after trauma, potentially *increasing* the risk of PTSD (CANMAT 2014). The Indian Psychiatric Society CPGs, aligned with NICE and BAP, put trauma-focused psychotherapy first, then an SSRI (sertraline, paroxetine) or venlafaxine, with prazosin (Minipress, Prazopress) reserved for nightmares; the benzodiazepine has no maintenance role. Indian brands of the anchor antidepressants (sertraline, paroxetine, escitalopram) are named in the Mood disorders: pharmacotherapy notes.

INDIA

The highest-yield Indian point is that complex PTSD is doubly failed in Indian practice: the chronic-abuse trauma is under-recognised, and the affective-instability presentation is misrouted to a personality-disorder label (or an alprazolam prescription) instead of trauma-focused care. Against India's wide trauma treatment gap and its benzodiazepine over-prescription problem, the IPS-aligned answer is to name the complex PTSD, treat it psychologically first (trauma-focused CBT or EMDR), add an SSRI or venlafaxine only as an adjunct, use prazosin for nightmares, and never a benzodiazepine as maintenance.

6B41	3 + 3	8 to 12	12 months
ICD-11 CODE FOR COMPLEX PTSD (PTSD IS 6B40)	PTSD CORE CLUSTERS PLUS DISTURBANCES IN SELF-ORGANISATION	TRAUMA-FOCUSED CBT / EMDR SESSION RANGE (NICE 2018)	MINIMUM CONTINUATION OF DRUG IN RESPONDERS (BAP 2014)

HOLD THIS

Complex PTSD (ICD-11 6B41, NOT in DSM-5) = the full PTSD triad (re-experiencing in the here and now, deliberate avoidance, persistent current threat) PLUS all three disturbances in self-organisation (affect dysregulation, a persistent negative self-concept, interpersonal difficulties), after prolonged/repeated/inescapable trauma; the critical discrimination is from borderline personality disorder, and although affective dysregulation is shared, complex PTSD is set apart by trauma-reminder avoidance and a persistent sense of current threat (absent in PD), a STABLE (not unstable) negative self-view, relationships driven by avoidance/disconnection (not fear of abandonment), and suicidality that is less impulsive but higher-lethality; treatment is trauma-focused psychotherapy FIRST (trauma-focused CBT or EMDR), with an SSRI or venlafaxine as adjunct and prazosin for nightmares, never a benzodiazepine.

24 · Acute stress reaction and acute stress disorder

These two labels sit in the hours-to-weeks window immediately after a terrifying event, and the whole examinable point is that they are *not* the same kind of thing. **Acute stress reaction** is the ICD-11's name for a **transient stress response**, a normal reaction to an exceptional stressor that the classification deliberately keeps *outside* the mental disorders; **acute stress disorder** is the DSM-5's *diagnosable* disorder in the first month after trauma. Getting the framing right, which is a disorder and which is not, which classification owns which, and how each relates to **ptsd**, is exactly what a viva examiner probes.

Why it matters clinically. Most people exposed to horror react and then recover; a minority stay ill. The early window is where clinicians must decide who is having an expectable acute stress reaction that needs support and time, and who is developing a disorder that needs treatment, without medicalising the first or missing the second. The trap that runs through the whole area is reflexively reaching for a benzodiazepine in the acute aftermath, which is not a treatment and may actually worsen the trajectory. The amygdala and fear-circuit anatomy that drives the acute autonomic storm is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; the full-blown syndrome and its clusters belong to the PTSD notes and are not re-derived here.

24.1 The core distinction: a reaction that is not a disorder versus a disorder

Two different objects. The single most tested fact is definitional. ICD-11 acute stress reaction (code **QE84**) is *not* considered a mental disorder: it is placed in Chapter 24, on factors influencing health status or contact with health services, precisely to signal that a transient response to an extreme stressor is normal (ICD-11 CDDR). It is only secondary-parented into the grouping of disorders specifically associated with stress to aid differential diagnosis. DSM-5-TR acute stress disorder (F43.0), by contrast, is a full trauma- and stressor-related *disorder* with operational criteria, a symptom threshold and a duration window (DSM-5-TR 2022; Kaplan & Sadock CTP 2024).

The consequence for the two systems. ICD-11 therefore has *no* "acute stress disorder" among its disorders: its stress grouping runs PTSD, complex PTSD, prolonged grief disorder and adjustment disorder, with acute stress reaction sitting outside as a non-disorder (ICD-11 CDDR).

DSM-5 *does* carry acute stress disorder as a diagnosis. So the same distressed trauma survivor in the first weeks may be given an ICD-11 "acute stress reaction" (a health-status factor, no disorder) or a DSM-5 "acute stress disorder" (a diagnosis), depending entirely on which manual is used.

RULE **Reaction is normal; disorder is diagnosable.** ICD-11 acute stress reaction is a transient normal response classified *outside* the mental disorders (Chapter 24, QE84); DSM-5 acute stress disorder is a diagnosable disorder in the first month. If the manual is ICD-11 there is no "acute stress disorder" to give.

24.2 Acute stress reaction: what it is and its time frame

The ICD-11 description. Acute stress reaction is the development of transient emotional, somatic, cognitive or behavioural symptoms after exposure to an event or situation, short- or long-lasting, of an *extremely threatening or horrific* nature (natural or human-made disasters, combat, serious accidents, sexual violence, assault) (ICD-11 CDDR). The picture is mixed and shifting: autonomic signs of anxiety (tachycardia, sweating, flushing), being in a daze, confusion, sadness, anxiety, anger, despair, over-activity, inactivity, social withdrawal, or at the extreme a stupor. Crucially, "the response to the stressor is considered to be normal given the severity of the stressor, and usually begins to subside within a few days after the event or following removal from the threatening situation".

The classic ICD-10 timings to carry. The older ICD-10 acute stress reaction, still the version most exam stems use, sets sharp temporal anchors: symptoms appear *within minutes* of the exceptional stressor and resolve rapidly, typically within a few hours once the stressor is removed, and within **1 to 3 days** even if it is not, so that a transient reaction lasts considerably less than **48 hours** (Companion to Psychiatric Studies; ICD-10). It is more likely to develop, and to be more severe, in the presence of physical exhaustion or at the extremes of age. The point that unifies both editions is transience: this is a storm that passes.

WORKED EXAMPLE

A previously well 40-year-old man is pulled from a collapsed scaffold at a construction site. For the next couple of hours he is dazed and disoriented, cannot recall parts of the rescue, is tremulous, tachycardic and sweating, alternates between agitation and withdrawal, and briefly cannot take in what is said to him. By the evening, moved to a quiet ward and reassured, he is oriented, calmer and communicative, and by the following morning he is largely settled. This is an *acute stress reaction*, a transient stress response that subsided once he was removed from the threat, not a disorder; the correct management was safety, orientation and support, not a benzodiazepine drip.

GOOD TO REMEMBER

- **Acute stress reaction (the syndrome):** the defining criterion is a transient, mixed, rapidly shifting emotional/autonomic/dissociative reaction beginning within minutes of an *exceptional* stressor and resolving fast (within hours to 1 to 3 days, typically under 48 hours); the discriminator is that it is judged *normal given the severity of the stressor* and is classified *outside* the mental disorders in ICD-11 (QE84, Chapter 24), so the first step is support and safety, not diagnosis or a drug.

24.3 Acute stress disorder: the DSM-5-TR criteria and the 9-of-14 rule

The gateway and the threshold. DSM-5-TR acute stress disorder requires the same Criterion A traumatic stressor as PTSD (exposure to actual or threatened death, serious injury or sexual violence, experienced, witnessed, learned of, or through repeated occupational exposure to aversive details), and then a symptom threshold that is distinctive: the presence of **nine (or more) of 14** symptoms drawn from *any* of five categories, all beginning or worsening after the trauma (DSM-5-TR 2022). The five categories are *intrusion*, *negative mood*, *dissociation*, *avoidance* and *arousal*. Because the nine can come from any mix of the five, the symptom profile of two people with the same diagnosis can look very different.

The 14 symptoms, by category. Intrusion (four): intrusive distressing memories, distressing dreams, dissociative flashback reactions, and intense/prolonged distress or marked physiological reactivity to reminders. Negative mood (one): a persistent inability to experience positive emotions. Dissociation (two): an altered sense of reality of self or surroundings (derealisation/depersonalisation), and inability to remember an important aspect of the event (dissociative amnesia). Avoidance (two): effortful avoidance of internal reminders (memories, thoughts, feelings) and of external reminders. Arousal (five): sleep disturbance, irritability or angry outbursts, hypervigilance, concentration problems, and exaggerated startle (DSM-5-TR 2022).

> **COMMON TRAP**
>
> Assuming acute stress disorder still *requires* dissociation. DSM-IV demanded a set number of dissociative symptoms, so ASD was historically taught as "the dissociative early trauma reaction". DSM-5 deliberately dropped that requirement: dissociation is now just *one of five* symptom categories, and the nine symptoms can be reached with none from the dissociation category at all (DSM-5-TR 2022; Kaplan & Sadock CTP 2024). Marking a survivor as "not ASD because they did not dissociate" is a DSM-IV-era error.

24.4 The time frames that separate acute stress disorder from PTSD

The window is the whole point. Acute stress disorder is a diagnosis of the *first month*. DSM-5-TR fixes the duration of the disturbance at **3 days to 1 month** after trauma exposure: symptoms typically begin immediately, but persistence for at least three days is needed before the label applies, and the diagnosis cannot outlive the first month (DSM-5-TR 2022). This is the mirror image of PTSD, whose duration criterion is *more than* one month. The two are, by construction, temporally exclusive: before the third day, neither applies; from three days to a month it is ASD; beyond a month it is PTSD.

The floor and the ceiling. The *floor* of three days exists so that the transient acute stress *reaction* of the first hours and days is not over-diagnosed as a disorder. The *ceiling* of one month exists because at that point the diagnostic question changes: if the full syndrome is still present after a month, the correct label is PTSD, and ASD is retired. A patient who is symptomatic at five weeks does not "still have ASD"; they have crossed into PTSD (or another diagnosis) (DSM-5-TR 2022; Tasman Psychiatry).

FEATURE	ACUTE STRESS REACTION (ICD-11 QE84)	ACUTE STRESS DISORDER (DSM-5-TR F43.0)	PTSD
Status	**Not a mental disorder (Chapter 24, factors influencing health)**	**A diagnosable disorder**	A diagnosable disorder
Owning system	ICD-11 (also ICD-10 F43.0)	DSM-5 (no ASD exists in ICD-11)	Both DSM-5 and ICD-11
Onset	Within minutes of the stressor	May begin immediately; label needs at least 3 days	Any time; delayed expression if first met after 6 months
Duration	Hours to 1 to 3 days (typically under 48 hours)	3 days to 1 month	More than 1 month
Symptom rule	Transient, mixed, shifting; no operational count	9 or more of 14 across 5 categories	DSM-5 four clusters (or ICD-11 three)
Framing	Normal response given stressor severity	Early diagnosable syndrome; imperfect predictor of PTSD	Established disorder of persistent re-experiencing

The three labels placed on one timeline from the exceptional event outward; the load-bearing points are that ICD-11 acute stress reaction is a non-disorder, DSM-5 acute stress disorder occupies the 3-day-to-1-month window with a 9-of-14 rule, and PTSD takes over beyond a month (verified against ICD-11 CDDR, DSM-5-TR 2022 and Tasman Psychiatry).

GOOD TO REMEMBER

- **Acute stress disorder (the syndrome):** the defining criterion is a Criterion-A trauma followed by *9 or more of 14* symptoms from any of five categories (intrusion, negative mood, dissociation, avoidance, arousal), lasting *3 days to 1 month*; the discriminator from PTSD is purely the time window (ASD under a month, PTSD over a month) and from ICD-11 acute stress reaction is that ASD is a diagnosable *disorder*, while dissociation is no longer mandatory (contrast DSM-IV); the first step is to confirm the stressor, then count symptoms across the five categories.

24.5 The relationship to PTSD: who progresses, and the sensitivity problem

The asd trauma pathway. Acute stress disorder was introduced partly to flag people early on the road to PTSD, and it does carry predictive weight: roughly **half of those meeting ASD criteria go on to develop PTSD** (Tasman Psychiatry; Bryant et al. 2011). That is a clinically meaningful signal, and a positive ASD diagnosis in the first month should prompt monitoring and access to care.

Why it is a poor screen. The examinable subtlety is the other direction: *many people who develop PTSD never met criteria for ASD* in the first month (Tasman Psychiatry; Bryant et al. 2011). Some progress to PTSD from subthreshold early symptoms, and some show a delayed course. So ASD has reasonable positive predictive value but *poor sensitivity* as a screen for eventual PTSD: a clean first month does not rule out PTSD later, which is why guidelines favour active monitoring over reassurance-and-discharge for symptomatic trauma survivors (NICE 2018). ASD prevalence itself

varies by trauma type, estimated at about **13 to 25%** of motor-vehicle-accident survivors (Tasman Psychiatry).

TRAP **Treating absent ASD as reassurance.** A survivor who did not meet acute stress disorder criteria in the first month is *not* safe from PTSD; many who develop PTSD never had ASD. Do not discharge with false reassurance; use active monitoring with follow-up within a month for subthreshold symptoms (NICE 2018).

3 days to 1 month DSM-5 ACUTE STRESS DISORDER DURATION WINDOW	**9 of 14** DSM-5 ASD SYMPTOM THRESHOLD (ACROSS 5 CATEGORIES)	**~50%** OF ASD CASES PROGRESS TO PTSD	**under 48 hours** TYPICAL DURATION OF AN ICD ACUTE STRESS REACTION

24.6 Early management: what to do, and the benzodiazepine and debriefing traps

Support first, drugs rarely. The evidence-based early response is psychological first aid, safety, orientation, practical support and reconnection, with active monitoring and follow-up within a month for anyone with subthreshold symptoms (NICE 2018). Where the early syndrome is established, an *individual trauma-focused CBT* intervention is the treatment of choice, not a drug (NICE 2018). Two things are explicitly *not* to be done routinely: single-session psychological debriefing is ineffective at preventing PTSD and may increase the risk of developing it (BAP 2014; NICE 2018; Companion), and drug treatments, including benzodiazepines, should not be offered to *prevent* PTSD after trauma (NICE 2018).

The benzodiazepine point, stated twice over. A benzodiazepine is the wrong reflex in the acute aftermath for two separate reasons: it treats none of the core trauma symptoms, and early post-trauma benzodiazepine use may actually *increase* the risk of subsequently developing PTSD (CANMAT 2014). Where a specific peri-trauma preventive is considered at all, the guideline-supported options are trauma-focused CBT, or, more tentatively, propranolol (Ciplar, Inderal) or sertraline, never an early anxiolytic (BAP 2014). For established PTSD later, prazosin (Minipress, Prazopress) is the anchor for trauma nightmares (CANMAT 2014), but that belongs to the management of the persistent disorder, not the acute reaction.

GOOD TO REMEMBER

- **Early trauma management (the principle):** the mechanism is that recovery is the norm, so the first-line move is psychological first aid plus active monitoring, with individual trauma-focused CBT if an early syndrome is established (NICE 2018); the signature caution is that routine single-session debriefing may *increase* PTSD risk and a benzodiazepine both fails to treat trauma symptoms and may raise PTSD risk (CANMAT 2014), so the one thing not to do is sedate-and-debrief.

24.7 The India device: the treatment gap, benzodiazepine over-prescription and the IPS line

Where this lands in Indian practice. India carries a wide anxiety, OCD and PTSD treatment gap, and the early trauma window is exactly where it shows. Trauma is common (road-traffic and industrial accidents, disasters, interpersonal and domestic violence), distress after it is frequently somatised, and the reflex in over-stretched settings is a short course, then a long course, of a

benzodiazepine, usually alprazolam. Against that benzodiazepine over-prescription problem, the acute stress reaction is precisely the presentation that should *not* be medicalised: it is a transient normal response, best met with support and safety, and any benzodiazepine given past marked acute agitation risks doing harm rather than good (CANMAT 2014). The Indian Psychiatric Society CPGs, in line with NICE and BAP, put psychological first aid and active monitoring first, trauma-focused psychotherapy for established syndromes, and reserve pharmacotherapy for the persistent disorder, where the anchors are the SSRIs and the SNRI, with prazosin (Minipress, Prazopress) for nightmares and no maintenance benzodiazepine.

INDIA

The highest-yield Indian point: an acute stress reaction is a *non-disorder* that needs support, not a prescription, yet it is a common trigger for the benzodiazepine over-prescription seen across Indian practice. Set against India's wide trauma treatment gap, the IPS-aligned answer is psychological first aid and active monitoring first, trauma-focused CBT for an established early syndrome, and an SSRI (not alprazolam) only if the illness persists into PTSD, with prazosin (Minipress, Prazopress) reserved for nightmares.

PEARL

Line the whole area up on one clock and it becomes un-confusable. Minutes-to-hours after the event, mixed and settling: acute stress reaction (a normal response, not a disorder, ICD-11 QE84). Three days to a month, 9 of 14 symptoms: acute stress disorder (a DSM-5 diagnosis; ICD-11 has none). Beyond a month, the cluster syndrome: PTSD. Reaction, disorder-in-the-month, disorder-past-the-month, in that order.

HOLD THIS

Acute stress reaction is a *transient normal response* to an exceptional stressor, coded QE84 in ICD-11 *outside* the mental disorders (Chapter 24), beginning within minutes and settling within hours to 1 to 3 days (under 48 hours); acute stress disorder is a *DSM-5 diagnosable disorder* requiring a Criterion-A trauma plus 9 or more of 14 symptoms across five categories (intrusion, negative mood, dissociation, avoidance, arousal) lasting 3 days to 1 month, with dissociation no longer mandatory (unlike DSM-IV); ICD-11 has no acute stress disorder at all; about half of ASD cases progress to PTSD but many who develop PTSD never had ASD (poor sensitivity); and the acute management is psychological first aid plus active monitoring, never routine debriefing and never a benzodiazepine, which may raise PTSD risk.

25 · Adjustment disorder

Adjustment disorder is the diagnosis for a **maladaptive reaction** to an identifiable life event that is more than an expectable upset but less than a full syndrome such as a depressive episode or generalised anxiety disorder. The whole examinable tension sits in that middle ground: the reaction is real and can carry genuine morbidity (including suicide risk), yet the same clinical picture, in a slightly milder form, is simply *normal human distress* that must *not* be labelled a disorder. Getting the frame right, that a stressor is necessary but not sufficient, is exactly what a viva examiner probes.

Why it matters clinically. Adjustment disorder is one of the most frequently used diagnoses in consultation-liaison, primary-care and emergency settings, and it is also one of the most easily misused. The icd-11 changes reconceptualised it around two positive features, preoccupation with the stressor and a *failure to adapt*, moving it away from being a pure residual "not-quite-anything-else" category. The examinable traps run in two opposite directions at once: over-diagnosing a normal, self-limiting adaptive reaction as a disorder, and under-recognising that a genuine adjustment disorder carries a real, impulsive self-harm risk that can be greater per-episode than in major depression. The amygdala and fear-circuit anatomy that underpins the stress response is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; the wider CBT and problem-solving model that anchors treatment belongs to the Psychotherapies, clinical assessment, MSE and nosology notes and is not re-derived here.

25.1 The core concept: a maladaptive reaction bounded by a stressor at one end and another disorder at the other

The sine qua non. A precipitating stressor is the one non-negotiable requirement: adjustment disorder is the development of emotional or behavioural symptoms *in response to* an identifiable psychosocial stressor (Kaplan & Sadock CTP 2024). The stressor can be single (a relationship ending, job loss, a new medical diagnosis) or multiple, acute or continuous, and of *any* severity, it need not be extreme or life-threatening (DSM-5-TR 2022; ICD-11 CDDR). Unlike almost every other DSM-5-TR disorder, there is *no* defined symptom checklist; the diagnosis is defined by its relationship to the stressor, not by a signature symptom profile.

Bounded on both sides. The diagnosis is squeezed between two thresholds. At the lower boundary it must be more than normality: a **maladaptive reaction** with marked distress out of proportion to the stressor, *or* significant functional impairment (DSM-5-TR 2022). At the upper boundary it must be less than another disorder: if the picture meets criteria for a depressive episode, an anxiety disorder, PTSD or acute stress disorder, that diagnosis is made *instead*, and adjustment disorder is not given (ICD-11 CDDR; DSM-5-TR 2022). This is why it has historically read as a residual category, the diagnosis you reach when the reaction is clearly abnormal but fits no better-defined box.

RULE **Stressor necessary, but never sufficient.** No identifiable stressor, no adjustment disorder; but a stressor plus a full syndrome (depressive episode, an anxiety disorder, PTSD) means you diagnose *that* disorder, not adjustment disorder.

25.2 The ICD-11 reconceptualisation: preoccupation and failure to adapt as the positive core

From residual to defined. The single most testable point of the icd-11 changes is that adjustment disorder was given a *positive* core rather than being left as a leftover category. ICD-11 defines it as a **maladaptive reaction** to an identifiable psychosocial stressor whose two defining features are preoccupation with the stressor (excessive worry, recurrent distressing thoughts about the stressor, or constant rumination about its implications) and a *failure to adapt* that

produces significant impairment (ICD-11 CDDR). Symptoms of preoccupation characteristically worsen with reminders of the stressor and can drive avoidance of those reminders.

What this changes in practice. Because the core is now preoccupation-plus-failure-to-adapt, ICD-11 does *not* require the old affective subtypes: depressive and anxiety symptoms are listed as common *additional* features, not as the defining substance (ICD-11 CDDR). Two further ICD-11-specific anchors are examinable. First, ICD-11 tightens the onset window: symptoms usually emerge **within one month** of the stressor, tighter than the DSM-5-TR three-month window (ICD-11 CDDR; Kaplan & Sadock CTP 2024). Second, ICD-11 explicitly places adjustment disorder inside the grouping of "disorders specifically associated with stress" (code **6B43**) alongside PTSD, complex PTSD and prolonged grief disorder, all of which require a stressor by definition.

PEARL

The ICD-11 mnemonic for the core is simply *preoccupation plus failure to adapt*. If a candidate can only name one ICD-11 change, name that the diagnosis is now built on those two positive features rather than being a residual "everything else after a stressor" bin, with onset within one month rather than three.

GOOD TO REMEMBER

- **Adjustment disorder (the syndrome):** the defining criterion is a *maladaptive reaction to an identifiable psychosocial stressor* whose ICD-11 core is *preoccupation with the stressor* (worry, recurrent distressing thoughts, rumination) plus a *failure to adapt* causing significant impairment; the discriminators are that a stressor is *necessary* (below) and that it must not meet criteria for any better-defined disorder (above); the first step is to establish the stressor, confirm the reaction is out of proportion or impairing, and exclude a full depressive/anxiety/PTSD syndrome (ICD-11 CDDR; DSM-5-TR 2022).

25.3 The time frame: the onset window and the 6-month resolution rule

Onset and resolution. The temporal architecture is heavily examined. DSM-5-TR requires onset **within 3 months** of the stressor; ICD-11 tightens this to usually **within one month** (DSM-5-TR 2022; ICD-11 CDDR). Both systems agree the exit rule: once the stressor *or its consequences* have terminated, symptoms resolve **within 6 months** (DSM-5-TR 2022; ICD-11 CDDR). If symptoms outlast the stressor by more than six months, the diagnosis should generally be changed to a more appropriate one.

Acute versus persistent. DSM-5-TR carries two duration specifiers: *acute* (symptoms under six months) and *persistent (chronic)* (six months or longer). The persistent specifier applies only when the stressor itself is ongoing or has enduring consequences, a chronic disabling illness, or the lasting financial and emotional sequelae of a divorce, so that the diagnosis can legitimately run longer than six months *because the stressor has not actually ended* (DSM-5-TR 2022). The rule is not contradicted: what resolves within six months is the reaction after the stressor terminates.

FEATURE	ICD-11 (6B43)	DSM-5-TR
Onset after stressor	**Usually within one month**	**Within 3 months**
Defining core	Preoccupation with the stressor + failure to adapt	Emotional/behavioural symptoms, marked distress out of proportion or functional impairment
Resolution	Within 6 months of stressor/consequences ending	Within 6 months of stressor/consequences ending
Subtypes / specifiers	No affective subtypes; depression/anxiety are additional features	Five specifiers; plus acute vs persistent (chronic)
Relation to other disorders	Not diagnosed if another disorder accounts for symptoms	Must not meet criteria for another disorder; not merely an exacerbation of a pre-existing one

The two classifications side by side; the load-bearing contrasts are the tighter one-month ICD-11 onset window versus the DSM-5-TR three-month window, the shared six-month resolution rule, and ICD-11's positive preoccupation-plus-failure-to-adapt core replacing the DSM affective subtypes (verified against ICD-11 CDDR and DSM-5-TR 2022).

25.4 The DSM-5-TR subtypes: six specifiers by predominant symptom

The five plus one. Where ICD-11 dropped subtypes, DSM-5-TR retains a specifier for the *predominant* disturbance (DSM-5-TR 2022): *with depressed mood* (F43.21, low mood, tearfulness, hopelessness); *with anxiety* (F43.22, nervousness, worry, jitteriness, or in children separation anxiety); *with mixed anxiety and depressed mood* (F43.23); *with disturbance of conduct* (F43.24, e.g. rule-breaking, reckless behaviour); *with mixed disturbance of emotions and conduct* (F43.25); and *unspecified* (F43.20) for maladaptive reactions not classifiable as one of the above. The most common subtypes in adults carry prominent depressive symptoms.

Why the conduct subtypes matter. The conduct and mixed-conduct subtypes are the examinable reminder that adjustment disorder is not only an affective category: in adolescents it may present as acting-out, risk-taking or a rise in substance use, and in children the preoccupation is often not verbalised but somatised (stomach pains, headaches) or shown as regression, oppositional behaviour, tantrums or increased clinginess (ICD-11 CDDR; DSM-5-TR 2022). The reactive attachment and disinhibited engagement disorders that also follow adverse early environments are covered in the Child behavioural, emotional and other disorders notes and the Child psychiatry: assessment, treatment, services and protection notes.

MNEMONIC

DAMCU

DSM-5-TR adjustment disorder specifiers: **D**epressed mood, **A**nxiety, **M**ixed anxiety and depressed mood, **C**onduct disturbance, mixed emotions-and-conduct (the sixth being **U**nspecified). Five named subtypes plus unspecified.

25.5 Do not over-diagnose: the boundary with a normal adaptive reaction

The lower threshold is the hard part. The central clinical skill, and the most tested single caution, is distinguishing a diagnosable disorder from an expectable, self-limiting response to a hard event. A precipitant plus some distress is *not* a disorder: emotional reactions to negative life events that are *not* markedly out of proportion and do *not* cause significant impairment should not be diagnosed as adjustment disorder (ICD-11 CDDR). Transient responses that settle within a few days do not warrant the label at all, and where a reaction is judged normal given the severity of an extreme stressor, ICD-11 directs you to the non-disorder category *acute stress reaction* (QE84) rather than any diagnosis (ICD-11 CDDR).

The bereavement carve-out. Ordinary grief is explicitly excluded: DSM-5-TR requires that the symptoms do not represent normal bereavement and are not better explained by *prolonged grief disorder* (DSM-5-TR 2022). Adjustment disorder may still be diagnosed after a death when the intensity, quality or persistence of the grief exceeds what age, cultural and religious norms would expect and the picture does not meet prolonged grief criteria, but the default assumption is that grief is normal. Over-medicalising life's difficulties, treating "problems of daily living" as illness because families, community and religious supports have thinned, is the error the diagnosis most invites (Kaplan & Sadock CTP 2024).

TRAP **Labelling normal distress a disorder.** A stressor plus understandable upset is *not* adjustment disorder unless the reaction is markedly out of proportion *or* functionally impairing; transient distress settling in days, and ordinary bereavement, are normal, not diagnoses.

25.6 The self-harm signal: why "minor" is a dangerous word here

The other-direction error. Set against the over-diagnosis trap is its mirror image, dismissing a genuine adjustment disorder as trivial. Several studies link adjustment disorder to significant suicidal ideation and behaviour that belies its "minor and self-limiting" reputation (Kaplan & Sadock CTP 2024). Among emergency-department self-harm presentations, patients with adjustment disorder made *more impulsive* acts, were more often associated with alcohol use, and reached self-harm *earlier* in the course of illness than patients with major depression; poisoning is the commonest method (Kaplan & Sadock CTP 2024). Subthreshold conditions can therefore carry high morbidity, including death.

The clinical consequence. This is why ongoing suicide risk assessment is written into management, and why acuity, not the size of the stressor, drives the decision to intervene. A rapidly escalating reaction with impulsivity and alcohol involvement warrants crisis intervention and case management on a short-term basis to preclude suicide attempts and, where necessary, to avoid hospitalisation (Kaplan & Sadock CTP 2024).

HOLD THIS

Adjustment disorder is a *maladaptive reaction to an identifiable stressor* with, in ICD-11, *preoccupation with the stressor plus failure to adapt* at its core; onset is within one month (ICD-11) or three months (DSM-5-TR) and it resolves within six months of the stressor ending; it requires a stressor but is trumped by any full disorder (depression, an anxiety disorder, PTSD) and must be more than normal distress or grief; treatment is *predominantly psychological* (supportive, problem-solving, CBT) with drugs only complementary and symptom-targeted, and, despite its "minor" reputation, it carries a real impulsive self-harm risk that mandates active suicide-risk assessment.

25.7 Management: the predominantly psychological approach

Psychosocial strategies are the mainstay. The guiding principle is that adjustment disorder is treated *predominantly psychologically*: understand the meaning of the stressor to the patient, minimise its day-to-day impact, and mobilise adaptive coping (Kaplan & Sadock CTP 2024). The evidence base is thin, and the first formal systematic review appeared only in 2018, but the psychotherapeutic options that have been used are supportive psychotherapy, cognitive-behavioural and behavioural approaches, *problem-solving* techniques, relaxation training and brief psychodynamic work. Treatment is often short-term, with crisis intervention and case management layered on where acuity or self-harm risk demands it. Notably, in a Cochrane meta-analysis, *problem-solving therapy* was the intervention that reduced the time for patients to return to work.

The India device. Adjustment disorder is a high-volume presentation in Indian consultation-liaison and primary-care practice, exactly the settings where the benzodiazepine over-prescription problem is most entrenched: the reflex to reach for alprazolam or another short-acting benzodiazepine for a distressed patient after a life event. That reflex is doubly wrong here, the disorder is predominantly psychological, and even short-term benzodiazepine use in adjustment disorder can produce withdrawal (Kaplan & Sadock CTP 2024). Against India's wide anxiety, OCD and PTSD treatment gap, and in line with the Indian Psychiatric Society clinical practice guidelines, the answer is psychological support and problem-solving first, with medication reserved and symptom-targeted, never a benzodiazepine as the default.

INDIA

The highest-yield Indian point: adjustment disorder is one of the commonest reasons a distressed patient after a life event is handed a benzodiazepine (typically alprazolam) in Indian outpatient and consultation-liaison practice. It is precisely the presentation that should *not* be medicalised by reflex: the mainstay is psychological (supportive work, problem-solving, brief CBT), and even short-term benzodiazepine use risks withdrawal. The IPS-aligned line is support and problem-solving first, and any drug used briefly and only for a specific symptom such as severe insomnia or anxiety.

GOOD TO REMEMBER

- **Psychological treatment (the principle):** the mechanism is to help the patient process the *meaning* of the stressor and mobilise adaptive coping, so the first-line move is a brief, predominantly psychological intervention, supportive psychotherapy, problem-solving therapy (the option shown to speed return to work) or brief CBT; the signature caution is that adjustment disorder carries a real impulsive self-harm risk, so ongoing suicide-risk assessment and, where acuity demands, crisis intervention are built in; the first-line indication is essentially every case, with drugs kept complementary (Kaplan & Sadock CTP 2024).

25.8 Pharmacotherapy: complementary, symptom-targeted, and benzodiazepine-sparing

Where drugs fit. Medication is a *complementary*, not a primary, treatment, and the evidence is limited: Stein's 2018 systematic review of adjustment-disorder pharmacotherapy could identify only 11 randomised trials (Kaplan & Sadock CTP 2024). The sensible practice is to target specific symptoms in the short run, for example treating severe insomnia or severe anxiety, and to use an antidepressant for moderate-to-severe depressive symptoms. SSRI agents (fluoxetine, sertraline, escitalopram, and the others) have been found useful for some subthreshold depressive symptoms and certain subtypes, but the evidence for improving depressive symptoms in adjustment disorder is genuinely scant, and psychosocial strategies remain the mainstay.

The benzodiazepine problem. Benzodiazepines carry particular caution: even short-term use in adjustment disorder can result in withdrawal, and the harms are magnified in older adults and those with a substance use disorder (Kaplan & Sadock CTP 2024). Comparator studies in the anxiety subtype found the non-benzodiazepine GABA-A modulator etifoxine (a European agent) at least as effective as, and better tolerated than, lorazepam or alprazolam, with less rebound anxiety on discontinuation, a useful teaching point on why a benzodiazepine is not the natural first drug even when anxiety predominates. The deeper anxiolytic and hypnotic pharmacology, benzodiazepines, buspirone (Buspin), pregabalin and dependence, is developed in the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes; the SSRI pharmacology and dosing sit in the Mood disorders: pharmacotherapy notes.

COMMON TRAP

Reaching for a benzodiazepine as the default treatment for adjustment disorder because the patient is anxious after a life event. It is not first-line, the disorder is predominantly psychological; and even short-term benzodiazepine use here can cause withdrawal, especially in older adults and those with substance use disorder (Kaplan & Sadock CTP 2024). Target the specific symptom briefly if you must, but the mainstay is psychological, not sedative.

1 month	3 months	6 months	5 to 20%
ICD-11 USUAL ONSET WINDOW AFTER THE STRESSOR	DSM-5-TR ONSET WINDOW AFTER THE STRESSOR	RESOLUTION ONCE THE STRESSOR/CONSEQUENCES END	OF OUTPATIENT MENTAL-HEALTH CASES (PRINCIPAL DIAGNOSIS)

WORKED EXAMPLE

A previously well woman in her forties, redeployed under sustained pressure during a public-health crisis, presents after a low-lethality overdose. She has no prior psychiatric history. Over the preceding weeks she has been unable to sleep, tearful at work and at home, withdrawing from family meals, and consumed by worry about the risk she poses to an immunosuppressed spouse, clear *preoccupation with the stressor* and a failing effort to adapt, but she does not meet full criteria for a depressive episode. This is an adjustment disorder. Management was crisis intervention in the emergency setting, then individual psychotherapy and a peer-support group over about six months, with an antidepressant added as a *complement* and planned to taper once the stressor eased, not a standing benzodiazepine. She reached full remission. The example carries the whole topic: preoccupation-plus-failure-to-adapt below the depressive-episode threshold, a real self-harm risk, and psychological treatment first with medication complementary.

26 · The neurobiology of trauma and fear conditioning

The **neurobiology of trauma** is the story of a normal survival-learning system pushed past its design limits by an overwhelming event. A trauma is, in learning terms, an intensely aversive experience that teaches the brain, fast and durably, that a set of previously neutral cues now predict catastrophe. The machinery that does this learning is the same amygdala-centred fear circuit that underlies ordinary anxiety, but in post-traumatic stress disorder (PTSD) the learning is too strong, the context that should contain it fails, the stress-hormone axis that should switch off the alarm is dysregulated, and the prefrontal brake that should teach safety again is too weak to do so. Examiners test this as a four-part story, and the candidate who can name the four parts in order, amygdala over-learning, hippocampal context failure, HPA-axis dysregulation and impaired prefrontal extinction, has the answer.

Why it matters clinically. The neurobiology is not decoration; it is the rationale for every effective treatment. Trauma-focused psychotherapy works because it drives **fear extinction** through the prefrontal cortex, the very process that is impaired; a beta-blocker was trialled to blunt the noradrenergic consolidation of the traumatic memory; prazosin dampens the noradrenergic hyperarousal that fires the nightmares. Two ideas anchor the whole answer. First, PTSD is a disorder of fear learning that will not extinguish, an over-consolidated fear memory in the **amygdala** that the prefrontal cortex cannot teach the brain to switch off. Second, the disorder is maintained, not merely triggered, so the neurobiology explains why symptoms persist for years after the threat is gone. The detailed fear-circuit anatomy and the receptor systems are developed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; this topic applies that anatomy to trauma and refers to the accompanying figure for the fear-conditioning map.

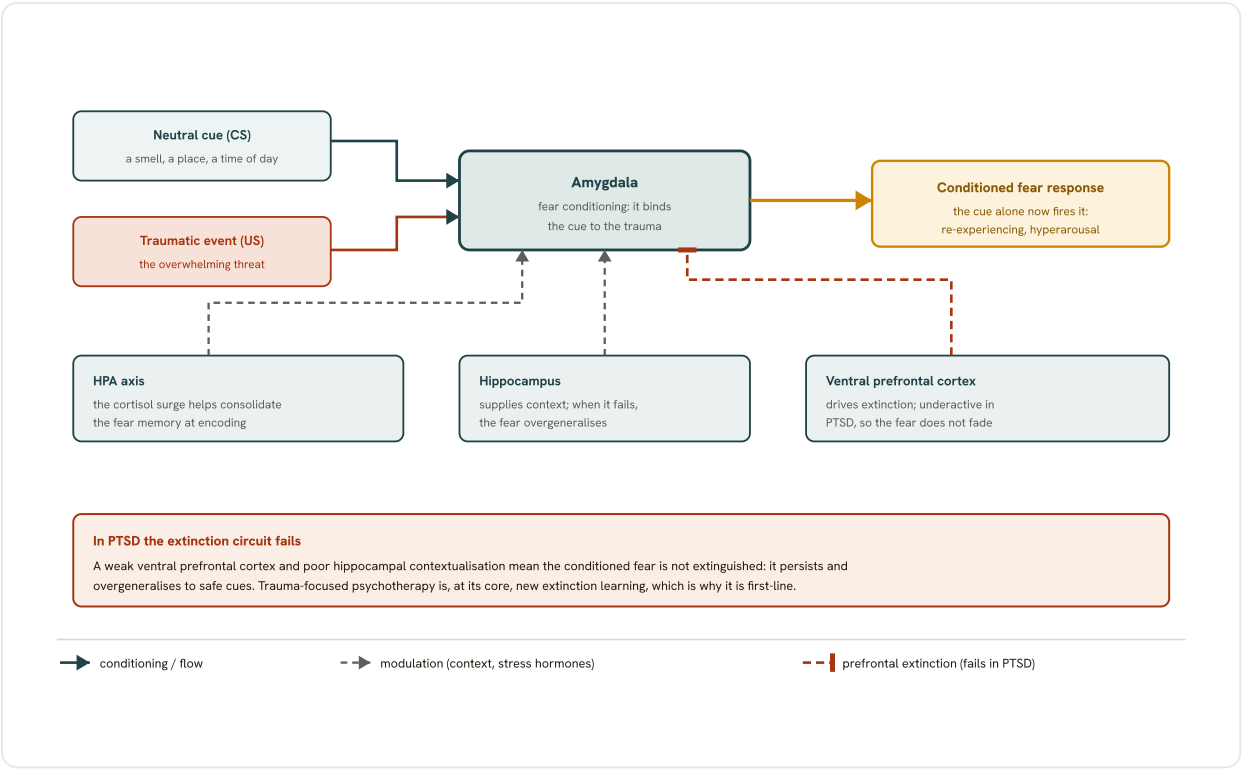

Fig 14.19 The neurobiology of trauma: fear conditioning and its failed extinction. At the moment of trauma the amygdala binds a neutral cue (the conditioned stimulus) to the overwhelming event (the unconditioned stimulus), so that afterwards the cue alone fires the conditioned fear response, the re-experiencing and hyperarousal of PTSD. The HPA-axis cortisol surge helps consolidate that memory, and the hippocampus normally tags it with a safe context. Recovery depends on extinction, new learning driven by the ventral prefrontal cortex that the cue is now safe. In PTSD the prefrontal extinction circuit is underactive and the hippocampus contextualises poorly, so the fear neither fades nor stays tied to its original context but overgeneralises; trauma-focused psychotherapy works precisely because it is new extinction learning. The pathway anatomy is taught in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes.

26.1 Fear conditioning: how a neutral cue becomes a trauma trigger

The learning paradigm to state first. **fear conditioning** is Pavlovian associative learning applied to threat. In the laboratory paradigm an animal meets an intrinsically neutral cue, the conditioned stimulus (CS, for example a tone), paired repeatedly with an inherently aversive **unconditioned stimulus** (UCS, for example a shock); after conditioning, the cue that was paired with the shock (the CS+) alone provokes the defensive response, freezing and a heightened startle, while the cue never paired with shock (the CS-) does not (Kaplan & Sadock CTP 2024). The neutral cue has acquired threat value.

The clinical translation. This is exactly what trauma does. The horn, the smell of diesel, the particular light of the time of day, whatever neutral cue happened to be present at the moment of the trauma (the UCS), becomes a conditioned fear cue (the CS+) that thereafter fires the full alarm on its own. The intrusive re-experiencing and the cue-driven panic of PTSD are conditioned fear responses to CS+ cues laid down at the time of the event; naming the trauma as the UCS and the trigger as the CS+ is the cleanest way to explain a flashback in circuit terms.

WORKED EXAMPLE

A survivor of a road collision hears a car horn (a neutral cue, present at the crash) and is instantly flooded with terror, a pounding heart and a vivid sense of the impact. In conditioning language the crash was the UCS, the horn was a co-occurring cue that became the CS+, and the terror is the conditioned fear response the CS+ now evokes on its own. The lateral amygdala is where that horn-to-terror association was welded, and it is why an apparently trivial sound reliably reproduces the alarm.

26.2 The amygdala: where the trauma memory is welded

The site of the plasticity. The amygdala, specifically its lateral nucleus, is the convergence point where the conditioned cue (CS) and the aversive trauma (UCS) meet; single lateral-nucleus neurons receive both streams, and the strengthening of that synapse (long-term potentiation) is the physical substrate of the acquired fear (Kaplan & Sadock CTP 2024). The central nucleus is the output that broadcasts the fear response to the hypothalamus, brainstem and periaqueductal grey. In trauma this plasticity is excessive: an overwhelming UCS produces an over-consolidated, easily reactivated fear memory.

The imaging signature. The consequence is an amygdala set on a hair trigger. Functional imaging in PTSD shows amygdala *hyper*-responsivity to trauma-related and even to generally threatening or fearful stimuli, the neural correlate of the exaggerated startle and the sense of current threat (Kaplan & Sadock CTP 2024; New Oxford Textbook of Psychiatry). The amygdala is the hub whose over-reactivity the whole rest of the circuit is meant to, and in PTSD fails to, restrain.

RULE **PTSD is over-consolidated fear learning the brain cannot extinguish.** A hyper-responsive amygdala holds an over-strong trauma memory (excessive fear conditioning), a failing hippocampus lets the fear generalise out of its context, a dysregulated HPA axis fails to shut the alarm down, and a weak ventromedial prefrontal cortex cannot drive the extinction that would teach safety; the fear therefore persists.

26.3 The hippocampus: encoding the context, and why it fails

Context is the hippocampus's job. The hippocampus supplies the *context* of a fear memory, the where and when that tells the brain whether a cue is dangerous *here and now* or only in the original setting; it is central to contextual fear conditioning and to telling a safe context apart from a dangerous one (Kaplan & Sadock CTP 2024). Intact hippocampal gating is what normally keeps a conditioned fear tied to its proper situation.

How the failure produces PTSD symptoms. When hippocampal contextual processing fails, the fear *over-generalises*: cues that merely resemble the trauma, or occur in plainly safe settings, trigger the full response, which is the over-generalisation that characterises PTSD (Kaplan & Sadock CTP 2024; New Oxford Textbook of Psychiatry). The hippocampus is also uniquely vulnerable to the very stress hormones the trauma unleashes: the dentate-gyrus to CA3 system is delicately balanced, and chronic stress lasting longer than about three weeks impairs hippocampal-dependent function while it *enhances* amygdala-dependent fear conditioning, a

double hit that reduced hippocampal volume in PTSD may reflect (New Oxford Textbook of Psychiatry). A weaker context signal and a stronger fear memory pull in the same maladaptive direction.

PEARL

Read the amygdala and the hippocampus as a pair of opposing dials that trauma turns the wrong way. Stress *up*-regulates amygdala fear conditioning and *down*-regulates hippocampal contextual function at the same time. The result is a fear memory that is both too strong (amygdala) and untethered from its context (hippocampus), so it fires everywhere. That single sentence answers "why does PTSD generalise?"

26.4 The HPA axis: the stress-hormone response and its dysregulation

The axis and its normal job. The **hpa axis** (hypothalamic-pituitary-adrenal axis) is the body's neuroendocrine stress response: the amygdala drives the hypothalamic paraventricular nucleus to release corticotropin-releasing hormone, which drives pituitary ACTH, which drives adrenal cortisol; cortisol then normally feeds back to terminate the stress response (Kaplan & Sadock CTP 2024; New Oxford Textbook of Psychiatry). Cortisol's job is, in part, to switch the alarm *off* once the threat has passed.

The dysregulation in PTSD, and its counter-intuitive direction. The examinable, counter-intuitive fact is that PTSD is associated with *low* or normal, not high, basal cortisol, together with an *enhanced* negative-feedback sensitivity of the axis (an exaggerated cortisol suppression to dexamethasone), a pattern distinct from the high-cortisol picture of melancholic depression (Kaplan & Sadock CTP 2024). Because glucocorticoids are thought to facilitate extinction learning and to constrain the over-consolidation of a traumatic memory, an inadequate cortisol response at the time of trauma is one proposed reason the fear memory is laid down too strongly and extinguishes too poorly; consistent with this, giving stress-dose hydrocortisone around a major stressor has been trialled to reduce later PTSD, hypothesised to work by facilitating extinction and impairing consolidation of the traumatic event (New Oxford Textbook of Psychiatry). The HPA story is thus not "too much stress hormone" but a dysregulated axis that fails to do its off-switch and extinction-facilitating work.

TRAP **Assuming PTSD means high cortisol.** Unlike melancholic depression, chronic PTSD is classically associated with *low or normal* basal cortisol and *enhanced* glucocorticoid negative feedback (exaggerated dexamethasone suppression); writing "raised cortisol" is the reflex error that loses the mark. The maladaptive point is a failure of the axis to regulate and to facilitate extinction, not a simple excess.

26.5 Fear extinction: the safety learning that is meant to switch the alarm off

What extinction is, and is not. **fear extinction** is the learned reduction of a conditioned fear when the CS+ is presented repeatedly *without* the UCS, so the cue no longer predicts the threat (Kaplan & Sadock CTP 2024). The crucial point, and a favourite examiner distinction, is that extinction does *not* erase the original fear memory; it creates a new, competing "safety" memory that *inhibits* the fear response. Because the original memory persists, extinguished fears can

return (spontaneous recovery, renewal in a new context, reinstatement after a stressor), which is exactly why PTSD relapses under stress and why treatment is safety-learning rather than deletion.

The prefrontal driver. Extinction is driven by the ventromedial prefrontal cortex (the infralimbic region in the rodent), which acts through the amygdala's GABAergic intercalated cells to inhibit central-nucleus output; a strong ventromedial prefrontal brake means a fear that can be extinguished (Kaplan & Sadock CTP 2024). This is the mechanism that trauma-focused exposure therapy recruits: repeated exposure to trauma-related cues in a safe environment leads to extinction of the fear response, and agents such as D-cycloserine (an NMDA partial agonist) have been trialled to enhance that extinction learning (New Oxford Textbook of Psychiatry).

MNEMONIC

A-H-H-E: the four-hit story of trauma

Run the neurobiology of trauma in four beats. **A**mygdala over-learns the fear (excessive conditioning, hyper-responsivity). **H**ippocampus loses the context, so fear over-generalises. **H**PA axis is dysregulated (low/normal cortisol, over-sensitive feedback, extinction not facilitated). **E**xtinction fails because the ventromedial prefrontal brake is too weak. Naming A-H-H-E in order is the fastest route to the "neurobiology of PTSD" marks.

26.6 Impaired prefrontal extinction: the lesion that maintains PTSD

The core maintaining lesion. The single circuit abnormality that best explains why PTSD *persists* is impaired prefrontal-mediated extinction. In PTSD the ventromedial prefrontal cortex is *hypo*-active and structurally reduced, while the amygdala is hyperactive; a weak prefrontal brake over a hot amygdala means the fear cannot be taught to switch off, and the conditioned response keeps firing to trauma cues long after any real danger has gone (Kaplan & Sadock CTP 2024; New Oxford Textbook of Psychiatry). Where ordinary recovery from a frightening event is spontaneous extinction, PTSD is the failure of that extinction.

Why this is the treatment target. This is why trauma-focused psychotherapy, not sedation, is the first-line treatment: exposure-based and cognitive trauma therapies work by driving successful extinction and safety learning through the prefrontal cortex, correcting the very process that is impaired. It is also why a benzodiazepine is the wrong tool, it sedates the alarm and can actually impair the extinction learning on which recovery depends, and why it has no place in PTSD treatment. The general exposure principle and the CBT model are developed in the Psychotherapies, clinical assessment, MSE and nosology notes; the licensed drugs, doses and the trauma-focused-first algorithm sit in the PTSD-treatment material.

WORKED EXAMPLE

Two soldiers survive the same ambush. Weeks later one no longer startles at a slammed door: repeated safe exposures let his ventromedial prefrontal cortex extinguish the conditioned fear. The other still dives for cover, has nightly nightmares and cannot enter a car park: his amygdala holds an over-consolidated fear his under-active prefrontal cortex cannot extinguish, his hippocampus has let the fear generalise to any enclosed space, and his HPA axis is not doing its off-switch work. The difference between recovery and PTSD is, in circuit terms, whether prefrontal extinction succeeds.

26.7 Noradrenaline and the consolidation of the traumatic memory

The amplifier that also fixes the memory. The noradrenergic system, driven by the locus coeruleus, does two things in trauma: it produces the peripheral hyperarousal (tachycardia, hypervigilance, exaggerated startle) that the patient feels, and, because noradrenaline released during a highly emotional event enhances the amygdala consolidation of that memory, it helps weld the traumatic memory in *more* strongly (Kaplan & Sadock CTP 2024; New Oxford Textbook of Psychiatry). A trauma is remembered vividly in part because it was encoded under a noradrenergic surge.

The pharmacological corollary. This gives two rational, noradrenergically targeted interventions. Peri-traumatic propranolol (Ciplar, Inderal), a beta-blocker, was trialled to blunt amygdala fear conditioning and the noradrenergic consolidation of the memory, though the evidence is insufficient to recommend it routinely for prevention (New Oxford Textbook of Psychiatry). And prazosin (Minipress, Prazopress), an alpha-1 antagonist, dampens the central noradrenergic hyperarousal that drives PTSD nightmares, which is why it is the targeted add-on for trauma-related nightmares. Both are the neurobiology cashed out as treatment; the prescribing detail sits in the PTSD-treatment material.

GOOD TO REMEMBER

- **Propranolol / prazosin (the noradrenergic handles on trauma):** noradrenaline released during trauma both drives the hyperarousal and strengthens amygdala consolidation of the memory; propranolol (Ciplar, Inderal), a beta-blocker, was trialled peri-traumatically to blunt that consolidation but is not routinely recommended for prevention, whereas prazosin (Minipress, Prazopress), an alpha-1 blocker, is the established add-on for trauma nightmares by lowering central noradrenergic tone, the signature caution for prazosin being first-dose hypotension.

26.8 Putting the trauma circuit together

One loop, four failures. The neurobiology of trauma is a single fear-learning loop failing at four nodes at once. The amygdala over-learns the fear (excessive conditioning, hyper-responsivity); the hippocampus loses the context, so fear generalises; the HPA axis is dysregulated and fails to facilitate the extinction and shut-down it should; and the ventromedial prefrontal cortex cannot drive the extinction that would teach safety. The result is a conditioned fear response, laid down under a noradrenergic surge, that fires to trauma cues indefinitely. Every effective treatment targets one of these nodes, and trauma-focused psychotherapy targets the most important, the failed prefrontal extinction.

NODE / PROCESS	WHAT IT DOES NORMALLY	THE FAILURE IN TRAUMA / PTSD
Amygdala (lateral nucleus)	Welds the CS-UCS association; site of fear conditioning (LTP)	Over-consolidated fear memory; amygdala hyper-responsive to threat
Amygdala (central nucleus)	Broadcasts the fear response to hypothalamus, brainstem, PAG	Drives exaggerated startle and sense of current threat
Hippocampus	**Supplies the context of the fear memory**	Context fails, so fear over-generalises to safe cues; reduced volume
HPA axis	Cortisol terminates the stress response; facilitates extinction	**Low/normal cortisol, enhanced feedback; extinction not facilitated**
Ventromedial prefrontal cortex	**Drives fear extinction via GABAergic intercalated cells**	Hypo-active and reduced; extinction fails, fear persists
Locus coeruleus / noradrenaline	Arousal; enhances emotional memory consolidation	Hyperarousal and over-strong memory encoding; nightmares
Extinction learning	New safety memory inhibits the conditioned fear	**Impaired; the target of trauma-focused psychotherapy**

The trauma fear-learning loop node by node, mapped to its normal role and its PTSD failure; the accompanying figure draws the fear-conditioning sequence (neutral cue paired with the trauma UCS becomes a CS+ that fires the amygdala, with the hippocampal context signal and the prefrontal extinction brake shown as the two systems that fail). Grounded in Kaplan & Sadock CTP 2024 and the New Oxford Textbook of Psychiatry.

26.9 Definitions to fix the vocabulary

Fear conditioning

Pavlovian learning in which a neutral cue (CS), paired with an aversive event (UCS), acquires the power to evoke a fear response.

Conditioned stimulus (CS+)

The cue that was paired with the trauma and now triggers the conditioned fear on its own; the CS- is the unpaired cue that does not.

Unconditioned stimulus (UCS)

The intrinsically aversive event, the trauma itself, that gives the cue its threat value.

Fear extinction

Learned reduction of a conditioned fear when the CS+ is met without the UCS; a new safety memory that inhibits, not erases, the fear.

HPA axis

Hypothalamic-pituitary-adrenal stress axis (CRH to ACTH to cortisol); cortisol normally terminates the stress response and facilitates extinction.

Contextual fear

Fear tied by the hippocampus to a specific setting; its failure produces the over-generalisation of PTSD.

GOOD TO REMEMBER

- **PTSD (the syndrome, in circuit terms):** the defining neurobiology is a conditioned fear memory over-consolidated in a hyper-responsive amygdala, stripped of its context by a failing hippocampus (fear over-generalises), against a dysregulated HPA axis (low/normal cortisol, enhanced negative feedback) and a hypo-active ventromedial prefrontal cortex that cannot drive extinction; the discriminator from ordinary recovery is that recovery *is* spontaneous extinction while PTSD is its failure, and the first therapeutic step is trauma-focused psychotherapy to re-drive prefrontal extinction (never a benzodiazepine, which impairs it).

INDIA

Trauma is abundant in India, road-traffic collisions, interpersonal and gender-based violence, disasters and displacement, yet PTSD is under-recognised and under-treated, folded into vague "tension" or somatic complaints and rarely reaching a psychiatrist; the trauma treatment gap is wide. Into that gap steps the country's **benzodiazepine over-prescription** problem: alprazolam and clonazepam are handed out freely, often long-term, for post-trauma distress and insomnia, which is precisely the wrong move on this circuit, because a benzodiazepine sedates the alarm and can *impair* the prefrontal extinction learning on which real recovery depends, while breeding dependence. The neurobiology gives the corrective the Indian Psychiatric Society CPG endorses: trauma-focused psychotherapy first (it drives the failed extinction), an SSRI or SNRI where a drug is needed, and prazosin (Minipress, Prazopress) for nightmares, with no role for a benzodiazepine. The correct answer treats the fear circuit, not merely the sleeplessness.

4	2	21
FAILING NODES TO NAME (AMYGDALA, HIPPOCAMPUS, HPA AXIS, PREFRONTAL EXTINCTION)	TRAUMA-CONDITIONING TERMS (CS+ TRIGGER, UCS TRAUMA)	DAYS OF STRESS BEYOND WHICH HIPPOCAMPAL FUNCTION IS IMPAIRED AND AMYGDALA CONDITIONING ENHANCED

HOLD THIS

PTSD is a fear-conditioning disorder: an overwhelming trauma (UCS) welds an over-strong conditioned fear to neutral cues (CS+) in a hyper-responsive amygdala, a failing hippocampus lets that fear generalise out of its context, a dysregulated HPA axis (low or normal cortisol, over-sensitive feedback) fails to facilitate extinction, and a hypo-active ventromedial prefrontal cortex cannot drive the fear extinction that would teach safety, so the alarm keeps firing, which is why trauma-focused psychotherapy (re-driving prefrontal extinction) is first-line and a benzodiazepine, which impairs extinction, is never used.

27 . Prolonged grief disorder

A new diagnosis, and an examiner's favourite trap. **Prolonged grief disorder** is the pathological grief syndrome added to DSM-5-TR (2022) and codified in ICD-11 (6B42). It sits in the trauma- and stress-related grouping alongside PTSD and adjustment disorder, and its whole diagnostic weight rests on one judgement: has grief persisted, and become impairing, *beyond* what this person's social, cultural and religious context would expect. The syndrome the DSM once parked in an appendix as **persistent complex bereavement disorder** is now a full disorder.

The examiner is rarely testing whether you can list the symptoms. They are testing whether you know the **time thresholds**, whether you can separate this from a depressive episode and from PTSD, and above all whether you resist the reflex to medicalise ordinary mourning. Grief is not a disease; only a grief response that is atypically prolonged, pervasive and disabling earns the label.

27.1 What the entity is

Persistent grief. Both classifications describe a **persistent and pervasive grief response** following the death of someone close, dominated by yearning or longing for the deceased, or by persistent preoccupation with them, and carrying intense emotional pain (sadness, guilt, anger, denial, difficulty accepting the death, emotional numbness, a sense that part of the self has died). This is **persistent grief** that has not moved through the normal arc of adaptation. The phrase to memorise is that the response **markedly exceeds expected social, cultural or religious norms** for that person's context.

27.2 The time thresholds (where marks are won and lost)

Two systems, two numbers. The single highest-yield discriminator is duration, and the two manuals differ. ICD-11 requires the response to have persisted for an atypically long time, giving a floor of at least **6 months** (longer in some cultural contexts). DSM-5-TR sets a higher adult bar: the death must have occurred at least **12 months** ago for adults (at least **6 months** for children and adolescents), and the symptoms must have been present nearly every day for at least the last month. Do not conflate the two.

FEATURE	ICD-11 (6B42)	DSM-5-TR
Minimum time since death	**at least 6 months**	**12 months adult; 6 months child/adolescent**
Core (one or both)	yearning/longing OR preoccupation with the deceased	intense yearning OR preoccupation, nearly every day, last month
Accompanying symptoms	intense emotional pain features (not a fixed count)	at least 3 of 8 (identity disruption, disbelief, avoidance of reminders, intense emotional pain, difficulty reintegrating, emotional numbness, life feels meaningless, intense loneliness)
Threshold clause	exceeds cultural/religious norms; impairment	exceeds social/cultural/religious norms; distress or impairment

The ICD-11 versus DSM-5-TR criteria for prolonged grief disorder; the duration cells are the ones examiners probe.

RULE **Duration is the discriminator.** ICD-11 says at least 6 months; DSM-5-TR says at least 12 months in adults. Anchor every answer to the number for the system being asked.

27.3 Do not pathologise normal grief too early

The threshold is cultural, not just temporal. Normal bereavement is protective, self-limiting and does not need psychiatric treatment. Both manuals build in a boundary-with-normality clause: a grief reaction within the normative period for the person's cultural and religious context

is *normal*, and it is often decisive to ask whether family, friends and community who share that perspective regard the duration or intensity as abnormal. Some traditions prescribe grieving that lasts a year or is deliberately reawakened at the first anniversary; a mourning ritual that runs its expected course is not a disorder.

TRAP **Labelling grief as disorder from the outset.** Applying the diagnosis before the time threshold, or against the person's own cultural norm, medicalises normal mourning; the community's reading of what is abnormal is part of the criterion.

27.4 Discriminating from depression and PTSD

Circumscribed versus pervasive. Prolonged grief disorder and a depressive episode share sadness, loss of interest, social withdrawal, guilt and suicidal ideation, but grief is *focused on the loss*: the yearning, the difficulty accepting the death, the sense that part of the self has died, feeling bitter about the loss. Depressive cognitions spread across many areas of life and pervasive low mood dominates. Against PTSD, the person with prolonged grief may be preoccupied with the circumstances of the death but does **not re-experience** them as happening again in the here and now; intrusive re-experiencing, flashbacks and hyperarousal point to PTSD. All three can co-occur, and each should be diagnosed where full criteria are met.

WORKED EXAMPLE

A widow, 14 months after her husband's death, still lays out his belongings untouched, longs for him nearly every day, cannot re-engage with friends and feels life is meaningless, yet finds joy in her grandchildren and has no pervasive anhedonia. The distress is circumscribed to the loss and the death is more than 12 months past: this meets DSM-5-TR prolonged grief disorder, not a depressive episode. Had she instead relived the moment of his death as if it were happening now, PTSD would move up the list.

27.5 Where it fits in the Indian setting

An old idea with a new name. Indian teaching has long distinguished normal grief from a **morbid grief reaction** (Gurmeet Singh's classification), where symptoms of grief are exaggerated or run prolonged beyond about 6 months without spontaneous recovery. Bowlby's three phases of response to loss, protest then despair then detachment, remain the standard developmental scaffold. The clinical caution matters in Indian practice: with the anxiety, OCD and PTSD treatment gap already leaving most common mental disorders untreated, scarce specialist time should not be spent converting culturally sanctioned mourning into a prescription, and the reflex to reach for a **benzodiazepine** for an acutely grieving person, a real over-prescription problem in Indian outpatient settings, is exactly the wrong move.

INDIA

Gurmeet Singh's normal-versus-morbid grief distinction predates the ICD-11 entity and is the classification most likely quoted by Indian examiners. Frame prolonged grief disorder as the formalised successor to morbid/pathological grief, hold the cultural-norm clause front and centre in a society with elaborate, lengthy mourning customs, and keep benzodiazepines off the acute-grief prescription.

27.6 Management: grief-targeted psychotherapy first

Talk before pills. Uncomplicated grief needs no drug. For prolonged grief disorder the evidence base points to a grief-targeted psychotherapy as first-line, most notably complicated grief treatment (the manualised approach developed by Shear), a structured therapy that combines processing the reality of the loss with re-engaging in life, and family-focused grief therapy in palliative and bereavement settings. Antidepressants are **not** routinely indicated for the grief itself: trials of SSRIs for grief have been largely negative, and drug treatment is reserved for a co-occurring depressive episode or another comorbid disorder diagnosed in its own right. If an antidepressant is used for comorbid depression, it is an SSRI (for example sertraline; Indian brands include the generic across many manufacturers), not a benzodiazepine.

RULE **Grief-targeted psychotherapy is the treatment; drugs treat comorbidity.** Complicated grief treatment first; reserve an SSRI for a diagnosed comorbid depression, and never a benzodiazepine for the grief.

MNEMONIC

GRIEF-TOO-LONG

Grief that is persistent and pervasive; **R**eaction exceeds cultural/**R**eligious norms; **I**ntense yearning or preoccupation is the core; **E**motional pain plus impairment; **F**ocused on the loss (not pervasive like depression, not re-experienced like PTSD); **TOO LONG** = past the threshold (6 months ICD-11, 12 months DSM-5-TR adult). The unpacking is the diagnosis.

PEARL

The term you will meet under several names points to one construct: **complicated grief**, morbid/pathological grief, persistent complex bereavement disorder (the old DSM-5 appendix name) and prolonged grief disorder (the current entity) are the historical layers of the same idea. When an examiner uses any of these, answer with the current ICD-11/DSM-5-TR criteria.

GOOD TO REMEMBER

- **Prolonged grief disorder (syndrome):** defining criterion is a persistent, pervasive grief response with intense **yearning** or preoccupation with the deceased that exceeds the person's cultural/religious norm; time floor is at least 6 months (ICD-11) or at least 12 months in adults (DSM-5-TR); the first discriminator against depression is that grief is circumscribed to the loss, and against PTSD that the death is not re-experienced in the here and now.
- **Complicated grief treatment (psychotherapy):** the grief-targeted, manualised first-line therapy (Shear); principle is to process the reality of the loss while restoring engagement with life; signature caution is that antidepressants do not treat the grief itself and are reserved for comorbid depression, never a benzodiazepine for acute grief.

HOLD THIS

Prolonged grief disorder = persistent yearning/preoccupation exceeding the cultural norm, at least 6 months (ICD-11) or at least 12 months in adults (DSM-5-TR) after the death; treat with grief-targeted psychotherapy, and do not pathologise normal mourning too early.

28 · Reactive attachment and disinhibited social engagement disorders

Two disorders of early, severe neglect. These are the trauma- and stressor-related disorders of the very young child. **Reactive attachment disorder** (RAD) is the emotionally withdrawn, inhibited pattern toward caregivers; **disinhibited social engagement disorder** (DSED, formerly disinhibited attachment disorder of childhood) is indiscriminate, over-familiar behaviour toward strangers. Both are named here briefly and criterion-led; the fuller developmental and services detail belongs to the child-psychiatry chapters. The exam hook is that both require the same aetiology, **early neglect** so severe it prevents normal attachment forming, yet they express in opposite behavioural directions.

Keep two nosological facts in front of you. First, DSM-5-TR and ICD-11 agree in splitting the old single "attachment disorder" into these two distinct disorders, both classed as trauma- and stressor-related, not as childhood-onset residuals. Second, both need a developmental age of at least **9 months** (the level at which selective attachment becomes possible) and onset before **5 years**. This note stays deliberately short: the point is the criterion, the discrimination, and the fact that treatment is psychosocial, never a drug.

28.1 Shared aetiology: pathogenic care

Insufficient care is the gateway criterion for both. Neither disorder is diagnosed without a documented history of a pattern of extremes of insufficient care: persistent social neglect or deprivation of basic emotional needs, repeated changes of primary caregiver that limit stable attachment (for example serial foster placements), or rearing in unusual settings with high child-to-caregiver ratios (institutions) that severely limit selective attachment. This "grossly insufficient care" is presumed causative, so the history of **early neglect** is not optional context, it is a criterion. Absent such a history the diagnoses are rare and, if made, are likely wrong.

28.2 Reactive attachment disorder: the withdrawn, inhibited child

Minimal comfort-seeking and minimal response to comfort. The child with RAD shows a consistent pattern of emotionally withdrawn, inhibited behaviour toward adult caregivers: rarely or minimally seeking comfort when distressed, and rarely or minimally responding to comfort when it is offered. Layered on this is a persistent social and emotional disturbance, reduced positive affect, and episodes of unexplained irritability, sadness or fearfulness even during non-threatening interactions. It is, in effect, the absence of an organised attachment where one should have formed. RAD is diagnosed only when the child does not meet criteria for autism spectrum disorder.

28.3 Disinhibited social engagement disorder: the over-familiar child

Indiscriminate over-familiarity with unfamiliar adults. The child with DSED actively approaches and engages unfamiliar adults with a striking lack of the normal stranger wariness that emerges between **7 to 9 months**. DSM-5-TR requires at least **two** of: reduced or absent reticence in approaching unfamiliar adults; overly familiar verbal or physical behaviour beyond age-appropriate and culturally sanctioned bounds; diminished or absent checking back with the caregiver after venturing away, even in unfamiliar settings; and willingness to go off with an unfamiliar adult with little or no hesitation. The behaviour is sometimes called "indiscriminate friendliness," but it is intrusive, boundary-crossing, and self-endangering rather than sociable.

28.4 RAD versus DSED versus their mimics

Two discriminators carry the marks. First, the direction of behaviour: RAD is under-social and withdrawn, DSED is over-social and disinhibited. Second, the exclusion pattern: **autism spectrum disorder** excludes RAD (both show diminished social reciprocity, but the ASD child has restricted, repetitive behaviours and a history without required neglect), whereas ASD does not exclude DSED. DSED must also be more than the behavioural impulsivity of **ADHD**, which may co-occur; the DSED behaviour is specifically social disinhibition toward strangers, not general impulsivity. The table alongside sets out the split.

AXIS	REACTIVE ATTACHMENT DISORDER (RAD)	DISINHIBITED SOCIAL ENGAGEMENT DISORDER (DSED)
Core behaviour	**Emotionally withdrawn, inhibited toward caregivers**	**Indiscriminate over-familiarity with unfamiliar adults**
Comfort	Minimal seeking and minimal response to comfort	Reduced checking-back with the caregiver
Required threshold	Full withdrawn pattern plus social/emotional disturbance	**At least 2 disinhibited behaviours**
Developmental age / onset	At least 9 months; before age 5	At least 9 months; before age 5
Autism spectrum disorder	**Excludes the diagnosis**	**Does NOT exclude the diagnosis**
Response to good care	Signs typically recede within weeks of adequate caregiving	**May persist even after a stable attachment forms**

Same neglectful root, opposite behavioural expression; the autism exclusion and the response to remediation are the two most-tested discriminators.

28.5 Course: why the two diverge under good care

RAD tends to remit, DSED can stick. This is the highest-yield prognostic point. In children moved from institutional to adequate caregiving (the Bucharest Early Intervention Project randomised foster care against continued institutional care), RAD signs typically recede within weeks of an adequate caregiving environment. DSED behaviours improve but can persist in a minority even after the child forms a selective attachment to a foster or adoptive parent, which is why some argue the core deficit in DSED is not simply the absence of an attachment relationship. Earlier placement helps: signs of DSED are not reported when deprivation begins only after age 2, and attachment disorders are very rare in children adopted before **6 months** of age.

28.6 Management: the intervention is the caregiving environment

Change the care, not the child, and never a drug. There is no established pharmacotherapy for RAD or DSED; the treatment is a stable, sensitive, individualised caregiving relationship, delivered by placing the child with a committed caregiver (foster or adoptive) and coaching that caregiver to respond to the child's distress as if it had been requested, so the child learns comfort is available. The clinician also protects the child (DSED carries real danger from going off with strangers). Critically, the coercive "attachment therapies", holding, restraint and rebirthing, are unproven and dangerous, having caused child deaths, and are formally discredited (AACAP practice parameter). This is the one point where the benzodiazepine over-prescription theme becomes a pure trap: there is nothing to prescribe here.

RULE **No neglect, no diagnosis.** A documented history of grossly insufficient care is a criterion for both RAD and DSED, not background colour; without it, look elsewhere.

TRAP **Do not reach for medication.** There is no drug treatment for RAD or DSED; prescribing a sedative or antipsychotic for the "difficult" neglected child treats the clinician's discomfort, not the disorder, and misses that the intervention is the caregiving environment.

WORKED EXAMPLE

A boy of nearly four, adopted at 30 months from an orphanage with rotating caregivers, is brought for "hyperactivity." He approaches and chats with complete strangers, has more than once followed a stranger willingly, tolerates injury with an oddly high pain threshold, and his warmth toward adults feels shallow rather than selective. Teachers find him charming yet attention-seeking. The history of institutional early neglect plus at least two disinhibited-approach behaviours, beyond ADHD-type impulsivity, gives disinhibited social engagement disorder. Management is protective and relational, focused on curbing self-endangering approach and rewarding age-appropriate social hesitance; his approach to strangers persists at a reduced, more manageable level.

INDIA

Institutional care of orphaned, abandoned and maltreated young children remains widely used across Asia, India included, which is exactly the pathogenic-care setting that produces RAD and DSED; child-protection and alternative-care law (the Juvenile Justice framework and CARA-regulated foster care and adoption) is the practical lever, since the treatment is the caregiving environment, not a prescription. This is also the sharpest place to name the **benzodiazepine over-prescription** problem by its absence: the temptation to sedate a "hyperactive" or "withdrawn" neglected child must be resisted, because no anxiolytic or antipsychotic treats an attachment disorder, and the wider Indian pattern of handing out clonazepam or alprazolam against the IPS Clinical Practice Guidelines has no foothold here at all.

9 mo	before 5 yr	2	12 mo
MINIMUM DEVELOPMENTAL AGE FOR EITHER DIAGNOSIS	REQUIRED AGE OF ONSET	DISINHIBITED BEHAVIOURS NEEDED FOR DSED	PERSISTENCE FOR THE "PERSISTENT" SPECIFIER

MNEMONIC

IN versus OUT

RAD turns IN (withdrawn, inhibited, minimal comfort-seeking, and autism is excluded); **DSED turns OUT** (over-familiar, approaches strangers, checks back less, and autism is NOT excluded). Same neglect at the root, opposite direction of travel.

PEARL

The clean way to remember the prognosis split: RAD, being about the missing relationship, largely repairs when a good relationship arrives; DSED, being about missing stranger-wariness and inhibitory control, can outlast the arrival of a secure attachment.

GOOD TO REMEMBER

- **Reactive attachment disorder (RAD):** defining criterion is a consistent emotionally withdrawn, inhibited pattern toward caregivers, minimal comfort-seeking and minimal response to comfort, on a history of grossly insufficient care, developmental age at least 9 months and onset before 5 years; autism spectrum disorder excludes it, and the first step is to confirm the neglect history and check the child is not autistic.
- **Disinhibited social engagement disorder (DSED):** defining criterion is at least two disinhibited behaviours toward unfamiliar adults (over-familiarity, reduced reticence, diminished checking-back, willingness to go off with a stranger) beyond ADHD impulsivity, on the same neglect history and same age window; autism does NOT exclude it, and the discriminator from RAD is the outward, over-social direction of behaviour.
- **Caregiving intervention (the "therapy"):** the principle is that a stable, sensitive, individualised caregiving relationship is itself the treatment; there is no established medication, and coercive holding or "attachment" therapies are dangerous and discredited, so the first-line move is protective placement with a committed caregiver plus coaching of responsive care.

HOLD THIS
RAD (withdrawn, autism excluded) and DSED (over-familiar, autism not excluded) are the two trauma-related disorders of early neglect, both needing a developmental age of at least 9 months and onset before 5, and both treated by fixing the caregiving environment, never with a drug.

Apply and consolidate

29 · Worked cases

The anxiety, OCD and trauma syllabus rewards a candidate who can *reason* a case from the door to the discharge letter, not one who recites lists. This note is the arc closer: four **worked cases**, each taken as a **vignette** and reasoned aloud, so that the diagnostic discriminator, the criterion that clinches it, and the guideline-anchored management fall out in the right order. Read each as the examiner reads it, the story first, then "which disorder, and is it even a psychiatric disorder at all?", then "what, in what order, at what dose, for how long?".

Why it matters, and how to use this note. Every fact here is developed at depth elsewhere in the chapter; this note only assembles them into four reasoned walk-throughs and ends each named syndrome and each named drug or psychotherapy with an anchored Good-to-remember box. The Clark cognitive loop behind the first case lives in the Clark cognitive model note; the OCD algorithm behind the second in the OCD management note; the PTSD algorithm behind the third in the PTSD treatment note; and the organic-mimic grid behind the fourth in the anxiety differential note. The deep antidepressant pharmacology (SSRIs, SNRIs, clomipramine, doses, interactions) sits in the Mood disorders: pharmacotherapy notes; the anxiolytic and benzodiazepine pharmacology in the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes; the general CBT and exposure principle in the Psychotherapies, clinical assessment, MSE and nosology notes; and the deep brain stimulation option for refractory OCD in the ECT and neurostimulation notes. Each case refers to a *case:* line so you can find it fast on revision.

29.1 Case one, the presentation: panic disorder with agoraphobia

case: the vignette. A 28-year-old teacher gives a several-month history of episodes that begin from a calm state with a pounding heart, breathlessness and a lurching certainty that she is having a heart attack; the surge crests within about **10 minutes** and subsides. Two cardiology work-ups have been normal. She now avoids crowded markets, buses and being far from home alone, in case an attack strikes where she "cannot get out or get help", and she carries an alprazolam tablet "just in case". **The reasoning.** The fear is of the *attacks themselves* (anticipatory

anxiety about the next surge), which names panic disorder; the fear of situations where escape is difficult or help unavailable names the comorbid agoraphobia. Normal cardiac work-up and the out-of-the-blue onset from calm exclude an arrhythmia driving it.

29.2 Case one, the criterion that clinches panic disorder and agoraphobia

Panic disorder. The defining criterion is *recurrent unexpected panic attacks* not restricted to a particular stimulus or situation, followed by persistent concern about further attacks or a maladaptive change in behaviour to avoid them (ICD-11 6B01; DSM-5-TR 2022). The word that does the work is *unexpected*: the attack arrives from a calm state, which is exactly what separates panic disorder from the cued surges of a phobia. **Agoraphobia.** The defining criterion is marked fear or anxiety about *multiple* situations where escape might be difficult or help unavailable should a panic-like or incapacitating symptom occur (crowds, public transport, open or enclosed spaces, being alone outside the home), consistently avoided or endured with dread (ICD-11 6B02; DSM-5-TR 2022). The focus is on escape and rescue, not on the place itself.

GOOD TO REMEMBER

- **Panic disorder (the syndrome):** defining criterion is *recurrent unexpected* panic attacks (from a calm state, not cued) plus persistent concern about further attacks or behavioural change to avoid them; the discriminator is the "out-of-the-blue" onset, and the first step is to exclude an organic mimic (arrhythmia, thyrotoxicosis) before the label (ICD-11 6B01; DSM-5-TR 2022).
- **Agoraphobia (the syndrome):** defining criterion is fear of *multiple* situations where escape is difficult or help unavailable (crowds, transport, open or enclosed spaces, being alone out), avoided or endured with dread; the discriminator is that the fear is of being unable to escape or get help, not of the place itself (ICD-11 6B02; DSM-5-TR 2022).

29.3 Case one, the formulation: Clark's cognitive model applied

The loop, drawn on this patient. Clark's model formulates her disorder as the *catastrophic misinterpretation of benign bodily sensations*: a benign internal trigger (a fleeting palpitation) is read as an imminent catastrophe ("heart attack"), which produces fear, which drives more autonomic arousal, which is again misinterpreted, tightening a self-amplifying vicious cycle until a full attack crests (the accompanying figure lays out the loop). Her carried alprazolam and her habit of sitting down and gripping a companion's arm are safety behaviours: they feel protective but prevent the belief from ever being *disconfirmed*, because she attributes surviving each attack to the prop rather than to the harmlessness of the sensation. That is the engine of chronicity and of the widening agoraphobic avoidance.

GOOD TO REMEMBER

- **Clark cognitive model (the formulation):** the mechanism is catastrophic misinterpretation of benign bodily sensations feeding a vicious cycle; the signature principle is that *safety behaviours* (the pocketed benzodiazepine, sitting down, gripping) block disconfirmation and maintain the disorder; the first therapeutic move is to drop the safety behaviour and let the sensation prove itself harmless (Clark 1986).

29.4 Case one, the management: an SSRI plus CBT, and the activation warning

What the guidelines say. First-line is an SSRI licensed for panic (escitalopram, sertraline, paroxetine or citalopram) or venlafaxine, *with* CBT built on Clark's protocol; combination of CBT and an antidepressant has the best outcomes (IPS 2025; NICE 2011; BAP 2014). CBT for panic is delivered in the optimal range of **7 to 14 hours**, typically weekly over about **4 months** (NICE 2011), using cognitive restructuring, interoceptive exposure and the dropping of safety behaviours. **The activation caution to state.** An SSRI started for panic must carry an explicit warning about *early activation* and a transient worsening of anxiety in the first days, because in Clark's terms the initial jitteriness supplies fresh bodily sensations to misinterpret; start low and titrate. A responder continues the drug for at least six months (BAP 2014). **The benzodiazepine is not the answer.** NICE explicitly advises *against* benzodiazepines in panic disorder, associated with a worse long-term outcome; her carried alprazolam is a chemical safety behaviour to be withdrawn, not the treatment.

RULE **SSRI plus CBT, never a standing benzodiazepine.** First-line panic disorder is an SSRI licensed for panic (escitalopram, sertraline, paroxetine, citalopram) or venlafaxine combined with Clark-protocol CBT; benzodiazepines are advised against because they worsen long-term outcome and act as a safety behaviour (NICE 2011; BAP 2014).

TRAP **Starting the SSRI without the activation warning.** Beginning an SSRI in panic disorder without warning of early activation invites the patient to misread the first-week jitteriness as "the tablets are giving me attacks", abandon treatment, and reach back for the benzodiazepine; start low, titrate, and forewarn from the outset.

GOOD TO REMEMBER

- **SSRI (first-line, panic disorder):** serotonin re-uptake inhibitor; the one first-line indication is an SSRI licensed for panic (escitalopram Nexito, sertraline Daxid/Zosert, paroxetine Paxidep, citalopram) with CBT; the signature caution is early activation, so start low, titrate, and warn from the outset; continue at least six months in a responder (BAP 2014; NICE 2011).
- **CBT for panic (first-line psychotherapy):** the mechanism is breaking the Clark vicious cycle by cognitive restructuring, interoceptive exposure and dropping safety behaviours; the one dose to quote is 7 to 14 hours over about 4 months; it is co-equal first-line with an SSRI and combination gives the best outcomes (NICE 2011; IPS 2025).

29.5 Case two, the presentation: OCD worked up the management algorithm

case: the vignette. A 26-year-old man has intrusive contamination thoughts he recognises as his own and as excessive, and washes his hands until they crack, spending four hours a day on rituals; his baseline Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) is 28, in the *severe* band. His wife has taken over "clean" tasks to keep the peace (family accommodation). **The reasoning.** Ego-dystonic, recognised-as-own intrusive obsessions plus repetitive neutralising compulsions that consume more than an hour a day and impair function name OCD; the Y-BOCS objectifies severity and will govern every rung of the algorithm. This is a *worked example* of the four-rung ladder.

GOOD TO REMEMBER

- **Obsessive-compulsive disorder (the syndrome):** defining criterion is persistent *obsessions* (intrusive, unwanted, recognised as one's own) and/or *compulsions* (repetitive behaviours or mental acts the person feels driven to perform) that are time-consuming (conventionally more than an hour a day) or cause marked distress or impairment; the discriminator from a psychotic disorder is preserved insight that the thoughts are excessive, and the first step is to rate the Y-BOCS (ICD-11 6B20; DSM-5-TR 2022).

29.6 Case two, rung one: a high-dose SSRI for a long trial, plus ERP

The governing principle. OCD is *under-treated by default* because the doses are timid and the trials cut short; the first rung is a high-dose SSRI for a long trial, together with CBT incorporating exposure and response prevention (ERP) (BAP 2014; IPS 2025). **Applied to him.** He is started on fluoxetine (Fludac, Prodep) and escalated to **60 mg** over about five to six weeks, the OCD target being roughly the 60 to 80 mg fluoxetine-equivalent, higher than the depression dose (IPS 2025; Maudsley). It is held at the maximum tolerated dose for a *long trial*: continue for at least **12 weeks** (about 10 to 12 weeks at ceiling, with at least 6 of those weeks at the maximum) before judging efficacy (IPS 2025; New Oxford Textbook). Alongside, therapist-guided ERP works up a graded hierarchy, exposing him to a "contaminated" object and preventing the washing ritual so anxiety habituates and the belief that the ritual averts catastrophe is disconfirmed; his wife's accommodation is assessed and reduced, since high accommodation predicts poor outcome (IPS 2025).

RULE **High dose, long trial, with ERP.** First-line OCD is an SSRI pushed to the maximum tolerated dose above the depression range (fluoxetine 60 mg equivalent) for about 10 to 12 weeks, combined with CBT incorporating exposure and response prevention; this is unanimous across BAP, IPS, NICE, CANMAT and WFSBP.

TRAP **Calling the SSRI a failure too early or at too low a dose.** An OCD trial is not adequate until roughly 10 to 12 weeks at the maximum tolerated dose, with at least 6 weeks at the ceiling; switching or augmenting on a depression-range dose stopped at six weeks mislabels a slow-but-real responder as treatment-resistant.

GOOD TO REMEMBER

- **Y-BOCS (the scale):** clinician-rated 10-item scale, each item 0 to 4, total **0 to 40**; bands 0-7 subclinical, 8-15 mild, 16-23 moderate, 24-31 severe, 32-40 extreme; response is a 25 to 35% reduction and remission a score of 12 or below; it is rated at baseline and every 4 weeks and governs every rung of the OCD algorithm (Goodman 1989; IPS 2025).
- **CBT with ERP (first-line psychotherapy, OCD):** the mechanism is graded exposure to the feared stimulus with prevention of the neutralising ritual, driving habituation and belief disconfirmation; the signature principle is that exposure and response prevention must be delivered *together* (either alone is inferior, Foa); the first-line indication is mild-to-moderate OCD as monotherapy and severe OCD combined with a high-dose SSRI (IPS 2025; CANMAT 2014).

29.7 Case two, the next rungs: switch, augment, then refer

Reading the trial. At 12 weeks his Y-BOCS is 25, under a 25% reduction, so despite an adequate high-dose long trial this is *non-response*. The dose is optimised toward 80 mg for a further period;

he remains a partial responder. **Rung two, switch.** The next step is to switch, either to a second SSRI or to clomipramine (Anafranil), the one tricyclic with genuine anti-obsessional efficacy and historically the first drug shown to work in OCD, at **150 to 225 mg/day** under ECG monitoring (IPS 2025; BAP 2014). Clomipramine sits at the margins of superiority over the SSRIs but is *less well tolerated* (anticholinergic burden, cardiac conduction effects, seizure risk in overdose), which is exactly why an SSRI is tried first and clomipramine held in reserve. **Rung three, augment.** On continued partial response, low-dose antipsychotic augmentation is added to the continuing serotonergic drug: risperidone **1 to 3 mg/day** (strongest augmentation evidence) or low-dose aripiprazole, continued for at least 8 weeks, with intensive ERP throughout (IPS 2025; BAP 2014). Antipsychotics are augmentation only, never monotherapy for OCD (NICE 2005). **Rung four, refer.** Only after this whole sequence, with each trial genuinely adequate, is he refractory; the refractory rung is intensive therapist-led ERP and, at a specialist centre such as NIMHANS, IV clomipramine then deep brain stimulation or ablative neurosurgery (cross-referenced to the ECT and neurostimulation notes).

RUNG	STEP FOR THIS PATIENT	DOSE / DURATION
1 First-line	**High-dose SSRI (fluoxetine) + ERP**	60 (up to 80) mg for at least 12 weeks at ceiling
2 Switch	Optimise dose, then another SSRI or clomipramine	Clomipramine 150 to 225, ECG-monitored
3 Augment	**Add low-dose risperidone or aripiprazole to the SRI**	Risperidone 1 to 3, at least 8 weeks
4 Refer	Intensive ERP, then IV clomipramine, DBS, neurosurgery	Specialist centre only

The OCD management algorithm worked through case two; doses are bare numbers in the cells with the unit in the header (BAP 2014; IPS 2025; NICE 2005). The full ladder is drawn in the accompanying figure.

GOOD TO REMEMBER

- **Clomipramine (Anafranil):** the most serotonergic tricyclic and the original anti-obsessional drug; mechanism is potent serotonin (and noradrenaline) re-uptake inhibition; the one dose is 150 to 225 mg/day in OCD; the signature caution is poorer tolerability than an SSRI (anticholinergic, cardiac conduction, seizure in overdose) requiring ECG monitoring, so it is the switch after an adequate SSRI trial fails, not the first drug (BAP 2014; IPS 2025).
- **Antipsychotic augmentation (risperidone / aripiprazole, OCD):** low-dose dopamine blockade *added* to a continuing SSRI or clomipramine for treatment-resistant OCD; the one dose is risperidone 1 to 3 mg/day for at least 8 weeks (strongest evidence risperidone); the signature caution is that antipsychotics are augmentation only and never monotherapy for OCD (IPS 2025; NICE 2005).

29.8 Case three, the presentation: PTSD, and choosing psychotherapy first

case: the vignette. A 40-year-old lorry driver, six months after a fatal highway collision he survived, has nightly nightmares of the crash that feel as if it is happening again, cannot drive past the accident stretch, startles violently at horns and is convinced the world is now lethally dangerous. He asks for "something to calm the nerves". **The reasoning.** A qualifying trauma

(directly experiencing a life-threatening event, Criterion A) followed by re-experiencing *in the present*, avoidance of reminders and a persistent sense of current threat, all lasting more than one month, names PTSD (ICD-11 6B40; DSM-5-TR 2022). The pathognomonic feature is that the crash is re-lived here-and-now, not merely remembered, which is the line that separates PTSD from ordinary painful recollection.

GOOD TO REMEMBER

- **Post-traumatic stress disorder (the syndrome):** defining criterion is a qualifying trauma (Criterion A) followed by the ICD-11 triad, *re-experiencing in the present*, deliberate avoidance of reminders, and a persistent sense of current threat, lasting more than one month; the single discriminator is that the event is re-lived here-and-now (flashbacks, nightmares that feel current), not simply recalled; the first management step is to offer a trauma-focused psychotherapy, not a drug (ICD-11 6B40; DSM-5-TR 2022).

29.9 Case three, the management: trauma-focused therapy first, SSRI and prazosin considered

The governing rule. The single most examinable statement in PTSD management is that a trauma-focused psychotherapy, not a drug, is first-line: trauma-focused CBT (cognitive processing therapy, cognitive therapy for PTSD, narrative exposure, prolonged exposure) or EMDR, typically over **8 to 12** sessions, offered in preference to medication (NICE 2018; BAP 2014; VA/DoD 2023). Drugs are second, offered when psychotherapy is declined, unavailable or insufficient. **Applied to him.** He is told that trauma-focused psychotherapy would be the first choice; because he presses for medication, a licensed SSRI, sertraline (Daxid, Zosert) or paroxetine (Paxidep), or the SNRI venlafaxine, is appropriate, titrated to the maximum tolerated dose, with the warning that a therapeutic effect may take up to **12 weeks** to assess and a responder continues for at least **12 months** (BAP 2014; NICE 2018). Because trauma nightmares are prominent, prazosin (Minipress, Prazopress), a selective alpha-1 blocker, is *considered* as a targeted add-on for the nightmares, started at 1 mg nocte and titrated to **2 to 15 mg** nocte to avoid first-dose hypotension (CANMAT 2014; Maudsley). **The hard negative.** The "something to calm the nerves" he wants must *not* be a benzodiazepine: it treats none of the PTSD clusters, blunts the emotional engagement trauma-focused therapy needs, and may *increase* PTSD risk if given early after trauma (VA/DoD 2023; CANMAT 2014).

RULE **Trauma-focused therapy first; never a benzodiazepine.** In PTSD the first-line treatment is a manualised trauma-focused psychotherapy (TF-CBT or EMDR); where a drug is used it is a licensed SSRI (sertraline, paroxetine) or venlafaxine, with prazosin for nightmares; the benzodiazepine is excluded at every step (NICE 2018; VA/DoD 2023).

GOOD TO REMEMBER

- **Trauma-focused psychotherapy (first-line, PTSD):** the mechanism is deliberate processing of the traumatic memory so the event is refiled as past rather than relived as present (TF-CBT or EMDR); the one indication is that it is offered *before* drugs, typically over 8 to 12 sessions; the signature principle is that generic supportive counselling does not qualify, only memory-processing therapies (NICE 2018; VA/DoD 2023).
- **Sertraline / paroxetine (SSRI, PTSD):** the two SSRIs licensed for PTSD and the first-line drug once psychotherapy is set aside; mechanism is serotonin re-uptake inhibition; the signature caution is that a full trial takes up to 12 weeks and early activation can transiently worsen symptoms; continuation after response is at least 12 months (BAP 2014; NICE 2018).
- **Prazosin (Minipress / Prazopress, alpha-1 blocker):** the targeted add-on for PTSD trauma nightmares and sleep disturbance; mechanism is alpha-1 blockade lowering central noradrenergic tone; the one dose is 1 mg nocte titrated to 2 to 15 mg; the signature caution is first-dose hypotension, and it augments, never replaces, first-line psychotherapy or an SSRI/SNRI (CANMAT 2014; Maudsley).

29.10 Case four, the presentation: anxiety versus a medical mimic

case: the vignette. A 45-year-old man is referred with "treatment-resistant panic": episodic palpitations, pounding headache, drenching sweats and a surge of dread, several times a week, unresponsive to an SSRI. He drinks six cups of coffee a day and takes an over-the-counter decongestant. **The reasoning, in the right order.** Before any anxiety label, ask "is this organic?". The *tempo* is the pivot: these are *episodic, paroxysmal* autonomic storms, which mimic panic rather than GAD, and the pounding headache plus recorded blood-pressure spikes point away from a primary disorder. The work-up must clear the body first, and only then, if all negative, settle on a primary anxiety disorder. This is a *worked example* of "exclude the body before you name the disorder".

29.11 Case four, excluding the three mimics: hyperthyroidism, phaeochromocytoma, substance

Hyperthyroidism, the sustained mimic of GAD. Thyrotoxicosis reproduces the somatic tail of anxiety (irritability, tremor, tachycardia), but because the thyroid drive is *continuous* it mimics *sustained* GAD, not his episodic picture; still, it is the commonest organic mimic and is screened with thyroid function (a suppressed TSH with raised free T4), looking for goitre, exophthalmos, atrial fibrillation and weight loss with a preserved appetite (Shorter Oxford Textbook). **Phaeochromocytoma, the paroxysmal mimic of panic.** This catecholamine-secreting tumour releases adrenaline and noradrenaline in *bursts*, producing exactly his paroxysmal palpitations, pounding headache and sweating; because the secretion is episodic it mimics panic. The pointing feature is *paroxysmal hypertension*, blood pressure spiking with each attack, and the screening test is plasma or 24-hour urinary metanephrines and catecholamines; the discriminator is the recorded hypertensive surge and the headache, which panic disorder does not produce (Shorter Oxford Textbook; New Oxford Textbook). **The substance cause.** His six coffees and the sympathomimetic decongestant are a substance mimic: DSM defines caffeine intoxication as recent intake usually over **250 mg** with **five or more** autonomic and neuropsychiatric symptoms, and the discriminator is that the anxiety settles on cutting the load (DSM-5-TR 2022). Only with thyroid function, metanephrines and the substance history all clear would a primary panic disorder be diagnosed, and the SSRI failure re-read as a mislabelled organic case.

MIMIC IN THIS CASE	POINTING FEATURE	SCREENING TEST
Hyperthyroidism	Goitre, exophthalmos, AF, weight loss with appetite (sustained, mimics GAD)	Thyroid function (TSH, free T4)
Phaeochromocytoma	**Paroxysmal hypertension, pounding headache (episodic, mimics panic)**	Plasma/urinary metanephrines, catecholamines
Substance (caffeine / sympathomimetic)	High caffeine load, decongestant, intoxication signs	Substance history; caffeine over 250 mg + 5 or more symptoms

Case four, the three mimics excluded before settling on a primary anxiety disorder; the tempo (episodic vs sustained) tells you which physical test to send (Shorter Oxford Textbook; New Oxford Textbook; DSM-5-TR 2022).

COMMON TRAP

The exam-fatal error in case four is to accept "treatment-resistant panic" at face value and add a second psychotropic while an organic lesion sits in plain sight. Episodic autonomic storms with paroxysmal hypertension and a pounding headache are a phaeochromocytoma until proven otherwise; a high caffeine and decongestant load is a substance mimic; each is treated at its source, not with another SSRI or, worse, a benzodiazepine.

GOOD TO REMEMBER

- **Phaeochromocytoma (the mimic):** a catecholamine-secreting tumour producing paroxysmal palpitations, pounding headache and sweating that mimic panic; the discriminator is paroxysmal hypertension with a recorded blood-pressure surge in the attack; the screening test is plasma or urinary metanephrines and catecholamines; the first step is that episodic autonomic storms mean "exclude phaeochromocytoma" before a panic label (Shorter Oxford Textbook; New Oxford Textbook).
- **Hyperthyroidism (the mimic):** the sustained organic mimic of GAD (tremor, tachycardia, restlessness); the discriminator is the physical thyroid signs (goitre, exophthalmos, weight loss with appetite) and resolution on treating the thyroid; the screening test is thyroid function (suppressed TSH, raised free T4) (Shorter Oxford Textbook).

INDIA

All four cases sit inside the same Indian reality: a wide anxiety, OCD and PTSD treatment gap (these disorders are common, heavily somatised as palpitations, tremor and "gas", and under-recognised), and an entrenched benzodiazepine over-prescription problem, typically alprazolam, prescribed long-term in primary care against every guideline. Case one's carried alprazolam, case three's request to "calm the nerves", and case four's referral as "treatment-resistant panic" are each the habit in miniature; a large number of Indian patients labelled "anxiety" are actually in daily alprazolam micro-withdrawal, itself an iatrogenic mimic. The Indian Psychiatric Society clinical practice guidelines correct all of this, exclude the organic causes, treat the primary disorder with an SSRI or SNRI and a structured psychotherapy first, and keep the benzodiazepine a short, time-limited bridge rather than a standing prescription. Indian brands are available across the board, fluoxetine (Fludac, Prodep), sertraline (Daxid, Zosert), escitalopram (Nexito), paroxetine (Paxidep), clomipramine (Anafranil), prazosin (Minipress, Prazopress) and propranolol (Ciplar, Inderal), so the limiting factor is recognition and adequate dosing, not access.

10 to 12 weeks	28	2 to 15	250 mg
ADEQUATE OCD SSRI TRIAL AT MAXIMUM TOLERATED DOSE	Y-BOCS OF CASE TWO (SEVERE BAND, 24 TO 31)	PRAZOSIN NOCTE RANGE, MG (START 1, TITRATE)	CAFFEINE INTOXICATION THRESHOLD (PLUS 5 OR MORE SYMPTOMS)

MNEMONIC

READ THE TEMPO, THEN THE FOCUS, THEN THE LADDER

Across the four cases: **READ THE TEMPO** (episodic storms mean exclude phaeochromocytoma, hypoglycaemia, a substance; sustained tremor with weight loss means thyrotoxicosis) → **THEN THE FOCUS** of the fear names the anxiety disorder (the next attack = panic; escape/rescue = agoraphobia; re-lived here-and-now = PTSD; ego-dystonic obsessions = OCD) → **THEN THE LADDER** (SSRI + CBT for panic; high-dose SSRI + ERP then switch/augment/refer for OCD; trauma-focused therapy first then SSRI + prazosin for PTSD), never a standing benzodiazepine.

PEARL

Every one of these four vignettes has the same wrong answer hiding in it, the benzodiazepine: the pocketed alprazolam in case one, the "calm the nerves" request in case three, the reflex add-on in case four's mislabelled panic. Name why it is wrong in each (safety behaviour in panic, harmful in PTSD, masking an organic lesion in the mimic case) and you have shown the examiner the single thread that runs through the whole anxiety, OCD and trauma management syllabus.

HOLD THIS

Work every anxiety, OCD or trauma case in the same order, exclude the organic mimic by tempo first (episodic storms = phaeochromocytoma/hypoglycaemia/substance, sustained = thyrotoxicosis), then name the disorder by the focus of the fear, then climb the guideline ladder (SSRI plus CBT for panic; high-dose SSRI plus ERP then clomipramine then risperidone/aripiprazole augmentation for OCD; trauma-focused psychotherapy first then a licensed SSRI plus prazosin for PTSD), and at no step reach for a standing benzodiazepine.

30 · Consolidation

The whole chapter now sits in front of you, and this closing topic is not new content but the machinery that turns reading into recall. The examination does not reward the candidate who has *read* the anxiety, OCD and trauma block; it rewards the one who can, cold and under pressure, state the discriminating criterion for each syndrome, the one first-line agent for each disorder, the OCD ladder in order, the scale bands to the number, and the PTSD algorithm in a single line. Those retrievals are what this topic drills. The single most robust finding in the science of learning is that **active recall** (pulling an answer out of an empty page) and **retrieval practice** (repeatedly testing yourself rather than re-reading) beat every passive method for durable memory, so the design here is deliberately answer-sparse: prompts first, and the answers held elsewhere in the chapter so you must fetch them.

Why it matters, and what this note owns. This note owns three things: the **mnemonic** that ties the chapter together, paid off from where it was seeded at the generalised-anxiety-disorder opener; a set of answer-free prompt lists for **active recall** across the anxiety disorders and their

first-line agents, the OCD ladder, the Y-BOCS bands, the PTSD algorithm and the trauma-disorder discriminators; and a whole-chapter **synthesis map** you are meant to **redraw from memory**. It re-derives no criteria, doses or bands of its own; every number quoted here is a pointer back to the topic that verified it. The deep pharmacology behind the drug names lives in the Mood disorders: pharmacotherapy notes and the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes; the fear-circuit substrate in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; the general CBT and exposure model in the Psychotherapies, clinical assessment, MSE and nosology notes. The synthesis map that carries the whole block is drawn in the accompanying figure, framed cover-the-branches so it can be used as a retrieval test.

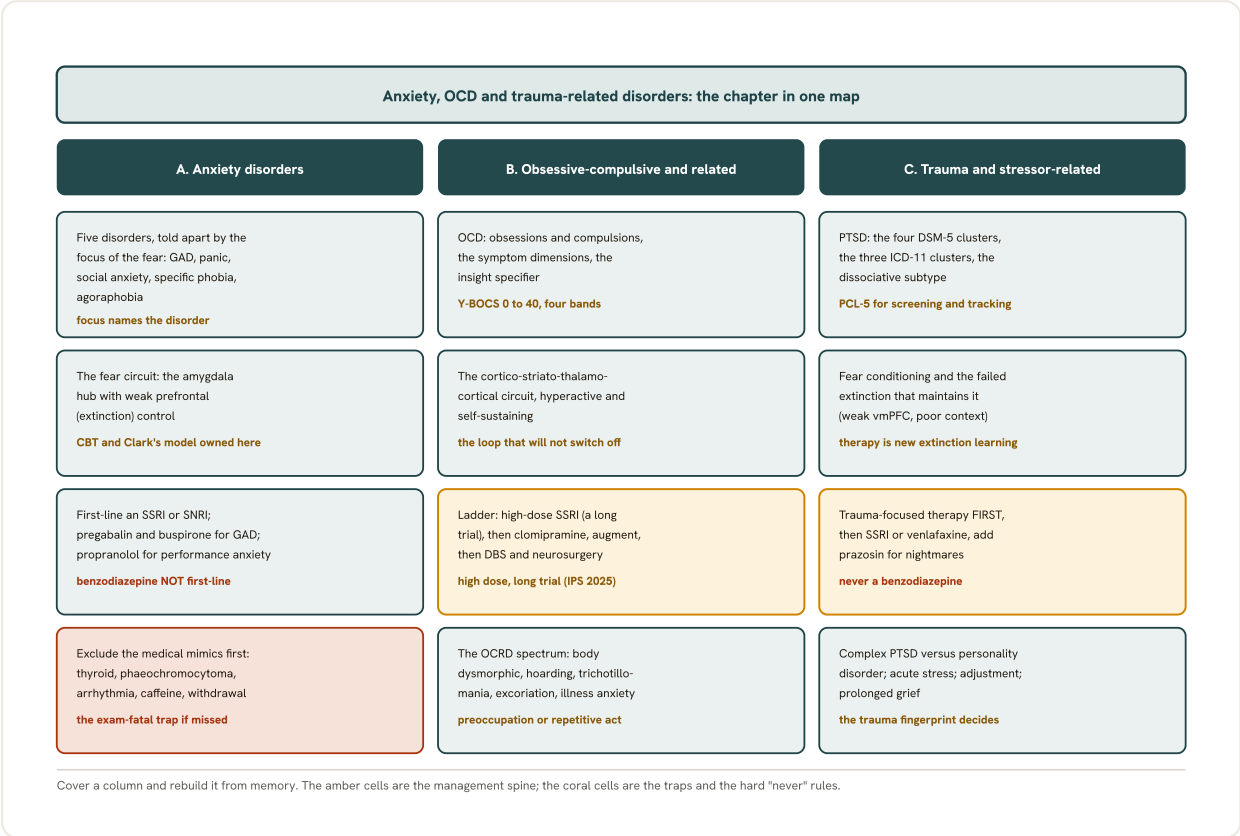

Fig 14.20 The whole chapter in one synthesis map, built for retrieval. Three columns, one per band: the anxiety disorders (told apart by the focus of the fear, treated with an SSRI or SNRI, the medical mimics excluded first); the obsessive-compulsive and related disorders (OCD and its cortico-striato-thalamo-cortical circuit, the high-dose long-trial ladder, the OCRD spectrum); and the trauma and stressor-related disorders (PTSD and its clusters, the fear-conditioning neurobiology, the trauma-focused-therapy-first algorithm, and the complex-PTSD discrimination). The amber cells are the management spine and the coral cells the traps and the hard rules. Cover a column and redraw it from memory, then check it against the note.

30.1 The master mnemonic, paid off: WORRIED FEARS

Seeded at the opener, closed here. The chapter opened by seeding the master mnemonic **"WORRIED FEARS"** at generalised anxiety disorder, and this is where it is paid off, because its two halves are not really about GAD alone: they encode the *template* that repeats across the whole anxiety block. **WORRIED** is the anxiety *picture* (worry that is free-floating and uncontrollable, on-edge restlessness, rumination and poor concentration, relaxation made impossible by muscle tension, irritability, easy fatigue, disturbed sleep). **FEARS** is the anxiety *management* template:

First-line SSRI or SNRI, **E**valuate for a long enough trial before judging failure, **A**lternatives such as pregabalin and buspirone, **R**efer to CBT as a co-equal first-line, and **S**hun the benzodiazepine as long-term monotherapy. If you can expand both halves without looking, you hold the spine of the entire block.

MNEMONIC

WORRIED FEARS

The chapter master mnemonic, paid off. **WORRIED** = the picture: **W**orry (free-floating, uncontrollable), **O**n edge/restless, **R**umination/poor concentration, **R**elaxation impossible (muscle tension), **I**rritability, **E**asily fatigued, **D**isturbed sleep. **FEARS** = the management template that repeats across the anxiety disorders: **F**irst-line SSRI/SNRI, **E**valuate over a long enough trial, **A**lternatives pregabalin and buspirone, **R**efer/CBT co-equal first-line, **S**hun the benzodiazepine long-term. Two further chapter mnemonics ride alongside it: **TIDRC** for the five Y-BOCS parameters, and **PTSD + A S R** for complex PTSD (the PTSD triad plus affect dysregulation, negative self-concept, relationship difficulty).

RULE **One template, many disorders.** For every anxiety disorder the default answer is SSRI (or SNRI) first-line plus CBT/exposure, with the benzodiazepine never the long-term monotherapy; learn the template once and vary only the twist (propranolol for performance, prazosin for nightmares, high-dose-long-trial for OCD).

30.2 Active-recall prompt list: the anxiety disorders and their first-line agents

Cover the answers and pull each one. This is a **retrieval practice** list, not a summary. For each disorder below, say aloud (or write) the one discriminating criterion and the first-line treatment before you check it against the topic that verified it. The point is the effort of retrieval: the harder the pull, the stronger the trace.

- **Generalised anxiety disorder.** Prompt: the discriminator from normal worry? The two numbers in DSM-5-TR? First-line drug and the two options? (Answers in the GAD topic: uncontrollable free-floating worry; **6 months**, 3 of 6; SSRI/SNRI first-line, pregabalin and buspirone as options.)
- **Panic disorder.** Prompt: what makes an attack diagnostic, and the one prescribing warning? (Recurrent *unexpected* attacks peaking within minutes plus a month of anticipatory anxiety; SSRI first-line started *low and slow* with a warning about early activation.)
- **Agoraphobia.** Prompt: the cognitive core, and is it tied to panic? (Fear that escape is difficult or help unavailable in at least two of five situations; a stand-alone disorder now, *irrespective* of panic disorder; exposure-based CBT core, SSRI for the panic component.)
- **Social anxiety disorder.** Prompt: the object of the fear, the one specifier, and the twist in treatment? (Fear of negative evaluation; the *performance-only* specifier; SSRI plus CBT for the generalised form, a situational beta-blocker for discrete performance anxiety.)
- **Specific phobia.** Prompt: the treatment of choice, and the drug trap? (Graded in-vivo exposure; a benzodiazepine is *not* first-line and blunts the extinction learning exposure

depends on.)

- **Separation anxiety disorder.** Prompt: the fear, and how it is easily missed? (Fear of separation from an attachment figure; presents as school refusal in a child or is sedated rather than diagnosed in an adult; exposure-based CBT, SSRI if needed.)

GOOD TO REMEMBER

- **The anxiety first-line map:** every one of GAD, panic disorder, agoraphobia, social anxiety and separation anxiety is SSRI (or SNRI) plus CBT/exposure first-line; specific phobia is *exposure-first* with drugs not first-line; the two disorder-specific twists are the situational beta-blocker (propranolol) for performance anxiety and starting the SSRI low-and-slow in panic; the benzodiazepine is never the long-term answer for any of them.

30.3 Active-recall prompt list: the OCD ladder and the trial rules

Recite the staircase in order. OCD management is a four-rung ladder governed by one idea, that OCD is under-treated by default because doses are timid and trials are cut short. Retrieve the rungs and the numbers before checking them against the OCD management topic.

- **Rung one.** Prompt: the first-line, and what makes it different from depression prescribing? (A *high-dose* SSRI for a *long* trial of about **10 to 12 weeks** plus CBT with exposure and response prevention; target roughly the 60 to 80 mg fluoxetine-equivalent.)
- **Rung two.** Prompt: what to do on partial or no response, and the classic contrast? (Optimise the dose, then switch SSRI or to clomipramine; the clomipramine-versus-SSRI point is that clomipramine sits at the margins of superiority but is *less tolerated*, so it is held in reserve, under ECG monitoring.)
- **Rung three.** Prompt: the augmentation step? (Low-dose antipsychotic augmentation, aripiprazole or risperidone, added to the continuing serotonergic drug for at least 8 weeks; augmentation only, never monotherapy.)
- **Rung four.** Prompt: the refractory options? (Intensive therapist-led ERP and, at a specialist centre only, intravenous clomipramine, then deep brain stimulation and ablative neurosurgery, cross-referenced to the ECT and neurostimulation notes.)
- **The judging rule.** Prompt: how is failure judged, and over what window? (By a less-than-25-to-35% fall on the Y-BOCS after a full high-dose trial of at least **12 weeks**, not by the patient's gestalt.)

TRAP **Calling an OCD trial a failure too early.** The commonest error is switching or augmenting before a high-dose SSRI has run about 10 to 12 weeks at the maximum tolerated dose, or judging on a depression-range dose; a slow-but-real responder is then mislabelled treatment-resistant and the ladder is climbed prematurely.

GOOD TO REMEMBER

- **The OCD ladder:** high-dose SSRI (about 60 to 80 mg fluoxetine-equivalent) for a long trial of roughly 10 to 12 weeks with ERP, then clomipramine (Anafranil) on failure, then aripiprazole or risperidone augmentation, then intensive ERP and specialist neurosurgery/DBS; judge response by a 25 to 35% Y-BOCS fall, continue a responder for at least 1 to 2 years, and the benzodiazepine has no place at any rung.

30.4 Active-recall prompt list: the Y-BOCS bands and the other scales

The bands are pure memorisation, so drill them. The scale numbers are the ones examiners ask for verbatim, so they reward the tightest retrieval practice. Cover the answers, recite each scale's structure and cut-off, and only then check against the scale topics. The instrument forms themselves are typeset centrally, so work from the accompanying scale plate rather than any pasted questionnaire.

SCALE	WHAT IT MEASURES	STRUCTURE AND THE NUMBER TO HOLD
Y-BOCS	**OCD *severity* (not diagnosis)**	10 items, each 0 to 4, total 0 to 40; bands subclinical 0 to 7, mild 8 to 15, moderate 16 to 23, severe 24 to 31, extreme 32 to 40; **16** is the trial-entry cut-off (floor of moderate); five parameters = TIDRC
GAD-7	GAD screen and severity	**7 items, each 0 to 3, total 0 to 21; bands 5/10/15; clinical cut-off 10; GAD-2 is the rapid screen**
HAM-A	Anxiety severity (clinician-rated)	14 items, each 0 to 4, max **56**; psychic and somatic factors; the GAD drug-trial outcome measure
PCL-5	PTSD screen and monitor	**20 items, each 0 to 4, total 0 to 80; provisional cut-off 31 to 33 for probable PTSD; not a diagnosis (CAPS-5/SCID is)**
LSAS	Social anxiety severity	24 items rating fear and avoidance, each 0 to 3; the social-anxiety trial outcome measure; Mini-SPIN is the rapid screen

The five chapter scales and the verified numbers to recall cold; the Y-BOCS bands and the PCL-5 cut-off are the two most-asked, and each instrument's form is set out on the accompanying scale plate (verified against the individual scale topics).

0 to 40 Y-BOCS TOTAL; MODERATE BAND FLOOR AT 16	**10** GAD-7 CLINICAL CUT-OFF (BANDS 5/10/15)	**31 to 33** PCL-5 PROVISIONAL CUT-OFF FOR PROBABLE PTSD	**10 to 12 weeks** ADEQUATE HIGH-DOSE SSRI TRIAL IN OCD

GOOD TO REMEMBER

- **The five scales:** Y-BOCS (10 items, 0 to 40, cut-off 16, bands 0-7/8-15/16-23/24-31/32-40); GAD-7 (7 items, 0 to 21, cut-off 10); HAM-A (14 items, max 56, clinician-rated); PCL-5 (20 items, 0 to 80, cut-off 31 to 33); LSAS (24 items, fear and avoidance) are the block's instruments; the defining fact each time is that a scale *grades severity or screens*, it never makes the diagnosis.

30.5 Active-recall prompt list: the PTSD algorithm and the two hard rules

State the ladder as one ordered line. PTSD management is one of the cleanest algorithms in the syllabus, and it hangs off two rules that should be the first sentence of any answer: *trauma-focused psychotherapy is first-line, and a benzodiazepine is never used*. Retrieve the sequence before checking it against the PTSD treatment topic.

- **First-line.** Prompt: which treatment, and which therapies qualify? (A manualised **trauma-focused psychotherapy**, either TF-CBT (cognitive processing therapy, cognitive therapy for PTSD, narrative exposure, prolonged exposure) or EMDR, over about 8 to 12 sessions, ahead of any drug.)
- **First-line drug.** Prompt: when a drug is used, which agents? (The two licensed SSRIs sertraline and paroxetine, or the SNRI venlafaxine; allow up to **12 weeks** for a trial.)
- **The symptom-targeted add-on.** Prompt: for nightmares and disturbed sleep? (Prazosin (Minipress, Prazopress), an alpha-1 blocker, started at **1 mg nocte** and titrated to 2 to 15 mg, as an add-on, never monotherapy.)
- **Non-response.** Prompt: the sequence? (Raise the dose, then switch, then augment with an antipsychotic (risperidone, olanzapine) or combine drug plus psychotherapy and refer.)
- **The exclusion.** Prompt: the one drug class ruled out? (The *benzodiazepine*, at every step, ineffective for the core clusters and possibly raising PTSD risk if given acutely.)

TRAP **A benzodiazepine in PTSD, or as monotherapy for any anxiety disorder.** Benzodiazepines touch none of the PTSD clusters and blunt the emotional engagement trauma-focused therapy needs; the exam-fatal error is to offer one for PTSD, or to write one up as the long-term treatment for GAD, panic or phobia.

GOOD TO REMEMBER

- **The PTSD algorithm:** trauma-focused psychotherapy (TF-CBT or EMDR) first everywhere; if a drug is used, a licensed SSRI (sertraline, paroxetine) or venlafaxine over a trial of up to 12 weeks; prazosin (Minipress, Prazopress) added for nightmares; on non-response raise, switch, then augment with an antipsychotic; continue a responder at least 12 months; and never a benzodiazepine at any step.
- **EMDR / trauma-focused CBT (the psychotherapies):** both process the traumatic memory directly and are the co-equal first-line for PTSD and complex PTSD over about 8 to 12 sessions; the principle is that generic supportive counselling does *not* qualify, and complex PTSD often needs a phased approach (stabilisation before trauma processing).

30.6 Active-recall prompt list: the trauma-disorder discriminators

The trauma cluster is discriminated by time and by structure. The stressor-related disorders are separated mainly by *duration* and by the *shape* of the reaction, and examiners test the boundaries, not the lists. Retrieve each discriminator before checking it against the relevant topic.

BOUNDARY	THE DISCRIMINATOR TO STATE
Acute stress reaction vs acute stress disorder	**ICD-11 acute stress reaction is *not a disorder* (QE84, a health-status factor, transient, hours to 1 to 3 days); DSM-5-TR acute stress disorder *is* a diagnosis (9 of 14 symptoms, 3 days to 1 month)**
Acute stress disorder vs PTSD	Purely the time window: acute stress disorder under a month; PTSD over a month
PTSD vs complex PTSD	**Complex PTSD = the full PTSD triad *plus* the three disturbances in self-organisation (affect dysregulation, negative self-concept, relationship difficulty)**
Complex PTSD vs personality disorder	**Trauma-reminder avoidance and current threat (absent in PD); a *stable* negative self-view (vs unstable); disconnection (vs abandonment-driven instability); less frequent but higher-lethality suicidality**
Prolonged grief disorder	Persistent yearning exceeding the cultural norm; at least 6 months (ICD-11) or at least 12 months in adults (DSM-5-TR); do not pathologise normal grief too early
Adjustment disorder	Maladaptive reaction to an identifiable stressor (ICD-11 core: preoccupation plus failure to adapt); onset within 1 month (ICD-11) or 3 months (DSM-5-TR); resolves within 6 months of the stressor ending; trumped by any full disorder

The trauma-disorder discriminator grid: the block is separated mainly by duration and by whether the reaction is a normal response, a diagnosable disorder, or a personality pattern (verified against the acute-stress, PTSD, complex-PTSD, prolonged-grief and adjustment-disorder topics).

GOOD TO REMEMBER

- **Complex PTSD versus personality disorder (the discrimination that unlocks treatment):** both share affective dysregulation, but complex PTSD carries the trauma fingerprint, reminder avoidance and a persistent sense of current threat, a *stable* negative self-view, relationships marked by disconnection (not fear of abandonment), and higher-lethality suicidality; getting the label right is what preserves a survivor's access to trauma-focused therapy.

30.7 The whole-chapter synthesis map, framed cover-the-branches

Build the tree, then redraw it blind. The strongest single revision act for this block is to **redraw from memory** a **synthesis map** that hangs every disorder off its trunk. The map has three trunks: the *anxiety disorders* (carved by the object of the fear), *OCD and the related disorders* (the obsessive-compulsive spectrum), and the *stressor-related disorders* (carved by time and structure). From each trunk hang the disorders, and from each disorder hang its one discriminator, its scale

and its first-line treatment. The accompanying figure draws this map; use it as a retrieval test by covering all the branches and regenerating them, then uncovering to score yourself, exactly the cover-the-branches method that makes **retrieval practice** work.

How to use it. First pass: cover everything but the three trunks and name the disorders under each. Second pass: for each disorder, cover the discriminator and pull it. Third pass: cover the treatment column and recite the first-line agent and the one twist. A branch you cannot regenerate is a branch to re-read in its own topic; a branch you can is one you can leave. Repeated over spaced sittings, the map converts the chapter from something you recognise into something you can produce.

PEARL

The chapter collapses to three trunks and one template. Trunk one, the *anxiety disorders*, are carved by the object of the fear (diffuse worry, unexpected attacks, escape impossible, negative evaluation, a cued object, separation) and all answer to SSRI/SNRI plus CBT. Trunk two, *OCD and its spectrum*, run the high-dose-long-trial ladder governed by the Y-BOCS. Trunk three, the *stressor-related disorders*, are carved by time (reaction, acute stress disorder, PTSD) and by structure (complex PTSD, prolonged grief, adjustment), with trauma-focused psychotherapy first for PTSD. Cover the branches, redraw the tree, and you own the block.

INDIA

The Indian thread runs through every trunk and is worth carrying as one line at consolidation: a very wide **anxiety, OCD and PTSD treatment gap** (most sufferers never reach formal care, distress is somatised and under-recognised), into which has flowed the entrenched **benzodiazepine over-prescription problem** (typically long-term alprazolam or clonazepam given first-line against every guideline). The corrective is the same across the block and is exactly what the **Indian Psychiatric Society CPGs** say: an SSRI or SNRI first-line with CBT or exposure, the high-dose-long-trial rule enforced in OCD, trauma-focused psychotherapy first in PTSD, and the benzodiazepine reserved and time-limited, never the maintenance treatment. The first-line agents are cheap and familiar as Indian brands, escitalopram (Nexito, Rexipra), sertraline, fluoxetine and fluvoxamine, with clomipramine (Anafranil), propranolol (Ciplar, Inderal) for performance anxiety, and prazosin (Minipress, Prazopress) for trauma nightmares.

HOLD THIS

Redraw the three-trunk synthesis map from memory: anxiety disorders (carved by the object of the fear, all SSRI/SNRI plus CBT), OCD and its spectrum (high-dose SSRI for a long trial with ERP, then clomipramine, then antipsychotic augmentation, governed by the Y-BOCS), and the stressor-related disorders (carved by time and structure, trauma-focused psychotherapy first for PTSD, prazosin for nightmares), with the benzodiazepine excluded from long-term use across the whole block.

Previously asked

This territory is examined at two levels at once: the syndrome (its clinical features, its differential diagnosis and its course) and the treatment (which first-line agent, the obsessive-compulsive-disorder ladder, the trauma-focused algorithm). The reliable pattern is that obsessive-compulsive disorder and panic disorder carry the most weight in the anxiety and related section, that post-traumatic stress disorder is the dominant trauma essay, and that a single disorder or a single treatment can be asked as a standalone note. Every long essay ends in a guideline-anchored management plan, so the first-line recommendation and the reason for it must be exam-ready. The genuine questions on record are grouped by band below. The anxiolytic and antidepressant pharmacology these disorders are treated with is developed in the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes and the Mood disorders: pharmacotherapy notes; the fear-circuit anatomy is developed in the Neurochemistry, neuroendocrinology, neuroimaging and basic psychopharmacology notes; and the wider cognitive behaviour therapy technique is cross-referenced to the Psychotherapies, clinical assessment, MSE and nosology notes, while exposure and response prevention, trauma-focused therapy and Clark's model are owned here.

HOW THIS TERRITORY IS ACTUALLY TESTED

- **The anxiety disorders, with panic and generalised anxiety leading.** "Describe various anxiety disorders. Discuss the clinical features and management of generalized anxiety disorder" has come as a full 25-mark essay, and panic disorder recurs at every length: "Discuss etiopathology, clinical features, differential diagnosis and management of panic disorder" as a 25-mark essay, "Differential diagnosis, clinical features and course of Panic disorders" as a 10-mark note, and "Panic disorder" and "Panic disorders" as standalone notes across several sittings. Prepare the anxiety-disorders differential (generalised anxiety versus panic versus social anxiety versus the phobias), the medical mimics that must be excluded, and the guideline-anchored first-line management for each. essay and short note, recurring

- **Obsessive-compulsive disorder, its management and its recent advances.** This is the most heavily examined disorder in the band: "Discuss etiopathogenesis, clinical features and management of obsessive compulsive disorders", "Discuss the etiology, clinical features and management of obsessive compulsive disorder", "Discuss the recent advances in the treatment of obsessive compulsive disorder" and "Discuss the nosological shift of OCD in DSM-5 and its spectrum" have all come as 25-mark essays, and "Management of OCD" recurs as a 10-mark note. Prepare the full management ladder (the high-dose serotonin reuptake inhibitor for a long trial, clomipramine, exposure and response prevention, antipsychotic augmentation and the refractory options), the cortico-striato-thalamo-cortical model and the obsessive-compulsive related spectrum. essay and short note, recurring

- **The obsessive-compulsive related disorders.** "Trichotillomania" has come as a standalone 10-mark note, and the obsessive-compulsive related disorders are drawn into the wider "impulse control disorders" essay. Prepare body dysmorphic disorder, hoarding, trichotillomania and excoriation as a compact spectrum, each recognised by its defining repetitive behaviour or preoccupation. short note, recurring

- **Post-traumatic stress disorder, its features and its evidence-based treatment.** "Describe the core symptoms and risk factors in PTSD. Discuss management strategies of PTSD" and "Discuss the etiopathogenesis, clinical features and management of post-traumatic stress disorder" have both come as 25-mark essays, and "Post traumatic stress disorder" recurs as a 10-mark note. Prepare the symptom clusters (the DSM-5 four and the ICD-11 three), the trauma-focused-psychotherapy-first algorithm with

the pharmacotherapy and prazosin behind it, and the rule that a benzodiazepine is not used. essay and short note, recurring

Q **Acute stress, grief and the other trauma and stressor disorders.** "Acute Stress Disorder" (paired with chronic fatigue syndrome in one sitting), "Complicated grief" and "Grief" have each come as 10-mark notes across several years, and eye movement desensitisation and reprocessing ("EMDR") as a standalone note. Prepare the acute-stress-reaction-versus-disorder distinction, complex post-traumatic stress disorder and its separation from a personality disorder, prolonged grief disorder against normal grief, and EMDR as a trauma-focused therapy. short note, recurring

Prepare this material to be diagnosed and treated, not just recited: the anxiety-disorders and medical-mimic differentials, the scale cut-offs (the GAD-7, HAM-A, Y-BOCS and PCL-5 bands), the dose-anchored good-to-remember boxes, the obsessive-compulsive-disorder ladder and the trauma-focused algorithm in these notes are built to the way the block is examined. The anxiolytic and hypnotic pharmacology lives in the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes; the deep antidepressant pharmacology in the Mood disorders: pharmacotherapy notes; the fear-circuit anatomy in the Neurochemistry, neuroendocrinology, neuroimaging and basic psychopharmacology notes; deep brain stimulation and neurosurgery for refractory obsessive-compulsive disorder in the ECT and neurostimulation notes; and the somatic-symptom and illness-anxiety boundary in the Somatic-symptom, sexual, impulse-control disorders and suicide notes.

Quick review

THE ANXIETY DISORDERS: THE FOCUS OF THE FEAR, THE FIRST-LINE, AND THE SCALES	
THE DISCRIMINATOR	The anxiety symptoms are shared; the disorders separate by the **focus of the fear**. GAD = free-floating worry about everything; panic = the next attack; social anxiety = negative evaluation; specific phobia = one circumscribed object; agoraphobia = no escape or help.
GENERALISED ANXIETY DISORDER	Chronic uncontrollable worry across domains. First-line an **SSRI or SNRI**; also **pregabalin** and **buspirone**; a benzodiazepine is **not** first-line and not for long-term use.
PANIC DISORDER AND CLARK'S MODEL	Recurrent unexpected panic; the vicious cycle is the **catastrophic misinterpretation** of benign body sensations, maintained by safety behaviours. First-line SSRI (start low, warn about early activation) and CBT.
SOCIAL ANXIETY, PHOBIAS, AGORAPHOBIA	Social anxiety: SSRI and CBT, with **propranolol** for discrete performance anxiety. Specific phobia: graded exposure and systematic desensitisation (blood-injection-injury is diphasic vasovagal, use applied tension). Agoraphobia: exposure, now diagnosable independent of panic.
THE SCALES	**GAD-7**: 7 items 0 to 3, total **0 to 21**; 5, 10 and 15 mark mild, moderate and severe, and **10 or more** is the clinical cut-off. **HAM-A**: 14 clinician-rated items 0 to 4, total **0 to 56**.
EXCLUDE THE BODY FIRST	Before naming an anxiety disorder, exclude the mimics by tempo: **sustained** thyrotoxicosis (TSH) mimics GAD; **episodic** phaeochromocytoma (metanephrines) and hypoglycaemia mimic panic; the sign-first arrhythmia (ECG) and asthma; **worst on waking** is alcohol or benzodiazepine withdrawal; caffeine over **250 mg**. Missing a mimic is the exam-fatal error.
OBSESSIVE-COMPULSIVE AND RELATED DISORDERS: FEATURES, THE CIRCUIT, THE LADDER	
OCD FEATURES	Obsessions (intrusive, unwanted, ego-dystonic) and compulsions (neutralising acts); symptom dimensions (contamination/washing, symmetry/ordering, forbidden thoughts, harm/checking); the **insight specifier** (good or fair, poor, absent or delusional) and the tic-related specifier.
Y-BOCS	10 clinician-rated items (5 obsession, 5 compulsion), each 0 to 4, total **0 to 40**. Bands: **0 to 7 subclinical, 8 to 15 mild, 16 to 23 moderate, 24 to 31 severe, 32 to 40 extreme**.

OBSESSIVE-COMPULSIVE AND RELATED DISORDERS: FEATURES, THE CIRCUIT, THE LADDER	
THE CSTC CIRCUIT	Orbitofrontal cortex and anterior cingulate to caudate to pallidum interna and substantia nigra reticulata to thalamus and back to cortex; the direct pathway disinhibits the thalamus, the indirect pathway brakes it. In OCD the direct loop is **overactive**, so the loop is hyperactive and self-sustaining.
THE MANAGEMENT LADDER	First-line a **high-dose SSRI** (fluoxetine 60, up to 80; sertraline 150 to 200; paroxetine 40 to 60; fluvoxamine to 300; escitalopram 20 to 30 mg) for a **long 10 to 12 week trial** plus CBT with ERP; then **clomipramine 150 to 225 mg** (ECG); then augment with **risperidone 1 to 3 mg** or aripiprazole for at least 8 weeks; then refractory options (DBS, neurosurgery). Continue a responder **1 to 2 years**.
CLOMIPRAMINE VERSUS SSRI, AND ERP	Clomipramine is marginally more efficacious on meta-analysis but less tolerable (cardiotoxicity, seizures), so an SSRI is first-line and clomipramine the switch. **Exposure and response prevention** (the exposure hierarchy plus prevention of the ritual, so anxiety habituates) is the core psychological treatment.
THE OCRD SPECTRUM	Body dysmorphic disorder (a perceived defect), hoarding, trichotillomania (hair-pulling) and excoriation (skin-picking); illness anxiety sits at the boundary with the somatic-symptom disorders. Each shares a repetitive act or a fixed preoccupation and responds in part to an SSRI and to behavioural therapy.

TRAUMA AND STRESSOR-RELATED DISORDERS: PTSD, ITS TREATMENT, AND THE REST	
PTSD CLUSTERS AND THE SCALE	DSM-5-TR requires four clusters (intrusion, avoidance, negative alterations in cognition and mood, arousal and reactivity); ICD-11 keeps three (re-experiencing in the here and now, avoidance, a persistent sense of current threat) and drops the negative-cognitions cluster. DSM-5 adds a dissociative subtype. **PCL-5**: 20 items 0 to 4, total **0 to 80**; provisional cut-off about **31 to 33**.
THE PTSD ALGORITHM	Two hard rules: **trauma-focused psychotherapy is first-line** (trauma-focused CBT or EMDR, 8 to 12 sessions), and a **benzodiazepine is never used**. If a drug is used: a licensed SSRI (**sertraline or paroxetine**) or **venlafaxine 37.5 to 300 mg**, trialled up to 12 weeks; add **prazosin 1 to 15 mg nocte** for nightmares; augment with risperidone or olanzapine; continue a responder at least **12 months**.

TRAUMA AND STRESSOR-RELATED DISORDERS: PTSD, ITS TREATMENT, AND THE REST	
COMPLEX PTSD	ICD-11 6B41 = the PTSD triad **plus** three disturbances in self-organisation (affect dysregulation, a persistent negative self-concept, interpersonal difficulty). Versus borderline personality disorder: complex PTSD shows trauma-reminder avoidance and current threat (absent in the PD), a **stable** negative self-view (not unstable identity), relationships of avoidance and disconnection (not abandonment), and suicidality that is less impulsive but of higher lethality.
ACUTE STRESS AND ADJUSTMENT	ICD-11 **acute stress reaction** is a transient normal response, classified outside the disorders; the DSM-5 **acute stress disorder** is a diagnosable disorder in the first month. Adjustment disorder is a maladaptive reaction to an identifiable stressor (ICD-11: preoccupation with the stressor plus failure to adapt); do not over-diagnose a normal reaction.
PROLONGED GRIEF; THE ATTACHMENT DISORDERS	Prolonged grief disorder (ICD-11 and DSM-5-TR): persistent, pervasive grief and yearning beyond the expected social norm and time; not normal grief. Reactive attachment and disinhibited social engagement disorders are the trauma disorders of early severe neglect (child home).
THE GUIDELINE SPINE AND THE HARD RULES	
THE GUIDELINE ORDER	Guidelines-first on the where-to-treat, target-by-phase, modes-of-treatment spine: **BAP leads**, then the **IPS CPG** (the 2025 guideline for OCD), NICE, CANMAT and WFSBP; state the BAP position first, then what the others recommend.
ANXIETY	**SSRI or SNRI first-line** for the anxiety disorders; the benzodiazepine is not first-line and not for long-term use; pregabalin and buspirone for GAD, propranolol for performance anxiety.
OCD	The anchoring rule is **high dose, long trial**: OCD needs a higher SSRI dose and a longer (10 to 12 week) trial than depression before it is called a failure; then clomipramine, then augmentation. A wrong first-line or an under-dose is critical.
PTSD	**Trauma-focused psychotherapy first**; then a licensed SSRI or venlafaxine with prazosin for nightmares; and **never a benzodiazepine**, which is not a treatment and may increase PTSD risk given early.
THE FIVE TRAPS	Missing a medical mimic of anxiety; under-dosing or stopping the OCD SSRI trial early; a benzodiazepine for PTSD; complex PTSD mislabelled as a personality disorder; and treating normal grief as prolonged grief disorder too soon.

References

The anxiety, obsessive-compulsive and trauma content is grounded in the standard psychiatry and psychopharmacology sources (the source hierarchy below), with Kaplan and Sadock and the Maudsley Prescribing Guidelines as the depth bar for the phenomenology, the neurobiology, the scale cut-offs and the doses, and Gelder's Shorter Oxford Textbook for the medical mimics of anxiety. The management is guideline-first, led by the British Association for Psychopharmacology, with the Indian Psychiatric Society (the 2025 clinical practice guideline for obsessive-compulsive disorder), NICE, CANMAT, the WFSBP, the United States VA/DoD and WHO mhGAP. Every scale cut-off, criterion, dose and first-line recommendation was checked against these sources and the adversarial content pass; anything that could not be confirmed was omitted and flagged rather than guessed. Each journal PMID below was verified against PubMed this build and matched on title, first author and year; identifiers that resolved to the wrong paper were corrected or dropped. Books and guideline documents are cited by author, title and year without a PMID.

02 Anxiolytic and hypnotic pharmacology

03 Apply and consolidate

PAPER II

Dissociative, conversion and anxiolytic-hypnotic pharmacology

Two sections . one complete notes document

This material gathers the dissociative and conversion disorders and the anxiolytic and hypnotic drugs into one document, by syndrome and by mechanism. The first band is **the dissociative and conversion disorders**: the concept and classification of dissociation, the pathogenesis across the psychodynamic, trauma and neurobiological models, dissociative identity disorder, conversion or dissociative neurological symptom disorder with its positive rule-in signs, depersonalisation-derealisation, dissociative amnesia and fugue, and the possession and trance states. The second band is **the anxiolytic and hypnotic pharmacology**: the benzodiazepines in full, buspirone and the azapirones, the z-drugs, the dual orexin receptor antagonists, melatonin and ramelteon, etifoxine and the other non-benzodiazepine anxiolytics, and the beta-blockers, antihistamines and gabapentinoids used for anxiety. The examinable skill is twofold: the safe discrimination of the dissociative presentations from one another and, above all, of a conversion disorder from an organic disease by its positive signs; and the guideline-anchored selection of an anxiolytic or hypnotic, with the benzodiazepine mechanism, its half-life classes, its dependence and taper, and the short-course rule at the centre.

HOW TO USE THESE NOTES

Read the two bands as one account of a shared theme: the boundary between a functional and an organic disturbance, and the drugs that act on the same GABA-A receptor. The **dissociative and conversion** band builds the frame: the classification of the dissociative disorders, the models of how dissociation arises, each named syndrome discriminated from the others, and conversion or functional neurological disorder taught in full as a diagnosis made on POSITIVE signs (Hoover's sign, the give-way weakness, tremor entrainment, the tubular field) rather than by exclusion. The **anxiolytic and hypnotic** band teaches the drugs by mechanism: the benzodiazepines as positive allosteric modulators at the GABA-A receptor, their half-life-based classes, their dependence and the withdrawal-and-taper, and flumazenil as the antagonist, then buspirone, the z-drugs, the orexin and melatonergic hypnotics and the adjunctive anxiolytics. Every management recommendation is guideline-anchored, led by the BAP guidelines with the NICE, Maudsley and Indian Psychiatric Society positions stated, on the where-to-treat, target-by-phase, modes-of-treatment spine, and the benzodiazepine-sparing short-course rule is the anchor. Every named syndrome ends with a **Good to remember** box giving the criterion, the discriminator and the first step, and every named drug ends with one giving the mechanism or class, the signature caution and the one dose or half-life. Figures declare one axis and code it in colour: **petrol** marks structure and the neutral case, **coral** marks the trap or the danger, and **marigold** highlights the number to hold; the dissociation rating scales are reproduced as the actual instruments where the licence permits, credited to their sources, or typeset from their structure where it does not. Several boundaries are stated up front and cross-referenced, not re-taught: the GABA-A receptor and the wider receptor systems in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; the sedative and benzodiazepine use disorder as an addiction in the Substance use disorders notes; the lorazepam management of catatonia in the Other psychotic disorders, delusional syndromes and catatonia notes; the anxiety disorders where these anxiolytics are used in the Anxiety, OCD and trauma-related disorders notes; the SSRI and SNRI first-line anxiolytics in the Mood disorders: pharmacotherapy notes; clinical insomnia and CBT for insomnia in the Eating and sleep-wake disorders notes; the video-EEG work-up of dissociative convulsions in the Epilepsy and psychiatry notes; and the possession-trance states in the transcultural frame in the Consultation-liaison, geriatric and transcultural psychiatry notes. Conversion or dissociative neurological symptom disorder and the whole anxiolytic and hypnotic pharmacology are owned and fully taught here. This is doctor-facing revision, so the full technical vocabulary is used, brand names lead with the Indian brand, and every dose, half-life, scale cut-off, positive sign and first-line recommendation is verified against a source or omitted and flagged.

Dissociative and conversion disorders

1 . Dissociative disorders: classification and clinical types

Why this leads the chapter. This topic is the orienting map for everything that follows. Dissociation is the **disruption of the normal integration** of consciousness, memory, identity, emotion, perception, body representation, motor control and behaviour (DSM-5-TR; ICD-11). Once you can name the components that can come apart, the whole family of **dissociative disorders** falls into place as a small number of **clinical types**, each defined by *which* integrative

function has failed. The examiner reward here is a clean **disorder-class map**: the ICD-11 grouping, the DSM-5-TR grouping, and the single organising split that separates the disorders of mind from the disorder of body. Get the map right and every individual criterion set hangs off it; get it wrong and you will confuse a depersonalisation state for psychosis, a functional seizure for epilepsy, or a possession trance for delusional identification.

This fragment first defines dissociation and its positive and negative symptoms, then draws the **classification of dissociative disorders** as a decision-tree, then walks each named clinical type with its defining criterion, and closes on how dissociation is measured. The accompanying figure sets the same content out as a classification tree (a decision-tree, or criteria map) to be memorised as one image. The wider anxiety context and the dissociative subtype of PTSD live in the Anxiety, OCD & trauma-related disorders notes; the video-EEG work-up of dissociative (non-epileptic) convulsions is developed in the Epilepsy & psychiatry notes; the transcultural reading of possession and trance is expanded in the Consultation-liaison, geriatric & transcultural psychiatry notes; and the somatic-symptom, functional and factitious boundary sits in the Somatic-symptom, sexual, impulse-control disorders & suicide notes.

Fig 15.1 The classification of dissociative disorders as a decision tree: dissociation splits into disorders of mind and a single disorder of body, with ICD-11 keeping conversion inside the family and DSM-5 filing it elsewhere.

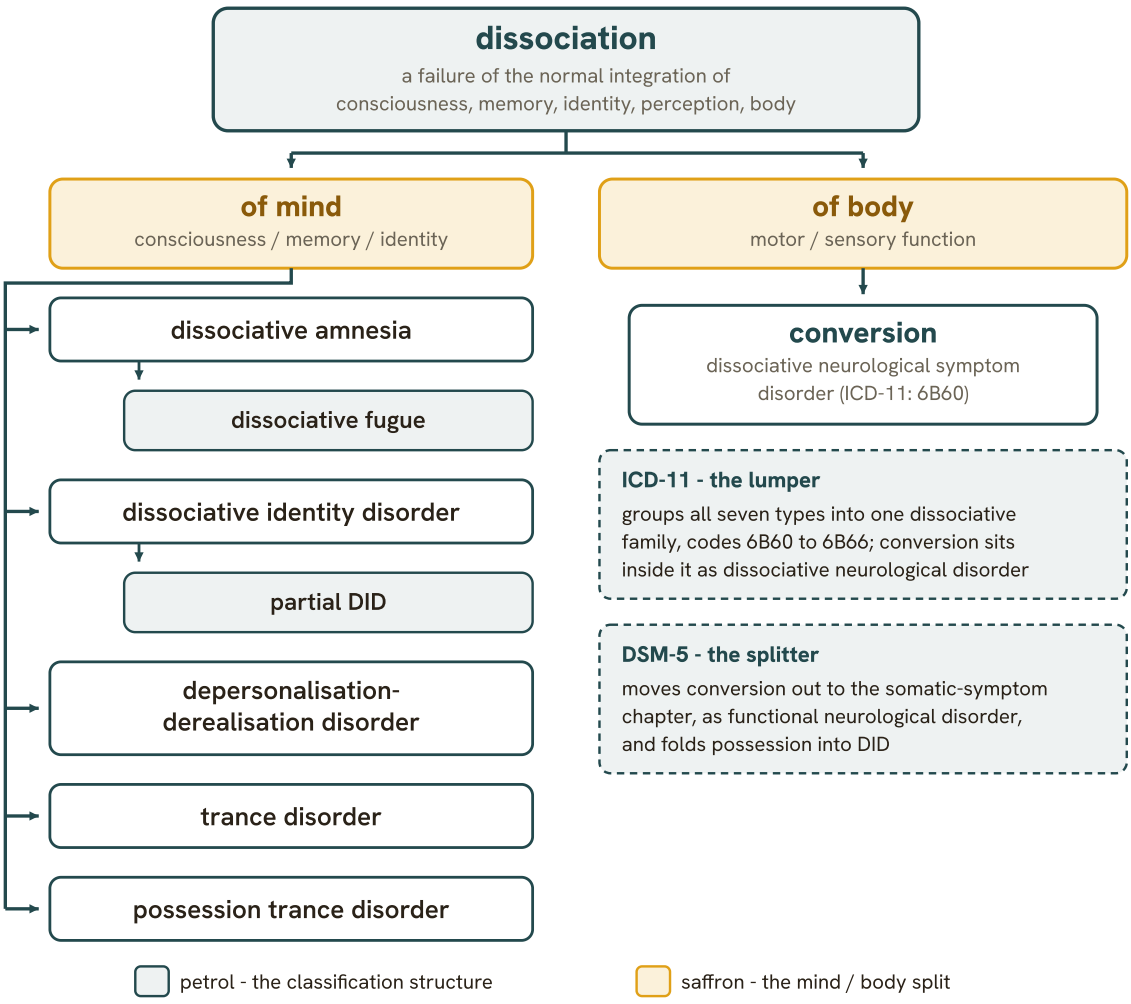

Fig 15.2 The Dissociative Experiences Scale (DES-II) reproduced in full: the 28-item self-report screen for dissociative experiences, scored as the mean of all items.

Dissociative Experiences Scale (DES-II)

Instructions. This questionnaire asks about experiences that you may have in your daily life. We are interested in how often you have these experiences. It is important that your answers show how often these experiences happen to you when you are not under the influence of alcohol or drugs. For each item, mark the percentage of the time the experience applies to you.

0% (never) · 10 · 20 · 30 · 40 · 50 · 60 · 70 · 80 · 90 · 100% (always)

1. Some people have the experience of driving or riding in a car or bus or subway and suddenly realizing that they don't remember what has happened during all or part of the trip.
2. Some people find that sometimes they are listening to someone talk and they suddenly realize that they did not hear part or all of what was said.
3. Some people have the experience of finding themselves in a place and have no idea how they got there.
4. Some people have the experience of finding themselves dressed in clothes that they don't remember putting on.
5. Some people have the experience of finding new things among their belongings that they do not remember buying.
6. Some people sometimes find that they are approached by people that they do not know, who call them by another name or insist that they have met them before.
7. Some people sometimes have the experience of feeling as though they are standing next to themselves or watching themselves do something and they actually see themselves as if they were looking at another person.
8. Some people are told that they sometimes do not recognize friends or family members.
9. Some people find that they have no memory for some important events in their lives (for example, a wedding or graduation).
10. Some people have the experience of being accused of lying when they do not think that they have lied.
11. Some people have the experience of looking in a mirror and not recognizing themselves.
12. Some people have the experience of feeling that other people, objects, and the world around them are not real.
13. Some people have the experience of feeling that their body does not seem to belong to them.
14. Some people have the experience of sometimes remembering a past event so vividly that they feel as if they were reliving that event.
15. Some people have the experience of not being sure whether things that they remember happening really did happen or whether they just dreamed them.
16. Some people have the experience of being in a familiar place but finding it strange and unfamiliar.
17. Some people find that when they are watching television or a movie they become so absorbed in the story that they are unaware of other events happening around them.
18. Some people find that they become so involved in a fantasy or daydream that it feels as though it were really happening to them.
19. Some people find that they sometimes are able to ignore pain.
20. Some people find that they sometimes sit staring off into space, thinking of nothing, and are not aware of the passage of time.
21. Some people sometimes find that when they are alone they talk out loud to themselves.
22. Some people find that in one situation they may act so differently compared with another situation that they feel almost as if they were two different people.
23. Some people sometimes find that in certain situations they are able to do things with amazing ease and spontaneity that would usually be difficult for them (for example, sports, work, social situations, etc.).
24. Some people sometimes find that they cannot remember whether they have done something or have just thought about doing that thing (for example, not knowing whether they have just mailed a letter or have just thought about mailing it).
25. Some people find evidence that they have done things that they do not remember doing.
26. Some people sometimes find writings, drawings, or notes among their belongings that they must have done but cannot remember doing.
27. Some people sometimes find that they hear voices inside their head that tell them to do things or comment on things that they are doing.

28. Some people sometimes feel as if they are looking at the world through a fog, so that people and objects appear far away or unclear.

Scoring and interpretation. Score each item 0 to 100. The DES-II score is the **mean** of all 28 items (range 0 to 100). A mean of about **30 or more** is a positive screen that warrants a full clinical interview for a dissociative disorder (a threshold of 20 to 30 is used across studies; only about 1 percent of people with dissociative identity disorder score below 30). The 8-item **DES-Taxon** (items 3, 5, 7, 8, 12, 13, 22, 27) estimates the probability of pathological dissociation. The DES is a screen, not a diagnosis.

Dissociative Experiences Scale (DES-II). Bernstein EM, Putnam FW (1986); Carlson EB, Putnam FW (1993), Dissociation 6(1):16-27. Fig 15.3 The Somatoform Dissociation Questionnaire (SDQ-20): structure and cut-offs, typeset from the published instrument (not reproduced verbatim).

Somatoform Dissociation Questionnaire (SDQ-20)

A 20-item self-report measure of **somatoform (bodily) dissociation**: the disruption of the normal integration of sensory, motor and pain functions. It complements the DES, which measures the psychological forms of dissociation. Each item is rated on a five-point scale from 1 (this applies to me not at all) to 5 (this applies to me extremely).

Negative somatoform symptoms (losses)

Analgesia and kinaesthetic anaesthesia, blurred or tunnel vision, difficulty swallowing or passing urine, motor inhibition or functional paralysis, and loss of taste or smell.

Positive somatoform symptoms

Localised bodily pain and unusual, hard-to-explain bodily sensations.

Scoring and interpretation. Sum the 20 items (range **20 to 100**); a higher score indicates more somatoform dissociation. A total above about **30** is suggestive of a somatoform dissociative disorder. A derived five-item screener, the **SDQ-5**, uses a cut-off of **8 or more** to flag a probable dissociative disorder. The questionnaire is a screen, not a diagnosis.

1.1 What dissociation actually is

An integration failure, not a content abnormality. Normal mental life binds perception, memory, affect, identity and the sense of a body-in-control into one continuous stream owned by one self. In **dissociation** that binding fails, so functions that are normally seamless become detached, inaccessible or intrusive (DSM-5-TR; Kaplan 2024). DSM-5-TR frames the symptoms in two directions worth reproducing verbatim: **positive** dissociative symptoms are unbidden intrusions with loss of continuity in subjective experience (division of identity, depersonalisation, derealisation), while **negative** dissociative symptoms are an inability to access information or control mental functions that are normally available (amnesia). The historical spine runs from Pierre Janet, who described *desagregation*, the disaggregation of functions that should be integrated (Tasman 2024). Crucially, dissociation is best understood as a *transdiagnostic* process: a large meta-analysis of 219 studies across 19 diagnostic categories found dissociation cutting across most disorders and predicting poorer treatment response, which is why it should be assessed routinely rather than only when a dissociative disorder is suspected (Kaplan 2024).

RULE **Ask which function came apart.** Every dissociative disorder is named by the integrative function that has failed: memory (amnesia), identity (identity disorder), self and surroundings (depersonalisation-derealisation), awareness (trance), or motor and sensory control (conversion). Localise the failure and the diagnosis names itself.

1.2 The organising split: mind versus body

Psychoform against somatoform dissociation. The single most useful cut across the family is between dissociation of the *mind* (consciousness, memory and identity) and dissociation of the *body* (voluntary motor and sensory function). The first branch holds dissociative amnesia, dissociative identity disorder and its partial form, depersonalisation-derealisation disorder, and the trance and possession-trance disorders. The second branch is a single entity, conversion, which ICD-11 places *inside* the dissociative disorders as dissociative neurological symptom disorder, whereas DSM-5-TR keeps it under the somatic symptom disorders as functional neurological symptom disorder (Kaplan 2024). This is the heart of the **conversion versus dissociation** question: they are the same underlying process expressed in different currencies, one in the medium of consciousness and memory, the other in the medium of the body. Holding this split is what lets you place any new presentation on the **disorder-class map** in one step.

MNEMONIC

MIND SPLITS, BODY SPEAKS, GABA SLEEPS

The master hook for the whole chapter. **MIND SPLITS** is the psychoform half, the dissociative disorders of consciousness, memory and identity (amnesia, dissociative identity disorder and partial dissociative identity disorder, depersonalisation-derealisation, trance and possession trance). **BODY SPEAKS** is the somatoform half, conversion or dissociative neurological symptom disorder, the mind speaking through the body in motor and sensory symptoms. **GABA SLEEPS** hands over to the second half of the chapter, the anxiolytic and hypnotic pharmacology that acts on the GABA-A receptor. Carry these three beats and the whole chapter reassembles at consolidation from one line.

1.3 The ICD-11 dissociative grouping

The seven named types, in code order. ICD-11 defines dissociative disorders by "involuntary disruption or discontinuity in the normal integration of one or more of the following: identity, sensations, perceptions, affects, thoughts, memories, control over bodily movements, or behaviour" (ICD-11 CDDR). It then lists seven specified entities plus two residual codes. Reproduce the block as one table; the ICD-11 dissociative grouping is the version most examiners now expect first because it keeps conversion within the family.

ICD-11 CODE	DISORDER	INTEGRATIVE FUNCTION DISRUPTED
6B60	**Dissociative neurological symptom disorder**	Motor and sensory control (conversion)

ICD-11 CODE	DISORDER	INTEGRATIVE FUNCTION DISRUPTED
6B61	Dissociative amnesia (specify with or without dissociative fugue)	Autobiographical memory
6B62	Trance disorder	Awareness of surroundings, narrowed consciousness
6B63	Possession trance disorder	Identity replaced by an external agent
6B64	Dissociative identity disorder	Identity split into distinct personality states
6B65	Partial dissociative identity disorder	Identity intruded on, without executive takeover
6B66	Depersonalisation-derealisation disorder	Sense of self and of reality (with intact reality testing)
6B6Y / 6B6Z	Other specified / unspecified dissociative disorder	Residual

The ICD-11 dissociative-disorders grouping, ordered by code; conversion (6B60) sits inside the family.

1.4 The DSM-5-TR grouping and where conversion sits

The one deliberate difference to memorise. The DSM-5-TR dissociative disorders are dissociative identity disorder, dissociative amnesia (with dissociative fugue as a specifier), depersonalisation-derealisation disorder, other specified and unspecified dissociative disorder (Kaplan 2024). The load-bearing contrast is placement of conversion: ICD-11 keeps it as a dissociative disorder, DSM-5-TR classifies it under the somatic symptom disorders as functional neurological symptom disorder. DSM-5-TR also folds pathologic possession *into* dissociative identity disorder rather than giving it a separate code, and has no standalone trance or partial dissociative identity disorder categories, handling those subtler presentations under other specified dissociative disorder. The comparison, read side by side, is the examinable core of the **classification of dissociative disorders**.

ENTITY	ICD-11	DSM-5-TR
Amnesia	Dissociative amnesia (6B61)	Dissociative amnesia (fugue = specifier)
Identity fragmentation	Dissociative identity disorder (6B64)	**Dissociative identity disorder**
Sub-threshold identity intrusion	Partial dissociative identity disorder (6B65)	Other specified dissociative disorder
Detachment from self / world	Depersonalisation-derealisation (6B66)	Depersonalisation-derealisation disorder
Narrowed awareness	Trance disorder (6B62)	Other specified (dissociative trance)

ENTITY	ICD-11	DSM-5-TR
Possession	Possession trance disorder (6B63)	Folded into dissociative identity disorder
Conversion	**Dissociative neurological symptom disorder (6B60)**	Functional neurological symptom disorder (under somatic symptom disorders)

ICD-11 versus DSM-5-TR: same clinical types, two different filing decisions, conversion the pivotal one.

PEARL

The two manuals disagree in exactly one direction. ICD-11 is the "lumper" that keeps conversion, trance, possession and partial identity states inside the dissociative family; DSM-5-TR is the "splitter" that exports conversion to the somatic disorders and absorbs possession into dissociative identity disorder. Learn the ICD-11 list of seven, then learn what DSM-5-TR *moves*.

1.5 Dissociative amnesia (and dissociative fugue)

Retrograde loss of autobiographical memory. Dissociative amnesia is an inability to recall important autobiographical information, usually of a traumatic or stressful nature, that is inconsistent with ordinary forgetting (DSM-5-TR). The deficit is predominantly *retrograde* and the new-learning (anterograde) capacity is preserved, which is the discriminator from organic amnesia. It takes recognised patterns: **localised** (a circumscribed event or period), **selective** (some aspects of an event), **generalised** (whole life history and identity, and rare), and the older descriptors **continuous** and **systematised** (Kaplan 2024). Dissociative fugue, purposeful travel or bewildered wandering with amnesia for identity, is a specifier of dissociative amnesia rather than a free-standing disorder. Most patients are initially unaware of the gap, noticing it only when confronted with evidence of events they cannot recall.

TRAP **Calling organic amnesia dissociative.** Dissociative amnesia is retrograde and autobiographical with intact new learning; a dense *anterograde* deficit, clouding, or a focal neurological picture points to delirium, a seizure, transient global amnesia, Wernicke-Korsakoff or a head injury. Exclude the organic cause before you reach for a dissociative label.

GOOD TO REMEMBER

- **Dissociative amnesia:** defining criterion is an inability to recall important autobiographical information (usually stressful) inconsistent with normal forgetting; deficit is *retrograde*, new learning intact; subtypes localised / selective / generalised (continuous, systematised); fugue is a *specifier*, not a separate disorder. First step: rule out an organic amnestic cause.

1.6 Dissociative identity disorder and partial dissociative identity disorder

Two or more identity states, plus amnesia. Dissociative identity disorder is defined by (a) two or more distinct personality states, or an experience of possession, producing marked discontinuity in the sense of self and agency, and (b) recurrent episodes of *dissociative amnesia* (DSM-5-TR). The amnesia criterion is not optional: it is what separates dissociative identity disorder from non-pathological possession or from a purely intrusive picture. DSM-5 deliberately dropped the older requirement that states visibly "take control", because phenomenological studies showed most

cases are subtle, with overlapping and interfering states rather than dramatic switching; amnesia was endorsed by essentially all such patients. ICD-11 adds partial dissociative identity disorder for the common presentation in which one dominant state runs daily life but is intruded on by non-dominant states that take executive control only briefly; in DSM-5-TR most of these fall under other specified dissociative disorder because they lack the full amnesia picture.

The trauma model against the sociocognitive model. The dominant *trauma (posttraumatic) model*, formalised as structural dissociation theory, holds that the personality fails to integrate under severe, repeated early-childhood trauma, and cites consistently high verified trauma rates across cultures. The competing *sociocognitive (fantasy) model* argues the disorder is shaped by suggestion, media exposure and inadvertent therapist cueing in highly hypnotisable, fantasy-prone individuals. The examinable position is that the evidence robustly links dissociation to early trauma, while structural dissociation theory itself remains contested even among dissociation experts (Kaplan 2024).

GOOD TO REMEMBER

- **Dissociative identity disorder:** defining criteria are two or more distinct personality states (or possession) *plus* recurrent dissociative amnesia; DSM-5 removed the "takes control" requirement. Discriminator: the *amnesia* criterion. Debate: trauma / structural-dissociation model versus sociocognitive (fantasy) model.
- **Partial dissociative identity disorder (ICD-11):** one dominant state that functions in daily life, intruded on by non-dominant states that seize executive control only transiently; sits under other specified dissociative disorder in DSM-5-TR.

1.7 Depersonalisation-derealisation disorder

Detachment with the reality check intact. Depersonalisation-derealisation disorder is persistent or recurrent depersonalisation (unreality or detachment from one's own mind, self or body) and/or derealisation (unreality or detachment from surroundings), during which *reality testing remains intact* (DSM-5-TR criterion B). That intact reality testing, and the "as if" quality of the experience without any delusional or dereistic explanation, is the defining differential-diagnostic point separating the disorder from a psychotic disorder (Kaplan 2024). The symptoms must cause distress or impairment, not be attributable to a substance or medical condition (notably seizures), and not be better explained by another disorder. Transient depersonalisation is extremely common in the general population and after cannabis, ketamine or hallucinogens; it becomes a disorder only when persistent and impairing.

TRAP **Reading detachment as psychosis.** The patient who says the world feels unreal, "as if behind glass", but *knows* it is not truly unreal has intact reality testing and depersonalisation-derealisation, not schizophrenia. A delusional, ideas-of-reference or Schneiderian colouring, or belief that the unreality is literal, moves you toward the psychotic spectrum.

GOOD TO REMEMBER

- **Depersonalisation-derealisation disorder:** defining criterion is persistent/recurrent depersonalisation and/or derealisation with *intact reality testing* and an "as if" quality; the intact reality check is the discriminator from psychosis. Scale anchor: a Cambridge Depersonalisation Scale score of **70 or more** is the conventional diagnostic threshold (Kaplan 2024).

1.8 Trance disorder and possession trance disorder

Narrowed awareness, or replaced identity. Trance disorder is an acute narrowing or complete loss of awareness of immediate surroundings, with profound unresponsiveness or insensitivity to stimuli, and often stereotyped movements experienced as outside one's control. Possession trance disorder adds the replacement of the usual sense of personal identity by an external "possessing" identity, typically attributed to a spirit, deity or other agent, with amnesia for the episode. ICD-11 gives these two their own rubric, distinct from dissociative identity disorder; DSM-5-TR instead folds pathological possession into dissociative identity disorder and leaves non-possession trance under other specified dissociative disorder. The decisive criterion for both is the cultural exclusion: the state must be *involuntary, unwanted and outside accepted collective cultural or religious practice*. A trance willingly entered by a healer within an accepted ritual, causing no distress, is not a disorder (Kaplan 2024).

INDIA

Trance and possession presentations are among the most frequent dissociative presentations in Indian practice; the Indian texts describe them directly as "trance and possession disorders (possession hysteria)" and list conversion and dissociative signs such as pseudo-seizures and possession states together. This is the genuine culture-bound edge of the topic: possession and mediumship are woven into accepted ritual across many Indian communities, so the same phenomenology may be normative in one setting and pathological in another. The reading turns entirely on the ICD-11 and DSM-5-TR cultural-exclusion criterion and a proper cultural formulation, not on the surface picture. The transcultural frame is expanded in the Consultation-liaison, geriatric & transcultural psychiatry notes.

GOOD TO REMEMBER

- **Trance disorder:** defining criterion is acute narrowing/loss of awareness of surroundings with unresponsiveness; identity is *not* replaced.
- **Possession trance disorder:** defining criterion is replacement of identity by an external possessing agent with amnesia; both require the state to be involuntary, distressing and *outside accepted cultural or religious practice*. First step: apply the cultural-exclusion criterion.

1.9 Conversion: dissociative neurological symptom disorder

Diagnosed by positive signs, not by exclusion. Dissociative neurological symptom disorder (ICD-11), the functional neurological symptom disorder of DSM-5-TR, is motor, sensory or seizure-like symptoms that are genuinely experienced but incompatible with recognised neurological disease. The modern rule, from Stone and Carson, is that this is *not* a diagnosis of exclusion: it requires **positive signs of internal inconsistency** demonstrating that the nervous

system can work normally when attention is diverted (New Oxford 2024). The cardinal example is Hoover's sign: hip-extension weakness that returns to normal strength during contralateral hip flexion against resistance. The tremor entrainment test shows a functional tremor changing frequency to, or stopping with, a copied rhythm in the other hand. A "give-way" or collapsing weakness, a tubular visual field of the same width at 1 m and 2 m, and astasia-abasia are further positive findings. DSM-5-TR also *removed* the old requirement for an identifiable psychological stressor, and la belle indifference and the mere presence of a stressor are unreliable and are not diagnostic. Because it can coexist with true neurological disease, the positive sign is what rules it in.

POSITIVE SIGN	POSITIVE FINDING THAT RULES IN A FUNCTIONAL CAUSE
Hoover's sign	**Hip-extension weakness that normalises with contralateral hip flexion against resistance**
Tremor entrainment test	Unilateral tremor entrains to, stops with, or cannot copy a rhythm set by the other hand
Give-way (collapsing) weakness	Ratchety, inconsistent power that gives way rather than a fixed pyramidal pattern
Tubular visual field	A field defect of the same width at 1 m as at 2 m (physiologically it should widen)
Astasia-abasia / dragging gait	Bizarre, non-physiological gait, or a leg dragged with the forefoot kept on the floor

Positive rule-in signs of functional (conversion) neurological symptoms (Stone and Carson, New Oxford 2024).

RULE **Rule in, do not rule out.** Conversion is diagnosed on a positive sign of internal inconsistency (Hoover's, entrainment, tubular field), not on the absence of a lesion or the presence of a stressor. The sign shows the system works when attention is elsewhere.

WORKED EXAMPLE

A patient reports a dense right-leg weakness after an argument. Direct right hip extension is flaccid. You then ask her to flex the *left* hip against your hand; as she does, involuntary right hip extension presses firmly into your other palm. That is a positive Hoover's sign: the "paralysed" extensors fire automatically when attention shifts to the good leg. You have ruled the diagnosis *in* at the bedside, without imaging and without invoking the stressor.

COMMON TRAP

The mirror error: an early multiple sclerosis, a spinal cord lesion, a stroke or a focal seizure labelled "conversion" because the presentation seemed emotional or a stressor was present. A positive functional sign coexists with real disease more often than expected, so a rule-in sign never removes the duty to screen for an organic lesion when the picture is atypical, progressive or accompanied by hard neurological findings.

GOOD TO REMEMBER

- **Dissociative / functional neurological symptom disorder:** defining criterion is a neurological symptom with a *positive* sign of internal inconsistency (Hoover's sign, tremor entrainment, tubular field); it is *not* a diagnosis of exclusion, no stressor is required (DSM-5-TR), and la belle indifference is unreliable. First step: elicit a positive sign.

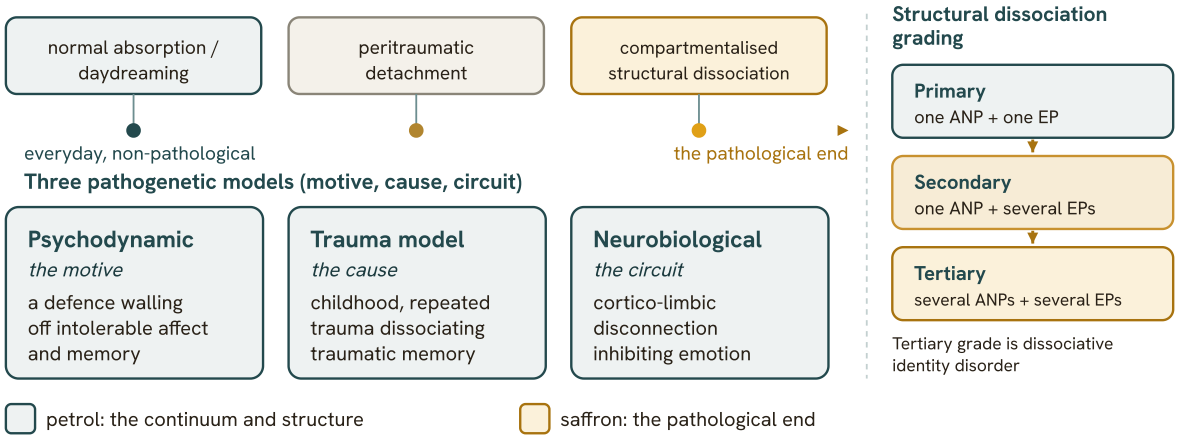
1.10 Measuring dissociation: the DES and the two-tier screen

Screen, then interview. The Dissociative Experiences Scale (DES) is the workhorse self-report measure: subjects rate the percentage of time, from 0 to 100, that each dissociative experience occurs. Most epidemiology uses a two-tier approach, screening with the DES and then applying a structured interview (the SCID-D or the DDIS) to everyone above a cut-off "generally **20 to 30**", with **30** the conventional screening threshold (Kaplan 2024). Mean DES scores rank the family in a way worth memorising: dissociative identity disorder **48.7**, all dissociative disorders combined 38.9, PTSD 28.6, borderline personality disorder 27.9, functional neurological (conversion) disorder 25.6, against a non-clinical mean near 8. The eight-item *DES-Taxon* (DES-T) subscale isolates pathological dissociation and identifies a distinct high-scoring group; the population point-prevalence of this dissociative taxon is about **3.4%**. Somatoform (bodily) dissociation is captured separately by the Somatoform Dissociation Questionnaire (SDQ-20). The instrument forms themselves are reproduced on the accompanying scale plate; a high DES is a flag for further interview, never a diagnosis on its own.

30	8	48.7	3.4%
USUAL DES SCREENING CUT-OFF	ITEMS IN THE DES-T TAXON SUBSCALE	MEAN DES IN IDENTITY DISORDER	POPULATION DISSOCIATIVE TAXON

HOLD THIS

The whole family divides once: dissociation of the mind (amnesia, identity, depersonalisation-derealisation, trance and possession) against dissociation of the body (conversion), with ICD-11 keeping conversion inside the dissociative disorders and DSM-5-TR exporting it to the somatic symptom disorders.



2 · The pathogenesis of dissociation

The **pathogenesis of dissociative disorders** is a favourite viva topic precisely because there is no single mechanism to recite; the examiner wants to hear that you can hold three complementary explanations at once and say what each adds. **The frame to open with.** Dissociation is a disruption of the normally integrated stream of consciousness, memory, identity, emotion, perception and body-sense; the question of pathogenesis asks how that integration comes to fail. The classical answer runs across a **psychodynamic model** (dissociation as a defence that walls off intolerable affect and memory), a **trauma model** (childhood and repeated trauma driving the dissociation of traumatic memory, formalised as the theory of structural dissociation of the personality), and a **neurobiological model** (a fronto-limbic, or cortico-limbic, disconnection with cortico-limbic inhibition visible on imaging). These are not

rival hypotheses to be scored against one another so much as three levels of the same process, and the candidate who names all three, and links them, has the marks.

Why it matters clinically. The three models are not academic; each tells you something the others cannot. The trauma model tells you to take a developmental and abuse history and to expect comorbid post-traumatic disorder. The psychodynamic model tells you why the patient cannot simply "remember" on command and why phased, safety-first therapy, not forced abreaction, is the treatment grammar. The neurobiological model tells you that reality testing stays intact (so this is not psychosis) and explains the numbing and detachment as emotional over-regulation rather than absence of feeling. Teach the **aetiology of dissociation** as one concept model with three faces; the accompanying figure sets it out as a dissociation continuum, from everyday absorption through peritraumatic detachment to the compartmentalised structural dissociation of the severe disorders. The wider dissociative subtype of post-traumatic stress disorder is developed in the Anxiety, OCD & trauma-related disorders notes; here we own the pathogenesis.

Fig 15.4 Dissociation as one continuum with three complementary pathogenetic models, and the primary-to-tertiary grading of structural dissociation (ANP the apparently-normal part, EP the emotional part).

2.1 The three-model scaffold and the dissociation continuum

The concept to fix first. Dissociation runs along a continuum. At one end are normal, non-pathological experiences (absorption in a book, highway hypnosis, momentary "spacing out"); at the other are the compartmentalised amnesias and identity alterations of the severe disorders. Overlaid on that continuum is a genuine debate about whether pathological dissociation is merely the high end of a smooth dimension or a discontinuous *type*; taxonometric work (see the scale section) argues for a distinct pathological taxon rather than a pure continuum. Either way, the pathogenetic question is the same: what pushes a person from normative, transient dissociation into the persistent, involuntary, compartmentalising kind?

Three answers, three levels. The psychodynamic model answers at the level of *meaning and motive* (a defence against unbearable experience); the trauma model answers at the level of *developmental cause* (early, repeated, relationship-based trauma); and the neurobiological model

answers at the level of *mechanism and circuit* (a cortico-limbic disconnection that inhibits emotion). Read them as motive, cause and circuit and they stop competing and start cooperating. The accompanying figure draws this as the concept model to carry through the whole answer.

RULE **Dissociation is a failure to integrate, not a loss of contact with reality.** The three models describe one process at three levels, a psychodynamic defence that walls off intolerable affect and memory, a developmental response to early repeated trauma, and a cortico-limbic disconnection that inhibits emotion; reality testing stays intact throughout, which is what separates dissociation from psychosis.

MNEMONIC

Three D's: Defence, Developmental trauma, Disconnection

Run the pathogenesis in three beats. **Defence** is the psychodynamic model (dissociation walls off intolerable affect and memory). **Developmental trauma** is the trauma model (childhood and repeated trauma, formalised as structural dissociation into an apparently-normal and an emotional part). **Disconnection** is the neurobiological model (cortico-limbic disconnection with prefrontal inhibition of the limbic system). Name the three D's, then link them, and the "aetiology of dissociation" answer writes itself.

2.2 The psychodynamic model: dissociation as a defence

The founding schism. The **psychodynamic model** descends from the late-nineteenth-century split between Pierre Janet and Sigmund Freud. Janet described *désagrégation*, a passive splitting-off of "fixed ideas" and traumatic memory from the integrated personality under the impact of overwhelming events; Freud, by contrast, moved toward *repression* and, later, "splitting" as the governing defences, and psychoanalysis broadened the word trauma to mean almost any developmental stressor. The consequence, as Kaplan & Sadock note, is that psychoanalytic theory has long had difficulty treating dissociation as a *specific* intrapsychic defence against awareness of trauma, tending instead to fold it into "splitting"; David Rapaport's Menninger group in the 1940s, and the older notion of "hypnoid states," were among the few attempts to reconcile the Freudian and Janetian lines.

The defensive core, and the autohypnosis variant. Stripped to its clinical claim, the psychodynamic model says dissociation protects the person by keeping intolerable affect, memory and self-knowledge out of integrated awareness. The most exam-relevant developmental version is the autohypnosis model (associated with Bliss and with Richard Kluft): a traumatised child recruits an innate hypnotic capacity to induce a self-protective dissociative state during overwhelming or repetitive abuse, and with continuous use that autohypnotic state becomes personified into self-states. It is supported by the observation that dissociative patients, especially those with dissociative identity disorder, are the most highly hypnotisable clinical group, though the model is criticised for reasoning backward from adults and for the fact that more systematic research has not confirmed that childhood trauma reliably raises hypnotisability. The grounding of grounding and hypnosis as psychotherapy technique sits in the Psychotherapies, clinical assessment, MSE & nosology notes.

2.3 The trauma model: childhood and repeated trauma

Trauma as the necessary antecedent. The **trauma model** is the dominant contemporary account of the **aetiology of dissociation**. Since the 1980s, several hundred studies across many cultures have found significantly higher dissociation, measured on the Dissociative Experiences Scale and comparable instruments, in traumatised groups than in non-traumatised clinical and general-population samples. **Childhood trauma** is the strongest correlate: childhood sexual and physical abuse, emotional abuse and neglect, and non-maltreatment traumas such as repeated painful medical procedures or wartime displacement, are all over-represented, and survivors of severe, chronic adult trauma (prisoners of war, torture survivors, trafficked and prostituted women, victims of intimate-partner violence) carry high dissociation scores. A meta-analysis by Vonderlin and colleagues of 65 DES studies (7,532 participants) found that a childhood history of abuse or neglect predicted significantly higher DES scores, with combined physical and sexual abuse, earlier onset, longer duration and parental (intrafamilial) abuse driving the highest scores.

Two mechanisms the model adds. First, *peritraumatic dissociation*, dissociation measured at or right after the event (depersonalisation, derealisation, time distortion, trance-like automatism, amnesia), predicts later post-traumatic stress disorder, and dissociation statistically *mediates* the relationship between trauma and subsequent psychopathology. Second, betrayal trauma theory (Jennifer Freyd) explains why abuse by a trusted, depended-upon caregiver is especially likely to be walled off: amnesia here is protective of the attachment the child cannot afford to lose, which is why intrafamilial childhood abuse produces more amnesia than, say, a natural disaster. This is the model that makes dissociation a target for early intervention after trauma.

2.4 Structural dissociation of the personality

The formal trauma theory to name. The trauma model's most cited theoretical elaboration is the theory of structural dissociation of the personality (Onno van der Hart, Ellert Nijenhuis and Kathy Steele), especially influential in Europe and the guiding force behind the ICD-11 criteria for dissociative identity disorder and partial dissociative identity disorder. It proposes that severe traumatic experience produces a "split" between an apparently normal personality (ANP), which is constricted and avoidant, focused on daily functioning, unaware of and phobic toward the traumatic material, and an emotional personality (EP), which carries the unintegrated, unprocessed traumatic memory and its raw affect. The degree of splitting is graded, which is the examinable part.

LEVEL OF STRUCTURAL DISSOCIATION	CONFIGURATION	PROTOTYPICAL DISORDER
Primary	one ANP + one EP	**Post-traumatic stress disorder (and simple conversion presentations)**
Secondary	**one ANP + several EPs**	Complex / "less complex" dissociative disorders, complex PTSD
Tertiary	several ANPs + several EPs	**Dissociative identity disorder**

Structural dissociation graded from primary to tertiary; the accompanying figure renders it as the compartmentalised end of the dissociation continuum. Grounded in Kaplan & Sadock CTP 2024 (van der Hart, Nijenhuis & Steele).

Hold the critique too. Examiners reward a candidate who can also say why the theory is contested: it over-reifies the mind as a "structure" made of "parts," it reasons backward from adult dissociative identity disorder rather than forward from child development, it posits adult-style psychological "structures" in infants (mapping the ANP/EP alternation onto Type-D attachment), and meta-analytic data fit dissociation better as a subtype or component of post-traumatic stress disorder than as the substrate of all of it. A cleaner contemporary framing treats these conditions as disorders of self-organisation, complex dynamic self-state systems, rather than a lesioned "personality."

2.5 The neurobiological model: cortico-limbic disconnection

The core hypothesis. The **neurobiological model** reframes dissociation as a hard-wired inhibitory response of the psychobiological survival system, one that damps anxiety and physiological hyperarousal under extreme threat and becomes pathological when it persists outside danger. Its anatomical statement is the corticolimbic disconnection hypothesis of Mauricio Sierra and German Berrios: in depersonalisation and derealisation there is a bilateral cortico-limbic disconnection with *prefrontal activation and limbic inhibition*, yielding hypoemotionality (the flat, detached, "unreal" quality) together with attentional difficulty. This is the fronto-limbic / cortico-limbic disconnection the question is pointing at.

The imaging and the PTSD bridge. The signature is captured on functional imaging: a positron-emission study using intravenous tetrahydrocannabinol found that cerebral blood-flow *increases* in right frontal and anterior cingulate cortex tracked depersonalisation/derealisation severity, while subcortical blood flow *fell* in the amygdala, hippocampus, basal ganglia and thalamus, exactly the "cortex up, limbic down" pattern. Ruth Lanius and colleagues extended this model to trauma: the dissociative subtype of post-traumatic stress disorder is a state of emotional *over*-modulation (prefrontal over-activation inhibiting the limbic system, producing hypoarousal, numbing and detachment), the mirror image of the emotional *under*-modulation (weak prefrontal restraint over a hyperaroused amygdala) seen in ordinary re-experiencing PTSD. The receptor systems and the wider fear circuitry are developed in the Neurochemistry, Neuroendocrinology, Neuroimaging & Basic Psychopharmacology notes and in the Anxiety, OCD & trauma-related disorders notes; that transcranial magnetic stimulation of the dorsolateral and ventrolateral prefrontal cortex and the temporoparietal junction can *reduce* depersonalisation symptoms, while deep stimulation over medial prefrontal cortex can *induce* depersonalisation in healthy volunteers, is direct causal support for the circuit.

> **PEARL**
>
> One circuit, two directions. Non-dissociative, re-experiencing PTSD is emotional *under*-modulation, a weak prefrontal brake over a hyperaroused amygdala. The dissociative subtype, and depersonalisation-derealisation disorder, is the mirror image, emotional *over*-modulation, prefrontal over-activation that inhibits the limbic system and produces numbing, detachment and hypoarousal. Same cortico-limbic axis, opposite setting; that one sentence answers "what is the neurobiology of dissociation?"

GOOD TO REMEMBER

- **Depersonalisation-derealisation disorder (the criterion anchor):** persistent or recurrent depersonalisation (detachment from one's own mind or body, an "as-if-in-a-dream" unreality) and/or derealisation (unreality of surroundings) with *reality testing kept intact throughout*; the intact reality testing is the discriminator from psychosis, and the cortico-limbic disconnection signature (prefrontal over-activation inhibiting the limbic system) is its putative mechanism, so the first step when it is mislabelled "psychotic" is to confirm that the patient knows the experience is not real.

2.6 The trauma model versus the sociocognitive challenge

The debate to state. The pathogenesis of dissociative identity disorder is where the models are fought over hardest, and this trauma-model-versus-sociocognitive debate is the single most examinable controversy in the chapter. The trauma model holds that severe, early, repeated (often betrayal-laden) trauma drives the disorder (tertiary structural dissociation, or a developmental failure to consolidate one self across states). Against it stand a family of sceptical accounts, the iatrogenic model (states cued and shaped by suggestible therapy, including hypnosis and "recovered-memory" work), the sociocognitive model (a socially learned role reinforced by media and culture), and the fantasy model (dissociation as a trait of fantasy-proneness and suggestibility, with the trauma link an artefact of confabulation).

Where the evidence sits. A systematic comparison by Dalenberg and colleagues (2012) tested the trauma and fantasy models against multiple predictions and found the trauma model confirmed on the great majority, including the point that neurobiological research supports dissociation as a regulatory response to fear with measurable biological correlates. The sociocognitive and iatrogenic accounts, by contrast, rest largely on old, small, analogue studies and cannot account for the large, cross-cultural epidemiological samples ascertained with validated instruments in ordinary clinical settings. The honest examination answer is that trauma is the principal driver, while sociocognitive and cultural factors shape the *secondary structuring* (the number, form and content of self-states) rather than manufacturing the disorder wholesale.

TRAP **Diagnosing dissociative identity disorder without the dissociative-amnesia criterion.** Distinct "states" or role enactments are not enough; the diagnosis requires a disruption of identity with two or more distinct personality states *plus* recurrent dissociative amnesia (gaps in recall for everyday events, personal information or trauma). If the amnesia is absent, or the picture is florid and suggestion-shaped, go back to the sociocognitive and iatrogenic differentials before you commit.

GOOD TO REMEMBER

- **Dissociative identity disorder (the criterion anchor):** on the trauma model it is the tertiary structural dissociation of a child overwhelmed by early, repeated, betrayal-laden **childhood trauma**; the defining criterion is a disruption of identity with two or more distinct personality states *and* recurrent dissociative amnesia, with the presentation not a normal part of a broadly accepted cultural or religious practice; never diagnose it without the amnesia criterion, and weigh the sociocognitive and iatrogenic challenge before accepting a suggestion-shaped presentation.

2.7 Measuring the process: the DES and the dissociative taxon

The instrument to name. Pathogenesis research runs on measurement, and the workhorse is the Dissociative Experiences Scale (DES; Bernstein & Putnam 1986, with the DES-II by Carlson & Putnam 1993), a self-report screen for the frequency of dissociative experiences. It is used in a two-tier way: the DES screens a population, and those above a cut-off are taken to a structured diagnostic interview (the SCID-D-R or the DDIS). The commonly cited screen cut-off is a DES mean of the order of 20 to 30, with a score above 30 indicating severe dissociative psychopathology; the meta-analytic mean DES climbs with severity, from around 25 in conversion disorder and 28 in post-traumatic stress disorder to about 39 across the dissociative disorders and 49 in dissociative identity disorder. The actual instrument is shown in the accompanying scale plate rather than pasted here.

Continuum or taxon. The DES also feeds the continuum-versus-type debate: a taxonometric analysis (Waller, Putnam & Carlson) isolated a DES-Taxon (the DES-T), a subset of items that identifies a discrete subgroup of genuinely pathological dissociators rather than simply high scorers on a smooth dimension. A large Finnish general-population study put the point prevalence of that pathological taxon at about 3.4%. The taxon reading implies a different developmental trajectory (and different treatment) from the merely-high end of normal, and dovetails with the trauma and neurobiological models by pointing to a distinct, trauma-linked pathological process.

2.8 The culture-bound lens and the Indian setting

Culture shapes the presentation. Sociocognitive and cultural factors do not create dissociation, but they strongly shape how it is expressed. Conversion-like dissociative presentations are, on cross-cultural data, more common in India than in certain affluent Western settings, and possession and trance phenomena are a major idiom of dissociative distress in the Indian clinic. The nosologies diverge here: DSM-5 folds pathological possession into dissociative identity disorder, whereas ICD-11 keeps trance disorder and possession trance disorder as categories distinct from dissociative identity disorder. The transcultural framing of possession, trance and the culture-bound syndromes is developed in the Consultation-liaison, geriatric & transcultural psychiatry notes.

The prescribing distortion. Onto this genuinely trauma-and-culture-driven presentation the Indian system too often lays a pharmacological reflex. Benzodiazepines are well documented to be over-prescribed for long-term anxiety, and alprazolam in particular is the widely used, default anxiolytic, dispensed freely for the "tension," insomnia and dissociative or possession-flavoured distress that actually call for a trauma-informed, phased psychotherapy. This is the wrong tool on every one of the three models: it addresses neither the defence, nor the developmental trauma, nor the cortico-limbic circuit, and it breeds dependence. The sedative and benzodiazepine use disorder, intoxication and dependence in the addiction sense are taught in the Substance use disorders notes.

TRAP **Reading a possession or trance state as a dissociative disorder without the cultural formulation.** Possession trance that is a sanctioned, time-limited part of a collective religious or cultural practice is normative, not pathological; the diagnosis requires that the state be unwanted, involuntary, distressing or impairing and occur outside an accepted cultural or religious practice.

INDIA

Dissociation is arguably *more* visible in Indian practice than in the Western textbook: conversion-like and possession/trance presentations are common, culturally embedded and frequently the first idiom in which trauma is spoken. The pathogenesis lens gives two correctives. First, formulate possession and trance culturally before pathologising them (ICD-11's possession trance disorder is defined by the involuntary, distressing, out-of-context state, not by belief in possession itself). Second, resist the country's **benzodiazepine over-prescription** pattern: alprazolam (Alprax, Restyl) is the default anxiolytic and is handed out long-term for exactly these presentations, which suits neither the defence, the developmental trauma, nor the cortico-limbic circuit, and courts dependence. The trauma-informed answer is a phased psychotherapy that builds safety and grounding first, with any anxiolytic kept to a genuine short course.

GOOD TO REMEMBER

- **Alprazolam (Alprax or Restyl), the dose anchor and the anti-pattern:** a high-potency, short-to-intermediate-acting benzodiazepine and India's default anxiolytic, a positive allosteric modulator at the GABA-A receptor (the mechanism is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging & Basic Psychopharmacology notes); the licensed anxiolytic range is 1 to 4 mg per day (about 5 to 6 mg per day for panic), yet it does *not* treat dissociation. Its short action causes interdose rebound anxiety and its seizure risk is greatest in the first three days after abrupt discontinuation, so if used at all it is kept to the lowest effective dose for the shortest time (a course of the order of 4 weeks) with a slow taper; it is not a substitute for trauma-focused psychotherapy.

2.9 Putting the three models together

One process, three faces. The pathogenesis answer is strongest when the three models are stitched into a single developmental story: early, repeated, relationship-based **childhood trauma** (the trauma model) recruits a defensive walling-off of intolerable affect and memory (the psychodynamic model), and that defence is instantiated as a cortico-limbic disconnection in which the prefrontal cortex over-inhibits the limbic system (the neurobiological model), so the person is protected from unbearable feeling at the cost of an integrated, continuous sense of self. Structural dissociation names the endpoint of that process; the DES and its taxon measure it; culture shapes how it is expressed. Every effective treatment targets one of these levels, and none of them is a benzodiazepine.

MODEL	CORE CLAIM / MECHANISM	KEY FIGURES	SIGNATURE EVIDENCE	TREATMENT IMPLICATION
Psychodynamic	**Dissociation is a defence walling off intolerable affect and memory**	Janet, Freud; Bliss, Kluft (autohypnosis)	High hypnotisability of dissociative patients; clinical case material	Phased, safety-first therapy; not forced abreaction
Trauma (incl. structural dissociation)	Early, repeated trauma drives dissociation of traumatic memory; ANP / EP split	**van der Hart, Nijenhuis, Steele; Freyd (betrayal); Putnam**	Raised DES in traumatised groups; Vonderlin & Dalenberg meta-analyses; peritraumatic dissociation predicts PTSD	Trauma history mandatory; trauma-focused, integration-oriented therapy
Neurobiological	Cortico-limbic disconnection: prefrontal overactivation inhibits the limbic system	Sierra & Berrios; Lanius	**PET (cortex up, amygdala/limbic down); over- vs under-modulation in PTSD; rTMS reverses/induces symptoms**	Reality testing intact (not psychosis); circuit-targeted and psychotherapeutic approaches

The three complementary models of the pathogenesis of dissociative disorders, read as motive, cause and circuit; the accompanying figure carries the same three-model concept as a dissociation continuum. Grounded in Kaplan & Sadock CTP 2024.

Dissociation

A disruption of the normally integrated functions of consciousness, memory, identity, emotion, perception and body-sense, with reality testing preserved.

Structural dissociation

A trauma-driven "split" of the personality into an apparently-normal part and one or more emotional parts; graded primary, secondary and tertiary.

Apparently normal personality (ANP)

The constricted, avoidant part focused on daily life, unaware of and phobic toward the traumatic material.

Emotional personality (EP)

The part that holds the unintegrated, unprocessed traumatic memory and its raw affect.

Peritraumatic dissociation

Dissociation occurring at or immediately after the traumatic event; a predictor of subsequent post-traumatic stress disorder.

Cortico-limbic disconnection

The neurobiological model of dissociation: prefrontal (cortical) over-activation inhibiting limbic structures, producing hypoemotionality and detachment.

WORKED EXAMPLE

A woman with a history of chronic intrafamilial childhood sexual abuse presents with hours she cannot account for, a persistent sense that she is watching herself from outside her body, and two coworkers who describe her as "a different person" on some days. Read her through the three models at once. The *trauma model*: early, repeated, betrayal-laden abuse is the necessary antecedent, and her amnesia is the attachment-protective forgetting betrayal-trauma theory predicts. The *psychodynamic model*: the amnesia and the self-states are a defence that keeps unbearable memory and affect out of integrated awareness (an over-learned autohypnotic protection). The *neurobiological model*: her depersonalisation is the cortico-limbic disconnection, prefrontal over-modulation inhibiting the limbic system, which also tells you her reality testing is intact and this is not psychosis. No single model is complete; together they give the formulation, and the management is a phased trauma-focused psychotherapy, not a benzodiazepine.

30	48.7	3.4%	3
DES SCREEN CUT-OFF ABOVE WHICH SEVERE DISSOCIATIVE PSYCHOPATHOLOGY IS LIKELY (TWO-TIER THRESHOLD 20 TO 30)	MEAN DES IN DISSOCIATIVE IDENTITY DISORDER (META-ANALYSIS)	GENERAL-POPULATION PREVALENCE OF THE PATHOLOGICAL DISSOCIATIVE TAXON	LEVELS OF STRUCTURAL DISSOCIATION (PRIMARY, SECONDARY, TERTIARY)

HOLD THIS

The pathogenesis of dissociation is one process told at three levels: early, repeated **childhood trauma** (the trauma model) recruits a defence that walls off intolerable affect and memory (the psychodynamic model), instantiated as a cortico-limbic disconnection in which the prefrontal cortex over-inhibits the limbic system (the neurobiological model); structural dissociation into an apparently-normal and an emotional part names the endpoint, reality testing stays intact (so it is not psychosis), and the treatment is a phased trauma-focused psychotherapy, never a long-term benzodiazepine.

3 · Dissociative identity disorder

The examiner's whole target is one criterion. **Dissociative identity disorder** is a low-volume topic that punches above its weight because it is decided by a single discriminating fact. The disorder is defined by two or more distinct personality (identity) states with a marked discontinuity in the sense of self and agency, layered on *recurrent gaps in autobiographical memory*. That memory criterion is the pivot: the **dissociative-amnesia criterion is required**, and its absence is the classic trap that turns a confident answer into a wrong one.

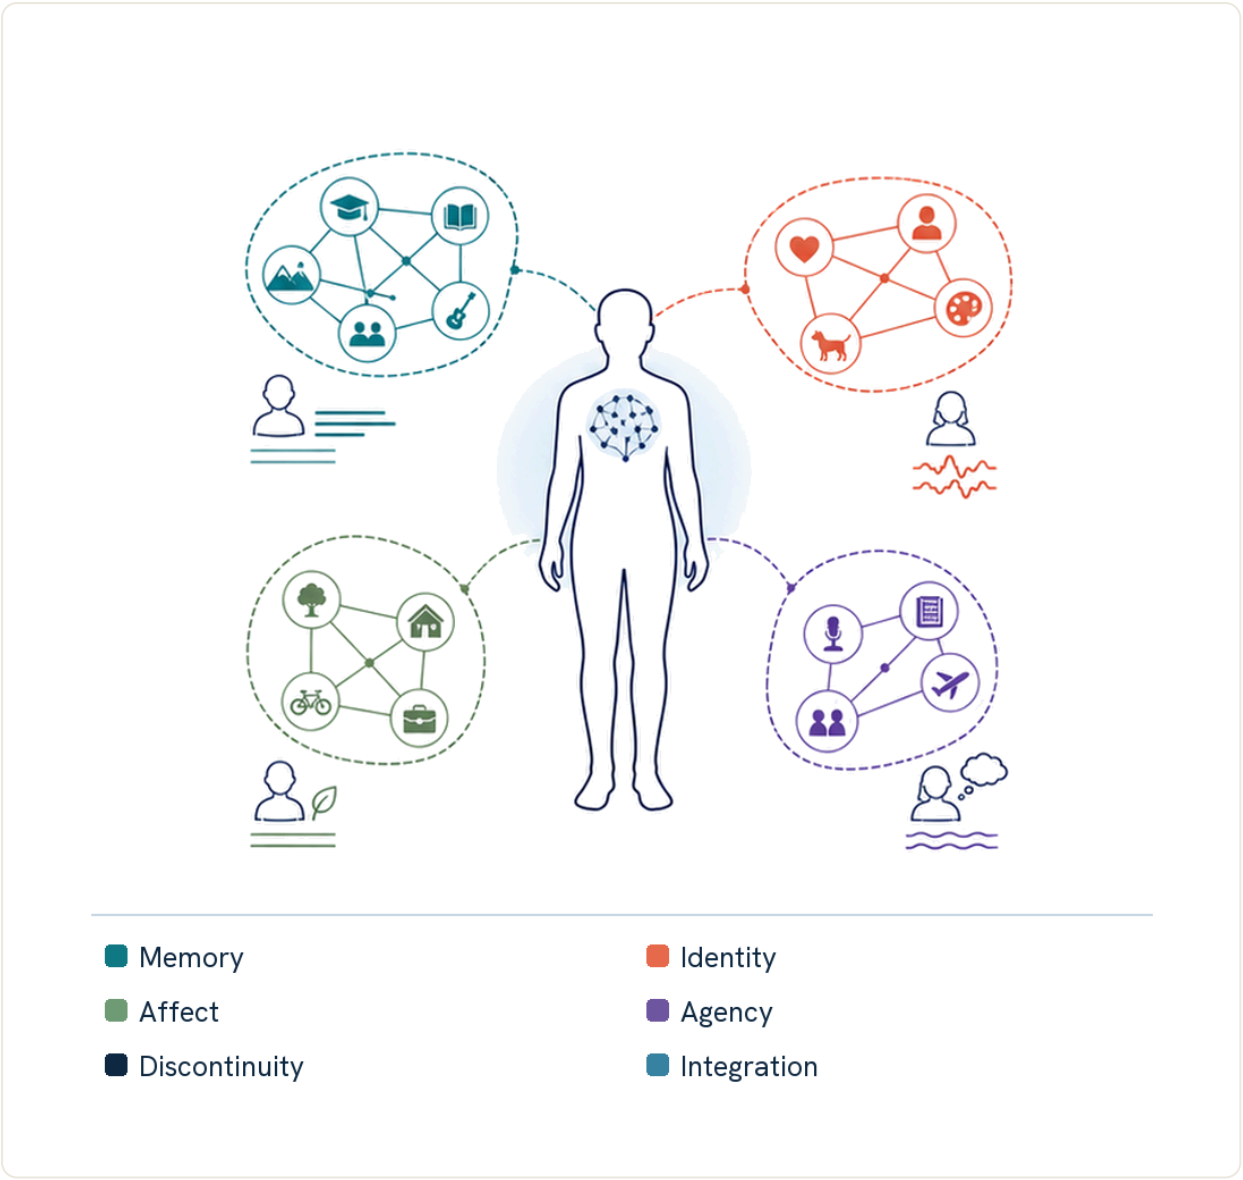


Fig 15.5 Dissociative identity disturbance is represented as discontinuity in the integration of autobiographical memory, identity, affect and agency rather than as separate literal people.

Two things must travel together in every answer. First, the criterion set, because DID without recurrent amnesia is a different (residual) diagnosis. Second, the **controversy**, because the viva examiner reliably asks whether the disorder is a genuine post-traumatic condition or an artefact of therapy and culture, the **trauma model versus sociocognitive model** debate. The older name multiple personality disorder is worth knowing, as is the fact that the flamboyant, fully personified **alter identities** of popular culture are the exception, not the diagnostic rule.

3.1 Criterion A: the disruption of identity

Two or more distinct states, discontinuity of self and agency. DSM-5-TR Criterion A requires a disruption of identity characterised by two or more distinct personality states (which may be described in some cultures as an experience of possession), involving marked discontinuity in the sense of self and sense of agency, with related alterations in affect, behaviour, consciousness, memory, perception, cognition or sensory-motor functioning. Crucially, the elaboration of states with different names, wardrobes, handwriting and accents occurs in only a *minority* of cases and

is *not* essential to diagnosis; in most people the switching is subtle and inferred from sudden discontinuities in the sense of self, not from theatrical alter identities.

3.2 Criterion B: recurrent dissociative amnesia (the anchor)

The required, most-tested criterion. DSM-5-TR Criterion B demands **recurrent gaps** in the recall of everyday events, important personal information and/or traumatic events that are inconsistent with ordinary forgetting. This dissociative amnesia shows up as lost autobiographical memory (a wedding, all schooling before a certain age), lapses for well-learned skills (how to drive or cook), and the discovery of possessions or writings the person has no memory of acquiring. The remaining criteria fence the diagnosis: distress or impairment (C); the disturbance is *not* a normal part of a broadly accepted cultural or religious practice, and in children is not better explained by imaginary playmates or fantasy play (D); and it is not due to a substance (alcohol blackouts) or another medical condition such as complex partial seizures (E).

RULE **Identity disruption plus recurrent amnesia.** DID = two or more distinct identity states with discontinuity of self and agency AND recurrent dissociative amnesia; the amnesia is a required criterion, never an optional associated feature.

TRAP **Diagnosing DID without the amnesia.** An identity disturbance or an episode of possession with *no history of recurrent dissociative amnesia* is other specified dissociative disorder (OSDD, DSM-5-TR example 1), not DID. Do not upgrade it.

3.3 The ICD-11 framing and partial DID

Executive control is the ICD-11 hinge. ICD-11 codes DID at 6B64: two or more distinct personality states (dissociative identities) with marked discontinuities in the sense of self and agency, where at least two *recurrently take executive control* of consciousness and functioning. Its innovation is partial dissociative identity disorder (6B65): a single dominant personality state runs day-to-day life and is *intruded upon* by non-dominant states (intruding thoughts, affects, actions) that do *not* recurrently take executive control. The clean split to memorise is control (full DID: states seize control; partial DID: they only intrude).

3.4 Associated features, screening and the trauma load

Intrusions that mimic psychosis, on a heavy trauma base. People with DID report recurrent, ego-dystonic intrusions: voices (a child's voice, commenting or command voices), thoughts and impulses experienced as not their own, and made actions, phenomena that superficially resemble Schneiderian first-rank symptoms and drive the frequent misdiagnosis as schizophrenia. The overwhelming majority describe severe, chronic, early childhood trauma (abuse and neglect), and most meet criteria for comorbid PTSD (Kaplan and Sadock, CTP 2024). Screening and diagnosis use the Dissociative Experiences Scale (DES) as a self-report screen, with the structured SCID-D-R interview and the MID for diagnosis; a DES mean around **30** is the commonly cited screen threshold for a dissociative disorder (Carlson and Putnam 1993). The instrument itself is set out in the accompanying scale plate.

3.5 The discriminations that get tested

Four fast separations. Against *bipolar II with mixed features* (the commonest misdiagnosis): DID state shifts happen within minutes to hours, far too fast for even rapid-cycling bipolar disorder, and lack the classic reduced need for sleep. Against *schizophrenia*: the voices and passive-influence are dissociative intrusions in a person with intact reality testing and a trauma narrative, not a primary psychosis. Against *traumatic brain injury amnesia*: TBI carries loss of consciousness, disorientation and neurological signs, whereas dissociative amnesia sits with a discontinuity of self and agency. Against *conversion (functional neurological symptom) disorder*: conversion lacks the two-or-more distinct personality states. The factitious, imitative and malingered presentations (states built around a diagnosis, sometimes to evade responsibility) round out the differential.

3.6 The controversy: trauma model versus sociocognitive model

The one debate to be able to argue both ways. The *trauma (post-traumatic) model* holds that DID arises when severe, repeated, inescapable early-childhood trauma prevents the integration of a unified self, so identity develops in fragments. The rival *iatrogenic / sociocognitive / fantasy model* holds that DID is a socially constructed role, shaped by therapist suggestion (leading questions, hypnosis), cultural and media scripts, and high fantasy-proneness, rather than a naturally occurring post-traumatic disorder (Kaplan and Sadock, CTP 2024). This is the **trauma model versus sociocognitive model** question in one line. The examinable rejoinder in favour of the trauma model is that controlled neuroimaging and psychophysiology (the Reinders studies) distinguish genuine DID identity states from high-fantasy-prone individuals asked to simulate them, which a purely role-play account struggles to explain.

WORKED EXAMPLE

A woman in her late twenties is referred as "treatment-resistant bipolar II". She describes hearing a young child's voice narrating her actions, finds clothes and written notes she has no memory of buying or writing, and loses blocks of time at work. Her mood and behaviour shift within an hour, not over days, and she has a documented history of chronic childhood sexual abuse. The rapid within-hour switching, the recurrent amnesia (the notes and lost time), the discontinuity of self and agency, and the trauma history make this dissociative identity disorder, not bipolar II and not schizophrenia. Confirming recurrent dissociative amnesia is what secures the diagnosis; had it been absent, the correct label would be other specified dissociative disorder.

INDIA

The genuine India device here is culture, not pharmacology. Possession and trance presentations, in which an external spirit, deity or ancestor is felt to take over, are a common idiom of distress in Indian settings and can look like the possession form of DID. DSM-5-TR Criterion D and the cultural formulation are the safeguard: a possession or trance that is a *sanctioned, non-distressing part of a broadly accepted religious or cultural practice is not a disorder at all*. It becomes DID only when it is involuntary, unwanted, recurrent outside accepted ritual, and paired with recurrent amnesia and impairment. In practice such presentations are too often sedated (the reflex reach for a benzodiazepine such as alprazolam) or routed to faith healers rather than assessed with a proper cultural formulation and a trauma history. The transcultural framing of possession and trance is developed in the Consultation-liaison, geriatric & transcultural psychiatry notes.

2 or more	**1.5%**	**30**
DISTINCT IDENTITY STATES, DSM-5-TR CRITERION A	12-MONTH PREVALENCE (DSM-5-TR, SMALL US COMMUNITY SAMPLE)	DES SCREEN CUT-OFF FOR A DISSOCIATIVE DISORDER (CARLSON AND PUTNAM 1993)

PEARL

The showy, fully named alter identities are the minority presentation. Most DID is quiet: subtle switching, chronic amnesia and passive-influence intrusions, which is exactly why it is missed or mislabelled as bipolar disorder or psychosis for years.

GOOD TO REMEMBER

- **Dissociative identity disorder (the syndrome):** the defining criteria are two or more distinct personality (identity) states with a marked discontinuity in the sense of self and agency (Criterion A) PLUS recurrent dissociative amnesia inconsistent with ordinary forgetting (Criterion B, required), causing impairment, not accounted for by an accepted cultural or religious practice, a substance or another medical condition; the discriminator from other specified dissociative disorder is the presence of the recurrent amnesia, and the first step is to confirm that amnesia criterion before ever applying the DID label.

HOLD THIS

DID needs BOTH halves: two or more distinct identity states with discontinuity of self and agency AND recurrent dissociative amnesia; drop the amnesia and it is other specified dissociative disorder, and the whole examinable debate is the trauma model versus sociocognitive model, with controlled neuroimaging that separates patients from simulators tilting the evidence toward trauma.

For the broader dissociative-disorders classification, the pathogenesis models and the conversion boundary, see the neighbouring topics; for the dissociative subtype of PTSD, the Anxiety, OCD & trauma-related disorders notes; for the somatic-symptom, functional and factitious boundary, the Somatic-symptom, sexual, impulse-control disorders & suicide notes; and for grounding and the place of hypnosis in dissociative work, the Psychotherapies, clinical assessment, MSE & nosology notes.

4 · Conversion (dissociative neurological symptom) disorder

One idea rewrites this whole topic. **Conversion disorder** is no longer a diagnosis of exclusion. The modern rule, from Stone and Carson, is that it is ruled *in* at the bedside by **positive signs** of internal inconsistency, findings that demonstrate the nervous system working normally when attention is diverted, and only secondarily by the absence of a lesion. Learn the signs and this becomes one of the most answerable clinical topics in the paper; miss the principle and you will either over-call a real neurological disease or, worse, sedate a functional presentation and never treat it.

Dissociative neurological symptom disorder is the ICD-11 name (code 6B60), which keeps the condition *inside* the dissociative family; DSM-5-TR files the same entity under the somatic symptom disorders as **functional neurological symptom disorder (conversion disorder)**, and the umbrella clinical term is **functional neurological disorder** (FND). Whatever the label, the examinable core is a small set of **rule-in signs** across four presentations: functional weakness and paralysis, functional movement and tremor, functional gait, and the sensory or special-sense forms, plus the **dissociative convulsions** that must be separated from true **epilepsy**. The two figures for this topic set the signs out as a positive-signs plate and a conversion-versus-**organic** discriminator grid to be memorised as images. The video-EEG work-up of the seizure form is developed in the Epilepsy & psychiatry notes; the wider somatic-symptom and factitious boundary in the Somatic-symptom, sexual, impulse-control disorders & suicide notes.

Fig 15.6 The positive rule-in signs of a functional neurological disorder, grouped by domain - each one demonstrating internal inconsistency at the bedside.

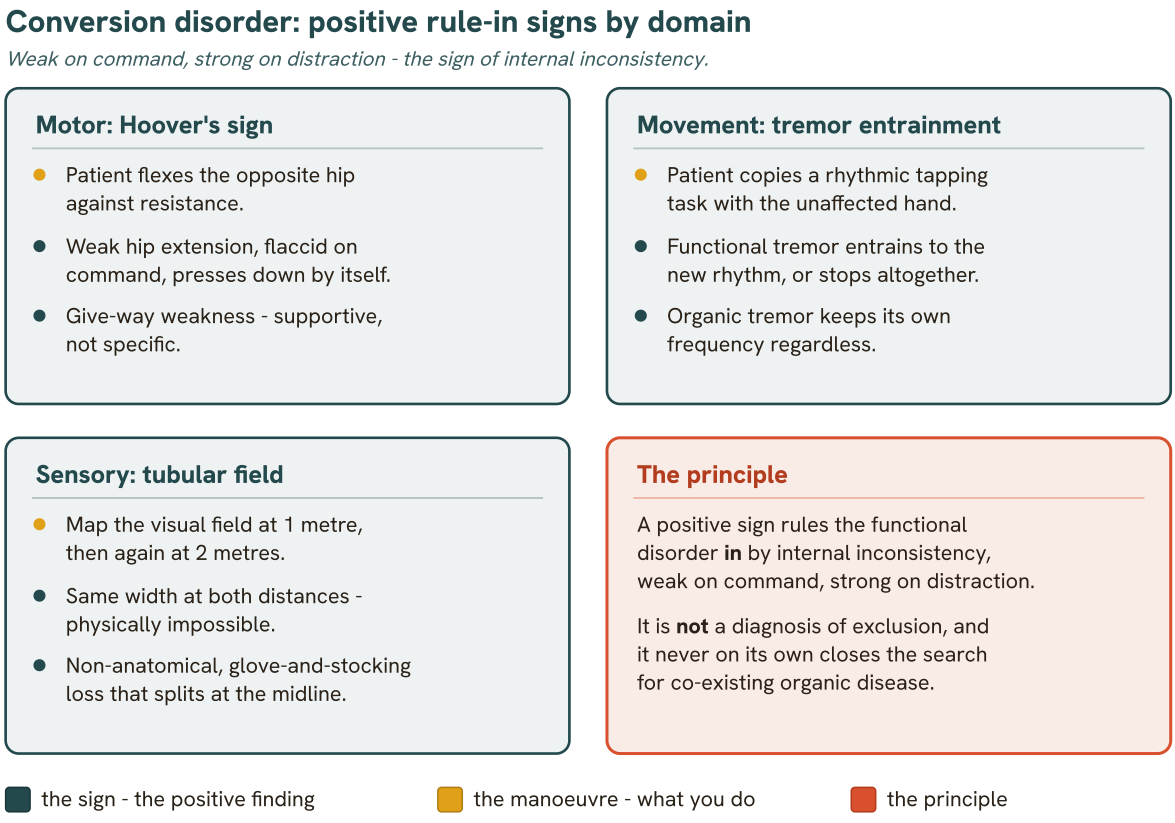

Fig 15.7 How to tell a functional (conversion) presentation from organic disease across five features, and why a positive sign never closes the organic work-up.

feature	functional (conversion)	organic disease
diagnostic basis	ruled in on a positive sign of internal inconsistency	a fixed anatomical or structural lesion
consistency	internally inconsistent, variable, distractible	consistent and reproducible on testing
signs	positive rule-in signs present: Hoover, entrainment, tubular field	hard neurological signs (reflexes, wasting, sensory level)
course and onset	often abrupt, may be linked to stress	progressive, vascular, or stepwise
imaging and investigations	investigations and imaging typically normal	structural or electrical abnormality (MRI, EEG)

Both can coexist.
A positive functional sign never ends the organic work-up.

functional (conversion) organic disease

Fig 15.8 Reading a convulsion: the reliable signs that separate a dissociative (non-epileptic) attack from an epileptic seizure, and the classic signs that do not.

reliable discriminator	dissociative (non-epileptic) convulsion	epileptic seizure
awareness during bilateral shaking	often preserved; can recall or interrupt it	lost in a bilateral tonic-clonic seizure
duration and pattern	long and fluctuating, over 2 to 3 minutes	short and stereotyped, under 2 minutes
the eyes	closed, with active resistance to opening	typically open
head movement	side-to-side	not side-to-side
post-ictal prolactin (at 10 to 20 min)	no rise	rises to over twice baseline (generalised)
ictal video-EEG (gold standard)	normal during an apparent attack	epileptiform discharge

unreliable on their own

occur in both and do not decide either way:
tongue-biting, urinary incontinence, injury, pelvic thrusting

dissociative convulsion · epileptic seizure · unreliable (occurs in both)

4.1 What conversion disorder is, and what it is not

Genuine symptoms, incompatible with disease, ruled in by a sign. Conversion disorder is one or more symptoms of altered voluntary motor or sensory function that are *genuinely experienced* (not feigned) yet demonstrably incompatible with recognised neurological or medical disease (DSM-5-TR Criterion B; ICD-11 6B60). DSM-5-TR deliberately *removed* the old requirement for an identifiable psychological stressor, so a stressor is neither necessary nor sufficient, and la belle indifference (bland unconcern) is unreliable and is *not* a diagnostic criterion. DSM-5-TR specifies the symptom type, which is the clinically useful map: with weakness or paralysis, with abnormal movement, with swallowing or speech symptoms, with attacks or seizures, with anaesthesia or sensory loss, with special-sensory symptoms, or mixed. The whole diagnosis now turns on Criterion B, the demonstration of internal inconsistency, not on Criterion D absence of disease.

RULE **Rule in, do not rule out.** Conversion disorder is a positive diagnosis made on a sign of internal inconsistency (Hoover, tremor entrainment, tubular field), never on the mere absence of a lesion or the presence of a stressor.

4.2 The positive-signs principle: internal inconsistency

The system works when attention is elsewhere. The unifying mechanism behind every rule-in sign is that the symptom depends on abnormally focused attention: divert attention and the "lost" function returns, revealing the pathways to be intact (Stone and Carson; New Oxford 2024). This is *internal inconsistency*, an incompatibility between the deficit shown on formal testing and the function that appears automatically or when the patient is distracted. It is a different logic from anatomical implausibility: a glove-and-stocking sensory loss is suggestive because it defies dermatomes, but a positive Hoover's sign is far stronger because it demonstrates the extensors *firing* a moment after they were "paralysed". The accompanying figure lays the signs out by domain as a single positive-signs plate. A skilled neurologist can make the positive diagnosis; the psychiatric assessment then secures a complete history and addresses the comorbid anxiety, panic, depression and PTSD that often travel with it (New Oxford 2024).

4.3 Functional weakness and paralysis: Hoover's sign

The single most testable sign in psychiatry. Hoover's sign exploits the automatic synergy of hip extension. With the patient supine, direct hip extension of the "weak" leg is flaccid; but when the patient flexes the *opposite* hip against resistance, the weak leg's extensors fire automatically and press down into the examiner's hand (Kaplan 2024). Weak on command, strong on distraction: that is a positive Hoover's sign, and it rules the diagnosis in at the bedside without imaging. Its sibling, the hip abductor sign, shows the same reversal in hip abduction. A give-way weakness (collapsing, ratchety power that builds then suddenly yields) and a global pattern of weakness affecting extensors and flexors equally are further pointers, but note the honest caveat: give-way weakness is *supportive, not specific*, because pain and poor effort in genuine organic disease can produce it too, whereas Hoover's sign is the discriminating one.

WORKED EXAMPLE

A woman develops a dense right-leg "paralysis" after a family argument. Direct right hip extension is flaccid. You cup your hand under the right heel and ask her to flex the *left* hip against your other hand; as she does, the right heel drives firmly down into your palm. The extensors she could not fire on command have fired automatically. That is a positive Hoover's sign, a rule-in for conversion disorder, elicited in seconds and without a scanner, and it doubles as the most persuasive thing you can later show her when you explain the diagnosis.

4.4 Functional movement disorder and tremor: the entrainment test

A tremor that copies the other hand is functional. The tremor entrainment test is the movement-domain equivalent of Hoover's sign. The patient with a unilateral tremor is asked to copy a rhythmical tapping movement with the *unaffected* limb; a functional tremor will *entrain* to the new rhythm (change its frequency to match), stop altogether, or the patient becomes unable to perform the simple copied rhythm at all (DSM-5-TR; New Oxford 2024). An organic tremor keeps its own frequency regardless. Other positive movement signs are a *fixed dystonic posture* (characteristically a flexed hand or a plantar-flexed, inverted ankle) and a typical functional facial overactivity (orbicularis or platysma over-contraction with jaw deviation) that masquerades as

facial weakness. The distractibility that defines these signs is the whole point: attention drives the symptom, so shifting attention exposes it.

4.5 Functional gait

Bizarre, effortful, and better when unwatched. The functional gaits are among the most recognisable presentations. A *dragging gait* keeps the forefoot in contact with the floor with the hip held externally or internally rotated, a pattern that fits no pyramidal or extrapyramidal disease. Astasia-abasia is a wide-based, staggering, dramatic and irregular gait with exaggerated near-falls yet a conspicuous absence of injury, the effort of not falling being greater than that of walking normally. The bedside rule-in is distraction: a patient with an apparently positive Romberg's test is asked to guess numbers written on the back or to carry out a complex task on a phone, and the balance improves markedly (New Oxford 2024). These motor and convulsive forms are especially common in Indian and other lower-income settings.

4.6 Sensory and special-sense presentations

Boundaries that disobey anatomy and physics. The classic sensory form is a glove-and-stocking anaesthesia: a loss of all modalities with a sharp boundary at the wrist or ankle that does not conform to any dermatome, and a splitting of vibration sense exactly at the midline, even though a tuning fork on the sternum or skull conducts through bone to both sides. In vision, the rule-in signs are the tubular field (also called tunnel vision): a visual-field defect of the *same* width at 1 metre as at 2 metres, which is physically impossible because a real field subtends a wider area with distance. The *fogging test* proves a claimed monocular blindness is functional, by progressively fogging the good eye with lenses while the patient reads an acuity chart; retained acuity at the end means the "blind" eye is doing the reading. Functional deafness and non-anatomical hemi-anaesthesia complete the group.

GOOD TO REMEMBER

- **Conversion / dissociative neurological symptom disorder (the syndrome):** defining criterion is a motor or sensory symptom, genuinely experienced, shown by a *positive* sign of internal inconsistency to be incompatible with neurological disease (Hoover's sign, tremor entrainment, tubular field); it is a *rule-in* diagnosis, *not* one of exclusion, no stressor is required (DSM-5-TR) and la belle indifference is non-diagnostic. First step: elicit a positive sign at the bedside.

4.7 Dissociative (non-epileptic) convulsions: the differentiation from epilepsy

The seizure form, and how it parts from true epilepsy. Dissociative convulsions (dissociative or psychogenic **non-epileptic** seizures, ICD-11 6B60.4 "with non-epileptic seizures") are paroxysmal episodes of altered movement, sensation or responsiveness that resemble an epileptic seizure but arise without epileptiform electrical discharge. The examinable skill is the **differentiation** from epilepsy on semiology (New Oxford 2024; Companion Box 13.12). Features that point to a dissociative convulsion are: preserved awareness during bilateral shaking, with the patient later able to recall being in the attack or even able to interrupt it; a long duration (often longer than 2 to 3 minutes, waxing and waning); closed eyes with active resistance to eye opening; side-to-side head movement and out-of-phase, asynchronous limb thrashing; and ictal or immediate post-ictal weeping. A post-ictal serum prolactin drawn 10 to 20 minutes after onset

that *rises to more than twice baseline* supports a true generalised or complex-partial seizure, so the *absence* of a prolactin rise is consistent with a dissociative convulsion, though the test has limited value (false positives and negatives) and a normal result never excludes epilepsy. The gold standard remains a normal *ictal* video-EEG captured during an apparently generalised attack (Companion), cross-referenced to the Epilepsy & psychiatry notes.

FEATURE	POINTS TO A DISSOCIATIVE CONVULSION	POINTS TO EPILEPSY (OR UNHELPFUL)
Awareness in bilateral shaking	**Preserved; can recall the attack or interrupt it**	Lost in a generalised tonic-clonic seizure
Duration	Often longer than 2 to 3 minutes, fluctuating	Usually under 2 minutes, stereotyped
Eyes	**Closed, with resistance to eye opening**	Typically open
Movements	Side-to-side head movement, out-of-phase asynchronous thrashing	Rhythmic, synchronous, evolving clonic jerks
Weeping	Ictal or immediate post-ictal crying	Rare
Post-ictal prolactin (10 to 20 min)	No rise (consistent with, not proof of)	Rise to more than twice baseline (limited value)
Ictal video-EEG	**Normal during an apparent generalised attack**	Epileptiform discharge (gold-standard test)
Tongue-biting, incontinence, pelvic thrust, injury	Unhelpful, occur in both; do not use to decide either way (Companion)	

Semiological differentiation of dissociative (non-epileptic) convulsions from epilepsy; the last row lists the classic unreliable discriminators.

GOOD TO REMEMBER

- **Dissociative convulsions (the seizure form):** defining criterion is a seizure-like attack with positive rule-in features (preserved awareness in bilateral shaking, duration over 2 to 3 minutes, closed and resisted eyes, no post-ictal prolactin rise) and a *normal ictal video-EEG*, the gold-standard confirmation; tongue-biting, incontinence and pelvic thrusting do NOT distinguish it from epilepsy. First step: capture the attack on video-EEG.

4.8 The conversion-versus-organic discrimination and its trap

A positive sign never cancels the duty to screen. The safe practice of this topic is a two-way **discrimination**: rule the functional disorder *in* on a positive sign, but keep screening for organic disease because the two coexist more often than expected. A sizable minority of patients with non-epileptic seizures *also* have epilepsy (Kaplan 2024), and functional signs are described alongside real disease. The accompanying discriminator grid contrasts the functional and organic pictures side by side. The classic misdiagnoses run in the mirror direction: early multiple sclerosis, a spinal cord lesion, frontal-lobe epilepsy (which can look bizarre and show a normal surface EEG), stiff-person syndrome, Wilson's disease and autoimmune encephalitis have all been

mislabelled conversion because the presentation seemed emotional or a stressor was present. So the positive sign rules the functional diagnosis in, but a progressive course, hard neurological findings, or an atypical picture reopens the organic search.

TRAP **Missing the organic cause behind a "conversion".** A stressor or a dramatic presentation is not evidence of a functional disorder; early MS, a cord lesion, frontal-lobe epilepsy or autoimmune encephalitis can all mimic it, and functional signs coexist with real disease, so never let a positive sign close the organic work-up in an atypical or progressive case.

4.9 Management: positive explanation, physiotherapy, CBT

The explanation is the first treatment. Management rests on three evidence-based pillars (New Oxford 2024). First, a clear *positive explanation* of the diagnosis: take the problem seriously, give it a positive diagnostic label rather than a list of what it is not, *show the patient their own positive sign* (the Hoover's sign, the tremor stopping on entrainment), use the software-versus-hardware metaphor to emphasise reversibility, and signpost written resources such as neurosymptoms.org. Second, *physiotherapy* is first-line for the functional motor forms (limb weakness and functional movement disorders), using distraction and retraining rather than generic stroke-style physiotherapy; a specific programme achieved a good outcome in about 72 percent despite years of symptoms. Third, *cognitive behavioural therapy*, generic tailored CBT for mixed functional symptoms and a dedicated CBT for dissociative seizures (number needed to treat around 5 for seizure remission). There is *no* specific drug for conversion disorder itself; medication is only for comorbid anxiety or depression, for which the SSRIs are the first-line agents taught in the Mood disorders: pharmacotherapy notes, and hypnosis and grounding sit in the Psychotherapies, clinical assessment, MSE & nosology notes.

2 min	10 to 20 min	2×
DURATION ABOVE WHICH A CONVULSION FAVOURS A DISSOCIATIVE ATTACK	POST-ICTAL PROLACTIN SAMPLING WINDOW AFTER SEIZURE ONSET	PROLACTIN RISE OVER BASELINE THAT SUPPORTS A TRUE SEIZURE

INDIA

Two genuine India devices meet here. First, the culture-bound one: dissociative motor and convulsive presentations, and the possession and trance states, are among the most frequent dissociative presentations in Indian practice, and the convulsive form is recorded as "very common" in India and other developing countries. Read through a cultural formulation, not the surface picture: a possession or trance sanctioned within an accepted religious practice is not a disorder, a boundary developed in the Consultation-liaison, geriatric & transcultural psychiatry notes. Second, the pharmacological one: the reflex Indian response to a dramatic dissociative or convulsive presentation is too often a sedative, and India has a well-recognised benzodiazepine over-prescription problem with alprazolam (Alprax, Restyl) as the default anxiolytic. A benzodiazepine treats nothing in conversion disorder, risks dependence, and is exactly the wrong move; the Indian Psychiatric Society and the wider benzodiazepine-sparing position favour a positive explanation, physiotherapy and CBT instead. The sedative and benzodiazepine use disorder as an addiction is covered in the Substance use disorders notes.

PEARL

The most powerful therapeutic tool is the diagnostic sign itself. Demonstrating a patient's own Hoover's sign or entrainment, and explaining that a leg that moves automatically is a leg that *can* move, converts the bedside examination into the opening move of treatment: it proves the diagnosis, shows reversibility, and replaces “there is nothing wrong” with “here is what is wrong and here is why it can get better”.

HOLD THIS

Conversion disorder is ruled *in* on positive signs of internal inconsistency, weak on command but strong on distraction (Hoover's sign, tremor entrainment, tubular field), never out by exclusion; and its seizure form is separated from epilepsy by preserved awareness, closed and resisted eyes, a long fluctuating attack, no post-ictal prolactin rise, and above all a normal ictal video-EEG.

For the wider dissociative-disorders map and the pathogenesis models see the neighbouring topics; the somatic-symptom, functional and factitious boundary sits in the Somatic-symptom, sexual, impulse-control disorders & suicide notes; the video-EEG work-up of dissociative convulsions in the Epilepsy & psychiatry notes; and the transcultural reading of possession and trance in the Consultation-liaison, geriatric & transcultural psychiatry notes.

5 · Depersonalisation-derealisation disorder

One discriminator carries this whole topic. **Depersonalisation-derealisation disorder** is a low-volume entity that is decided by a single question: is reality testing intact? The patient describes the world and the self as strange, flat and unreal, yet *knows* that this is only how things feel, not how they truly are. That preserved reality check is what separates the disorder from a psychotic illness, and forgetting it is the classic error that turns detachment into a mistaken diagnosis of schizophrenia.

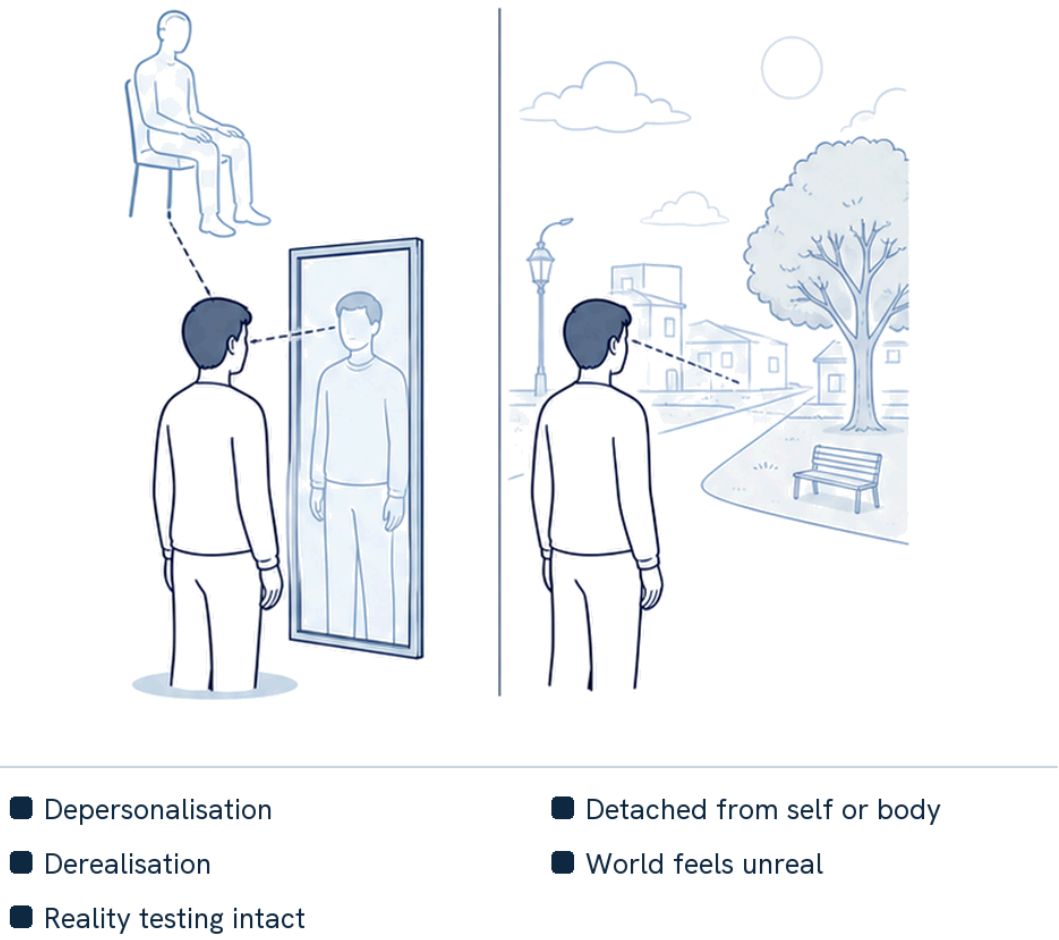

Fig 15.9 Depersonalisation is detachment from one's self, mental processes or body; derealisation is an altered sense of the external world as unreal. In both, reality testing remains intact.

Two experiences travel together in the name. **Depersonalisation** is a sense of **unreality** or **detachment from self**, one's own mind, feelings, actions or body. **Derealisation** is the same unreal, detached quality applied to the surroundings, the world seen as if behind glass or like a stage set. The examiner reward is small and precise: the definition, the intact-reality-testing anchor, the fact that transient forms are extremely common and benign, and the awkward truth that *no drug has an established place* in treatment.

5.1 The two halves: depersonalisation and derealisation

Detachment from the self, detachment from the world. The disorder is built from two symptom clusters that may occur singly or together (DSM-5-TR; ICD-11 6B66).

Depersonalisation

Unreality, detachment or being an outside observer of one's own thoughts, feelings, body or actions; emotional or physical numbing, a distorted sense of time, an unreal or absent self.

Derealisation

Unreality or detachment applied to surroundings; people or objects felt as unreal, dreamlike, foggy, lifeless or visually distorted (as if behind glass).

The "as if" quality

The experiences are described in the conditional, "as if" I were not real, "as if" the world were a painting; the person never asserts that it is *literally* so.

5.2 The DSM-5-TR criteria and the intact-reality-testing anchor

Persistent or recurrent, with the reality check preserved. DSM-5-TR requires persistent or recurrent experiences of depersonalisation, derealisation or both (Criterion A); crucially, *during these experiences reality testing remains intact* (Criterion B). The symptoms cause clinically significant distress or impairment (C); they are not attributable to a substance or another medical condition, notably seizures (D); and they are not better explained by another mental disorder such as schizophrenia, panic disorder, major depression or another dissociative disorder (E). Because transient depersonalisation is extremely common in the general population and after cannabis, ketamine or hallucinogens, the label is reserved for presentations that are persistent, recurrent and impairing.

RULE **Intact reality testing is the diagnosis.** Persistent unreality of self and/or world with an "as if" quality and a preserved reality check is depersonalisation-derealisation disorder; the moment the patient believes the unreality is literally true, you have left the diagnosis for the psychotic spectrum.

TRAP **Mislabelling depersonalisation-derealisation as psychosis.** "The world feels unreal, like a film" is not a delusion. Historically these patients were read as psychotic-spectrum and started on antipsychotics, for which there is no evidence and which can deepen the very emotional deadening they complain of (Kaplan and Sadock, CTP 2024).

5.3 Onset, course and the trauma signature

An adolescent onset with a heavy comorbidity load. The mean age of onset is **16 years**, and the disorder can begin in early or middle childhood; onset for the first time in later life is unusual and should prompt a search for an organic or substance cause (DSM-5-TR). The course splits into rough thirds: about one in three run an episodic, relapsing-remitting course, one in three a chronic course, and one in three an episodic course that becomes chronic (Kaplan and Sadock, CTP 2024). Comorbidity is the rule rather than the exception, with major depressive disorder in around **73%** and an anxiety disorder in around **64%**, which is why most patients are first treated for the secondary mood and anxiety symptoms. The trauma signature is distinctive: unlike the sexual-abuse loading of dissociative identity disorder, it is *emotional (verbal) abuse* that most specifically predicts depersonalisation-derealisation scores.

5.4 Screening: the Cambridge Depersonalization Scale

A dedicated instrument from the Maudsley unit. The standard screen is the Cambridge Depersonalization Scale (CDS), developed by Sierra and Berrios at the Depersonalization Research Unit (Maudsley Hospital, London); the same unit and Daphne Simeon's group in the United States generated most of the modern clinical picture. A depersonalisation-derealisation

subscale of the broader Dissociative Experiences Scale (the DES-D) is also used. The instrument forms are set out centrally in the accompanying scale plate; carry the CDS as the named screen and read its cut-off off the reproduced plate rather than committing an unverified threshold to memory.

5.5 Management: no drug cures it

Psychotherapy first, medication only for the comorbidity. The single most examinable management fact is a negative one: extensive treatment histories show *no* established pharmacotherapy for the core disorder, with benzodiazepines, serotonin reuptake inhibitors and stimulants only partially helpful in some patients, and no evidence at all for antipsychotics (Kaplan and Sadock, CTP 2024). Antipsychotics are reserved strictly for overwhelming associated anxiety or mood disturbance and may worsen the emotional numbing. The mainstays are a range of psychotherapies (psychodynamic, cognitive, cognitive-behavioural, hypnotherapeutic and supportive, with no comparative data favouring one) plus definitive treatment of the comorbid depression or anxiety. Where a short course of an anxiolytic is used for a crisis, the benzodiazepine-sparing short-course rule still holds: it is a brief measure, not a long-term treatment for the unreality itself. The grounding techniques and the place of hypnosis are developed in the Psychotherapies, clinical assessment, MSE & nosology notes; the SSRIs and SNRIs as first-line anxiolytics for the comorbid anxiety are in the Mood disorders: pharmacotherapy notes and the Anxiety, OCD & trauma-related disorders notes.

WORKED EXAMPLE

A man in his early twenties is referred with a query psychotic illness. Since his late teens he has felt "outside" himself, watching his own actions from a step to one side; his voice sounds tinny and far away, his emotions muffled, the street "like a painting". He is frightened and desperate to "get back to me", but when asked he is clear that the world is not *actually* unreal, it only feels that way. The persistence since adolescence, the detachment from self and surroundings, the distress, and above all the intact reality testing make this depersonalisation-derealisation disorder, not schizophrenia. Confirming the preserved reality check is what secures it; starting an antipsychotic would be both unsupported and likely to deepen the emotional deadening.

16 yrs	**73%**	**1 in 3**
MEAN AGE OF ONSET (DSM-5-TR)	CARRY COMORBID MAJOR DEPRESSION (KAPLAN 2024)	FOLLOW A CHRONIC COURSE (KAPLAN 2024)

INDIA

The genuine India device here is what *not* to prescribe. India carries a well-recognised benzodiazepine over-prescription problem, with alprazolam (Alprax or Restyl) functioning as the default anxiolytic reached for almost reflexively when a patient describes unreality, numbness or anxious detachment. Depersonalisation-derealisation disorder is precisely the presentation where that reflex fails: no benzodiazepine treats the core symptom, dependence and rebound follow long use, and the Indian Psychiatric Society position, like BAP and NICE, is benzodiazepine-sparing, a short course for crisis only. The safer move is to name the disorder, reassure about the intact reality check, treat the comorbid depression or anxiety, and refer for psychotherapy.

PEARL

Depersonalisation is best understood as a "hard-wired" protective response, an inhibitory dampening of overwhelming affect that is adaptive in acute terror or intoxication and pathological only when it persists. That is why transient unreality after trauma, a panic attack or cannabis is normal and self-limiting, and why the disorder sits at the anxious, not the psychotic, end of the spectrum.

GOOD TO REMEMBER

- **Depersonalisation-derealisation disorder (the syndrome):** the defining criterion is persistent or recurrent depersonalisation (unreality or detachment from self) and/or derealisation (unreality or detachment from the surroundings) during which *reality testing remains intact* (DSM-5-TR Criterion B), causing distress or impairment and not due to a substance, seizure or another disorder; the discriminator from psychosis is that intact reality check and the "as if" quality, and the first step is always to confirm reality testing is preserved before the label is applied.

HOLD THIS

Persistent unreality of self and world with an "as if" quality and INTACT reality testing is depersonalisation-derealisation disorder, onset around 16 years, screened with the Cambridge Depersonalization Scale, and it has no established drug treatment, so the answer is psychotherapy plus treating the comorbid mood or anxiety, never a reflex antipsychotic or a long-term benzodiazepine.

For the classification map and the pathogenesis models this disorder sits within, see the neighbouring dissociative-disorders topics; for the dissociative subtype of PTSD and the anxiolytics in anxiety, the Anxiety, OCD & trauma-related disorders notes; for possession and trance in the transcultural frame, the Consultation-liaison, geriatric & transcultural psychiatry notes; and for grounding and hypnosis, the Psychotherapies, clinical assessment, MSE & nosology notes.

6 · Dissociative amnesia and fugue

One discrimination decides this topic. **Dissociative amnesia** is an inability to recall important autobiographical information, usually of a traumatic or stressful nature, that is too extensive to be ordinary forgetting. The examiner is not really testing whether you can recite the criterion; he is

testing whether you can separate it from an *organic* amnesia at the bedside, because the two are worked up in opposite directions. The whole answer turns on one pattern: a retrograde loss of already-stored personal memory with an intact ability to lay down new memory, on a trauma trigger, and in the absence of a neurological or substance cause.

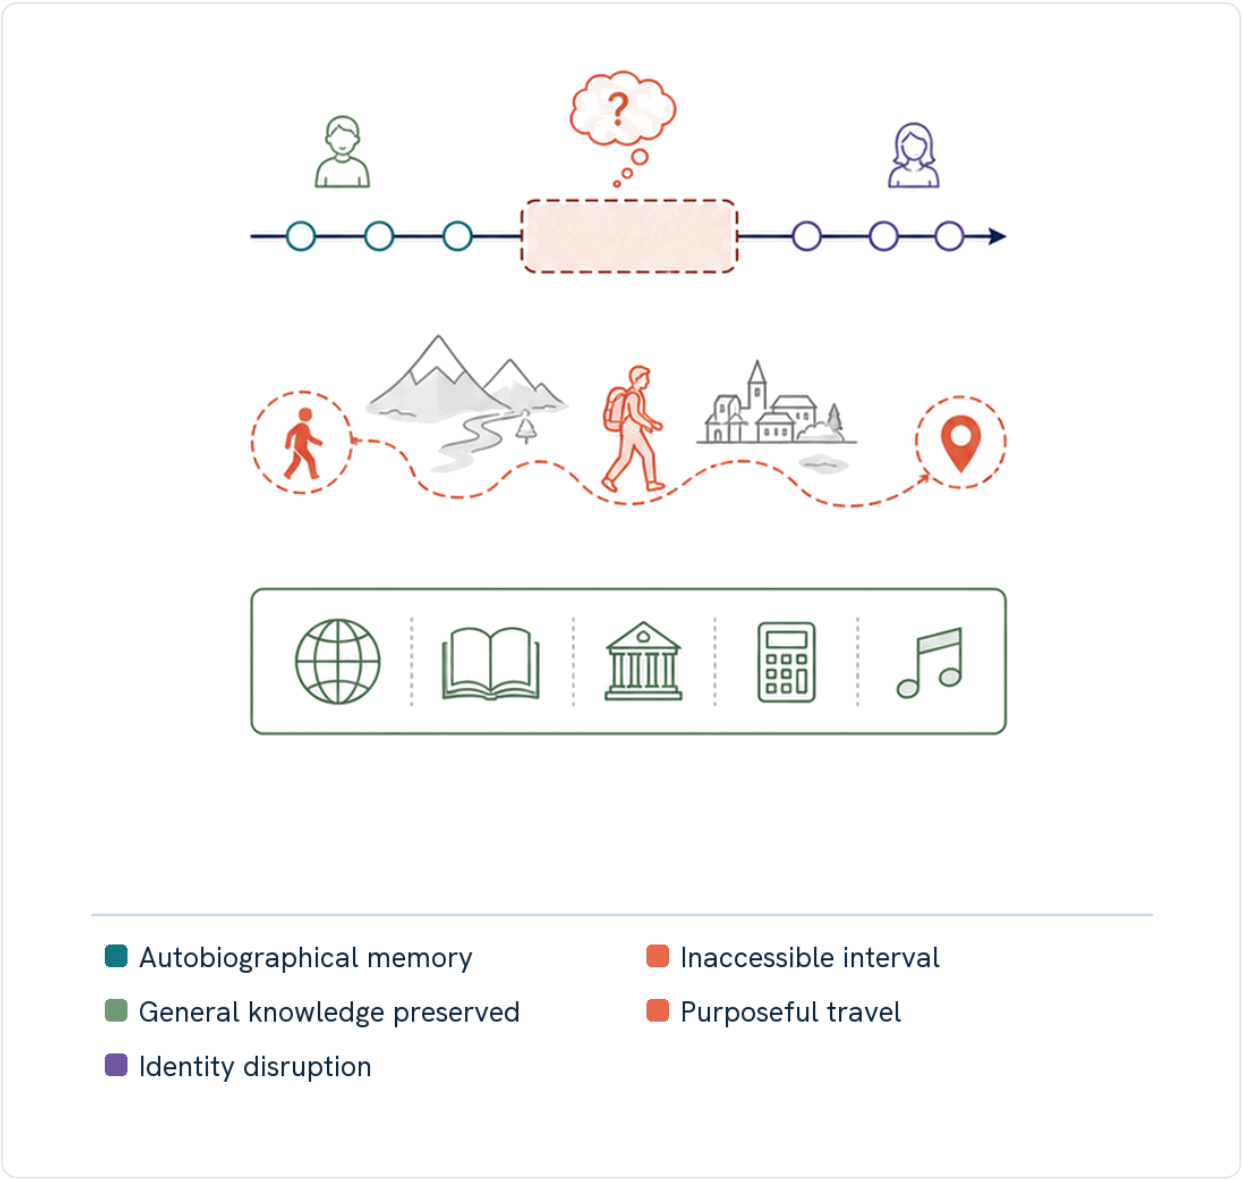

Fig 15.10 Dissociative amnesia produces an autobiographical memory gap that exceeds ordinary forgetting. Fugue adds apparently purposeful travel or wandering with disruption of autobiographical identity.

The disorder was long called psychogenic amnesia (the ICD-10 and older term), and dissociative fugue is now folded into it as a specifier rather than standing as a separate disorder. Keep two moves ready: name the *type* of amnesia (the commonest is a **localised amnesia**), and rule *in* the dissociative picture against the organic mimics, transient global amnesia, the amnestic (Korsakoff) syndrome and complex partial seizures, by the direction of the memory loss and the fate of personal identity.

6.1 What dissociative amnesia is

A reversible retrieval deficit for autobiographical memory. DSM-5-TR Criterion A is an inability to recall important autobiographical information, usually of a traumatic or stressful

nature, that is inconsistent with ordinary forgetting. The memory has been successfully stored and would ordinarily be freely recollected, so the deficit is one of *retrieval* and is potentially reversible; that is precisely how dissociative amnesia differs from the amnesias of neurobiological damage or toxicity, which impair storage. Criterion B requires distress or impairment; Criterion C excludes a substance and a neurological or other medical condition (complex partial seizures, transient global amnesia, a closed head injury); Criterion D excludes dissociative identity disorder, PTSD, acute stress disorder, somatic symptom disorder and a neurocognitive disorder. In DSM-5-TR the deficit is primarily *retrograde* and, except in the rare continuous type, there is no ongoing amnesia for contemporary life events.

6.2 The five types (name the shape of the gap)

Localised is the commonest. DSM-5-TR and ICD-11 define the recognised types by the shape of the memory gap, and the examiner expects you to label the pattern.

Localised
inability to recall all events in a circumscribed period, usually the period around the stressor (the commonest form)

Selective
recall of some but not all of the events within that circumscribed period

Generalised
failure to recall one's entire life, including personal identity (rare, acute, and it usually brings the person to the police or emergency services)

Continuous
failure to recall each new event as it occurs; this is the *anterograde* form of dissociative amnesia, and it is rare

Systematised
loss of a specific category of memory, for example all memories of one person or of the family

6.3 Dissociative fugue (now a specifier)

Purposeful travel plus amnesia for identity. DSM-5-TR codes fugue as the specifier "with dissociative fugue" (F44.1): apparently **purposeful travel** or bewildered wandering that is associated with amnesia for identity or for other important autobiographical information. It is commonly associated with generalised dissociative amnesia, has a sudden onset under severe stress, and terminates abruptly, with recovery of the earlier life and a residual amnesia for the episode itself. Both DSM-5-TR and ICD-11 judge that there are insufficient data to keep fugue as a disorder distinct from dissociative amnesia; ICD-11 makes it a presence specifier of 6B61 (6B61.0 with, 6B61.1 without). Note the nosological shift that gets tested: the older criterion of "assumption of a new identity" during the episode would now meet criteria for dissociative identity disorder, so the classic full identity-swap fugue has been reallocated.

6.4 The critical discrimination: dissociative versus organic amnesia

Direction of the loss, and the fate of identity. This is the single most examinable separation on the topic, and it is a positive comparison, not a hunch. Dissociative amnesia is a retrograde **loss**

of autobiographical memory with new learning intact and personal identity frequently lost; the organic amnestic syndrome is the mirror image.

FEATURE	DISSOCIATIVE AMNESIA	ORGANIC AMNESIA
Predominant deficit	**retrograde: loss of stored autobiographical memory**	anterograde: failure to form new memories, with a retrograde gradient
New learning (anterograde)	**intact**	impaired
Personal identity	**often lost (name, whole life history)**	preserved (the person knows who they are)
Trigger	acute psychological trauma or stress	a neurological insult or a substance
Onset and recovery	sudden onset, can recover suddenly and completely	tracks the lesion, recovery often incomplete
Consciousness and signs	clear sensorium, neurological examination normal	clouding or disorientation, focal signs may appear

The bedside separation of dissociative from organic amnesia rests on the direction of the deficit and on whether personal identity is lost.

RULE **Retrograde loss of identity with intact new learning is dissociative.** Dissociative amnesia loses the stored past and often the personal identity while new memories still form; the organic amnestic syndrome does the reverse, failing to lay down new memory while identity is preserved.

6.5 Ruling in against the organic mimics

Rule the picture in, do not just assume it. The same positive-versus-organic logic that governs conversion applies here: dissociative amnesia and fugue are rule-in diagnoses that still require the organic mimics to be excluded (Criterion C). Transient global amnesia gives an abrupt, isolated anterograde amnesia with repetitive questioning, preserved personal identity, typically in an older adult, and it resolves within 24 hours. Complex partial seizures and temporal lobe epilepsy can produce an epileptic wandering with no assumption of a new identity, with confusion or disorientation during the episode, episodes not tied to a psychological stressor, and an abnormal EEG. The amnestic (Korsakoff) syndrome gives a dense anterograde amnesia with confabulation on a thiamine-deficiency base. Head injury, post-ictal states and a substance blackout complete the exclusions. Screening for dissociation itself uses the Dissociative Experiences Scale (DES), where a mean around 30 flags a probable dissociative disorder; the instrument is set out in the accompanying scale plate.

TRAP **Labelling a wandering, amnesic patient "dissociative" too soon.** Purposeful travel with amnesia can be an epileptic automatism, transient global amnesia or a post-ictal fugue; missing the organic cause is the classic error. Get an EEG, imaging and a substance history before the label sticks. The video-EEG work-up that separates epileptic from dissociative events is set out in the Epilepsy & psychiatry notes.

6.6 Course and the one management principle

Recover the memory, do not sedate the patient. Onset is typically sudden and under stress, and the localised form often recovers abruptly and completely, so the prognosis is generally good. The management principle is a safe, contained environment, removal from or resolution of the precipitating stressor, and a phased, psychologically informed recovery of the memory; a drug-assisted (abreaction) interview has historically been used but is not first-line, and grounding and the place of hypnosis are developed in the Psychotherapies, clinical assessment, MSE & nosology notes. What the disorder does *not* need is a benzodiazepine: there is no anxiolytic indication for dissociative amnesia, and reflexive sedation both masks the picture and courts dependence.

WORKED EXAMPLE

A man in his thirties is brought in by railway police having been found several hundred kilometres from home, unable to give his name, address or occupation, and calm rather than distressed. On examination the sensorium is clear, there are no focal neurological signs, and he can learn and recall a new list of three objects without difficulty. A relative later reports that he left home the morning after being served with a large debt notice. The intact new learning, the clear sensorium, the loss of personal identity and the clear psychological precipitant point to a dissociative fugue with generalised dissociative amnesia, not an organic amnesia. The immediate job is still to exclude a seizure, transient global amnesia and a substance cause before the label is fixed, and the treatment is safety, contact with family and gentle memory recovery, not a sedative.

INDIA

Two genuine India devices meet here. First, culture: possession and trance states, in which a deity, spirit or ancestor is felt to take over, are a common idiom of distress in Indian settings and can present with amnesia and purposeful travel that mimic dissociative amnesia and fugue. ICD-11 keeps these as separate categories (trance disorder 6B62, possession trance disorder 6B63), and a sanctioned, non-distressing ritual state is not a disorder at all; the cultural formulation is the safeguard. Second, the treatment reflex: such presentations, and dissociative amnesia generally, are too often met with a reflexive benzodiazepine rather than an assessment. Alprazolam (Alprax, Restyl) is the default anxiolytic of Indian practice and the emblem of the country's benzodiazepine over-prescription problem; the standard rule is that a benzodiazepine should not ordinarily run beyond 2 to 4 weeks. Dissociative amnesia has no benzodiazepine indication. The transcultural reading of possession and trance is developed in the Consultation-liaison, geriatric & transcultural psychiatry notes.

30	6 to 20	2 to 4	0.5 to 6
DES SCREEN CUT-OFF FOR A DISSOCIATIVE DISORDER (CARLSON AND PUTNAM 1993)	ALPRAZOLAM HALF-LIFE IN HOURS	BENZODIAZEPINE SHORT-COURSE CEILING IN WEEKS	ALPRAZOLAM ANXIOLYTIC DOSE (MG PER DAY)

PEARL

A patient who cannot say who they are is far more likely to have a dissociative (or a malingered or factitious) amnesia than an organic one, because the organic amnestic syndromes leave personal identity intact. Loss of the name is a psychogenic flag until proven otherwise, and the feigned or factitious version is covered in the Somatic-symptom, sexual, impulse-control disorders & suicide notes.

GOOD TO REMEMBER

- **Dissociative amnesia and fugue (the syndrome):** DSM-5-TR Criterion A is an inability to recall important autobiographical information, usually traumatic or stressful, that is inconsistent with ordinary forgetting (localised is the commonest type); fugue is the specifier "with dissociative fugue", apparently purposeful travel or bewildered wandering with amnesia for identity; the deficit is retrograde and reversible, and the first step is to exclude an organic cause (Criterion C) and to check whether personal identity is lost, which points away from an organic amnesia.
- **Alprazolam (Alprax, Restyl):** a short-acting benzodiazepine and the default Indian anxiolytic, half-life about 12 to 15 hours with no clinically important active metabolite, usual anxiolytic range 1 to 4 mg per day; it has no role in dissociative amnesia and should not ordinarily run beyond 2 to 4 weeks, the short-course rule that guards against the Indian over-prescription pattern.

HOLD THIS

Dissociative amnesia is a retrograde, reversible loss of autobiographical memory (localised is commonest) on a trauma trigger, with personal identity often lost but new learning intact; the organic amnestic syndrome is the mirror image (anterograde, identity preserved), so exclude a neurological or substance cause before you commit, and never sedate it with a benzodiazepine.

For the wider dissociative-disorders classification and dissociative identity disorder, see the neighbouring topics; the benzodiazepine mechanism, the half-life classes and the taper are developed in the neighbouring benzodiazepine topic; for the dissociative subtype of PTSD and the trauma-related disorders, the Anxiety, OCD & trauma-related disorders notes; and for the somatic-symptom, functional and factitious boundary, the Somatic-symptom, sexual, impulse-control disorders & suicide notes.

7 · Possession and trance states

One question decides this whole topic: is this a disorder at all, or a sanctioned cultural act? **Possession** and **trance** presentations are a genuinely **culture-bound** corner of the dissociative disorders, and the examinable skill is not the phenomenology but the boundary. A narrowing of awareness with stereotyped, seemingly uncontrolled behaviour, or the sense of being replaced by an external identity, is a *disorder* only when it is involuntary, unwanted, distressing or impairing, and lies *outside* an accepted collective cultural or religious practice. Read as an accepted ritual, the very same behaviour is not pathology at all.

The two systems diverge here, so carry both. **ICD-11 keeps two separate categories**, trance disorder (6B62) and possession trance disorder (6B63); **DSM-5-TR keeps neither as a standalone**, folding possession-form presentations into dissociative identity disorder and listing

dissociative trance only as an example under Other Specified Dissociative Disorder. In the Indian setting this is high-yield because possession presentations are common, and the clinician's first move is a cultural formulation, decoding the local **idioms of distress** before any label is applied.

7.1 The two ICD-11 entities: trance versus possession trance

Narrowed awareness versus a replacing identity. Both are trance states with a marked alteration of consciousness or a loss of the normal sense of personal identity; what separates them is whether an *external identity takes over* (ICD-11 CDDR).

Trance disorder (6B62)

A trance state with narrowing of awareness of the immediate surroundings (or unusually narrow, selective focus) *and* restriction of movements, postures and speech to a small repertoire experienced as outside one's control; crucially, it is *not* experienced as being replaced by an alternate identity.

Possession trance disorder (6B63)

A trance state in which the normal sense of personal identity is *replaced by an external "possessing" identity*, with behaviours or movements experienced as controlled by the possessing agent (a spirit, deity, demon or the dead); full or partial amnesia for the episode is usual.

Shared thresholds

Episodes are recurrent, or, if the diagnosis rests on a single episode, that episode has lasted at least several days; the state is involuntary and unwanted, is not a sanctioned collective practice, is not organic or substance-related, and causes distress or impairment.

RULE **The sanctioned-practice line is the diagnosis.** An involuntary, unwanted, distressing or impairing trance or possession state that falls *outside* an accepted collective cultural or religious practice is a disorder; the identical experience embraced as ritual, without distress or impairment, is not.

7.2 The critical boundary: accepted cultural practice is not a disorder

Where possession is welcomed, it is not pathology. ICD-11 states the exclusion twice over: the diagnosis is *not* applied to experiences accepted in the person's context as collective cultural phenomena or religious practice, and *not* applied where there is no significant distress or impairment. Single, transitory experiences lasting minutes to hours, and states cultivated within religious or cultural groups where possession is normative, are explicitly excluded, and people who gradually gain control and acceptance of the experience within such a group carry no excess of mental disorder over the general population. DSM-5-TR draws the same line in its own words: dissociative trance "is not a normal part of a broadly accepted collective cultural or religious practice."

7.3 ICD-11 versus DSM-5-TR versus the old ICD-10 label

Same phenomenon, three homes. The classification map is itself the examiner's favourite question here.

SYSTEM	WHERE POSSESSION / TRANCE LIVES	KEY POINT
ICD-11	**Two categories: trance disorder (6B62), possession trance disorder (6B63)**	Possession trance = identity replaced by an *external* agent
DSM-5-TR	Possession folded into dissociative identity disorder; dissociative trance under Other Specified Dissociative Disorder	**No standalone possession/trance disorder**
ICD-10	F44.3 trance and possession disorder	A single combined rubric ("possession hysteria")

The one entity ICD-11 splits in two, DSM-5-TR scatters across DID and OSDD, and ICD-10 merged under F44.3.

7.4 Reading the differential: identity, psychosis, PTSD and the organic mimics

External agent, brief and stress-bound, normal EEG. Four boundaries decide the case. Against dissociative identity disorder and partial DID, the possession identity is attributed to an *external* agent, whereas DID identities are internal and not so attributed; someone describing both internally and externally attributed identities is diagnosed with DID, not possession trance. Against schizophrenia, the intrusive voices, inserted thoughts and controlled behaviours occur *primarily during* the brief possession state, with no other positive or negative psychotic symptoms. Against PTSD, if trance-like states are confined to flashback re-experiencing, no additional trance diagnosis is made. Against the organic mimics, possession trance can resemble focal unaware (complex partial) seizures of temporal lobe epilepsy or delirium, but trance disorder shows a *normal EEG even during episodes* and lacks the global confusion of delirium.

TRAP **Reading a possession state without the cultural formulation, or missing an organic cause.** Two errors sink this presentation: labelling a sanctioned ritual possession as a disorder because the culture was never assessed, and stamping "possession trance" on what is actually temporal lobe epilepsy, delirium or a substance effect. Take the cultural formulation and clear the organic differential before the label.

7.5 The Indian frame: a common presentation, decoded through culture

Common here, and best understood as an idiom of distress. Possession trance presentations are very commonly seen in India and certain African countries, where the possessing agent characteristically matches a figure from the local religious tradition and the episode is often precipitated by domestic disharmony, interpersonal conflict or acculturative stress. The clinical task is not to sedate the phenomenon but to read it: apply the cultural formulation, decode the **idioms of distress** the family is using, and separate a sanctioned, welcomed ritual possession from an involuntary, distressing state that meets criteria. The wider transcultural framing and the neighbouring culture-bound syndrome concept sit in the Consultation-liaison, geriatric & transcultural psychiatry notes; the dissociative subtype of PTSD and the trauma-linked trance in the Anxiety, OCD & trauma-related disorders notes; and the video-EEG work-up that excludes non-epileptic (dissociative) convulsions in the Epilepsy & psychiatry notes.

20 to 25	6B62 · 6B63	F44.3
MEAN AGE AT ONSET (YRS), ICD-11 CDDR	ICD-11 TRANCE AND POSSESSION TRANCE CODES	ICD-10 TRANCE AND POSSESSION DISORDER RUBRIC

INDIA

Possession is a mainstream idiom of distress across much of India, expressed through spirit intrusion, temple and dargah healing, mediumship and family-attended possession episodes, so the same behaviour can be devotional ritual in one setting and disorder in another. The examinable move is discipline: run the cultural formulation, ask whether the community accepts and welcomes the state, and reserve the diagnosis for the involuntary, unwanted, distressing or impairing form. The genuine local pitfall is the reflex to reach straight for a benzodiazepine, alprazolam (Alprax or Restyl) being the default anxiolytic in Indian practice, when the presentation calls first for cultural understanding and treatment of the underlying stress or comorbidity, not sedation of a culturally meaningful experience.

PEARL

The cleanest discriminator between the two ICD-11 entities is a single question: *who is acting?* If awareness narrows and behaviour shrinks to a small repertoire that feels outside control but the self is still the self, it is trance disorder; if the self is replaced by an external spirit, deity or demon that directs the behaviour, it is possession trance disorder. Replacement of identity by an external agent is the whole of the difference.

GOOD TO REMEMBER

- **Trance disorder (the syndrome):** the defining criterion is a trance state with a marked alteration of consciousness marked by *both* narrowing of awareness of the surroundings *and* restriction of movement, posture and speech to a small, seemingly uncontrolled repertoire, *without* replacement by an alternate identity; recurrent or a single episode of at least several days, involuntary and unwanted, outside sanctioned cultural practice, and distressing or impairing. The first step is always to check that it is not an accepted collective ritual and not organic (normal EEG even during the episode).
- **Possession trance disorder (the syndrome):** the defining criterion is a trance state in which the normal sense of identity is *replaced by an external "possessing" identity*, with behaviours experienced as controlled by that agent and usual full or partial amnesia; the discriminator from dissociative identity disorder is that the identity is attributed to an *external* agent, and the discriminator from all of them is that a sanctioned, non-distressing collective practice is not a disorder.

HOLD THIS

Trance disorder is narrowed awareness with a small uncontrolled behavioural repertoire and the self intact; possession trance disorder is the self replaced by an external agent; both are disorders ONLY when involuntary, unwanted, distressing or impairing and outside an accepted collective cultural or religious practice, which is why the cultural formulation, not sedation, is the first step in the Indian setting.

Anxiolytic and hypnotic pharmacology

8 · Benzodiazepines

This is the weightiest topic in the pharmacology block, and it rewards a single organising idea. A **benzodiazepine** is a **positive allosteric modulator** at the **GABA-A receptor**: it does nothing on its own, but where GABA is already present it turns the inhibitory signal up. Hold that mechanism and three examinable strands fall out of it in order, the *receptor* story (how it works), the *kinetic* story (how long it works, which sorts the agents into short-acting and long-acting classes), and the *clinical* story (that it is a powerful short-term drug and a dangerous long-term one). The paper tests the last strand hardest: the single most answerable management statement on this material is that a benzodiazepine is **not** a first-line long-term anxiolytic or hypnotic.

The guideline spine is fixed. For anxiety and insomnia the British Association for Psychopharmacology (BAP) leads, the National Institute for Health and Care Excellence (NICE) sets the short-course limit, the Maudsley Prescribing Guidelines carry the receptor detail, the doses, the half-lives and the diazepam-equivalence table, and the Indian Psychiatric Society carries the Indian layer. The receptor mechanism and the GABA-A detail here are the same ones cross-referenced to the Neurochemistry, Neuroendocrinology, Neuroimaging & Basic Psychopharmacology notes; the sedative and benzodiazepine *use* disorder as an addiction sits in the Substance use disorders notes; the lorazepam challenge in catatonia in the Other psychotic disorders, delusional syndromes & catatonia notes; and the SSRIs and SNRIs that outrank benzodiazepines as first-line anxiolytics in the Mood disorders: pharmacotherapy notes. The accompanying figures set out the receptor with its binding site, the half-life map, the withdrawal time-course, the class-and-mechanism map and the taper.

Fig 15.11 The anxiolytic and hypnotic class-and-mechanism map: five mechanism classes and the agents that sit under each, so the whole band recalls from the receptor action outward.

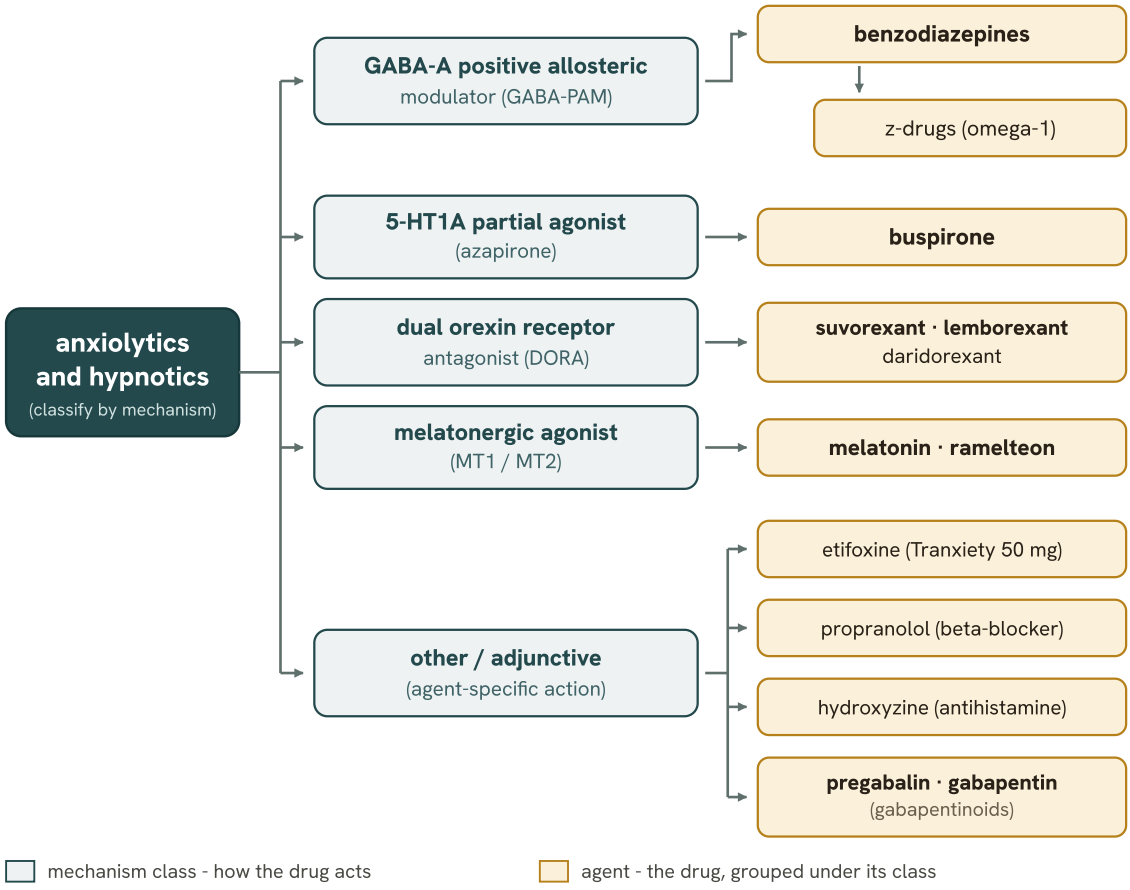

Fig 15.12 The GABA-A receptor is a pentameric chloride channel; the benzodiazepine binds the allosteric site at the alpha/gamma interface and, only with GABA present, raises the frequency of channel opening.

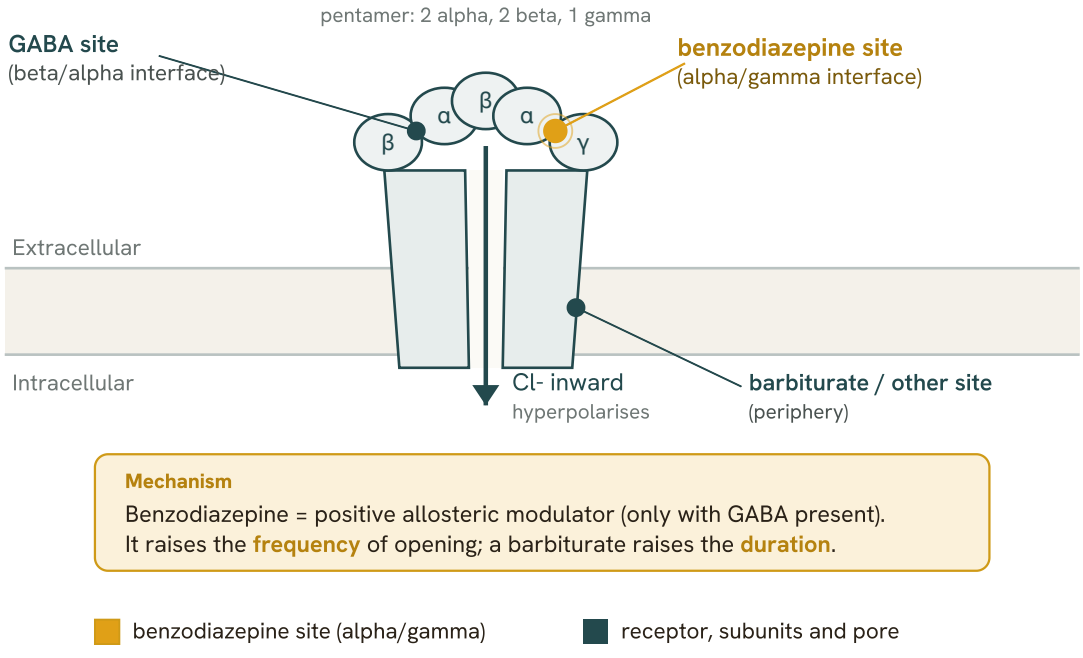

Fig 15.13 The benzodiazepines sorted by elimination half-life into short-, intermediate- and long-acting classes, with the shared long-acting metabolite and the duration-to-use rule.

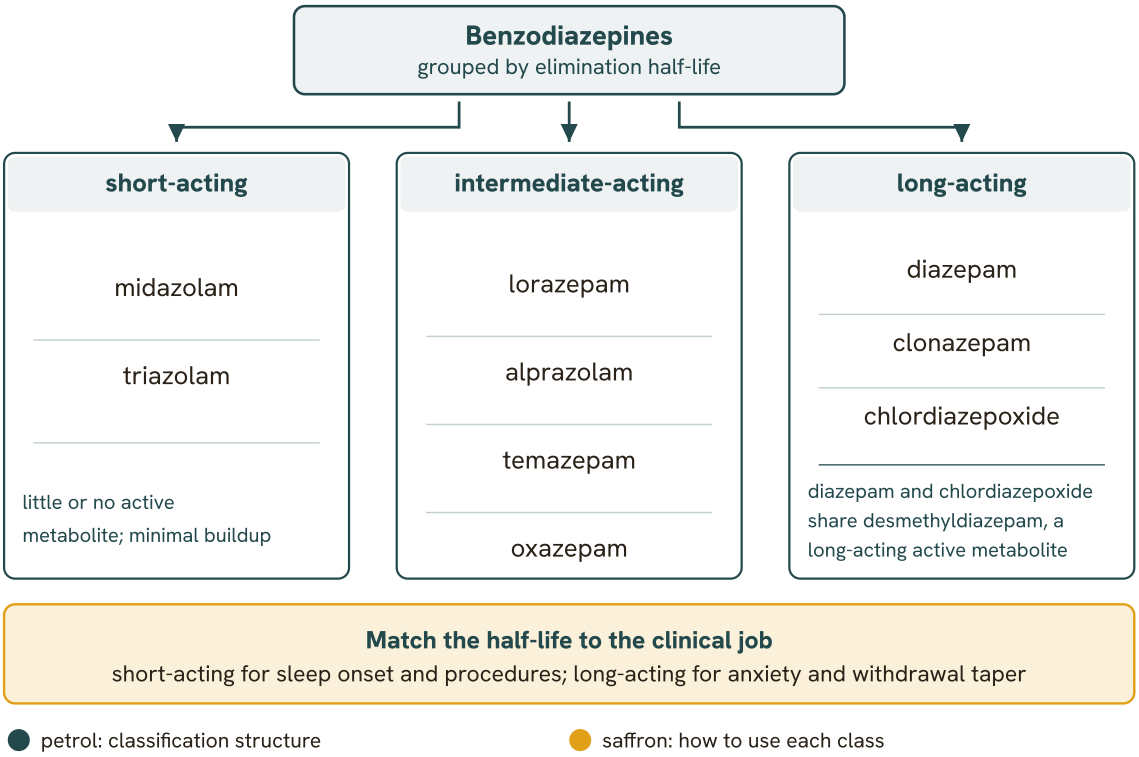

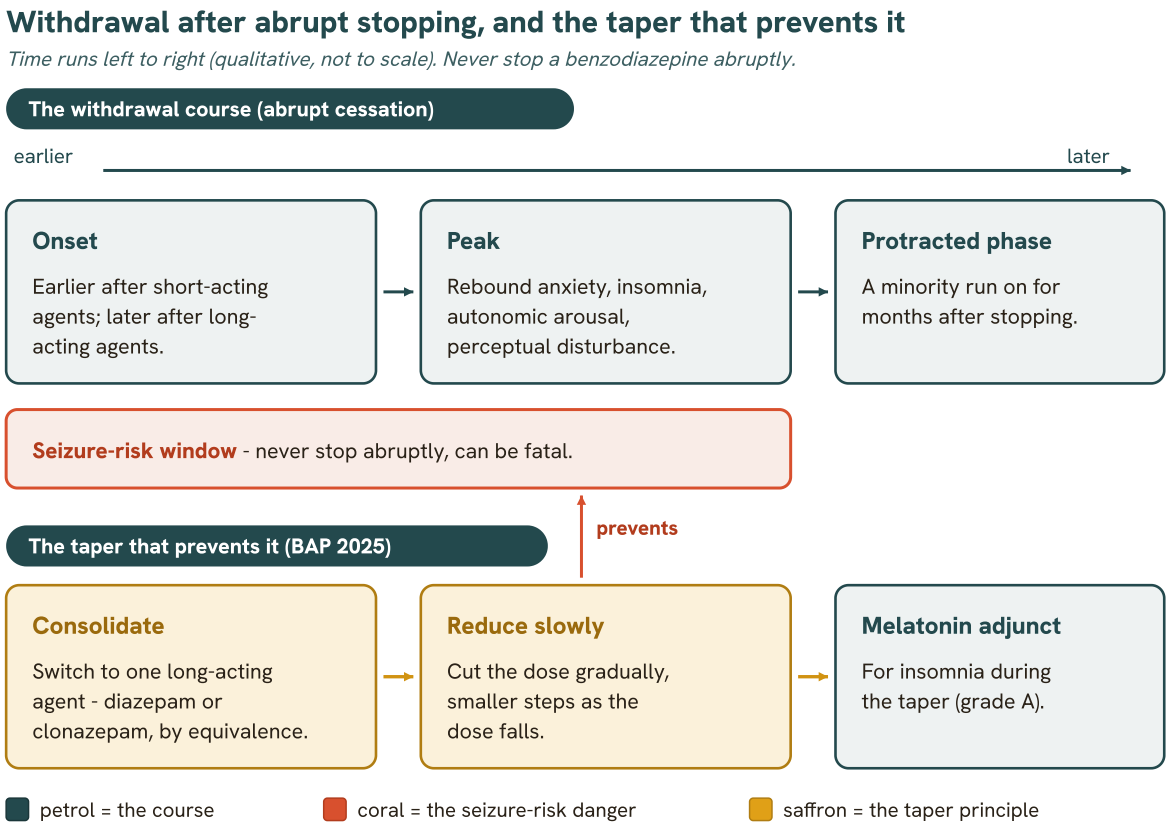

Fig 15.14 The benzodiazepine withdrawal course after abrupt cessation, and the long-acting taper that prevents it.

8.1 Mechanism: a positive allosteric modulator that raises the frequency of channel opening

Frequency, not duration, and only in the presence of GABA. A **benzodiazepine** binds the **benzodiazepine binding site** on the GABA-A receptor and, by **allosteric modulation**, increases the affinity of the receptor for its own transmitter GABA (Stahl; KDT). The functional result is an increase in the *frequency* of **chloride channel** opening when GABA is bound, more chloride enters, the neurone hyperpolarises, and inhibition deepens (KDT). Two properties define the class from this one fact. First, the drug is a *modulator*, not a direct agonist: with no GABA present it opens no channel, which is the pharmacological reason benzodiazepines have a ceiling on respiratory depression and are relatively safe in isolated overdose. Second, the contrast with barbiturates is a favourite: barbiturates increase the *duration* (lifetime) of each chloride channel opening, and at high concentration open the channel directly without GABA, which removes the ceiling and makes them lethal in overdose (KDT). In Stahl's neuroscience-based nomenclature the class is written literally as a GABA positive allosteric modulator (GABA-PAM).

RULE **Frequency up, GABA required.** A benzodiazepine is a positive allosteric modulator that raises the *frequency* of chloride-channel opening only when GABA is present (contrast the barbiturate, which raises channel-opening *duration* and can open the channel alone), and that GABA-dependence is why it has a ceiling effect and is relatively safe in a pure overdose.

8.2 The GABA-A receptor and the benzodiazepine binding site

GABA sits on the beta interface, the benzodiazepine between alpha and gamma. The **GABA-A receptor** is a pentameric ligand-gated chloride channel, most commonly two alpha, two beta and one gamma subunit. GABA itself, the orthosteric ligand, binds at the interface involving the beta subunit and gates the channel; the **benzodiazepine binding site** is a separate, allosteric site at the interface between the *alpha and gamma* subunits (KDT; Stahl). Because occupancy of that site only modulates a channel GABA is already working on, agonists such as diazepam facilitate inhibition while inverse agonists at the same site (the beta-carbolines) hinder it and are anxiogenic and convulsant, a clean demonstration that this is genuine allosteric modulation in both directions. The subtype detail is worth a line for the paper: benzodiazepine action at alpha-1-containing receptors mediates sedation and the amnestic and anticonvulsant effects, while alpha-2 (and alpha-3) receptors carry the anxiolytic and muscle-relaxant effects (Stahl). This receptor-and-site anatomy is the shared substrate developed further in the Neurochemistry, Neuroendocrinology, Neuroimaging & Basic Psychopharmacology notes, and the accompanying figure lays it out as the membrane-grammar plate.

GOOD TO REMEMBER

- **Benzodiazepine (the class):** a positive allosteric modulator at the GABA-A receptor, binding the benzodiazepine site at the *alpha-gamma* interface and increasing the *frequency* of chloride-channel opening in the presence of GABA; alpha-1 drives sedation, alpha-2 drives anxiolysis; the signature caution is dependence with long-term use and seizures on abrupt withdrawal.

8.3 The half-life classification and active metabolites

The clinically useful sort is by half-life, because that predicts accumulation, hangover and withdrawal. Agents split into **short-acting** or short-to-intermediate drugs, which clear quickly,

carry little or no active metabolite and so accumulate less, and **long-acting** drugs, which have long half-lives and long-lived active metabolites and therefore build up (a hazard in the elderly and in liver disease). The pivotal metabolite is desmethyldiazepam (nordiazepam), the long-lived active metabolite shared by diazepam and chlordiazepoxide, which is what makes those agents behave as long-acting even beyond their parent half-life (Stahl). The short-acting drugs with no clinically important active metabolite are the ones preferred when the liver is impaired, remembered as the LOT group. The half-lives below are the verified Stahl and Maudsley figures.

AGENT	ELIMINATION HALF-LIFE (HOURS)	ACTIVE METABOLITE	CLASS
lorazepam	**10 to 20**	none	short-to-intermediate
alprazolam	**12 to 15**	none of note	short-to-intermediate, high-potency
oxazepam / temazepam	short (not tabulated here)	none	short-acting (the LOT group, liver-safe)
chlordiazepoxide	24 to 48	nordiazepam (long-lived)	long-acting
clonazepam	**30 to 40**	none of clinical note	long-acting, high-potency
diazepam	**20 to 50 (parent)**	nordiazepam, oxazepam, temazepam	long-acting
zolpidem (z-drug, for contrast)	about 2.5	none	ultra-short

Half-life classification with verified Stahl elimination half-lives; the long-acting agents owe their duration to the shared active metabolite nordiazepam (desmethyldiazepam). Oxazepam and temazepam half-lives were not individually verified here.

MNEMONIC

LOT

Lorazepam, **O**xazepam, **T**emazepam: the short-acting benzodiazepines with *no* active metabolite. They do not accumulate, so they are the preferred choice in hepatic impairment (lorazepam is explicitly named for this in Stahl) and the safer choice in the elderly.

8.4 Clinical uses and the short-course rule

Powerful, fast, and reserved. Benzodiazepines are genuinely useful for a small set of jobs, acute and severe anxiety or agitation, alcohol withdrawal, status epilepticus and acute seizures, catatonia (the lorazepam challenge, developed in the Other psychotic disorders, delusional syndromes & catatonia notes), pre-medication, and very short-term insomnia. What the examiner wants is the **short-course** discipline around chronic anxiety and insomnia. For generalised anxiety disorder an SSRI is the **first-line** pharmacological treatment (BAP 2014; NICE CG113 2011 names sertraline first), with an SNRI or pregabalin as the alternative; buspirone and hydroxyzine cover acute anxiety only. A benzodiazepine is not first-line and not for maintenance: BAP reserves it only after non-response to an SSRI, an SNRI, pregabalin *and* buspirone, for

persistent, severe, distressing, impairing anxiety, and NICE says do not offer a benzodiazepine for generalised anxiety disorder except as a short-term measure of no more than 2 to 4 weeks during a crisis (NICE 2011). For chronic insomnia CBT for insomnia is first-line (BAP 2019), with a benzodiazepine or a z-drug only as a short-term option, matching the half-life to the pattern. If a benzodiazepine is genuinely effective and continued, it is continued for a defined period and then tapered, never open-endedly.

TRAP **Starting a benzodiazepine for chronic anxiety or insomnia.** The reflex prescription for persistent worry or poor sleep is exactly the error the guidelines forbid: the first-line agents are the SSRI (anxiety) and CBT for insomnia, and the benzodiazepine is a 2 to 4 week crisis measure at most (NICE 2011), because tolerance, dependence and a withdrawal seizure risk follow long-term use.

8.5 Agent selection and the benzodiazepine-sparing principle

Match the agent to the goal, and spare the benzodiazepine wherever a non-dependence option exists. The practical skill of **agent selection** is deciding **which agent** for which target, and the organising rule is **benzodiazepine-sparing**: reach past the benzodiazepine to a drug that does the job without dependence whenever the clinical goal allows it. The class-and-mechanism map below (also drawn as the accompanying figure) sets out the Band B options with their Indian brands. For sustained anxiety, prefer the SSRI or SNRI, pregabalin or buspirone; for the somatic and performance-anxiety picture, propranolol; for short-term insomnia, a z-drug, melatonin or very-low-dose doxepin; and keep the benzodiazepine for the acute crisis, the seizure, the alcohol withdrawal and catatonia.

CLASS	EXAMPLE AGENT (INDIAN BRAND)	MECHANISM	PLACE IN THERAPY
Benzodiazepine	diazepam (Valium, Calmpose)	GABA-A positive allosteric modulator, raises frequency of chloride-channel opening	**short-course / acute only**
Z-drug	zolpidem (Zolfresh, Nitrest)	GABA-A benzodiazepine-1 (omega-1) subtype selective	short-term hypnotic
Azapirone	buspirone (Buspin)	5-HT1A partial agonist	non-dependence anxiolytic, delayed onset
Gabapentinoid (alpha-2-delta ligand)	pregabalin (Pregeb, Pregastar)	voltage-gated calcium channel alpha-2-delta binding	GAD alternative first-line
Antihistamine	hydroxyzine (Atarax)	H1 antagonist	acute anxiolytic
Beta-blocker	propranolol (Ciplar, Inderal)	peripheral beta-adrenergic blockade	somatic / performance anxiety
Melatonergic	melatonin (Meloset, Zytonin)	MT1 / MT2 receptor agonist	circadian / insomnia over 55 years
Non-benzodiazepine GABA modulator	etifoxine (Tranxiety 50 mg)	GABA-A modulation (non-benzodiazepine site)	anxiolytic (brand unverified)
Orexin antagonist (DORA)	suvorexant	dual orexin / hypocretin receptor block	insomnia

The anxiolytic and hypnotic class-and-mechanism map; the SSRIs and SNRIs that outrank all of these as first-line anxiolytics are developed in the Mood disorders: pharmacotherapy notes.

8.6 Dependence, tolerance and the withdrawal syndrome

Three syndromes, and one of them can kill. Long-term use produces **tolerance** (a diminishing effect, so the dose is pushed up) and physical **dependence**. Kaplan separates three things that follow stopping. *Relapse* is the slow return of the original disorder over weeks to months. *Rebound* is a brief, more intense re-emergence of anxiety or insomnia, worse than baseline, lasting up to about 3 weeks; with a short-acting agent it appears as *interdose* rebound anxiety 3 to 4 hours after each dose (classically alprazolam, mistaken for craving). *Withdrawal* is the true discontinuation syndrome with new autonomic features. Its onset is kinetic: it begins within hours to a few days of stopping a **short-acting** benzodiazepine, but may not start for 1 to 2 weeks after abrupt cessation of a **long-acting** one (Kaplan). Minor symptoms are sweating, tachycardia, nausea, tremor, restlessness, and the characteristic *perceptual disturbance* (heightened sensitivity to light and sound, depersonalisation). The dangerous, major symptoms are *seizures*, psychosis and delirium, and seizures are the reason a benzodiazepine must never be stopped abruptly (Maudsley: abrupt cessation can cause seizures and can be fatal). Withdrawal is more severe with high-potency, short-half-life agents, typically lasts 2 to 4 weeks, and can occasionally become

protracted over many months. The accompanying figure lays this out as a withdrawal time-course timeline.

3 to 4 h	1 to 2 wk	2 to 4 wk
INTERVAL AT WHICH INTERDOSE REBOUND ANXIETY FOLLOWS A SHORT-ACTING AGENT	DELAY BEFORE WITHDRAWAL STARTS AFTER A LONG-ACTING AGENT IS STOPPED ABRUPTLY	USUAL DURATION OF THE WITHDRAWAL SYNDROME

GOOD TO REMEMBER

- **Benzodiazepine withdrawal syndrome (the syndrome):** the defining features are rebound anxiety and insomnia, perceptual disturbance and autonomic arousal, with the criterion-level dangers being *seizures*, psychosis and delirium; the discriminator from relapse is the timing (hours to days after a short-acting drug, up to 1 to 2 weeks after a long-acting one) and the new autonomic signs. First step: never stop abruptly, taper.

8.7 The taper: switch to a long-acting agent, then reduce slowly

Consolidate, convert, then come down in proportions. The evidence-based **taper** (BAP 2025; Maudsley) has a fixed shape. First *consolidate* the patient onto a single long-acting benzodiazepine, **diazepam** or **clonazepam**, chosen for their long half-life and dosing flexibility (use lorazepam or oxazepam instead where the liver is impaired). Converting to diazepam needs the diazepam-equivalence table, verified from the Maudsley Prescribing Guidelines below. Then *reduce gradually*: patients often tolerate reductions of about 10 percent of the last dose every 2 to 4 weeks, roughly 5 to 10 percent per month, with the steps becoming smaller as the dose falls (the dose-effect relationship is hyperbolic) and the final doses very small (often less than 1 mg of diazepam-equivalent). Melatonin is a useful adjunct for insomnia during the taper (BAP grade A). Two anchors for the paper: doses above 30 mg diazepam-equivalent daily may cause harm and are avoided (Maudsley), and the difficult final doses of alprazolam are often eased by substituting clonazepam (Kaplan).

BENZODIAZEPINE	DOSE EQUAL TO DIAZEPAM 10 MG (MG)
Diazepam	10
Chlordiazepoxide	25
Clonazepam	**0.5**
Lorazepam	**1**
Lormetazepam	1 to 2
Nitrazepam	10
Oxazepam	20
Temazepam	20

Approximate diazepam-equivalent doses, verified from the Maudsley Prescribing Guidelines (Table 3.29). Alprazolam is deliberately not tabulated there, so no alprazolam equivalence is asserted here (see gaps).

GOOD TO REMEMBER

- **Diazepam (Valium, Calmpose):** the long-acting anchor of the taper; oral 4 to 40 mg per day in divided doses; GABA-A positive allosteric modulator with the active metabolite nordiazepam; verified equivalence, diazepam 10 mg equals clonazepam 0.5 mg equals lorazepam 1 mg equals chlordiazepoxide 25 mg (Maudsley).
- **Clonazepam (Clonotril, Rivotril):** long-acting (half-life 30 to 40 hours), high-potency; panic 0.5 to 2 mg per day, seizures up to 20 mg per day; the other consolidation agent for the taper and the substitute that eases the final doses of alprazolam.
- **Alprazolam (Alprax, Restyl):** short-to-intermediate (half-life 12 to 15 hours), high-potency; anxiety 1 to 4 mg per day; the most toxic benzodiazepine in overdose (Maudsley) and the hardest to taper, manufacturer limit 2 to 4 weeks.
- **Lorazepam (Ativan, Loraz):** short-to-intermediate (half-life 10 to 20 hours), *no* active metabolite so liver-safe; oral 2 to 6 mg per day; the catatonia challenge agent at 1 to 2 mg.

8.8 Flumazenil: the antagonist and its seizure caution

The antidote that can precipitate the seizure it looks like it should treat. Flumazenil is the benzodiazepine-receptor *antagonist*, a competitive blocker at the benzodiazepine binding site used to reverse benzodiazepine sedation and respiratory depression (Stahl; Maudsley). Two facts matter clinically. Its half-life is short, only 41 to 79 minutes, much shorter than most benzodiazepines it reverses, so re-sedation follows a single dose and repeat dosing is often needed. And it carries a real *seizure* hazard: it can precipitate seizures in a patient who is tolerant to or dependent on benzodiazepines, in a mixed overdose (particularly with cyclic antidepressants), or where the benzodiazepine was suppressing seizures, so it is used cautiously and at the minimally effective dose, not reflexively in every benzodiazepine overdose. Because uncomplicated benzodiazepine overdose is usually benign with supportive care, the risk of flumazenil often outweighs the benefit.

GOOD TO REMEMBER

- **Flumazenil (the antagonist):** a competitive benzodiazepine-receptor antagonist with a short half-life of 41 to 79 minutes (so re-sedation and repeat dosing); the signature caution is that it can *precipitate seizures* in benzodiazepine dependence and in mixed or cyclic-antidepressant overdose, so it is used selectively at the lowest effective dose, not routinely.

8.9 Buspirone and the z-drugs: the non-benzodiazepine comparators

Two agents the paper contrasts against the benzodiazepine. **Buspirone** is an azapirone anxiolytic, a *5-HT1A partial agonist* (not a GABA drug at all), with a short half-life of 2 to 3 hours and a usual dose of 20 to 30 mg per day (up to 60 mg per day). Its defining contrast with the benzodiazepine is a *delayed* onset of 2 weeks or more and *no* dependence, sedation, anticonvulsant effect or interaction with alcohol, which is exactly why it is a benzodiazepine-sparing choice for sustained anxiety but useless for an acute crisis. The *z-drugs* (zolpidem, zopiclone, eszopiclone) act at the benzodiazepine-1 (omega-1) subtype of the GABA-A receptor, so they are hypnotic with less anxiolytic and muscle-relaxant effect; zolpidem is dosed 10 mg at bedtime for 7 to 10 days (short elimination half-life about 2.5 hours), and their signature warning is complex sleep behaviours (sleep-driving, sleep-eating with amnesia), plus dependence and

next-day impairment, so tolerance and rebound insomnia are real despite the earlier marketing that they were not.

GOOD TO REMEMBER

- **Buspirone (Buspin):** a 5-HT1A partial agonist, 20 to 30 mg per day; the mechanism-and-caution signature is a *delayed* onset (2 weeks or more) with *no* dependence, sedation or anticonvulsant effect, so it spares the benzodiazepine in sustained anxiety but is no use acutely.
- **Zolpidem (Zolfresh, Nitrest):** a z-drug at the benzodiazepine-1 (omega-1) GABA-A subtype, 10 mg at bedtime for 7 to 10 days; the signature caution is complex sleep behaviours (sleep-driving) with dependence and next-day impairment.

PEARL

Every hard fact on this topic is a corollary of one sentence: a benzodiazepine only turns up an inhibition that GABA is already producing. That is why it has a ceiling and is safe in a pure overdose (mechanism), why the receptor adapts and rebounds when it is removed (dependence and withdrawal), why the antidote flumazenil unmasks that rebound as a seizure, and why the long-term answer is a slow taper rather than an abrupt stop.

INDIA

India carries a genuine benzodiazepine over-prescription problem, and **alprazolam** (Alprax, Restyl) is the default anxiolytic reached for in general and psychiatric practice alike; benzodiazepines are among the most frequently prescribed drugs. Two consequences follow. First, alprazolam is the *most toxic* benzodiazepine in overdose (Maudsley) and, being short-acting and high-potency, the hardest to taper, so it is a poor default. Second, the Indian Psychiatric Society position and the wider benzodiazepine-sparing principle favour the SSRI or SNRI for sustained anxiety and CBT for insomnia, reserving the benzodiazepine for the genuine short course. The culture-bound relevance is real too: possession, trance and dissociative presentations are common in Indian settings and are frequently met with a reflex sedative, which treats nothing; read them through a cultural formulation (the Consultation-liaison, geriatric & transcultural psychiatry notes) rather than sedating them. The sedative and benzodiazepine use disorder as an addiction is developed in the Substance use disorders notes.

HOLD THIS

A benzodiazepine is a GABA-A positive allosteric modulator that raises the *frequency* of chloride-channel opening (barbiturates raise the *duration*); it is never a first-line long-term anxiolytic or hypnotic (NICE: a 2 to 4 week crisis course only); it is withdrawn by consolidating onto a long-acting agent (diazepam or clonazepam) and tapering slowly because *abrupt cessation can cause seizures*; and its antagonist flumazenil can itself precipitate seizures in dependence and mixed overdose.

For the receptor systems behind the GABA-A detail see the Neurochemistry, Neuroendocrinology, Neuroimaging & Basic Psychopharmacology notes; for the sedative use disorder as an addiction the Substance use disorders notes; for the lorazepam management of catatonia the Other psychotic disorders, delusional syndromes & catatonia notes; for the SSRIs

and SNRIs as first-line anxiolytics the Mood disorders: pharmacotherapy notes; and for clinical insomnia and CBT for insomnia the Eating & sleep-wake disorders notes.

9 · Buspirone and the azapirones

This is the anxiolytic the examiner uses to test whether you understand what a benzodiazepine is not. Buspirone is a non-benzodiazepine anxiolytic of the **azapirone** class (chemically an azaspiro-decanedione), and almost every mark on it comes from a single contrast: it is a **5-HT1A partial agonist** that works through slow serotonergic adaptation rather than fast GABAergic inhibition, so it carries a **delayed onset** of two weeks or more and, crucially, **no dependence**, no sedation, no anticonvulsant effect and no abuse potential (Stahl, Prescriber's Guide).

Hold two opposing lists in your head. The benzodiazepine works within minutes, sedates, is a good PRN rescue, and breeds tolerance, dependence and a withdrawal syndrome. Buspirone does the reverse on every count: useless as a PRN because the effect takes a fortnight to appear, but clean on dependence and sedation across long-term use. That is why the guidelines place it as an acute-GAD option sitting *after* an SSRI and *before* a benzodiazepine in the benzodiazepine-sparing ladder, and why the classic trap is to expect it to abort acute anxiety.

9.1 Mechanism: a 5-HT1A partial agonist

Serotonergic, not GABAergic. Buspirone binds the 5-HT1A receptor as a partial agonist. At the presynaptic somatodendritic autoreceptor its agonism damps 5-HT neuronal firing acutely, while its postsynaptic partial agonism modulates onward serotonergic tone; the therapeutic anxiolysis emerges only once these receptors down-regulate and adapt over weeks, which is precisely why the onset is delayed (Stahl). It *does not act on the benzodiazepine receptor or the GABA-A chloride channel at all*, so it confers none of the GABAergic effects, sedation, muscle relaxation, anticonvulsant cover or cross-tolerance with alcohol and barbiturates. It additionally shows weak dopamine autoreceptor antagonism. For the receptor biology of the 5-HT1A and GABA-A systems, see the Neurochemistry, Neuroendocrinology, Neuroimaging & Basic Psychopharmacology notes.

RULE **5-HT1A, weeks, no dependence.** Buspirone is a 5-HT1A partial agonist whose anxiolysis depends on slow receptor adaptation, so it has a delayed onset of two weeks or more and produces no dependence, sedation, anticonvulsant effect or abuse; it is an acute-GAD agent, never a PRN rescue.

9.2 The azapirone family

Buspirone is the only one in routine anxiolytic use. The **azapirones** are a small family of selective 5-HT1A partial agonists. Buspirone is the marketed anxiolytic; gepirone (extended-release) has since been approved as an *antidepressant* for major depression rather than as an anxiolytic; and ipsapirone, tandospirone and flesinoxan remained investigational 5-HT1A agonists that did not establish a first-line anxiety niche (New Oxford Textbook of Psychiatry;

Companion to Psychiatric Studies). The examinable point is the shared mechanism, not the minor agents.

AZAPIRONE	5-HT1A ACTION	ESTABLISHED ROLE
Buspirone	**Selective 5-HT1A partial agonist**	**Anxiolytic for GAD (acute)**
Gepirone (ER)	5-HT1A partial agonist	Antidepressant for major depression
Ipsapirone	5-HT1A partial agonist	Investigational / research agent
Tandospirone	5-HT1A partial agonist	Anxiolytic in some Asian markets
Flesinoxan	5-HT1A agonist	Investigational

The azapirone class shares one mechanism; only buspirone is a mainstream anxiolytic, and gepirone crossed over to depression.

9.3 The place in GAD: the guideline ladder

An acute-GAD option, not first-line, ahead of a benzodiazepine. BAP is explicit that buspirone (and hydroxyzine) are efficacious in the *acute* treatment of generalised anxiety disorder but that neither has published evidence for relapse prevention (BAP 2014, Baldwin et al.). The first-line pharmacological treatment for GAD is an SSRI, with an SNRI or pregabalin as alternatives; a benzodiazepine is reserved and, in the BAP sequence, considered only after non-response to an SSRI, an SNRI, pregabalin *and* buspirone. NICE CG113 (NICE 2011) builds its stepped care on the SSRI/SNRI/pregabalin sequence and restricts benzodiazepines to short-term crisis use; the Maudsley Prescribing Guidelines carry buspirone as a second-line/adjunctive anxiolytic option. The first-line SSRI position is developed in the Mood disorders: pharmacotherapy notes, and the wider anxiety-disorder pharmacology in the Anxiety, OCD & trauma-related disorders notes.

TRAP **Calling buspirone first-line, or using it as a PRN.** Buspirone is *not* first-line for GAD (an SSRI is) and is worthless taken as-needed for an acute surge; a delayed-onset drug given for immediate relief simply fails and gets abandoned.

9.4 Delayed onset: useless as a PRN anxiolytic

Two weeks to work is the whole clinical personality. Buspirone takes roughly **2 weeks** before its anxiolytic effect is evident, and if it has not worked within **6 to 8 weeks** it may not work at all (Stahl). Because relief is not tied to the plasma level of any single dose, it cannot be used to abort a panic surge or as an as-needed rescue, the exact niche where a benzodiazepine excels. This delayed onset also drives the higher discontinuation seen versus a benzodiazepine, and it means a patient must never be switched abruptly from a benzodiazepine to buspirone: buspirone does not suppress benzodiazepine withdrawal, so the patient takes a therapeutic buspirone dose for two to four weeks first, and only then is the benzodiazepine tapered (Kaplan and Sadock, CTP 2024).

FEATURE	BUSPIRONE (5-HT1A PARTIAL AGONIST)	A BENZODIAZEPINE (GABA-A PAM)
Onset of anxiolysis	**Delayed, 2 weeks or more**	**Minutes to hours**
PRN / as-needed rescue	**No, ineffective acutely**	Yes, effective
Sedation, psychomotor impairment	**None**	Yes
Anticonvulsant / muscle relaxant	**None**	Yes
Dependence, tolerance, withdrawal	**None; taper generally not needed**	Yes; seizure risk on abrupt stop
Respiratory depression	None	Yes (dose-related)
Abuse potential	**Low / none**	Present

The buspirone-versus-benzodiazepine contrast is the single most examinable content on this drug: fast-but-dependent against slow-but-clean.

9.5 The safety signature: no dependence, no sedation, no anticonvulsant, no abuse

Four clean "no"s. Buspirone does not appear to cause dependence and shows virtually no withdrawal symptoms; it is not habit-forming and a taper is generally not necessary on stopping (Stahl). It causes no sedation, psychomotor impairment, cognitive impairment or respiratory depression (Kaplan and Sadock, CTP 2024), and it is anxioselective with no anticonvulsant or muscle-relaxant properties. This profile makes it attractive where a benzodiazepine is hazardous, in respiratory disease, sleep apnoea, a history of substance misuse, or the older adult, though its efficacy may be diminished in patients previously maintained on a benzodiazepine. Its own side effects are limited and non-sedating: dizziness, headache, nausea and nervousness. The benzodiazepine dependence and withdrawal picture that buspirone deliberately avoids is covered in the Substance use disorders notes.

MNEMONIC

5-HT1A · TWO WEEKS · NO DEPENDENCE

The three anchors that answer any buspirone question: the mechanism (a selective 5-HT1A partial agonist azapirone), the delayed onset (two weeks or more, so never PRN), and the clean tail (no dependence, no sedation, no anticonvulsant, no abuse).

9.6 Dosing, half-life and pharmacokinetics

Short half-life, divided dosing, delayed clinical effect. Buspirone is given at **15 to 30 mg/day** in divided doses, typically a thrice-daily schedule because the elimination half-life is short at only about **2 to 3 hours** (Stahl). A common titration starts around 15 mg daily in divided doses and increases in 5 mg steps every two to three days; the usual effective range is 20 to 30 mg/day, and the maximum is generally 60 mg/day (Stahl; Kaplan and Sadock, CTP 2024). It is metabolised by CYP3A4 to an active metabolite, 1-(2-pyrimidinyl)piperazine (1-PP), so a 3A4 inhibitor (for example a CYP3A4-inhibiting antifungal or nefazodone) raises buspirone levels and a 3A4

inducer such as carbamazepine lowers them. The apparent paradox worth stating in a viva is that a very short-half-life drug still has a delayed clinical onset, because the effect depends on receptor adaptation, not on drug accumulation.

2 to 3	2 weeks+	20 to 30	60
ELIMINATION HALF-LIFE (HOURS)	ONSET BEFORE ANXIOLYTIC EFFECT APPEARS	USUAL EFFECTIVE DOSE (MG PER DAY)	MAXIMUM (MG PER DAY)

WORKED EXAMPLE

A woman in her fifties with chronic generalised anxiety and mild COPD asks for "something for the nerves" and has been buying alprazolam from a chemist for months. She wants immediate relief. Buspirone is a reasonable maintenance anxiolytic here precisely because it will not sedate or depress respiration and carries no dependence, but she must be told it will take about two weeks to help and is useless as a tablet-when-anxious. The correct plan is to start an SSRI as the first-line agent for her GAD, use buspirone as an add-on or alternative rather than a benzodiazepine, and, because she is already on alprazolam, keep the alprazolam running at a therapeutic buspirone dose for two to four weeks before tapering it slowly; buspirone will not cover benzodiazepine withdrawal.

INDIA

Buspirone (marketed in India as Buspin, verify locally) matters most in India as the answer to a real problem: benzodiazepine over-prescription, with alprazolam (alprazolam; Alprax or Restyl) as the default anxiolytic reached for reflexively and often continued long-term. The Indian Psychiatric Society position, in line with BAP and NICE, is that an SSRI or SNRI is first-line for GAD and that a benzodiazepine is a short-course measure only, not a maintenance anxiolytic. Buspirone is a genuinely useful non-dependence-forming alternative in the patient who would otherwise be parked on alprazolam, and the exam-safe line is that its delayed onset and lack of a "kick" are exactly why patients (and prescribers) drift back to the benzodiazepine, which is the behaviour the guidelines are trying to correct.

PEARL

A drug can have a very short half-life and still a long onset. Buspirone clears in two to three hours yet takes two weeks to work, because anxiolysis rides on 5-HT1A receptor adaptation, not on plasma concentration. State that dissociation and the mechanism mark is yours.

GOOD TO REMEMBER

- **Buspirone (the drug):** a selective 5-HT1A partial agonist of the azapirone class, dosed at 15 to 30 mg/day in divided doses (maximum 60 mg/day) with a short elimination half-life of about 2 to 3 hours but a delayed onset of two weeks or more, so it is never a PRN anxiolytic; it is efficacious in acute GAD (no relapse-prevention evidence) and its signature is no dependence, no sedation, no anticonvulsant effect and no abuse potential.

HOLD THIS

Buspirone is a 5-HT1A partial agonist azapirone with a short half-life (about 2 to 3 hours) but a delayed onset of two weeks or more, so it is useless as a PRN rescue; it has no dependence, sedation, anticonvulsant effect or abuse, and it sits in acute GAD after an SSRI and before a benzodiazepine.

10 · The z-drugs

The z-drugs are the examiner's test of whether you can separate a chemical class from a mechanism. The **z-drugs** (zolpidem, zopiclone, zaleplon and eszopiclone) are **non-benzodiazepine hypnotics**: they belong to different chemical families from the benzodiazepines, yet they act at the very same GABA-A benzodiazepine site, and specifically at its **benzodiazepine-1 (omega-1)** subtype. That single fact answers most questions on them, because it explains both why they work as hypnotics and why "non-benzodiazepine" does not mean non-addictive.

Almost every mark comes from four discriminators: the receptor (an omega-1-selective GABA-A positive allosteric modulator), the half-lives (short, and different from each other, which is how you choose one), the guideline place (a short-term hypnotic after CBT-I, never a long-term one), and the signature caution (**complex sleep behaviour**). Hold those four and the topic is yours.

10.1 The class: four non-benzodiazepine hypnotics

One shared site, three chemical families. The z-drugs are grouped by their shared action, not their structure. Zolpidem is an imidazopyridine, zaleplon a pyrazolopyrimidine, and zopiclone and its active S-enantiomer eszopiclone are cyclopyrrolones (Kaplan and Sadock, CTP 2024). None is a benzodiazepine, so the "z-drug" or "non-benzodiazepine hypnotic" label is a statement about chemistry; the pharmacology is benzodiazepine-like because the binding site is shared. Zopiclone is available across most of the world including India; eszopiclone (Lunesta) is chiefly a US agent, and zaleplon has been withdrawn in several markets. For the GABA-A receptor biology and the wider receptor systems, see the Neurochemistry, Neuroendocrinology, Neuroimaging & Basic Psychopharmacology notes.

10.2 Mechanism: the benzodiazepine-1 (omega-1) site

A GABA-A positive allosteric modulator, but selective for the alpha-1 subtype. Like a benzodiazepine, a z-drug is a **positive allosteric modulator** at the GABA-A receptor's benzodiazepine site, enhancing GABA-driven chloride-channel opening; it has no effect without GABA present (Stahl). The difference is selectivity. Whereas benzodiazepines bind fairly non-selectively across GABA-A receptors carrying the alpha-1, -2, -3 and -5 subunits, the z-drugs bind more selectively to receptors that contain the alpha-1 subunit, the population classically called the benzodiazepine-1 (BZ1, omega-1) receptor (Kaplan and Sadock, CTP 2024; Tasman). Because the alpha-1 subtype mediates sedation and hypnosis (and the amnestic effect), this selectivity gives a relatively cleaner hypnotic with comparatively less of the anxiolytic, myorelaxant and anticonvulsant action that the alpha-2, -3 and -5 subtypes carry. The examinable line is that the

z-drugs share the benzodiazepines' GABA-positive-allosteric-modulator mechanism but are a different chemical class acting preferentially at omega-1.

RULE **Same site, different molecule, same short-course rule.** A z-drug is a non-benzodiazepine hypnotic that still modulates the GABA-A benzodiazepine site, selectively at the omega-1 (alpha-1) subtype; it is a short-term hypnotic after CBT-I, not a long-term one.

10.3 Half-lives, and matching the drug to the insomnia pattern

The half-life is how you choose between them. All four are short-acting, but they differ enough to matter clinically. Elimination half-lives run from the ultrashort zaleplon at about **1 hour** (1 to 1.5 hours), through zolpidem at roughly **2.4 hours** and zopiclone at about **5.2 hours**, to eszopiclone as the longest at approximately **6 hours** (Tasman; Saunders, Addiction Medicine). The practical rule (which BAP states directly) is to match the half-life to the problem: a very short-acting agent (zaleplon, zolpidem) for sleep-onset insomnia, and a slightly longer-acting agent (zopiclone) for sleep-maintenance insomnia where the patient wakes in the second half of the night (BAP 2019). The trade-off is symmetrical: the shortest half-lives give the least next-morning hangover but the greatest rebound on stopping.

Z-DRUG	CHEMICAL CLASS	APPROX HALF-LIFE (HOURS)	BEST INSOMNIA MATCH
Zaleplon	Pyrazolopyrimidine	~1 (1 to 1.5)	Sleep-onset; middle-of-night dosing
Zolpidem	Imidazopyridine	~2.4	Sleep-onset
Zopiclone	Cyclopyrrolone	~5.2	Sleep-maintenance
Eszopiclone	Cyclopyrrolone (S-zopiclone)	~6	Sleep-maintenance (US agent)

Ascending half-life is the memorable spine: zaleplon < zolpidem < zopiclone < eszopiclone, and it drives the onset-versus-maintenance choice.

~1	2.4	5.2	5 to 10
ZALEPLON HALF-LIFE (HOURS)	ZOLPIDEM HALF-LIFE (HOURS)	ZOPICLONE HALF-LIFE (HOURS)	ZOLPIDEM DOSE (MG PER DAY)

MNEMONIC

zAleplon · zOlpidem · zOpiclone · Eszopiclone

Read left to right for ascending half-life (roughly 1, 2.4, 5.2 and 6 hours). The two at the short end (zaleplon, zolpidem) are your sleep-onset drugs; the two at the long end (zopiclone, eszopiclone) hold sleep through the night.

10.4 The guideline place: a short-term hypnotic after CBT-I

BAP leads: CBT-I first, then a short course of a GABA-positive hypnotic. BAP is explicit that CBT-I (with sleep restriction and stimulus control) is first-line for chronic insomnia, and that a pharmacological agent is offered where CBT-I fails, is unavailable, or the patient cannot engage with it (BAP 2019, Wilson et al.). When a drug is used, a GABA-positive-allosteric-modulator

hypnotic, meaning a benzodiazepine or a z-drug such as zolpidem or zopiclone, is the short-term option, with the half-life matched to the insomnia pattern (BAP 2019). NICE restricts the z-drugs (zaleplon, zolpidem and zopiclone) to the short-term management of insomnia at the lowest effective dose, and advises against switching from one z-drug to another if the first has not helped (NICE TA77 2004, reviewed 2010). The Maudsley Prescribing Guidelines carry the same short-course, lowest-dose framing, and the Indian Psychiatric Society (IPS_CPG 2017) mirrors the short-term hypnotic position for insomnia in the Indian setting. The wider treatment of clinical insomnia and CBT-I itself is developed in the Eating & sleep-wake disorders notes.

TRAP **Treating a z-drug as dependence-free because it is "non-benzodiazepine".** The z-drugs cause tolerance, dependence, rebound insomnia and complex sleep behaviours; prescribing one long-term for chronic insomnia contradicts BAP and NICE, which both restrict them to short-term use after CBT-I.

10.5 Doses and the diazepam equivalence

Low milligram doses at night; roughly a diazepam-5-mg equivalent each. Usual adult doses are zolpidem **5 to 10 mg** at night (immediate-release; prolonged-release 6.25 to 12.5 mg), zaleplon **5 to 10 mg**, zopiclone **3.75 to 7.5 mg**, and eszopiclone **1 to 3 mg** (Tasman; Geriatric Psychiatry Study Guide). In the older adult the dose is halved (zolpidem 5 mg, prolonged-release 6.25 mg; zopiclone 3.75 mg) because of falls, next-morning impairment and delirium risk. For the withdrawal-and-taper arithmetic that a benzodiazepine consolidation uses, the verified equivalences are that zolpidem 10 mg, zopiclone 7.5 mg and zaleplon 10 mg are each approximately equivalent to diazepam 5 mg (Saunders, Addiction Medicine, Table 3.4). The benzodiazepine-equivalence switch and the slow taper themselves belong to the Substance use disorders notes.

Z-DRUG	USUAL DOSE (MG PER DAY)	OLDER-ADULT DOSE (MG PER DAY)	APPROX DIAZEPAM-5-MG EQUIVALENT
Zolpidem	**5 to 10 (PR 6.25 to 12.5)**	5 (PR 6.25)	**10 mg**
Zaleplon	5 to 10	5	**10 mg**
Zopiclone	**3.75 to 7.5**	3.75	**7.5 mg**
Eszopiclone	1 to 3	1	Not established here

Doses are single-figure milligrams at night; the diazepam equivalence is the verified figure to quote when consolidating before a taper.

10.6 The z-drug-specific cautions: complex sleep behaviour, dependence, next-day impairment

Three cautions define the class. First, **complex sleep behaviour**: patients can carry out complex acts (sleep-walking, sleep-driving, sleep-eating, and even sleep-cooking or telephoning) while not fully awake and with no memory of the event afterwards. This prompted an FDA labelling change requiring warnings of complex sleep-related behaviours, and zolpidem in particular is associated with sleepwalking, sleep-driving and hallucinations (Dulcan; Maudsley Deprescribing Guidelines). Second, dependence: the z-drugs carry genuine abuse liability,

tolerance and a withdrawal syndrome, so "non-benzodiazepine" is not a safety guarantee (Lowinson and Ruiz). Third, next-day impairment: residual sedation, psychomotor and driving impairment, and, in the older adult, falls, fracture and delirium, which is why the 2019 Beers Criteria advise avoiding this class in older people (Kaplan and Sadock, CTP 2024). The sedative and z-drug use disorder as an addiction is covered in the Substance use disorders notes.

COMMON TRAP

A patient reports night-eating, an out-of-place car journey, or a partner's account of a full conversation, all with dense amnesia, and is worked up for a dissociative or nocturnal-seizure disorder. If they are on zolpidem or another z-drug, the first move is to stop the drug: this is a complex sleep behaviour until proven otherwise, and it is a reason to discontinue, not merely to reduce.

10.7 Choosing, dosing short, and stopping

Lowest dose, shortest course, taper alongside CBT-I. The management pattern that satisfies the guidelines is: reserve the z-drug for when CBT-I is not the route, pick the agent by half-life (onset versus maintenance), start at the lowest effective dose, and cap the intended duration to a short course rather than open-ended repeats. On stopping, taper slowly rather than ceasing abruptly, and deliver CBT-I concurrently during the taper to improve the outcome; melatonin is a useful adjunct for the insomnia that surfaces during withdrawal (BAP 2019). Abrupt cessation after regular use risks rebound insomnia and rebound anxiety, and where a z-drug has been co-prescribed with a benzodiazepine the seizure risk of the benzodiazepine dominates the taper plan.

WORKED EXAMPLE

A man in his forties with three weeks of sleep-onset insomnia after a job loss asks for "a sleeping tablet". CBT-I is offered first. Because he cannot access it quickly and the problem is falling asleep rather than staying asleep, a short course of zolpidem 10 mg at night (the short half-life suiting sleep-onset) is reasonable, explicitly time-limited and at the lowest effective dose. He is warned about next-morning driving and about complex sleep behaviours, told not to combine it with alcohol, and booked for CBT-I so the drug can be tapered rather than repeated indefinitely. Had he been waking at 4 a.m., zopiclone (longer half-life) would have been the better match.

INDIA

The z-drugs sit against a real Indian backdrop of benzodiazepine over-prescription, with alprazolam (Alprax or Restyl) as the default anxiolytic and hypnotic reached for reflexively and often continued long-term. Zolpidem (Indian brands Zolfresh or Nitrest) and zopiclone (Zopicon) are widely prescribed and easily obtained, and the same short-course discipline that the Indian Psychiatric Society applies to benzodiazepines applies to them: a hypnotic is a short-term measure after CBT-I, not a standing prescription. The exam-safe framing is that the z-drugs are marketed as the "safer, non-benzodiazepine" alternative, but they carry dependence, rebound and complex sleep behaviours of their own, so they do not solve the over-prescription problem, they simply relabel it.

PEARL

Selectivity, not chemistry, is the answer to "how do z-drugs differ from benzodiazepines". Both are GABA-A benzodiazepine-site positive allosteric modulators; the z-drugs are chemically distinct and bind preferentially at the omega-1 (alpha-1) subtype, which is why they are marketed as selective hypnotics yet still share the dependence and withdrawal liabilities.

GOOD TO REMEMBER

- **Zolpidem (imidazopyridine):** an omega-1-selective GABA-A positive allosteric modulator dosed 5 to 10 mg at night (prolonged-release 6.25 to 12.5 mg; 5 mg in the older adult), half-life about 2.4 hours, best for sleep-onset insomnia; the z-drug most linked to sleep-driving and sleepwalking; 10 mg approximately equals diazepam 5 mg. Indian brands Zolfresh, Nitrest.
- **Zopiclone (cyclopyrrolone):** the same omega-1-selective mechanism, dosed 3.75 to 7.5 mg at night (3.75 mg in the older adult), half-life about 5.2 hours, better for sleep-maintenance; 7.5 mg approximately equals diazepam 5 mg. Indian brand Zopicon.
- **Zaleplon (pyrazolopyrimidine):** the ultrashort z-drug, half-life about 1 hour, dosed 5 to 10 mg, useful for sleep-onset or middle-of-night dosing with the least next-morning hangover; 10 mg approximately equals diazepam 5 mg.
- **Eszopiclone (S-enantiomer of zopiclone):** the longest-acting z-drug, half-life about 6 hours, dosed 1 to 3 mg, chiefly a US agent (Lunesta) for sleep-maintenance insomnia.

HOLD THIS

The z-drugs (zolpidem, zopiclone, zaleplon, eszopiclone) are non-benzodiazepine hypnotics that bind selectively at the benzodiazepine-1 (omega-1, alpha-1) subtype of the GABA-A receptor; match half-life to the insomnia pattern (short-acting zolpidem or zaleplon for onset, longer zopiclone for maintenance), use them short-term after CBT-I, and watch for complex sleep behaviour, dependence and next-day impairment.

11 · Dual orexin receptor antagonists

This is the competitor-delta hypnotic: the newest way to make someone sleep without touching the GABA-A channel at all. The dual orexin receptor antagonist class (a **DORA**) contains suvorexant, lemborexant and daridorexant, and its entire examinable identity is one mechanistic pivot: instead of adding inhibitory GABAergic sedation the way a benzodiazepine or a Z-drug does, a DORA *subtracts the wake signal* by blocking the orexin (hypocretin) wake-promoting system, so the patient falls asleep because arousal is switched off rather than because the brain is chemically sedated.

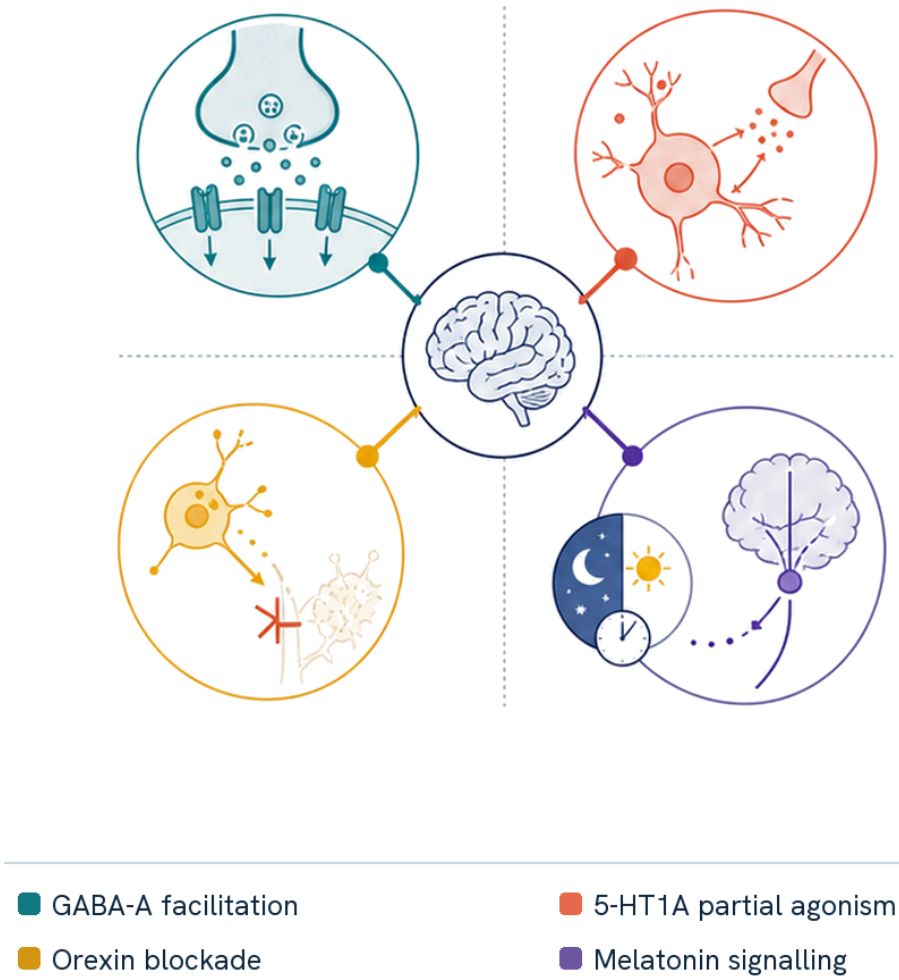

Fig 15.15 Four pharmacological systems used across anxiety and insomnia: GABA-A facilitation, serotonin 5-HT1A partial agonism, blockade of orexin-mediated wake drive and melatonin-linked circadian signalling.

For a low-yield, current-through-2026 class the mark is won by holding three things: the target (orexin, acting at the OX1 and OX2 receptors), the class action (dual antagonism of both, promoting sleep by removing wakefulness), and the fact that suvorexant is the agent named in the BAP 2019 insomnia evidence base among the pharmacological options when CBT-I is not the route. Everything else is dose detail. Where these agents sit relative to CBT-I and the GABAergic hypnotics belongs to the Eating & sleep-wake disorders notes.

11.1 The target: the orexin/hypocretin wake system

Orexin stabilises wakefulness; lose it and you get narcolepsy. **Orexin** A and orexin B (also called hypocretin, the same peptide under two names) are excitatory neuropeptides cleaved from a single precursor, released by a small cluster of neurons in the lateral hypothalamus that act as the master "wake-stabilising" switch (Stahl; KDT). They project to and drive the arousal nuclei, the noradrenergic locus coeruleus, the histaminergic tuberomammillary nucleus and the wider reticular activating system, and they signal through two G-protein-coupled receptors, the OX1 receptor and the OX2 receptor, whose stimulation raises arousal and wakefulness. The clinching

physiology, and a favourite viva mirror, is that selective loss of orexin neurons is the lesion in narcolepsy with cataplexy (hypocretin deficiency); a DORA therefore reproduces a slice of that orexin-deficient state on purpose, at night, to let sleep come. The receptor biology of the arousal systems is developed in the Neurochemistry, Neuroendocrinology, Neuroimaging & Basic Psychopharmacology notes.

11.2 The class action: block wakefulness, do not add sedation

Dual OX1 and OX2 antagonism, not a GABA-A modulator. A DORA is a competitive antagonist at *both* orexin receptors; by occupying OX1 and OX2 it removes the orexin drive onto the arousal network, so wakefulness is no longer actively maintained and the brain transitions into sleep (Stahl; KDT: "suvorexant blocks both OX1R and OX2R"). This is the whole point of the class: it initiates and maintains sleep without the positive allosteric modulation of the GABA-A chloride channel that a benzodiazepine or a Z-drug relies on, and it therefore lacks their signature of dependence, tolerance and a seizure-risk withdrawal to the same degree, while tending to preserve more of normal sleep architecture (Stahl notes the effect comes "without the side effects expected of a benzodiazepine or Z-drug hypnotic"). The GABAergic mechanism it deliberately avoids is the anchor of the Benzodiazepines topic and the wider Neurochemistry notes.

RULE **Subtract wakefulness, do not add sedation.** A DORA blocks OX1 and OX2 to switch off the orexin wake drive, so it promotes sleep without GABA-A modulation, and that non-GABAergic mechanism is the single fact every DORA question is testing.

PEARL

A DORA is pharmacologically induced, time-limited narcolepsy. Narcolepsy with cataplexy is the disease of orexin loss; a dual orexin receptor antagonist manufactures a brief orexin-blocked state at bedtime to produce sleep. State that mirror and the mechanism mark is yours, and it also explains the class cautions: next-morning somnolence and rare sleep paralysis, hypnagogic hallucinations or cataplexy-like phenomena.

11.3 The three agents and their doses

Suvorexant, lemborexant, daridorexant, each once nightly. All three are taken as a single dose shortly before bed. Suvorexant (international brand Belsomra) was the first, at **10 to 20 mg** nocte; lemborexant (Dayvigo) at **5 to 10 mg** nocte; and daridorexant (Quviviq), the most recently introduced agent, at **25 to 50 mg** nocte (Maudsley Prescribing Guidelines; KDT; Practical Psychopharmacology). The verified timing anchor for daridorexant is that it is taken within 30 minutes of going to bed with at least **7 hours** remaining before the planned waking time, precisely to keep the next-morning residual effect down; the same "leave a full sleep window" logic applies across the class.

AGENT (INTERNATIONAL BRAND)	NIGHTLY DOSE (MG PER DAY)	KEY POINT
Suvorexant (Belsomra)	**10 to 20**	First DORA; CYP3A4-metabolised, mean half-life about 12 hours; a stopping taper is not required
Lemborexant (Dayvigo)	**5 to 10**	Dual OX1/OX2 antagonist; cap at 5 nocte and use caution above it in patients 65 years and older (fall risk)
Daridorexant (Quviviq)	**25 to 50**	Most recent agent; take within 30 minutes of bed with at least 7 hours of sleep opportunity remaining

The three marketed dual orexin receptor antagonists and their once-nightly dose ranges; the numbers rise as the agents get newer.

12 SUVOREXANT MEAN HALF-LIFE (HOURS)	**10 to 20** SUVOREXANT DOSE (MG PER DAY)	**25 to 50** DARIDOREXANT DOSE (MG PER DAY)	**7** MINIMUM SLEEP WINDOW REMAINING (HOURS)

TRAP **Dosing without a full night ahead.** Taking a DORA when fewer than about seven hours of sleep remain, or the morning before driving, invites next-morning somnolence and impaired driving; the drug switches wakefulness off, and that suppression has to be allowed to wear off before the patient needs to be alert.

11.4 Place in therapy, cautions and the India reality

Not first-line, and still a controlled hypnotic. CBT-I is first-line for chronic insomnia; a DORA is a pharmacological option only where CBT-I fails, is unavailable or is declined, and the accompanying figure sketches the orexin wake-switch and where the class acts. BAP 2019 (Wilson et al.) names suvorexant among the evidence-based pharmacological choices in that scenario, and the class initiates *and* maintains sleep. Despite the lower dependence signal relative to GABAergic hypnotics, these agents are still handled as controlled/scheduled drugs, and the examinable cautions are next-morning somnolence and driving impairment, the sleep-paralysis and hypnagogic-hallucination/cataplexy-like phenomena that follow from the mechanism, complex sleep behaviours as a class labelling concern shared with the Z-drugs, and CYP3A4 interactions for suvorexant. Their positioning against CBT-I sits in the Eating & sleep-wake disorders notes, and the benzodiazepine dependence they are designed to sidestep in the Substance use disorders notes.

INDIA

The genuine Indian angle for this class is an absence. Indian insomnia and anxiety prescribing still defaults reflexively to a benzodiazepine, with alprazolam (alprazolam; Alprax or Restyl) the habitual first reach and often continued long-term, which is exactly the over-prescription problem the Indian Psychiatric Society position and the BAP/NICE short-course rule are trying to correct. A non-GABAergic hypnotic that carries far less dependence liability is precisely what that pattern needs, yet the dual orexin receptor antagonists remain a boutique, largely unavailable and prohibitively priced option in Indian practice as of 2026, so they do not yet displace the alprazolam habit. The exam-safe line is to know the mechanism and name the class as the dependence-sparing future of hypnotic prescribing, while noting it is not yet the ground reality in India.

GOOD TO REMEMBER

- **Suvorexant (Belsomra):** the first dual orexin receptor antagonist, blocking OX1 and OX2 to remove the orexin wake drive; dosed 10 to 20 mg nocte, CYP3A4-metabolised with a mean half-life of about 12 hours, and no taper needed on stopping.
- **Lemborexant (Dayvigo):** a dual OX1/OX2 antagonist for insomnia at 5 to 10 mg nocte, with the specific caution to cap at 5 mg and use care above it in patients 65 years and older because of fall risk.
- **Daridorexant (Quviviq):** the most recent DORA at 25 to 50 mg nocte, taken within 30 minutes of bed with at least 7 hours before planned waking to limit next-morning residual effect.

HOLD THIS

The DORAs (suvorexant 10 to 20 mg, lemborexant 5 to 10 mg, daridorexant 25 to 50 mg nocte) block both OX1 and OX2 to switch off the orexin/hypocretin wake system, promoting sleep by removing wakefulness rather than by GABAergic sedation, which is why they largely sidestep benzodiazepine-style dependence.

12 · Melatonin and ramelteon

These are the hypnotics the examiner uses to show you what a benzodiazepine is not. Melatonin and ramelteon are **melatonergic** agents: agonists at the MT1 and MT2 receptors of the suprachiasmatic nucleus, the brain's circadian pacemaker. They coax sleep by nudging the body clock rather than by depressing the cortex, so unlike a benzodiazepine or a z-drug they carry no dependence, no next-day cognitive impairment, no complex sleep behaviour and no controlled-substance status (Kaplan and Sadock, CTP 2024; Stahl; Kaufman's Clinical Neurology). That clean tail, set against a genuinely modest hypnotic effect, is the whole examinable delta.

Two facts carry most of the marks. First, prolonged-release **melatonin** is the guideline option in the patient over 55 and in the circadian sleep disorders, and it is the endorsed adjunct for insomnia *during a benzodiazepine taper* (BAP). Second, **ramelteon** is the prescription MT1/MT2 **circadian hypnotic** for sleep-onset insomnia. Keep both apart from agomelatine, the melatonergic *antidepressant*, which is developed in the Mood disorders: pharmacotherapy notes (agomelatine cross-ref).

12.1 Mechanism: MT1/MT2 melatonergic agonism

Melatonergic, not GABAergic. Endogenous **melatonin** is synthesised from serotonin in the pineal gland and signals darkness to the suprachiasmatic nucleus. Its two G-protein-coupled receptors divide the labour: stimulation of the MT1 receptor suppresses the firing of the suprachiasmatic pacemaker and so *promotes sleep onset*, while stimulation of the MT2 receptor mediates the *phase-shifting*, circadian-entraining effect (Stahl, Prescriber's Guide). Ramelteon is a full agonist at both MT1 and MT2. Because the drug works through the physiological sleep-timing system and not by opening the GABA-A chloride channel, it produces none of the sedation-by-CNS-depression, muscle relaxation, anticonvulsant cover, respiratory depression or cross-tolerance that define a GABAergic hypnotic. For the GABA-A receptor and the wider receptor systems, see the Neurochemistry, Neuroendocrinology, Neuroimaging & Basic Psychopharmacology notes.

MT1 receptor

Suppresses suprachiasmatic-nucleus firing; the sleep-*onset*-promoting arm of melatonergic signalling.

MT2 receptor

Mediates the *phase-shift* of the circadian clock; the entrainment arm used in jet lag and delayed sleep phase.

RULE **MT1 onset, MT2 phase, no dependence.** Melatonin and ramelteon are MT1/MT2 agonists acting on the circadian clock, not the GABA-A channel, so they cause no dependence, no cognitive impairment, no complex sleep behaviour and are not controlled substances.

12.2 Prolonged-release melatonin: the over-55 and circadian indications

The over-55 hypnotic and the body-clock drug. BAP names prolonged-release **melatonin** as an option to improve sleep-onset latency and sleep quality in patients over 55 years (BAP 2019, grade Ib), and the melatonergic agonists are the rational choice in the circadian rhythm sleep disorders, jet lag, shift work and delayed sleep phase, where the aim is to re-time rather than to sedate (Kaufman's Clinical Neurology; Kaplan and Sadock, CTP 2024). The licensed prolonged-release preparation is given as a **2 mg** bedtime dose; its effect on sleep latency is real but modest, comparable to other non-benzodiazepine hypnotics rather than to a benzodiazepine (Kaplan and Sadock, CTP 2024). Match a short-acting melatonergic agent to sleep-*onset* difficulty. Clinical insomnia, the sleep-wake disorders and CBT-I as the first-line are covered in the Eating & sleep-wake disorders notes.

GOOD TO REMEMBER

- **Melatonin (the drug):** an MT1/MT2 melatonergic agonist derived from serotonin in the pineal; the prolonged-release form is dosed at 2 mg at bedtime and is the BAP option for sleep-onset latency in patients over 55 and for the circadian sleep disorders; it does not enable benzodiazepine discontinuation on its own but is the endorsed adjunct for insomnia during the taper. Avoid in moderate-to-severe hepatic impairment.

12.3 Melatonin as an adjunct in benzodiazepine withdrawal

It settles the insomnia; it does not do the taper. BAP endorses **melatonin** as a useful adjunct for managing insomnia during benzodiazepine withdrawal (BAP 2025, grade A, strong). The important qualifier is that melatonin has *not* been shown to enable benzodiazepine discontinuation itself: a systematic review of six trials found it no better than placebo for that endpoint (Kaplan and Sadock, CTP 2024). So its role is symptomatic, to soften rebound insomnia while the actual work, consolidation onto a longer-acting benzodiazepine and a slow graded reduction, proceeds. The equivalence switch and the taper schedule, and the sedative or benzodiazepine use disorder in the addiction sense, are covered in the Substance use disorders notes.

TRAP **Leaning on melatonin to prevent withdrawal seizures.** Melatonin manages the insomnia of a benzodiazepine taper only; it does not cover the withdrawal syndrome or protect against the seizure. The slow graded reduction, never melatonin, is what prevents that.

12.4 Ramelteon: the MT1/MT2 circadian hypnotic

An 8 mg, sleep-onset, non-scheduled hypnotic. **Ramelteon** is a synthetic melatonin analogue and a full MT1/MT2 agonist, approved for insomnia characterised by difficulty with sleep *onset*. It is given as an **8 mg** dose about 30 minutes before bedtime (reports of efficacy span 4 to 64 mg), with no adjustment needed in renal impairment; use it cautiously in moderate hepatic impairment and avoid it in severe (Kaplan and Sadock, CTP 2024). The effect on sleep latency is small, roughly 4 minutes in a large meta-analysis, and is non-dose-dependent. Ramelteon is extensively metabolised by **CYP1A2**, so fluvoxamine, a potent CYP1A2 inhibitor, can raise ramelteon to toxic concentrations and is effectively contraindicated with it (Kaufman's Clinical Neurology). Its elimination half-life is short, under 2 hours, which is why it does not produce a next-day hangover. Being a melatonergic agonist, it is not a controlled substance.

2	8	55	< 2
PROLONGED-RELEASE MELATONIN (MG AT BEDTIME)	RAMELTEON (MG AT BEDTIME)	AGE FROM WHICH PR MELATONIN IS A BAP OPTION (YEARS)	MELATONERGIC AGONIST ELIMINATION HALF-LIFE (HOURS)

GOOD TO REMEMBER

- **Ramelteon (the drug):** a full MT1/MT2 melatonergic agonist for sleep-onset insomnia, dosed at 8 mg about 30 minutes before bedtime, with a short elimination half-life under 2 hours and no dependence or controlled-substance status; it is metabolised by CYP1A2, so co-prescription with fluvoxamine is dangerous, and it is used cautiously in hepatic impairment.

12.5 The class signature, and the agomelatine cross-ref

Clean where the GABAergic hypnotics are dirty. Set against a benzodiazepine or a z-drug, the melatonergic agonists reduce sleep latency and improve subjective sleep quality but, crucially, do not impair cognition, cause imbalance, induce dangerous complex sleep behaviour or fall into the controlled-substance category (Kaufman's Clinical Neurology). That is exactly the profile that makes them attractive where a benzodiazepine or a z-drug is hazardous, in the older adult, in respiratory disease and in anyone with a substance-misuse history, though the trade-off is a

decidedly gentler hypnotic effect. The wider family also includes tasimelteon (licensed for Non-24-Hour Sleep-Wake Disorder in the blind) and agomelatine, the melatonergic *antidepressant*, which combines MT1/MT2 agonism with 5-HT2C antagonism, is dosed at 25 mg at bedtime and needs liver-function monitoring; agomelatine is developed as an antidepressant in the Mood disorders: pharmacotherapy notes (agomelatine cross-ref). The z-drug complex-sleep-behaviour and dependence cautions that the melatonergic agents avoid are covered with the benzodiazepine-receptor hypnotics.

FEATURE	MELATONERGIC AGONIST (MELATONIN, RAMELTEON)	GABA-A HYPNOTIC (BENZODIAZEPINE, Z-DRUG)
Target	**MT1/MT2 on the suprachiasmatic clock**	**GABA-A chloride channel (PAM)**
Mode of action	Re-times sleep, promotes onset	Sedation by CNS depression
Hypnotic effect size	**Modest**	Larger, more reliable
Dependence, tolerance, withdrawal	**None**	Yes; seizure risk on abrupt stop
Cognitive impairment, imbalance	**None**	Yes
Complex sleep behaviour	**Not a feature**	Yes (notably the z-drugs)
Controlled substance	**No**	Yes

The melatonergic-versus-GABAergic contrast is the single most examinable point on these agents: clock-timing and clean against channel-opening and dependent.

INDIA

Melatonin is available over the counter in India (Meloset or Zytonin; verify the brand and strength locally), which is precisely why it matters against the real Indian problem: the over-prescription of benzodiazepines, with alprazolam (alprazolam; Alprax or Restyl) reached for reflexively as the default anxiolytic and hypnotic and too often continued long-term. A non-dependence-forming, non-controlled melatonergic hypnotic is a genuinely useful alternative in the patient who would otherwise be parked on alprazolam for sleep, and it is consistent with the Indian Psychiatric Society and BAP position that CBT-I is first-line and a benzodiazepine is a short-course measure only. Ramelteon is not widely marketed in India, so melatonin is the melatonergic agent you will actually reach for.

PEARL

Split the receptor to answer the mechanism question: MT1 quietens the suprachiasmatic pacemaker and brings sleep *on*, MT2 *shifts* the clock. That single distinction explains why these drugs help sleep-onset insomnia and jet lag but sedate far less forcefully than a benzodiazepine.

HOLD THIS

Melatonin and ramelteon are MT1/MT2 melatonergic agonists acting on the suprachiasmatic clock, not the GABA-A channel: prolonged-release melatonin 2 mg for the over-55 and as the taper-insomnia adjunct, ramelteon 8 mg for sleep-onset insomnia, both with a short half-life, a modest effect, and no dependence or controlled-substance status.

13 · Etifoxine and the non-benzodiazepine anxiolytics

This is the competitor-delta drug: the anxiolytic that quiets anxiety without being a benzodiazepine. Etifoxine is **a non-benzodiazepine anxiolytic** licensed in parts of Europe, and its whole exam value is a single claim, that it can match a benzodiazepine for short-term anxiety while carrying less of the benzodiazepine tail (rebound, central-nervous-system side effects). Kaplan and Sadock (CTP 2024) confirm it as a non-benzodiazepine that **modulates the GABA-A receptor**, and it is the one **novel anxiolytic** the examiner is likely to name against lorazepam and alprazolam.

Hold the frame that makes the marks. A benzodiazepine works fast but breeds tolerance, dependence and rebound. A translocator protein ligand such as etifoxine works on the same final channel by a different route, boosting the brain's own calming neurosteroids, so the trials show comparable anxiolysis with a cleaner discontinuation. The trap is to read "non-benzodiazepine" as "first-line": an SSRI remains first-line for generalised anxiety, and these agents are alternatives or short-course options, developed in the Anxiety, OCD & trauma-related disorders notes and the Mood disorders: pharmacotherapy notes.

13.1 What etifoxine is: a novel non-benzodiazepine anxiolytic

A European anxiolytic that is not a benzodiazepine. Etifoxine (a benzoxazine derivative) is marketed as an anxiolytic for the psychosomatic manifestations of anxiety and, in the trial literature, for the anxious subtype of adjustment disorder; Kaplan and Sadock (CTP 2024) describe it plainly as "a nonbenzodiazepine drug that modulates GABA-A receptors available in Europe" (New Oxford Textbook of Psychiatry likewise lists it as a non-BZD anxiolytic). It is not a controlled substance and it is not licensed in India through the mainstream pharmacopoeia, which is why the standard Indian textbooks (the Companion) do not carry a dose for it; treat it as the examinable European comparator drug rather than a routine Indian prescription.

13.2 Mechanism: GABA-A modulation plus the translocator protein

Two routes to the same chloride channel. Etifoxine acts by a dual mechanism. First, it is a direct positive modulator at the **GABA-A receptor** (Kaplan and Sadock, CTP 2024, confirm the GABA-A modulation). Second, and this is the part worth a mark, it is a ligand of the mitochondrial 18 kDa translocator protein (TSPO, the old peripheral benzodiazepine receptor), and by stimulating TSPO it drives **neurosteroidogenesis**, raising synthesis of the neurosteroid allopregnanolone, itself a powerful positive allosteric modulator of GABA-A. So etifoxine augments GABAergic inhibition both directly and indirectly through its own endogenous neurosteroid, a mechanism distinct from the benzodiazepine site. The GABA-A receptor and the

wider neurosteroid systems are developed in the Neurochemistry, Neuroendocrinology, Neuroimaging & Basic Psychopharmacology notes.

RULE **GABA-A directly, and again through the translocator protein.** Etifoxine is a non-benzodiazepine anxiolytic with a dual action, direct GABA-A modulation plus TSPO-driven neurosteroid (allopregnanolone) synthesis; it matches a benzodiazepine for short-term anxiety but is an alternative to it, never a substitute for a first-line SSRI.

13.3 The competitor-delta evidence: non-inferior to a benzodiazepine, better tolerated

Same anxiolysis, cleaner tail. The examinable data are head-to-head. A controlled protocol randomised **191** patients with DSM-IV adjustment disorder to etifoxine or lorazepam over **4 weeks**; on the Hamilton Anxiety Rating Scale (the primary outcome) etifoxine was *not inferior* to lorazepam, was better tolerated, produced more responders, and left fewer patients with **rebound anxiety** (Kaplan and Sadock, CTP 2024). A parallel comparison against alprazolam gave similar results, and after the drug was stopped the HAM-A scores kept falling in the etifoxine group while they rose again in the alprazolam group, which also carried more central-nervous-system adverse events. New Oxford records the same signal, a single-study superiority of etifoxine over lorazepam. The reading is that the benzodiazepine buys speed at the price of rebound and CNS load, while the translocator-protein route holds the gain after withdrawal.

AXIS	ETIFOXINE (GABA-A + TSPO)	A BENZODIAZEPINE (GABA-A PAM)
Site of action	**GABA-A modulation plus TSPO neurosteroid synthesis**	Benzodiazepine site on GABA-A
Short-term anxiolysis (HAM-A)	**Non-inferior to lorazepam / alprazolam**	Effective
Tolerability, CNS adverse events	**Better tolerated, fewer CNS events**	Sedation, psychomotor impairment
After discontinuation	**Gains maintained; less rebound anxiety**	Rebound anxiety, scores rise
Controlled-substance / dependence liability	Not scheduled; low reported abuse	Scheduled; dependence and withdrawal

The competitor-delta in one grid: etifoxine matches a benzodiazepine on anxiety scores but is better tolerated and holds the gain after stopping.

TRAP **Reading "novel" and "non-benzodiazepine" as "first-line".** A non-inferiority signal against lorazepam does not make etifoxine a first-line anxiolytic; an SSRI is first-line for generalised anxiety, and etifoxine (like hydroxyzine) is an alternative or short-course option, not the front of the ladder.

13.4 Dose and the Indian brand

The 50 mg capsule, given a few times a day. Etifoxine is supplied as a **50 mg** capsule and given in divided doses, with a usual daily dose of about **150 to 200 mg/day** (the standard European product information; the parsed textbook corpus confirms the drug and its mechanism but does not carry an exact dose, so treat the milligrams as standard-source rather than corpus-verified). In

India, Wilfred flags the brand **Tranxiety** (etifoxine 50 mg); the Indian brand and strength could not be independently confirmed against the Companion or the Maudsley Prescribing Guidelines, so it is carried as Wilfred-provided and flagged for a local check. A rare but recognised safety signal with etifoxine is idiosyncratic hepatocellular injury and severe cutaneous reactions, which is worth naming as the signature caution and is flagged as not corpus-confirmed.

50	150 to 200	191	4
ETIFOXINE CAPSULE STRENGTH (MG)	USUAL ETIFOXINE DOSE (MG PER DAY)	PATIENTS IN THE LORAZEPAM NON-INFERIORITY TRIAL	COMPARISON-TRIAL DURATION (WEEKS)

INDIA

Etifoxine matters in India as an answer to a genuine problem rather than as a common prescription. The problem is benzodiazepine over-prescription, with alprazolam (Alprax or Restyl) reached for reflexively as the default anxiolytic and continued far past any crisis. The Indian Psychiatric Society, in line with BAP and NICE, holds that an SSRI or SNRI is first-line for generalised anxiety and that a benzodiazepine is a short-course measure only, not a maintenance drug. A non-benzodiazepine anxiolytic that holds its gain after withdrawal is exactly the kind of agent that answers the alprazolam-default habit, and Wilfred flags a local brand (Tranxiety, etifoxine 50 mg); the exam-safe line is that etifoxine is a European comparator drug with a favourable discontinuation profile, not an established Indian first-line, and the brand and dose need local verification. The benzodiazepine dependence and withdrawal picture it is contrasted against is covered in the Substance use disorders notes.

13.5 The other non-benzodiazepine anxiolytics: a compact class

A small family, mostly historical or niche. Beyond etifoxine and the 5-HT1A azapirone buspirone, the label "non-benzodiazepine anxiolytic" gathers a scatter of agents. Chlormezanone is the historical one to name: a centrally acting drug with both anti-anxiety and neuro-hypnotic (muscle-relaxant) actions used for tension states (KDT, Essentials of Medical Pharmacology), which was largely withdrawn from world markets in the 1990s after reports of severe cutaneous reactions and hepatotoxicity, so it survives as an exam name rather than a live prescription (the withdrawal reason is flagged as not corpus-confirmed). Hydroxyzine (Atarax) is the H1-antihistamine anxiolytic that BAP names, with buspirone, as efficacious in acute generalised anxiety. Two further historical roots complete the picture: the carbamate meprobamate, the mid-century "minor tranquilliser" the benzodiazepines displaced, and tofisopam, an atypical 2,3-benzodiazepine promoted as a non-sedating daytime anxiolytic. Buspirone itself is developed in its own topic.

AGENT	CLASS / MECHANISM	STATUS
Etifoxine	**GABA-A modulator + TSPO neurosteroid ligand**	Licensed anxiolytic (Europe)
Buspirone	5-HT1A partial agonist (azapirone)	Current; acute GAD (own topic)
Hydroxyzine	H1 antihistamine	Current; acute GAD option (BAP)
Chlormezanone	**Central anxiolytic / muscle relaxant**	Historical; largely withdrawn
Meprobamate	Carbamate	Historical; displaced by benzodiazepines
Tofisopam	Atypical 2,3-benzodiazepine (non-sedating)	Niche; limited markets

The compact class: etifoxine is the live novel agent, chlormezanone and meprobamate are the historical names, hydroxyzine the current antihistamine option.

PEARL

The translocator protein has two lives on this paper. As a drug target it is how etifoxine raises its own GABA-modulating neurosteroid; as an imaging marker (TSPO PET tracers such as [11C]PK11195) it flags activated microglia in the neuroinflammation literature. Same protein, one pharmacological and one radiological. Say which you mean and the mark is yours.

GOOD TO REMEMBER

- **Etifoxine (the drug):** a non-benzodiazepine, novel anxiolytic acting by a dual mechanism, direct GABA-A modulation plus translocator-protein (TSPO)-driven neurosteroid (allopregnanolone) synthesis; supplied as a 50 mg capsule at about 150 to 200 mg/day, it was non-inferior to lorazepam and alprazolam on the HAM-A over 4 weeks with better tolerability and less rebound anxiety; the signature caution is rare hepatic and severe cutaneous reactions (dose and brand standard-source, not corpus-verified).
- **Chlormezanone (historical):** a centrally acting anxiolytic with muscle-relaxant / neuro-hypnotic properties for tension states, largely withdrawn from world markets for severe skin and liver reactions; an exam name, not a current prescription.
- **Hydroxyzine (the class option):** an H1-antihistamine anxiolytic that BAP names, alongside buspirone, as efficacious in acute generalised anxiety, with no dependence liability.

HOLD THIS

Etifoxine is a non-benzodiazepine anxiolytic that hits GABA-A two ways, directly and through translocator-protein-driven neurosteroid synthesis, and in adjustment-disorder anxiety it was non-inferior to lorazepam and alprazolam on the HAM-A while causing less rebound and fewer CNS effects, yet it is an alternative to a benzodiazepine, never a replacement for a first-line SSRI.

14 · Beta-blockers, antihistamines and gabapentinoids as anxiolytics

These are the adjunctive and off-label anxiolytics, and they earn their marks by testing one clinical reflex: can you match a drug to a symptom? Grouped here are three non-serotonergic,

non-benzodiazepine options reached for around the edges of anxiety management: a **beta-blocker anxiolytic** for the autonomic and performance-anxiety symptoms, a sedating **antihistamine anxiolytic** with genuine acute-generalised-anxiety evidence, and the two **gabapentinoid** agents, one of which is a licensed alternative first-line treatment for generalised anxiety disorder (GAD). None is a first-line agent for the psychic anxiety of GAD except pregabalin, and the single most current examinable point is that the gabapentinoids are no longer regarded as dependence-free.

Hold the group as a spread of receptor targets: propranolol at the peripheral **beta-adrenergic receptor**, hydroxyzine at the H1 histamine receptor, and pregabalin and gabapentin at the alpha-2-delta subunit of the voltage-gated calcium channel. Where each SSRI and SNRI sits as the true first-line anxiolytic belongs to the Mood disorders: pharmacotherapy notes, and the wider place of the anxiolytics across the anxiety disorders to the Anxiety, OCD & trauma-related disorders notes; this topic owns the adjuncts.

14.1 Propranolol: the beta-blocker anxiolytic

Blocks the body, not the mind. Propranolol (Ciplar or Inderal) is a non-selective **beta-adrenergic antagonist** whose anxiolytic action is peripheral: it abolishes the somatic, sympathetically driven symptoms of anxiety, the palpitations, tachycardia, tremor and dry mouth, without touching the cognitive dread itself (Kaplan and Sadock, CTP 2024; Practical Psychopharmacology). Its established anxiety niche is social anxiety disorder, performance type: a single dose of **10 to 40 mg** is taken about an hour before the feared performance, with a test dose tried on an ordinary occasion beforehand. Because relief comes from switching off the peripheral adrenergic surge rather than from sedation, it is a useful non-dependence-forming alternative to a benzodiazepine for the situational performer, the musician or the examinee with a pounding heart. It has a short half-life of about **3 to 5 hours** (immediate-release). Cautions are cardiorespiratory: avoid in asthma and COPD (beta-2 bronchoconstriction), in significant bradycardia or heart block, and do not withdraw abruptly in the cardiac patient. The beta-1-selective agent atenolol is an alternative. It has no useful effect on the pervasive worry of GAD.

> **PEARL**
>
> The beta-blocker treats the pulse, not the panic. Propranolol strips out the palpitations and tremor of the performance surge by blocking peripheral beta-adrenergic drive, but leaves the anticipatory dread intact, which is exactly why it shines for the time-limited somatic storm of stage fright and fails as a treatment for generalised, cognitively driven anxiety.

14.2 Hydroxyzine: the antihistamine anxiolytic

A sedating H1 antagonist with real acute-GAD evidence. Hydroxyzine (Atarax) is a first-generation piperazine antihistamine; its central antagonism of the **H1 histamine receptor** produces the sedation and anxiolysis that make it an **antihistamine anxiolytic** rather than merely an allergy drug. It carries a place most of this group lacks: BAP is explicit that hydroxyzine (alongside buspirone) is efficacious in the *acute* treatment of generalised anxiety disorder, though neither has published evidence for relapse prevention (BAP 2014, Baldwin et al.). The anxiety

dose is **50 to 100 mg** up to four times a day, and the elimination half-life is long at about **20 hours** (Stahl, Prescriber's Guide). It is not a controlled drug and does not cause dependence, so it is a reasonable short-term or as-needed alternative to a benzodiazepine. The examinable cautions are its sedation (warn about driving and machinery), its anticholinergic effects (dry mouth, constipation) and QT prolongation with cardiac conduction delay at higher doses.

RULE **Match the drug to the symptom.** Propranolol for the somatic autonomic surge of performance anxiety and hydroxyzine for short-term or acute generalised anxiety; of this whole group only pregabalin is a licensed alternative first-line agent for GAD, and an SSRI remains the true first-line drug.

14.3 The gabapentinoids: one mechanism, not a GABA drug

Alpha-2-delta ligands despite the name. The **gabapentinoid** class holds two agents, pregabalin and gabapentin, and the trap built into the name is that neither acts on the GABA-A receptor or on GABA metabolism at all (Kaplan and Sadock, CTP 2024; Stahl). Both bind the **alpha-2-delta subunit** of voltage-gated (P/Q-type) calcium channels on presynaptic terminals, reducing calcium influx and dampening the release of excitatory neurotransmitters such as glutamate, noradrenaline and substance P; the net effect is a reduction in neuronal excitability that translates into anxiolytic, analgesic and anticonvulsant activity. Both are excreted largely unchanged by the kidney rather than metabolised in the liver, so they carry few pharmacokinetic drug interactions but need dose reduction in renal impairment. The fast, frequency-increasing GABA-A mechanism they are so often confused with is the benzodiazepine's, developed in the Neurochemistry, Neuroendocrinology, Neuroimaging & Basic Psychopharmacology notes.

14.4 Pregabalin: the licensed alternative first-line agent

The one non-serotonergic drug licensed for GAD. Pregabalin (Pregeb or Pregastar) is licensed for generalised anxiety disorder in the UK and Europe, and both BAP and NICE place it as an alternative initial treatment where an SSRI or SNRI is unsuitable or not tolerated, and as an augmentation option after non-response to an SSRI or SNRI (BAP 2014; NICE CG113). Its different side-effect profile and faster onset than an SSRI are exactly why it is useful in the patient who cannot tolerate serotonergic agents (Shorter Oxford Textbook of Psychiatry). The dose is **150 to 600 mg** per day in two to three divided doses, and the half-life is short at about **5 to 7 hours** (Stahl). The signature caution, and the reason it is a scheduled/controlled drug (Schedule V in the United States), is a genuine dose-related misuse and dependence potential with euphoria and a withdrawal syndrome; it must never be stopped abruptly (seizure risk), and it can cause sedation, dizziness, peripheral oedema and weight gain, with the anticonvulsant-class suicidality signal to bear in mind.

14.5 Gabapentin: the off-label cousin

Off-label, weaker evidence, the same cautions. Gabapentin (Gabapin or Gabantin) is used off-label for anxiety, with controlled-trial evidence in social phobia (social anxiety disorder) and a post-hoc signal in panic disorder, but it is not licensed for GAD and does not carry pregabalin's guideline status (Kaplan and Sadock, CTP 2024). When used for anxiety the dose is broadly **900**

to 1800 mg per day in three divided doses, titrated upward over several days, with the same short half-life of about **5 to 7 hours** and the same renal excretion. Crucially it shares pregabalin's dependence and misuse liability and its abrupt-withdrawal seizure risk, so it is not the safe, consequence-free benzodiazepine substitute it is sometimes assumed to be. The sedative and benzodiazepine dependence picture these agents are compared against is developed in the Substance use disorders notes.

TRAP **Treating a gabapentinoid as dependence-free.** Pregabalin and gabapentin are now recognised drugs of misuse with a withdrawal syndrome; never stop either abruptly (seizure risk) and screen actively for misuse, especially alongside opioid or benzodiazepine use, rather than reaching for them as a "safe" alternative.

AGENT (INDIAN BRAND)	CLASS / TARGET	USUAL DOSE (MG PER DAY)	HALF-LIFE (HOURS)	PLACE IN ANXIETY
Propranolol (Ciplar, Inderal)	Non-selective beta-adrenergic antagonist	**10 to 40 (single pre-event dose)**	3 to 5 (IR)	**Somatic symptoms of performance / social anxiety**
Hydroxyzine (Atarax)	H1 antihistamine antagonist	**50 to 100, up to four times a day**	about 20	**Efficacious in acute GAD (no relapse-prevention data)**
Pregabalin (Pregeb, Pregastar)	Alpha-2-delta calcium-channel ligand	**150 to 600**	5 to 7	**Licensed alternative first-line for GAD; misuse potential**
Gabapentin (Gabapin, Gabantin)	Alpha-2-delta calcium-channel ligand	**900 to 1800**	5 to 7	Off-label (social phobia evidence); misuse potential

The adjunctive and off-label anxiolytics at a glance; the accompanying figure maps each agent to its receptor target and its symptom niche.

10 to 40	150 to 600	900 to 1800	5 to 7
PROPRANOLOL PRE-EVENT DOSE (MG PER DAY)	PREGABALIN DOSE (MG PER DAY)	GABAPENTIN DOSE (MG PER DAY)	GABAPENTINOID HALF-LIFE (HOURS)

INDIA

These agents matter in India as the answer to a real problem: benzodiazepine over-prescription, with alprazolam (alprazolam; Alprax or Restyl) the reflexive default anxiolytic, often begun from the outset and continued long-term. The Indian Psychiatric Society position, in line with BAP and NICE, is that an SSRI or SNRI is first-line for GAD and that a benzodiazepine is a short-course measure only. Propranolol for the situational performer, hydroxyzine for short-term anxiety, and pregabalin as the licensed alternative are all genuine non-benzodiazepine options in the patient who would otherwise be parked on alprazolam. The important caveat is that the gabapentinoids are themselves a recognised and rising drug of misuse, so they are a considered swap and not a free pass.

GOOD TO REMEMBER

- **Propranolol (Ciplar / Inderal):** a non-selective beta-adrenergic antagonist that treats the peripheral autonomic symptoms (palpitations, tremor) of performance / social anxiety at a single 10 to 40 mg dose about an hour before the event; short half-life about 3 to 5 hours, no effect on psychic anxiety, avoid in asthma and bradycardia.
- **Hydroxyzine (Atarax):** a sedating H1 antihistamine anxiolytic efficacious in acute GAD (BAP), dosed 50 to 100 mg up to four times a day with a long half-life of about 20 hours; not a controlled drug and no dependence, but sedating and anticholinergic.
- **Pregabalin (Pregeb / Pregastar):** an alpha-2-delta calcium-channel gabapentinoid, licensed and guideline-endorsed as an alternative first-line treatment for GAD, at 150 to 600 mg per day in divided doses (half-life about 5 to 7 hours); signature caution is a genuine misuse and dependence potential with a seizure-risk withdrawal, so never stop abruptly.
- **Gabapentin (Gabapin / Gabantin):** an off-label alpha-2-delta anxiolytic (evidence in social phobia) at about 900 to 1800 mg per day in three divided doses (half-life about 5 to 7 hours), sharing pregabalin's misuse liability and abrupt-withdrawal seizure risk.

HOLD THIS

Of the adjuncts, propranolol (a beta-adrenergic antagonist, 10 to 40 mg before a performance) treats only the somatic surge, hydroxyzine (an H1 antihistamine, efficacious in acute GAD) is a non-dependence-forming short-term option, and the gabapentinoids act on the alpha-2-delta calcium-channel subunit (not GABA-A), with only pregabalin licensed as an alternative first-line agent for GAD and both now recognised as drugs of misuse.

Apply and consolidate

15 · Worked cases

This closing set of cases lands where the paper actually lives, at the bedside and the prescription pad. Four **worked cases** gather the dissociative, conversion and anxiolytic threads into the four decisions the examiner most reliably tests: rule a **functional neurological disorder** in on a positive sign, separate a **dissociative** from an **organic** amnesia, taper a benzodiazepine dependence, and select the right anxiolytic or hypnotic for a specific patient. Each vignette is reasoned rather than recited, and each is a worked example of one two-beat method: name the positive finding that rules the decision in, then keep screening or apply the guideline anchor.

The textbook spine is the one carried through the block: Stone and Carson and DSM-5-TR for the conversion signs, DSM-5-TR and ICD-11 for the dissociative criteria, and BAP, NICE and the Maudsley Prescribing Guidelines for the taper and the agent choice, with the Indian Psychiatric Society for the Indian layer. Nothing new is introduced here; the cases only make the earlier topics decide something.

15.1 How to work a case: rule in, then keep screening

A positive finding first, an open mind second. Every case on this material is worked in two beats. The first beat is a **rule-in**: elicit the sign or the pattern that makes the diagnosis positively, a Hoover's sign, an entraining tremor, a retrograde memory loss with identity gone but new learning intact, or an interdose rebound that betrays dependence. The second beat is the

safeguard: a positive sign never closes the organic work-up, and a diagnosis never licenses the wrong drug. This is the Stone and Carson logic for conversion generalised to the whole block, and it is why the reflex sedative, reached for so readily in Indian practice, is so often the wrong answer. Two of the cases are diagnostic (conversion, dissociative amnesia) and two are managerial (the taper, the agent choice), but the shape is identical.

15.2 Case one: functional leg weakness and a positive Hoover's sign

Weak on command, strong on distraction. case: a woman in her late twenties develops a dense weakness of the right leg over several hours after a bitter family confrontation, with no sensory level, normal reflexes and a flexor plantar response. Direct hip extension of the "weak" leg is flaccid. You cup a hand under the right heel and ask her to flex the *left* hip against your other hand; as she does, the right heel drives firmly down into your palm. That is a positive Hoover's sign, the extensors she could not fire on command firing automatically when attention moves to the other leg (Kaufman; Kaplan and Sadock, CTP 2024). It rules a functional neurological disorder in at the bedside, in seconds and without a scanner. A give-way weakness (ratchety power that builds then suddenly collapses) supports the picture but is not specific, because pain and poor effort in genuine disease can produce it too.

RULE **Rule in, then still screen.** A functional disorder is diagnosed on a positive sign of internal inconsistency (weak on command, strong on distraction), never on the absence of a lesion or the presence of a stressor; the positive sign does not close the organic search in a progressive or atypical case.

WORKED EXAMPLE

The Hoover manoeuvre doubles as the first move of treatment. Having shown the patient that her heel pressed down of its own accord, you can say that a leg which moves automatically is a leg that *can* move, replacing "there is nothing wrong" with "here is what is wrong, and here is why it can recover". The demonstrated sign proves the diagnosis and its reversibility in one gesture.

15.3 Case one continued: the functional tremor that entrains

A tremor that copies the other hand is functional. The same patient, at a later review, has a coarse tremor of the right hand. You ask her to copy a slow rhythmical tapping with the *left* hand; the right-hand tremor shifts its frequency to match the tapping, then stops, and she cannot keep the copied rhythm going. That is a positive tremor entrainment test, the movement-domain equivalent of Hoover's sign: an organic tremor holds its own frequency regardless, a functional one entrains, stops or disrupts the copied rhythm (DSM-5-TR; New Oxford 2024). The unifying mechanism across both signs is that the symptom depends on abnormally focused attention, so diverting attention exposes the intact pathway. The visual analogue the examiner likes is the tubular field, a visual-field defect the same width at 1 metre as at 2 metres, which is physically impossible and so rules the functional picture in.

GOOD TO REMEMBER

- **Functional neurological disorder / conversion disorder (the syndrome):** defining criterion is a motor or sensory symptom, genuinely experienced, shown by a *positive* sign of internal inconsistency to be incompatible with neurological disease (Hoover's sign, tremor entrainment, tubular field); it is a *rule-in* diagnosis, not one of exclusion, no stressor is required (DSM-5-TR) and la belle indifference is non-diagnostic. First step: elicit a positive sign at the bedside, then keep screening for coexisting organic disease.

15.4 Case two: a fugue told apart from an organic amnesia

Direction of the loss, and the fate of identity. case: a man in his thirties is brought in by railway police, found several hundred kilometres from home, unable to give his name, address or occupation, and calm rather than distressed. The sensorium is clear, there are no focal neurological signs, and he learns and recalls a new list of three objects without difficulty; a relative later reports he left home the morning after a large debt notice arrived. The reasoning is a positive comparison, not a hunch. Intact new learning, a clear sensorium, a *lost personal identity* and a clear psychological precipitant point to a dissociative fugue with generalised dissociative amnesia, because the organic amnestic syndrome is the mirror image, an anterograde failure to form new memory with personal identity preserved. Loss of the name is a psychogenic flag until proven otherwise. Screening for dissociation itself uses the Dissociative Experiences Scale, where a mean around **30** flags a probable dissociative disorder, set out in the accompanying scale plate.

The rule-in does not end the work. Criterion C still requires the organic mimics to be excluded: transient global amnesia (an abrupt, isolated anterograde amnesia with repetitive questioning, identity preserved, resolving within some hours), a complex partial seizure or epileptic automatism (confusion, no assumption of a new identity, an abnormal EEG), the amnestic (Korsakoff) syndrome and a substance blackout. Only when those are cleared does the label fix, and the treatment is safety, contact with family and a gentle, phased recovery of the memory, never a sedative.

GOOD TO REMEMBER

- **Dissociative amnesia and fugue (the syndrome):** DSM-5-TR Criterion A is an inability to recall important autobiographical information, usually traumatic or stressful, that is inconsistent with ordinary forgetting (localised is the commonest type); fugue is the specifier "with dissociative fugue", apparently purposeful travel or bewildered wandering with amnesia for identity. The deficit is retrograde and reversible; the first step is to exclude an organic cause (Criterion C) and to check whether personal identity is lost, which points away from an organic amnesia.

15.5 Case three: consolidating an alprazolam dependence onto a long-acting agent

Consolidate, convert, then come down. case: a man has been taking alprazolam (Alprax, Restyl) for insomnia and worry, the dose creeping up over many months, and now describes anxiety and tremor 3 to 4 hours after each tablet that he reads as the illness returning. That interdose rebound, 3 to 4 hours after a short-acting high-potency agent, is the fingerprint of dependence, not relapse. The evidence-based taper (BAP 2025; Maudsley) begins by *consolidating* him onto a single long-acting benzodiazepine, diazepam (Valium, Calmpose) or clonazepam (Clonotril,

Rivotril), using the verified diazepam-equivalence below; where the liver is impaired, lorazepam (Ativan, Loraz) or oxazepam is used instead. The Maudsley table deliberately omits alprazolam, so no alprazolam equivalence is asserted here; in practice the difficult final alprazolam doses are eased by substituting clonazepam (Kaplan).

BENZODIAZEPINE	DOSE EQUAL TO DIAZEPAM 10 MG (MG)
Diazepam	10
Clonazepam	**0.5**
Lorazepam	**1**
Chlordiazepoxide	25

The consolidation switch uses the verified diazepam-equivalent doses (Maudsley Prescribing Guidelines, Table 3.29); alprazolam is not tabulated there, so its equivalence is not asserted.

15.6 Case three continued: reducing slowly and managing the withdrawal

Small proportional steps, and never an abrupt stop. Once consolidated, the dose comes down *gradually*: patients often tolerate reductions of about 10 percent of the last dose every 2 to 4 weeks (roughly 5 to 10 percent per month), the steps becoming smaller as the dose falls because the dose-to-effect relationship is hyperbolic, so the final reductions before cessation are often less than 1 mg of diazepam-equivalent (Maudsley). The usual maximum diazepam dose for anxiety is around 30 mg daily. Melatonin (Meloset, Zytonin) is a useful adjunct for the insomnia of withdrawal (BAP grade A). The withdrawal to manage is rebound anxiety and insomnia, autonomic arousal and perceptual disturbance, beginning within hours to a few days of stopping a short-acting agent but only 1 to 2 weeks after a long-acting one; the danger that governs the whole plan is *seizures*. The benzodiazepine use disorder as an addiction is developed in the Substance use disorders notes.

TRAP **Stopping the benzodiazepine abruptly.** Abrupt cessation risks a withdrawal syndrome of rebound anxiety, autonomic arousal and, dangerously, *seizures* (Maudsley: it can be fatal); the whole point of consolidating onto a long-acting agent and reducing in small proportional steps is to never stop suddenly.

10% USUAL TAPER STEP OF THE LAST DOSE EVERY 2 TO 4 WEEKS	**0.5 mg** CLONAZEPAM EQUAL TO DIAZEPAM 10 MG (MAUDSLEY)	**30** USUAL MAX DIAZEPAM FOR ANXIETY (MG PER DAY)	**3 to 4 h** INTERDOSE REBOUND AFTER A SHORT-ACTING AGENT

GOOD TO REMEMBER

- **Diazepam (Valium, Calmpose):** the long-acting anchor of the taper, oral 4 to 40 mg per day in divided doses; a GABA-A positive allosteric modulator with the long-lived active metabolite nordiazepam; verified equivalence, diazepam 10 mg equals clonazepam 0.5 mg equals lorazepam 1 mg equals chlordiazepoxide 25 mg (Maudsley Table 3.29).
- **Alprazolam (Alprax, Restyl):** short-to-intermediate high-potency benzodiazepine, anxiolytic range 1 to 4 mg per day, with 5 to 6 mg per day reserved for panic; the default Indian anxiolytic, the most toxic in overdose and the hardest to taper, with interdose rebound at 3 to 4 hours and a manufacturer short-course limit of 2 to 4 weeks.

15.7 Case four: selecting the anxiolytic to the patient and the goal

Match the agent to the target, and spare the benzodiazepine. case: three patients ask for "something for the nerves", and the right answer differs for each. A junior doctor with palpitations and hand tremor only before an examination viva needs the *somatic* surge blunted for a discrete event: propranolol (Ciplar, Inderal) 10 to 40 mg taken about 20 to 30 minutes before the performance blocks the peripheral autonomic symptoms without sedation or dependence (Kaplan and Sadock, CTP 2024). A woman with chronic generalised anxiety and mild COPD, already buying alprazolam from a chemist, needs a sustained non-dependence anxiolytic: an SSRI is the first-line agent, with buspirone (Buspin), a 5-HT1A partial agonist with no dependence or respiratory depression, as the benzodiazepine-sparing option, provided she is told it takes about a fortnight to work and is useless taken as-needed. A student with a short run of stress-related sleep-onset insomnia needs the briefest possible cover: zolpidem (Zolfresh, Nitrest) 10 mg at bedtime for 7 to 10 nights, or melatonin, with CBT for insomnia as the durable answer. The accompanying figure lays these choices out as an agent-selection map.

PATIENT AND GOAL	FIRST CHOICE (INDIAN BRAND)	DOSE (MG PER DAY)	WHY NOT A BENZODIAZEPINE
Performance or situational anxiety (palpitations, tremor)	propranolol (Ciplar, Inderal)	**10 to 40**	blunts the autonomic surge without sedation or dependence
Sustained GAD with respiratory disease or a substance history	SSRI first-line; buspirone (Buspin) as the non-dependence add-on	buspirone 15 to 30	no dependence, no respiratory depression, but two weeks to work
Short-term sleep-onset insomnia	zolpidem (Zolfresh, Nitrest) or melatonin (Meloset, Zytonin)	zolpidem 10	z-drug complex-sleep-behaviour and dependence caution; CBT-I is durable
Acute severe crisis, alcohol withdrawal, status epilepticus, catatonia	a benzodiazepine (diazepam or lorazepam)	**short course only**	this IS the benzodiazepine's genuine niche, time-limited

The agent-selection map: the anxiolytic is matched to the patient and the goal, and the benzodiazepine is spared for its genuine acute niche. The SSRIs that outrank all of these for sustained anxiety are developed in the Mood disorders: pharmacotherapy notes.

15.8 Case four continued: applying the short-course rule

Not first-line, not for maintenance. The anchor that decides all three sub-cases is the **short-course rule**: a benzodiazepine is not a first-line long-term anxiolytic or hypnotic. For generalised anxiety an SSRI is first-line (BAP 2014; NICE CG113 names sertraline first), and NICE says a benzodiazepine may be offered for generalised anxiety disorder only as a short-term crisis measure of no more than 2 to 4 weeks; for chronic insomnia CBT for insomnia is first-line (BAP 2019), with a z-drug or benzodiazepine only as a brief option matched to the pattern. Two corollaries fall out for this case. The delayed onset of buspirone means the woman must not be switched abruptly from alprazolam to buspirone, which does not cover benzodiazepine

withdrawal; she takes a therapeutic buspirone dose for two to four weeks first, and only then is the alprazolam tapered. And flumazenil, the benzodiazepine antagonist, is not a shortcut out of dependence, because it can precipitate seizures in a dependent patient. The wider anxiety pharmacology sits in the Anxiety, OCD & trauma-related disorders notes, and clinical insomnia and CBT-I in the Eating & sleep-wake disorders notes.

GOOD TO REMEMBER

- **Propranolol (Ciplar, Inderal):** a peripheral beta-adrenergic blocker for somatic and performance anxiety, 10 to 40 mg taken about 20 to 30 minutes before a performance (Kaplan and Sadock, CTP 2024); it blunts palpitations and tremor without sedation or dependence and has no effect on the psychic component.
- **Buspirone (Buspin):** a 5-HT1A partial agonist, 15 to 30 mg per day (maximum 60 mg per day), short half-life of about 2 to 3 hours but a delayed onset of two weeks or more, so never a PRN rescue; no dependence, sedation, anticonvulsant effect or abuse.
- **Zolpidem (Zolfresh, Nitrest):** a z-drug at the benzodiazepine-1 (omega-1) GABA-A subtype, 10 mg at bedtime for 7 to 10 nights (short half-life about 2.5 hours); the signature caution is complex sleep behaviours with dependence and next-morning impairment.

15.9 The single method behind all four

One move, four applications. Stand back and the four cases are one skill practised four ways. The two diagnostic cases rule a functional or dissociative disorder *in* on a positive finding, then keep the organic search open. The two managerial cases apply the short-course discipline, consolidating and tapering a dependence rather than continuing it or stopping it abruptly, and matching the anxiolytic to the patient rather than reaching for the default alprazolam. Across all four the reflex to resist is the same, the sedative given in place of an assessment, which is precisely the habit the Indian benzodiazepine-sparing position exists to correct.

INDIA

Every case here has an Indian edge. The benzodiazepine over-prescription problem is real, and **alprazolam** (Alprax, Restyl) is the default anxiolytic reached for reflexively and continued long-term; benzodiazepines are among the most frequently prescribed drugs, and a benzodiazepine should not ordinarily run beyond 2 to 4 weeks. The Indian Psychiatric Society position, in line with BAP and NICE, is that an SSRI or SNRI is first-line for generalised anxiety and that a benzodiazepine is a short-course measure only, so buspirone and propranolol are genuinely useful in the patient who would otherwise be parked on alprazolam. The culture-bound edge is just as genuine: possession and trance states, in which a deity, spirit or ancestor is felt to take over, are a common idiom of distress and can present with the amnesia and purposeful travel of case two; ICD-11 keeps these as separate categories (trance disorder 6B62, possession trance disorder 6B63), and a sanctioned, non-distressing ritual state is not a disorder at all. Read them through a cultural formulation, not a sedative, as developed in the Consultation-liaison, geriatric & transcultural psychiatry notes.

PEARL

The most powerful move in three of these four cases is a demonstration rather than a drug: the patient's own Hoover's sign or entraining tremor proves the functional diagnosis and its reversibility, the intact new learning proves the amnesia is not organic, and the interdose rebound proves the anxiety is dependence, not relapse. In each, the finding that rules the diagnosis in is also the thing you show the patient to explain it.

HOLD THIS

Win each case with a positive move: rule a functional disorder in on a sign that is weak on command but strong on distraction (Hoover, entrainment, tubular field), separate a dissociative from an organic amnesia by a retrograde loss with identity gone but new learning intact, and treat a benzodiazepine dependence by consolidating onto a long-acting agent (diazepam or clonazepam) and tapering slowly because abrupt cessation causes *seizures*, since a benzodiazepine is never the first-line long-term anxiolytic.

For the receptor detail behind the benzodiazepine mechanism see the Neurochemistry, Neuroendocrinology, Neuroimaging & Basic Psychopharmacology notes; for the video-EEG separation of dissociative from epileptic events the Epilepsy & psychiatry notes; for the lorazepam challenge and benzodiazepine management of catatonia the Other psychotic disorders, delusional syndromes & catatonia notes; for grounding, abreaction and hypnosis in the recovery of dissociative memory the Psychotherapies, clinical assessment, MSE & nosology notes; and for the somatic-symptom, functional and factitious boundary the Somatic-symptom, sexual, impulse-control disorders & suicide notes.

16 · Consolidation

The last step is not new material, it is retrieval. This closing topic exists to turn a chapter you have *read* into a chapter you can *reproduce* under exam pressure. The evidence is one-directional: testing yourself on half-learned material, **retrieval practice**, fixes it far more durably than reading it again, and the most efficient way to study this material is to **cover the answer** and force each fact out of memory before checking it. Everything below is built for that, a **mnemonic** that reassembles the whole chapter from one line, answer-free **retrieval prompt** lists, two answer vaults to check against, and a whole-chapter **synthesis map** to reproduce.

Use it actively, not by rereading. Say the master mnemonic once, then close the notes and work the retrieval prompts with the answer covered; only then uncover the Good-to-remember vaults and mark what you missed. Finish by reproducing the synthesis map on a blank sheet. Do those three things and the chapter is consolidated; the gaps you find are exactly where to go back. The wider study technique of active recall and spaced retrieval sits alongside the clinical material, and the grounding and hypnosis techniques touched on across the dissociative half are developed in the Psychotherapies, clinical assessment, MSE & nosology notes.

Fig 15.16 The whole-chapter synthesis map as a cover-the-columns grid: each dissociative entity reduced to its one discriminator and first step, and each anxiolytic-hypnotic class to its mechanism, use and key caution.

A. Dissociative and conversion: entity, discriminator, first step		
entity	**the one discriminator**	**the first step**
dissociative amnesia and fugue	retrograde loss, intact new learning; fugue is a specifier	exclude an organic amnestic cause
dissociative identity disorder	two or more identity states, plus recurrent amnesia	confirm the dissociative-amnesia criterion
depersonalisation-derealisation	detachment with intact reality testing ('as if')	confirm reality testing is intact (not psychosis)
conversion / functional neurological disorder	a positive rule-in sign, not a diagnosis of exclusion	elicit a positive sign
possession and trance	involuntary, outside accepted cultural or religious practice	apply the cultural-exclusion criterion

B. Anxiolytics and hypnotics: class, mechanism, use and key caution		
class	**mechanism**	**use and the key caution**
benzodiazepines	GABA-A positive allosteric modulator; frequency, not duration	short course only; dependence and seizure on abrupt withdrawal
z-drugs (zolpidem, zopiclone)	benzodiazepine-1 (omega-1) GABA-A subtype	short-term sleep onset; complex sleep behaviours
buspirone	5-HT1A partial agonist	sustained anxiety, spares BZD; delayed onset, no dependence
DORAs (suvorexant, lemborexant)	orexin (hypocretin) receptor antagonist	insomnia; blocks the wake-promoting orexin system
melatonergic (melatonin, ramelteon)	MT1 / MT2 receptor agonist	sleep onset; prolonged-release an option over age 55
adjuncts (propranolol, hydroxyzine, pregabalin)	beta-blocker, H1 antihistamine, alpha-2-delta ligand	somatic and acute anxiety; none is a GABA-A hypnotic

structure: section and column headers the exam anchor to hold the danger to hold

16.1 The master mnemonic, paid off

One line rebuilds the whole chapter. The chapter opened by seeding a single **mnemonic**, and this is where it is redeemed. *MIND SPLITS, BODY SPEAKS, GABA SLEEPS* is not decoration, each beat is a doorway into a third of the material, and saying the line should make the branches beneath it unfold. **MIND SPLITS** recovers the psychoform dissociative disorders of consciousness, memory and identity; **BODY SPEAKS** recovers conversion, the somatoform half; **GABA SLEEPS** hands over to the anxiolytic and hypnotic pharmacology that acts on the GABA-A receptor. If the line is solid, the chapter is recoverable from it.

MNEMONIC

MIND SPLITS, BODY SPEAKS, GABA SLEEPS

MIND SPLITS unfolds to the mind-side entities, dissociative *amnesia* (autobiographical memory), *identity* disorder and its partial form (identity), *depersonalisation-derealisation* (self and reality), and *trance* and *possession trance* (awareness and identity-replacement). **BODY SPEAKS** unfolds to the one body-side entity, conversion or dissociative neurological symptom disorder, diagnosed by positive signs. **GABA SLEEPS** unfolds to the benzodiazepine and its comparators, the mechanism (frequency, not duration), the half-life classes, dependence and the taper, flumazenil, and the short-course rule. Three beats, three branches, the whole chapter.

16.2 How to run the recall

Cover, retrieve, check, redraw. The mechanics of **active recall** for this chapter are fixed and worth stating so the rest of the topic is usable. First, **cover the answer**, keeping the two Good-to-remember vaults below hidden. Second, work each **retrieval prompt** out loud or on paper from memory. Third, uncover the vault and mark every miss. Fourth, close on the **synthesis map** and **redraw from memory** on a blank sheet. The order matters, because the effortful pull of retrieval is what lays down the memory, so a prompt you struggle with and then check is worth more than a paragraph reread. That is why the prompt lists below are deliberately answer-free.

RULE **Three anchors hold the chapter.** One split (dissociation of the mind versus dissociation of the body), one mechanism (the benzodiazepine raises the *frequency* of chloride-channel opening, not its duration), and one management rule (the benzodiazepine is a short-course drug, never a first-line long-term anxiolytic). Recover those three and the detail hangs off them.

16.3 Retrieval prompts: the dissociative discriminators

Cover the vaults below and answer from memory. Each prompt targets the single discriminator the examiner tests, not a general description. Work them as **retrieval practice**, then check against the criterion vault.

1. Name the seven ICD-11 dissociative types and, for each, the one integrative function that has failed.
2. What single discriminator separates dissociative amnesia from an organic amnestic syndrome, and is fugue a disorder or a specifier?
3. Beyond two or more distinct personality states, which criterion is mandatory for dissociative identity disorder, and what two competing models explain its cause?
4. What distinguishes partial dissociative identity disorder from the full disorder?
5. What keeps depersonalisation-derealisation disorder on the non-psychotic side of the line, and what scale threshold is conventionally diagnostic?
6. State the cultural-exclusion criterion that both trance disorder and possession trance disorder must satisfy, and how the two differ.
7. Where does conversion sit in ICD-11 versus DSM-5-TR, and why is that the pivotal filing difference?

16.4 Retrieval prompts: the conversion signs and the measure

Still covered. These carry the highest bedside yield of the mind-and-body half, the positive signs that rule conversion *in*, and the screen that flags dissociation for interview.

1. Name the five positive rule-in signs of a functional neurological symptom, and say what each one demonstrates.
2. Is conversion a diagnosis of exclusion, and is an identifiable psychological stressor required? What is the diagnostic status of la belle indifference?
3. Which single sign would you elicit first at the bedside for a functional leg weakness, and what is the positive finding?
4. What is the conventional Dissociative Experiences Scale (DES) screening cut-off, and what do you do for a patient who scores above it?
5. What does the DES-Taxon subscale add, and what does the SDQ-20 capture that the DES does not?

GOOD TO REMEMBER

- **Dissociative amnesia:** defining criterion is an inability to recall important autobiographical information inconsistent with normal forgetting; the deficit is *retrograde* with intact new learning (the discriminator from organic amnesia); fugue is a specifier. First step: exclude an organic amnestic cause.
- **Dissociative identity disorder:** two or more distinct personality states (or possession) *plus* recurrent dissociative amnesia; the amnesia criterion is the discriminator; trauma / structural-dissociation model versus the sociocognitive (fantasy) model.
- **Depersonalisation-derealisation disorder:** persistent detachment with *intact reality testing* and an "as if" quality, the intact reality check being the discriminator from psychosis; a Cambridge Depersonalisation Scale score of 70 or more is the conventional threshold.
- **Trance / possession trance disorder:** narrowed awareness with identity intact (trance) versus identity replaced by an external agent with amnesia (possession); both require the state to be involuntary, distressing and *outside accepted cultural or religious practice*. First step: apply the cultural-exclusion criterion.
- **Dissociative / functional neurological symptom disorder:** a neurological symptom with a *positive* sign of internal inconsistency (Hoover's sign, tremor entrainment, give-way weakness, tubular visual field, astasia-abasia); it is *not* a diagnosis of exclusion, no stressor is required, and la belle indifference is unreliable. First step: elicit a positive sign.

16.5 Retrieval prompts: the benzodiazepine mechanism and kinetics

Cover the dose vault below. The pharmacology half rewards the mechanism first, then the half-life sort, because everything clinical follows from those two.

1. State the benzodiazepine mechanism at the GABA-A receptor, which parameter of chloride-channel opening it raises, where its binding site lies, and how the barbiturate differs.
2. Why is a benzodiazepine relatively safe in a pure overdose while a barbiturate is not?
3. Sort lorazepam, alprazolam, clonazepam, diazepam and chlordiazepoxide into short-to-intermediate versus long-acting, and name the shared active metabolite of the long-acting agents.

4. Which three benzodiazepines have no active metabolite, making them the liver-safe choice, and what mnemonic names them?
5. Which receptor subtype carries sedation, and which carries anxiolysis?

16.6 Retrieval prompts: withdrawal, taper and selection

Still covered. These are the single most examinable management statements of the material, so retrieve them cleanly and check against the dose vault.

1. What are the dangerous features of benzodiazepine withdrawal, and why must the drug never be stopped abruptly?
2. Describe the taper, onto which agent you consolidate and at what rate you reduce.
3. Name the benzodiazepine antagonist, its half-life problem, and its signature hazard.
4. What is the first-line pharmacological treatment for generalised anxiety disorder, precisely where does the benzodiazepine sit, and what is the NICE ceiling on a benzodiazepine course?
5. What is first-line for chronic insomnia, and which non-benzodiazepine anxiolytic works only after a delay and carries no dependence?

30	0.5 to 6	20 to 50	10%
DES SCREENING CUT-OFF	ALPRAZOLAM ANXIETY DOSE (MG PER DAY)	DIAZEPAM ELIMINATION HALF-LIFE (HOURS)	TAPER: FRACTION OF LAST DOSE EVERY 2 TO 4 WEEKS

GOOD TO REMEMBER

- **Diazepam (Valium, Calmpose):** GABA-A positive allosteric modulator; 4 to 40 mg per day in divided doses; long-acting through the active metabolite nordiazepam; the consolidation anchor of the taper, with diazepam 10 mg equal to clonazepam 0.5 mg, lorazepam 1 mg and chlordiazepoxide 25 mg (Maudsley).
- **Alprazolam (Alprax, Restyl):** short-to-intermediate (half-life 6 to 20 hours), high-potency; anxiety 1 to 4 mg per day (5 to 6 mg per day is the panic figure, not the anxiolytic range); the most toxic benzodiazepine in overdose and the hardest to taper, and the Indian default anxiolytic despite both.
- **Clonazepam (Clonotril, Rivotril):** long-acting (half-life 30 to 40 hours), high-potency; panic 0.5 to 2 mg per day; the other taper-consolidation agent and the substitute that eases the final doses of alprazolam.
- **Lorazepam (Ativan, Loraz):** short-to-intermediate (half-life 10 to 20 hours), no active metabolite so liver-safe; oral 2 to 6 mg per day; the catatonia challenge agent at 1 to 2 mg.
- **Buspirone (Buspin):** a 5-HT1A partial agonist, 20 to 30 mg per day; a *delayed* onset of 2 weeks or more with no dependence, sedation or anticonvulsant effect, so it spares the benzodiazepine in sustained anxiety but is useless acutely.
- **Zolpidem (Zolfresh, Nitrest):** a z-drug at the benzodiazepine-1 (omega-1) GABA-A subtype, 10 mg at bedtime for short-term use; the signature caution is complex sleep behaviours, dependence and next-day impairment.
- **Flumazenil (the antagonist):** a competitive benzodiazepine-receptor antagonist with a short half-life of 41 to 79 minutes (so re-sedation and repeat dosing); it can *precipitate seizures* in benzodiazepine dependence and in mixed or cyclic-antidepressant overdose, so it is used selectively.

16.7 The whole-chapter synthesis map

Cover the branches and redraw from memory. The final and highest-value exercise is to reproduce the chapter as one picture. The accompanying figure sets out the **synthesis map** as a single tree, a trunk labelled by the master mnemonic, three primary branches (mind, body, GABA), and the named entities and anchors hanging off each. Study it once, then cover every branch and **redraw from memory** on blank paper, writing the discriminator or the dose at each leaf. The mind branch should regrow its five entities, each with its failed integrative function; the body branch its one entity with the positive-sign list; the GABA branch the mechanism, the half-life classes, the withdrawal-and-taper, flumazenil and the short-course rule. A branch you cannot regrow is a branch to reread. This cover-the-branches redraw is the most compact single test of whether the chapter is genuinely consolidated.

INDIA

Two Indian threads run the length of this chapter and belong on the synthesis map. On the pharmacology side, India carries a genuine benzodiazepine over-prescription problem, with **alprazolam** the reflex default anxiolytic despite being the most toxic in overdose and the hardest to taper; the Indian Psychiatric Society position and the wider benzodiazepine-sparing principle favour the SSRI or SNRI for sustained anxiety and CBT for insomnia, keeping the benzodiazepine to a genuine short course. On the dissociative side, trance, possession and conversion presentations are among the most frequent dissociative pictures in Indian practice, which makes the cultural-exclusion criterion and a proper cultural formulation, not a reflex sedative, the examinable core. The transcultural reading is expanded in the Consultation-liaison, geriatric & transcultural psychiatry notes.

TRAP **The chapter's recurring errors, in one line.** Missing an organic cause behind a "conversion" picture, diagnosing dissociative identity disorder without the dissociative-amnesia criterion, reading depersonalisation-derealisation as psychosis, starting a benzodiazepine for chronic anxiety or insomnia, and stopping a benzodiazepine abruptly and risking a seizure, five traps, one per section.

HOLD THIS

If you can say *MIND SPLITS, BODY SPEAKS, GABA SLEEPS* and, from it, regrow the mind-side discriminators, the conversion positive signs, the DES cut-off of 30, the frequency-not-duration mechanism and the never-abrupt, short-course-only benzodiazepine rule, the chapter is consolidated; wherever you cannot, that gap is the reread.

For the receptor systems behind the GABA-A detail see the Neurochemistry, Neuroendocrinology, Neuroimaging & Basic Psychopharmacology notes; for the sedative and benzodiazepine use disorder as an addiction the Substance use disorders notes; for the SSRIs and SNRIs that outrank the benzodiazepine as first-line anxiolytics the Mood disorders: pharmacotherapy notes; and for chronic insomnia and CBT for insomnia the Eating & sleep-wake disorders notes.

Previously asked

This territory is examined at two levels at once: the syndrome (the dissociative and conversion presentations, the positive signs that rule them in, the organic differential that must be excluded and the management that follows) and the pharmacology (the benzodiazepines and the wider anxiolytic and hypnotic agents, their receptor action and the dependence and withdrawal they carry). The dissociative and conversion questions on record are written in the older hysteria vocabulary, so the same case can be labelled hysterical unconsciousness, conversion disorder or functional neurological disorder across sittings, and a strong answer reconciles the ICD-11 and DSM-5 naming with the term used in the stem. Every long essay ends in a differential and a guideline-anchored management plan, so the organic-versus-functional decision and the first-line plan must be exam-ready. The genuine questions on record are grouped below. The clinical anxiety and obsessive-compulsive disorders these agents actually treat are developed in the Anxiety, obsessive-compulsive and trauma- and stressor-related disorders notes; the somatic-symptom and illness-anxiety boundary that sits beside conversion is developed in the Somatic-symptom, sexual, impulse-control disorders and suicide notes; and the GABA-A receptor pharmacology behind the anxiolytics and hypnotics is developed in the Neurochemistry, neuroendocrinology, neuroimaging and basic psychopharmacology notes, while the dissociative classification, the positive functional signs, the conversion management and the anxiolytic and hypnotic agents are owned here.

HOW THIS TERRITORY IS ACTUALLY TESTED

Q **Conversion disorder and the dissociative presentation of unconsciousness.** "Define consciousness. Differential diagnosis for unconsciousness in middle aged male. How to investigate and manage a case of Hysterical Unconsciousness?" has come as a full 25-mark essay, "Discuss etiology, clinical features and management of Hysterical Conversion Disorder" has come as a 25-mark essay, and "Clinical features and differential diagnosis of Conversion Disorder" has come as a 25-mark essay in its own right. Prepare the conversion and functional-neurological presentation, the positive signs that rule the disorder in (Hoover's sign, the hip-abductor and give-way patterns, tremor entrainment and the tubular visual field), the organic differential for unconsciousness that must be excluded first, the dissociative mechanism behind the symptom and the caveat that la belle indifference is neither sensitive nor specific, and the management line (exclude organic disease, explain the diagnosis as a real and reversible one, physiotherapy-led rehabilitation and treatment of the comorbid depression or anxiety). 25-mark essay, 2013 / 2014 / 2016

Q **Benzodiazepine dependence and the anxiolytic and hypnotic agents.** "Benzodiazepine Dependence" has come as a standalone 10-mark note. Prepare the receptor pharmacology (the GABA-A benzodiazepine site and its chloride-channel action), the tolerance and dependence that follow continued use, the withdrawal syndrome with its rebound anxiety, perceptual disturbance and seizure risk, the over-prescription context that drives the problem in Indian practice where a somatising anxious patient is handed alprazolam or clonazepam rather than started on the agent that treats the disorder, and the management (a slow graded taper, the switch to a long-acting agent such as diazepam, and the reservation of these drugs for short-term crisis use only). 10-mark note, 2016

Prepare this material to be diagnosed and treated, not just recited: the organic-versus-functional differential, the positive functional-sign figures, the dissociative classification set against the ICD-11 and DSM-5, the dose-anchored good-to-remember boxes and the benzodiazepine taper schedule in these notes are built to the way the block is examined. The dissociative amnesia and fugue, the depersonalisation and derealisation, the dissociative identity and the possession and trance

presentations are not on the question record but sit squarely inside the classification the stems ask you to apply, and the non-benzodiazepine anxiolytics and hypnotics (the Z-drugs, buspirone, melatonin and ramelteon, and flumazenil as the antidote) are catalogued as an essay only in the basic-pharmacology paper, so both are prepared here to the same depth. The clinical anxiety and obsessive-compulsive disorders these agents treat live in the Anxiety, obsessive-compulsive and trauma- and stressor-related disorders notes; the somatic-symptom and illness-anxiety boundary in the Somatic-symptom, sexual, impulse-control disorders and suicide notes; and the receptor-level pharmacology in the Neurochemistry, neuroendocrinology, neuroimaging and basic psychopharmacology notes.

Quick review in one table

THE DISSOCIATIVE DISORDERS OF THE MIND: THE DISCRIMINATOR AND THE FIRST STEP	
THE ORGANISING SPLIT	Dissociation of the **mind** (consciousness, memory, identity) versus the **body** (motor and sensory control). ICD-11 keeps conversion inside the family (6B60); DSM-5-TR exports it to the somatic disorders. First step: name which integrative function came apart and the diagnosis names itself.
DISSOCIATIVE AMNESIA (AND FUGUE)	Discriminator: a **retrograde** loss of autobiographical memory with **new learning intact** and identity often lost (the mirror of organic amnesia); localised is commonest, fugue is a specifier. First step: exclude an organic amnestic cause.
DISSOCIATIVE IDENTITY DISORDER	Discriminator: two or more distinct identity states **plus recurrent dissociative amnesia** (the required, most-tested criterion; drop it and it is other specified dissociative disorder). First step: confirm the amnesia criterion. Debate: trauma model versus sociocognitive (fantasy) model.
PARTIAL DISSOCIATIVE IDENTITY DISORDER	Discriminator: one dominant state runs daily life, intruded on by non-dominant states that do **not** take executive control (full disorder = states seize control, partial = they only intrude); an ICD-11 category, filed under other specified dissociative disorder in DSM-5-TR.
DEPERSONALISATION-DEREALISATION DISORDER	Discriminator: persistent detachment from self and/or world with an "as if" quality and **intact reality testing** (the separator from psychosis). First step: confirm reality testing is preserved. A Cambridge Depersonalisation Scale score of 70 or more is the conventional threshold.
TRANCE DISORDER	Discriminator: narrowed awareness of surroundings with a small, seemingly uncontrolled behavioural repertoire, the **self still intact** (no identity replacement); normal EEG even during episodes. First step: apply the cultural-exclusion criterion and clear the organic mimics.
POSSESSION TRANCE DISORDER	Discriminator: the sense of identity is **replaced by an external possessing agent** (spirit, deity, demon) with amnesia; the external attribution separates it from dissociative identity disorder. First step: apply the cultural-exclusion criterion (a sanctioned, non-distressing ritual is not a disorder).
CONVERSION, ITS SEIZURE FORM, AND MEASURING DISSOCIATION	
CONVERSION (DISSOCIATIVE NEUROLOGICAL SYMPTOM DISORDER)	Discriminator: a motor or sensory symptom with a **positive sign of internal inconsistency** (Hoover's sign, tremor entrainment, tubular field), weak on command but strong on distraction; a **rule-in** diagnosis, no stressor required, la belle indifference unreliable. First step: elicit a positive sign.

CONVERSION, ITS SEIZURE FORM, AND MEASURING DISSOCIATION	
DISSOCIATIVE (NON-EPILEPTIC) CONVULSIONS	Discriminator: a seizure-like attack with preserved awareness in bilateral shaking, closed and resisted eyes, a long fluctuating course, no post-ictal prolactin rise, and a **normal ictal video-EEG** (the gold standard). Tongue-biting and incontinence do not distinguish it. First step: capture the attack on video-EEG.
MEASURING DISSOCIATION (DES)	The Dissociative Experiences Scale is the self-report screen; a **mean of 30 or more** flags a probable dissociative disorder and prompts a structured interview (SCID-D, DDIS). The DES-Taxon isolates pathological dissociation; the SDQ-20 captures somatoform dissociation. A high score is a flag, never a diagnosis.

THE GABA-A SEDATIVE-HYPNOTICS: MECHANISM, USE AND CAUTION	
BENZODIAZEPINES (THE CLASS)	A **positive allosteric modulator** at the GABA-A receptor (benzodiazepine site, alpha-gamma interface): raises the **frequency** of chloride-channel opening only when GABA is present (barbiturates raise the **duration**). GABA-dependence gives a ceiling, so relatively safe in pure overdose. Alpha-1 sedation, alpha-2 anxiolysis.
AGENTS AND HALF-LIFE	Short-to-intermediate: lorazepam (10 to 20 h, no metabolite, liver-safe), **alprazolam** (12 to 15 h, high-potency). Long-acting through shared nordiazepam: diazepam, chlordiazepoxide; clonazepam (30 to 40 h). LOT group (lorazepam, oxazepam, temazepam) has no active metabolite. Alprazolam **1 to 4 mg per day for anxiety** (5 to 6 mg per day only for panic), most toxic in overdose, hardest to taper.
WITHDRAWAL AND TAPER	Withdrawal: rebound anxiety, perceptual disturbance and autonomic arousal, with the criterion-level dangers of **seizures**, psychosis and delirium. **Never stop abruptly.** Taper: consolidate onto a long-acting agent (diazepam or clonazepam), reduce about 10% of the last dose every 2 to 4 weeks (diazepam 10 = clonazepam 0.5 = lorazepam 1 = chlordiazepoxide 25 mg).
FLUMAZENIL (THE ANTAGONIST)	The competitive benzodiazepine-receptor **antagonist**; short half-life 41 to 79 minutes, so re-sedation and repeat dosing. Signature caution: it can **precipitate seizures** in benzodiazepine dependence and in mixed or cyclic-antidepressant overdose, so it is used selectively, not routinely.
Z-DRUGS (ZOLPIDEM, ZOPICLONE, ZALEPLON, ESZOPICLONE)	Non-benzodiazepine hypnotics that still modulate the GABA-A benzodiazepine site, selective for the **omega-1 (alpha-1)** subtype. Use: a short-term hypnotic after CBT for insomnia, matched by half-life (zolpidem 5 to 10 mg for onset, zopiclone for maintenance). Caution: **complex sleep behaviour**, dependence, next-day impairment.

THE NON-GABA ANXIOLYTICS AND THE OTHER HYPNOTICS	
BUSPIRONE (AZAPIRONE)	A **5-HT1A partial agonist**, not a GABA drug; 15 to 30 mg per day (short half-life 2 to 3 h). Use: acute GAD, sitting after an SSRI and before a benzodiazepine. Caution: a **delayed onset of 2 weeks or more**, so useless as a PRN, but no dependence, sedation or anticonvulsant effect.
GABAPENTINOIDS (PREGABALIN, GABAPENTIN)	**Alpha-2-delta calcium-channel ligands** (despite the name, not GABA drugs). Pregabalin 150 to 600 mg per day is the licensed **alternative first-line** for GAD; gabapentin 900 to 1800 mg per day is off-label. Caution: now recognised drugs of **misuse and dependence**, never stop abruptly (seizure).
PROPRANOLOL (BETA-BLOCKER)	A peripheral **beta-adrenergic antagonist**: strips the palpitations and tremor, not the dread. Use: the somatic symptoms of **performance and social anxiety**, a single 10 to 40 mg dose about an hour before the event. Caution: no effect on psychic anxiety; avoid in asthma and bradycardia.
HYDROXYZINE (ANTIHISTAMINE)	A sedating **H1 antagonist**; 50 to 100 mg up to four times a day (half-life about 20 h). Use: efficacious in **acute GAD** (BAP), no dependence, not controlled. Caution: sedation, anticholinergic effects, and QT prolongation at higher doses.
ETIFOXINE	A non-benzodiazepine anxiolytic with a **dual action**: direct GABA-A modulation plus translocator-protein (TSPO)-driven neurosteroid (allopregnanolone) synthesis; about 150 to 200 mg per day. Non-inferior to lorazepam and alprazolam over 4 weeks with less rebound. Caution: rare hepatic and severe cutaneous reactions; an alternative, not a first-line SSRI.
MELATONERGIC AGONISTS (MELATONIN, RAMELTEON)	**MT1/MT2 agonists** on the suprachiasmatic clock (MT1 onset, MT2 phase-shift), not the GABA channel. Use: prolonged-release melatonin 2 mg for the over-55 and as a taper-insomnia adjunct; ramelteon 8 mg for sleep-onset. Caution: a modest effect, no dependence; ramelteon with fluvoxamine is dangerous (CYP1A2).
DUAL OREXIN RECEPTOR ANTAGONISTS (DORAS)	**Dual OX1/OX2 orexin (hypocretin) antagonists** that promote sleep by subtracting wakefulness, not by adding GABAergic sedation. Use: insomnia when CBT for insomnia is not the route (suvorexant 10 to 20, lemborexant 5 to 10, daridorexant 25 to 50 mg nocte). Caution: next-morning somnolence, so leave a 7-hour sleep window.
THE GUIDELINE SPINE AND THE HARD RULES	
ANXIETY, FIRST-LINE	**An SSRI or SNRI is first-line** for GAD; pregabalin and buspirone are the alternatives, hydroxyzine and buspirone cover acute anxiety, and propranolol the performance type. A benzodiazepine is not first-line and not for maintenance.

THE GUIDELINE SPINE AND THE HARD RULES	
INSOMNIA, FIRST-LINE	**CBT for insomnia is first-line** for chronic insomnia; a hypnotic (benzodiazepine, z-drug, melatonin or a DORA) is a short-term option only, matched by half-life to the onset-versus-maintenance pattern.
THE BENZODIAZEPINE SHORT-COURSE RULE	A benzodiazepine is a **2 to 4 week crisis measure** at most (NICE), then tapered, and is **never stopped abruptly** because withdrawal seizures can be fatal. India's alprazolam-default habit is exactly the pattern the benzodiazepine-sparing position corrects.
THE DISSOCIATIVE FIRST-MOVE	For a possession, trance or dramatic dissociative presentation the first move is a **cultural formulation and exclusion of an organic cause**, not a reflex sedative; a sanctioned, non-distressing ritual is not a disorder, and dissociation has no benzodiazepine indication.
THE FIVE TRAPS	Missing an organic cause behind a "conversion"; diagnosing dissociative identity disorder **without the amnesia** criterion; reading depersonalisation-derealisation as psychosis; starting a benzodiazepine for chronic anxiety or insomnia; and stopping a benzodiazepine abruptly.

References

The dissociative, conversion and anxiolytic-and-hypnotic content is grounded in the standard psychiatry and psychopharmacology sources (the source hierarchy below), with Kaplan and Sadock as the depth bar for the dissociative phenomenology, the three pathogenesis models and the scale cut-offs, the New Oxford Textbook (Stone and Carson) for the positive-sign, rule-in approach to functional neurological disorder, and the Maudsley Prescribing Guidelines and Stahl as the depth bar for the receptor mechanisms, the half-life classes, the doses, the diazepam-equivalence table and the taper. The management is guideline-first, led by the British Association for Psychopharmacology (anxiety 2014, insomnia 2019, substance dependence), with NICE and the Indian Psychiatric Society. Every criterion, receptor detail, dose, half-life, equivalence and first-line or short-course statement was checked against these sources and the adversarial content pass; anything that could not be confirmed was omitted and flagged rather than guessed. Each journal PMID below was verified against PubMed this build and matched on title, first author and year; identifiers that resolved to the wrong paper were corrected or dropped. Books, classifications and guideline documents without a MEDLINE record are cited by author, title and year without a PMID.

PAPER II

Personality disorders: framework, types and treatment

Three sections . one complete notes document

This material gathers the personality disorders into one document, first the framework and the classification, then the disorders themselves, then how they are assessed and treated. The first band is **the framework and classification**: the definition and the general diagnostic criteria that must hold before any type is named, the ICD-11 dimensional model that abolished the categorical types for a severity gradient and a set of trait domains, the DSM-5 categorical clusters and their ten types with the alternative hybrid model alongside, and the comparison of the two approaches. The second band is **the personality disorders by cluster**: the cluster A odd and eccentric disorders, borderline personality disorder as the highest-yield type with its features, course and complications, antisocial personality disorder and its forensic significance, the histrionic and narcissistic disorders, the cluster C anxious and fearful disorders, and the borderline-versus-bipolar-II differential that examiners return to. The third band is **aetiology, assessment and treatment**: the genetic, neurobiological and developmental aetiology and the Linehan biosocial model, the assessment instruments and structured interviews, and the treatment block, dialectical behaviour therapy, schema therapy, mentalisation-based and transference-focused psychotherapy, the symptom-targeted pharmacotherapy, and the integrated borderline plan. The examinable skill is the safe, guideline-anchored diagnosis and treatment of each disorder: which criteria gate a personality-disorder diagnosis, how the classification shifted and why exams still test the categorical names, which disorder behind which presentation, the borderline-versus-bipolar-II boundary, which structured psychotherapy for which patient, and the rule that a drug is not the first-line treatment for borderline personality disorder.

HOW TO USE THESE NOTES

Read the three bands as one continuous account of how the personality disorders are classified, recognised and treated. The **framework and classification** band builds the frame: the general criteria that gate every diagnosis, the headline nosology shift where ICD-11 replaced the categorical types with a dimensional model of severity and trait domains, the DSM-5 categorical clusters and their ten types cross-mapped, and why exams still test both. The **personality disorders by cluster** band teaches the disorders themselves, cluster A, borderline personality disorder in full, antisocial personality disorder and its forensic frame, the histrionic and narcissistic disorders, cluster C, and the borderline-versus-bipolar-II differential. The **aetiology, assessment and treatment** band teaches the aetiology and the Linehan biosocial model, the assessment instruments, and the treatment block, where structured psychological therapy is primary and dialectical behaviour therapy, schema therapy, mentalisation-based and transference-focused psychotherapy are owned and fully taught here. Every management recommendation is guideline-anchored, led by NICE with the Indian Psychiatric Society and WFSBP positions stated, on the where-to-treat, target-by-phase, modes-of-treatment spine; every named disorder ends with a **Good to remember** box giving the defining criterion, the discriminator and the first step, and every named therapy ends with one giving the mechanism, the indication and the signature caution. Figures declare one axis and code it in colour: **petrol** marks structure and the neutral case, **coral** marks the trap or the danger, and **marigold** highlights the number to hold. Several boundaries are stated up front and cross-referenced by chapter name: the deep pharmacology of the mood stabilisers, low-dose antipsychotics and serotonin reuptake inhibitors used in symptom-targeted treatment is taught in the Mood disorders: pharmacotherapy notes and the Schizophrenia: management, antipsychotics and adverse effects notes; the bipolar-II side of the differential in the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes; the forensic frame of antisocial personality disorder in the Mental health legislation and forensic psychiatry notes; the complex-PTSD boundary in the Anxiety, OCD and trauma-related disorders notes; the schizotypal-versus-schizophrenia boundary in the Schizophrenia: aetiology, phenomenology, classification and course notes; and the wider psychotherapy models in the Psychotherapies, clinical assessment, MSE and nosology notes. This is doctor-facing revision, so the full technical vocabulary is used, brand names lead with the Indian brand, and every criterion, trait domain, cluster mapping, severity anchor, dose and guideline rule is verified against a source or omitted and flagged.

Framework and classification

1 . Definition, concept and general diagnostic criteria

Why this leads the chapter. Every personality-disorder question turns on one gate that most candidates skip. Before any of the ten named types can be diagnosed, a set of **general diagnostic criteria** must ALL hold: an **enduring pattern** of inner experience and behaviour that is **pervasive and inflexible**, deviates markedly from the person's culture, begins by adolescence, is stable over time, is not better explained by another disorder or a substance, and causes clinically significant impairment or distress. A personality disorder is not diagnosed by pattern-matching a vignette to a type; it is diagnosed by first clearing this general threshold and only then asking

which type fits. Get the gate right and the whole family, however you later classify it, becomes a disciplined exercise; get it wrong and you will pin a lifelong label on a situational mood state.

This fragment sets the **definition of personality disorder**, walks the six-part general threshold criterion by criterion, and isolates the four features an examiner rewards: the **ego-syntonic** quality, the trait-versus-state caution, the cultural reading, and the rule that no type is named until the general criteria are met. The accompanying figure lays the same content out as a general-criteria decision map to be carried as one image. The forward split into the ICD-11 dimensional model and the DSM-5-TR categorical clusters is developed in the topics that follow; the borderline-versus-bipolar-II boundary is cross-referenced to the Mood disorders: classification, depressive & bipolar syndromes, neurobiology notes, the forensic weight of antisocial personality disorder to the Mental health legislation & forensic psychiatry notes, the complex-PTSD boundary to the Anxiety, OCD & trauma-related disorders notes, and the wider technique of the psychological therapies to the Psychotherapies, clinical assessment, MSE & nosology notes.

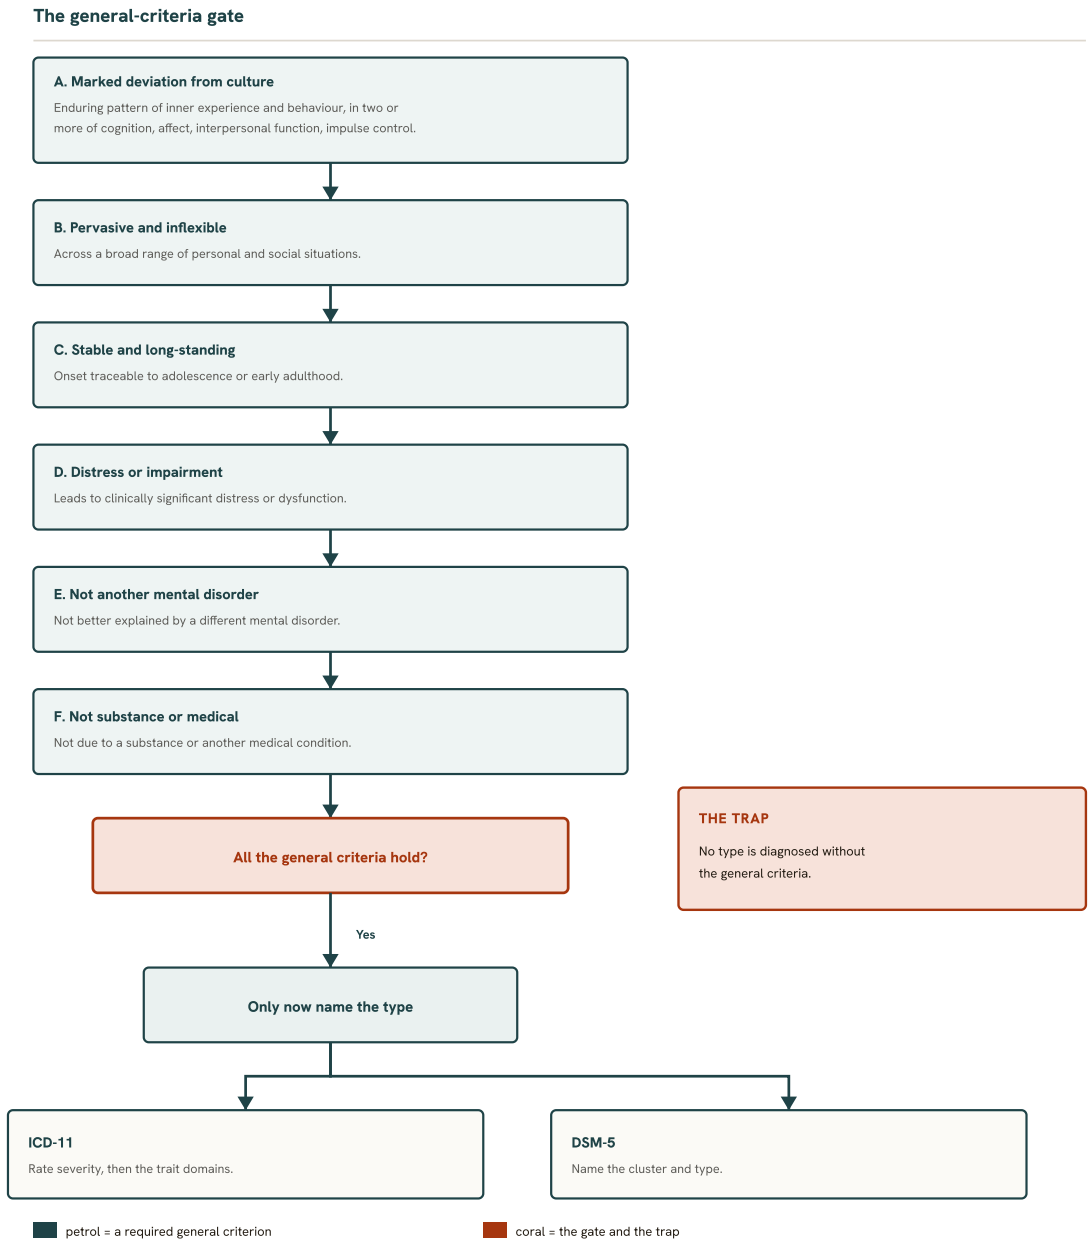

Fig 16.1 The general criteria for a personality disorder are a gate: the pattern must be enduring, pervasive and inflexible, deviate from cultural expectation, begin by adolescence or early adulthood, cause distress or impairment, and not be better explained by another disorder or a substance before any specific type is named.

1.1 Personality, trait, and what makes a disorder

A disorder is the maladaptive extreme of a normal continuum. Personality is the characteristic, deeply ingrained pattern of perceiving, relating to and thinking about oneself and the environment (DSM-5-TR). *Personality traits* are the normal, prominent aspects of that pattern; they become a disorder only when they are inflexible and maladaptive and cause significant functional impairment or subjective distress (DSM-5-TR). That single hinge, from normal-but-prominent to inflexible-and-impairing, is the working **definition of personality disorder**. The concept has a long descriptive spine: Kurt Schneider defined the abnormal (psychopathic) personalities as those who suffer from their abnormality or make society suffer, dissolving the older moral reading into a clinical one. ICD-11 phrases the modern definition as a

marked disturbance in personality functioning, with the central manifestations being impairments in aspects of the *self* (identity, self-worth, capacity for self-direction) and in *interpersonal* functioning (forming and keeping close relationships, understanding others, managing conflict). Hold both halves, self and other, because the dimensional model that follows is built on exactly this pair.

PEARL

The two manuals fight over how to sub-type personality pathology but barely differ on what it *is*: DSM-5-TR and the ICD systems give very similar GENERAL definitions of personality disorder, each locating the core pathology in cognition about self and others, emotional experience and regulation, interpersonal relating and behavioural control (Companion). Learn the general definition once; it survives every classification change.

1.2 The general diagnostic criteria: the six-part gate

All six must hold before any type. The DSM-5-TR general personality disorder criteria are the cleanest checklist to memorise, and the ICD equivalents map onto them almost one to one. They run: an enduring pattern deviating markedly from cultural expectation, shown in at least two areas of functioning (Criterion A); the pattern is inflexible and pervasive across situations (B); it causes clinically significant distress or impairment (C); it is stable and long-standing with onset traceable to adolescence or early adulthood (D); it is not better explained by another mental disorder (E); and it is not due to a substance or another medical condition (F). Reproduce the block as one table; this is the highest-yield single object in the chapter.

CRITERION	WHAT IT REQUIRES
A - Pattern and areas	**An enduring pattern of inner experience and behaviour deviating markedly from the person's culture, shown in two or more of four areas: cognition, affectivity, interpersonal functioning, impulse control**
B - Pervasiveness	The pattern is inflexible and pervasive across a broad range of personal and social situations
C - Impairment	It leads to clinically significant distress or impairment in social, occupational or other important functioning
D - Onset and stability	The pattern is stable and of long duration, with onset traceable back at least to adolescence or early adulthood
E - Not another disorder	Not better explained as a manifestation or consequence of another mental disorder
F - Not organic or substance	Not attributable to the physiological effects of a substance or another medical condition (for example head trauma)

The DSM-5-TR general criteria for a personality disorder (A to F); the ICD-11 essential features map closely onto the same requirements.

RULE **Clear the gate, then name the type.** No specific personality disorder is diagnosed unless every general criterion (enduring, pervasive and inflexible, culturally deviant, onset by adolescence, impairing, and not better explained) is first satisfied. The type is a sub-question that only opens once the gate is passed.

1.3 The four channels of deviation (Criterion A)

Two or more of four must be involved. Criterion A is not satisfied by trouble in one domain of life; the enduring pattern must show up in **two or more of the four** channels below. Learning these four is what lets you defend a diagnosis, because they force you to demonstrate that the disturbance is broad rather than a single symptom.

Cognition

Ways of perceiving and interpreting self, other people and events (for example pervasive suspiciousness, or a chronically fragile self-image).

Affectivity

The range, intensity, lability and appropriateness of emotional response (for example constricted flat affect, or rapidly reactive mood).

Interpersonal functioning

The characteristic pattern of relating (for example detachment and avoidance, or intense and unstable relationships).

Impulse control

The regulation of urges and behaviour (for example recurrent recklessness, aggression or self-damaging impulsivity).

1.4 Enduring, pervasive and inflexible, with onset by adolescence (Criteria B and D)

Trait-like breadth and lifelong reach are what separate a disorder from an episode. The words are load-bearing. *Enduring* and *stable* mean the pattern has run for years, not weeks; ICD-11 asks for a disturbance persisting over an extended period, typically two years or more. *Pervasive and inflexible* mean it holds across a broad range of personal and social situations rather than being triggered by one relationship or setting, and that the person cannot flex out of it when circumstances change. *Onset by adolescence* or early adulthood means the roots are developmental: an **enduring pattern** that first appears in mid or late adult life is a red flag for a personality change due to another medical condition or an unrecognised substance use disorder, not a primary personality disorder (DSM-5-TR). A pattern that is genuinely pervasive and inflexible with onset by adolescence is the developmental signature you are hunting for.

1.5 Deviation from cultural expectation (the cultural criterion)

The yardstick is the person's own culture, not the clinician's. Criterion A demands **deviation from cultural expectation**: the pattern must depart markedly from what the individual's *own* culture expects in cognition, affect, relating and impulse control. DSM-5-TR is explicit that personality disorder must not be confused with problems of acculturation after migration, or with habits, customs, and religious or political values rooted in the person's background; behaviour that looks rigid or dysfunctional may in fact be an adaptive response to real cultural

constraints. This is not a soft caveat but part of the criterion itself, and it is where cross-cultural over-diagnosis happens.

TRAP **Reading personality through one culture's norms.** Scoring deference, family-embeddedness, religiously framed experience or protest that risks the person's own safety as pathological dependence, oddness or callousness, when it is normative in their community, converts a cultural difference into a false diagnosis. Judge deviation against the patient's culture, with an informant if needed.

1.6 Impairment or distress, and the two exclusions (Criteria C, E and F)

Deviance alone is not a disorder. A culturally deviant, enduring, pervasive pattern still is not a personality disorder unless Criterion C is met: it must cause clinically significant **impairment or distress** in social, occupational or other important functioning. Many people have marked, inflexible traits and function well; without the impairment or distress they carry a personality *style*, and ICD-11 formalises this as personality difficulty (QE50.7), a factor influencing health status rather than a mental disorder. The final two criteria are exclusions that protect against mislabelling: the pattern must not be better explained by another mental disorder (E), and must not be attributable to a substance or medical condition such as head trauma (F).

COMMON TRAP

The mirror error to over-diagnosis: reading the enduring interpersonal and cognitive changes of a chronic Axis I illness (long-standing depression, an anxiety disorder, early psychosis, a frontal lesion or ongoing substance use) as a personality disorder. Criteria E and F exist precisely to catch this. If a supposedly lifelong pattern in fact tracks the course of another disorder or a drug, the personality label is wrong.

1.7 The ego-syntonic quality, and trait versus state

The patient rarely complains of the very thing you are diagnosing. Classically the abnormal personality traits are **ego-syntonic**: they are experienced as part of the self and are not felt as problematic, in sharp contrast to the ego-dystonic symptoms of the neurotic disorders, which distress the patient and drive help-seeking. Two consequences follow. First, people with a personality disorder often do not present for the personality disorder itself, but for a comorbid depression, anxiety or crisis, so the diagnosis is easy to miss and easy to make only from collateral history. Second, and the single commonest error, the traits must be distinguished from *states*: features that emerge in response to a specific situational stressor or a transient mental state (a mood episode, an anxiety disorder, or substance intoxication) are not personality (DSM-5-TR). Because the pattern is developmental, in a person under eighteen the features must have been present for at least one year before a personality disorder is diagnosed, and antisocial personality disorder is never diagnosed before eighteen (DSM-5-TR), a rule with direct medico-legal force.

TRAP **Calling a state a trait.** The affective lability, impulsivity and stormy relationships of an acute mood episode, an intoxication or a fresh crisis are not a personality disorder unless the same pattern is enduring, pervasive and predates the current state. Diagnose personality when the patient is at baseline, not mid-storm.

INDIA

Personality disorders are substantially under-recognised in Indian practice, and the ego-syntonic quality is a large part of why: patients present for the comorbid depression, self-harm or family conflict, not for the personality pattern, so it is recorded only when it is actively looked for. Two further Indian angles are genuine. The cultural criterion bites hardest here: deference, joint-family interdependence and religiously framed experience are normative and must not be read as dependent, avoidant or odd pathology. And the disorder-specific psychotherapies are arriving but unevenly available: dialectical behaviour therapy and schema therapy are being delivered and culturally adapted at Indian tertiary and private centres rather than being widely accessible, which shapes what a realistic management plan can offer. The forensic reading of antisocial personality disorder in the Indian court context is carried in the Mental health legislation & forensic psychiatry notes.

1.8 The rule that governs the whole chapter, and the forward map

General criteria first; classification second. With the gate cleared, the chapter splits into two ways of describing what lies beyond it, both cross-mapped in the topics that follow. DSM-5-TR keeps the familiar *categorical* system: the ten types grouped into three clusters (A odd or eccentric, B dramatic or erratic, C anxious or fearful), plus a Section III alternative hybrid model. ICD-11 takes the opposite route, abolishing the categorical types for a *dimensional* model that rates a severity level first and then adds trait-domain qualifiers and an optional borderline pattern. Whichever framework an examiner uses, it is downstream of the same general criteria you have just cleared. The ten categorical types are worth carrying as a single skeleton from the outset.

CLUSTER	TYPE	DESCRIPTOR
A	Paranoid	Odd or eccentric
A	Schizoid	Odd or eccentric
A	**Schizotypal**	Odd or eccentric (schizophrenia-spectrum edge)
B	Antisocial	Dramatic, emotional or erratic
B	**Borderline**	Dramatic, emotional or erratic
B	Histrionic	Dramatic, emotional or erratic
B	Narcissistic	Dramatic, emotional or erratic
C	Avoidant	Anxious or fearful
C	Dependent	Anxious or fearful
C	Anankastic (obsessive-compulsive)	Anxious or fearful

The three DSM-5-TR clusters and ten categorical types; ICD-11 abolishes these types for a dimensional model, developed in the topics that follow.

WORKED EXAMPLE

A woman in her twenties is referred after an overdose following a break-up, described as having "borderline personality disorder". You do not accept the label yet; you run the gate. Is the pattern of stormy relationships, identity instability and impulsivity *enduring* and traceable to adolescence, or does it date from a recent depressive episode (Criterion D, and E)? Is it *pervasive* across settings, or confined to one relationship (B)? Does it cause impairment at baseline, not only in crisis (C)? Only when every general criterion holds do you move to the type-specific criteria. If the pattern proves to be a first depressive episode with situational distress, you have prevented a lifelong misdiagnosis.

GOOD TO REMEMBER

- **Personality disorder (general):** defining requirement is an enduring pattern of inner experience and behaviour, pervasive and inflexible, deviating markedly from cultural expectation in two or more of cognition, affectivity, interpersonal functioning and impulse control, with onset by adolescence, causing impairment or distress, and not better explained by another disorder, a substance or a medical condition. Discriminator from a personality *style*: the impairment or distress (Criterion C); ICD-11 codes the style short of this as personality difficulty. First diagnostic step: clear all the general criteria before naming any type.

1.9 The master hook for the whole chapter

One scaffold to reassemble the day. The chapter has four countable skeletons: the clusters and types, the ICD-11 trait domains, the borderline criterion count, and the core skills therapy. Carry them as one mnemonic now and every later topic hangs off it; the pieces are paid off in full at consolidation.

MNEMONIC

MAD BAD SAD, FIVE DOMAINS, NINE-FOR-FIVE, FOUR TO COPE

MAD BAD SAD are the three clusters holding the ten types: *mad* = Cluster A odd or eccentric (Paranoid, Schizoid, Schizotypal); *bad* = Cluster B dramatic or erratic (Antisocial, Borderline, Histrionic, Narcissistic); *sad* = Cluster C anxious or fearful (Avoidant, Dependent, Anankastic). **FIVE DOMAINS** are the ICD-11 trait qualifiers, hooked as *New Dogs Do Dig Antiques*: Negative affectivity, Detachment, Dissociality, Disinhibition, Anankastia (plus the optional borderline pattern). **NINE-FOR-FIVE** is borderline personality disorder, defined by **five or more of the nine** criteria. **FOUR TO COPE** is dialectical behaviour therapy and its four skills modules (mindfulness, interpersonal effectiveness, emotion regulation, distress tolerance). Four numbers, and the chapter rebuilds from one line.

3	10	5	4
DSM-5-TR CLUSTERS	CATEGORICAL PERSONALITY TYPES	ICD-11 TRAIT DOMAINS	DBT SKILLS MODULES

HOLD THIS

The general diagnostic criteria are a gate, not a description: an enduring, pervasive and inflexible pattern, deviating from cultural expectation, with onset by adolescence, causing impairment or distress, and not better explained otherwise, must all hold before any specific personality-disorder type is diagnosed.

2 · ICD-11 dimensional classification: severity and trait domains

Why this matters. This is the single highest-yield nosology point of the personality-disorders chapter, and the examiner knows it. The **ICD-11 dimensional** system did something no previous classification dared: it **abolished the categorical personality-disorder types altogether**. There is no ICD-11 code for paranoid, schizoid, dissocial, histrionic, anankastic, avoidant or dependent personality disorder. In their place stands a model that first rates **severity** and then, optionally, describes style. Get the architecture of that model straight, the severity gradient that leads and the five trait domain qualifiers that follow, and you can answer almost any framework stem the paper sets.

The governing idea is a reversal of habit. The old question was "which type is this?"; the ICD-11 question is "how severe is the personality dysfunction, and what is its flavour?". Severity is rated **first and leads** because the degree of disturbance in self and interpersonal functioning predicts outcome, service need and risk far better than any type label ever did (ICD-11 CDDR; New Oxford Textbook of Psychiatry). The alternative model of personality disorders in DSM-5-TR Section III (the hybrid AMPD) and the retained DSM-5-TR categorical clusters are cross-mapped here so the two systems can be held side by side, and a legacy ICD-10 box records exactly what was removed and why the categorical names still get tested. The accompanying figure lays the whole model out as one object: the severity gradient down one axis and the trait-domain qualifiers across the other, with the borderline pattern qualifier hung off to the side.

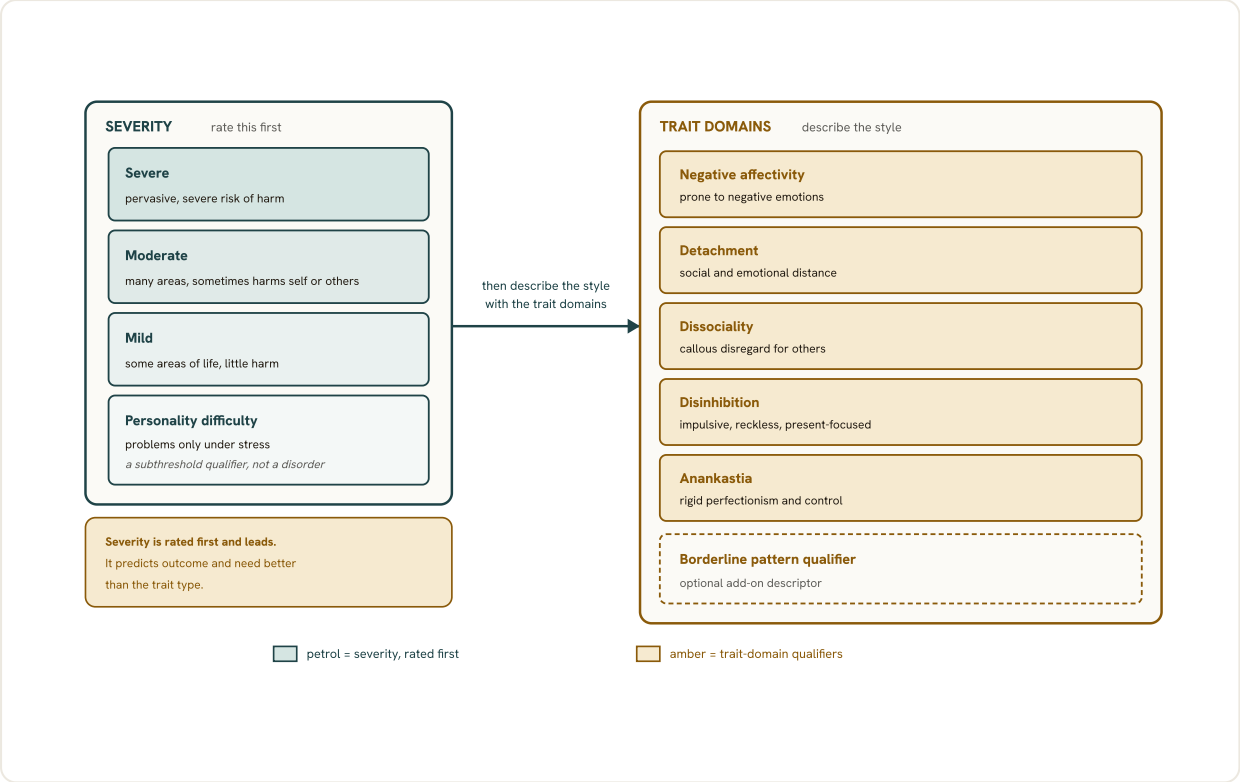

Fig 16.2 The ICD-11 model abolished the categorical types: rate severity first (personality difficulty, then mild, moderate or severe on a harm gradient), then describe the style with the five trait-domain qualifiers, negative affectivity, detachment, dissociality, disinhibition and anankastia, plus the optional borderline pattern qualifier.

2.1 The headline shift: types out, a dimensional model in

The ICD-11 dimensional model replaces the entire list of named types with a single diagnostic pathway (ICD-11 CDDR, grouping 6D10 to 6D11). You confirm the general criteria of a personality disorder (an enduring, pervasive, inflexible pattern of the self and of relationships, deviating from cultural expectation, with onset by adolescence or early adulthood and causing distress or impairment, all taught in the general-framework topic alongside), and then you make three moves in order. **First, rate severity** on a graded scale. **Second, add any of the five trait-domain qualifiers** that best describe the style of the disturbance. **Third, add the borderline pattern qualifier** if that specific picture is present. The type has vanished; the diagnosis is now a severity level plus a set of descriptive qualifiers. This is why the model is called dimensional rather than categorical: personality pathology is placed on continua of severity and trait, not sorted into boxes.

RULE **Severity is rated first and leads.** In the ICD-11 personality classification the degree of self-and-interpersonal dysfunction, not the type, is the primary axis, because severity predicts outcome and need better than any category.

2.2 How severity is defined, and why it carries the weight

Severity is judged on two linked capacities and one consequence. The capacities are **self functioning** (the stability and accuracy of identity, self-worth, self-direction and self-view) and **interpersonal functioning** (the desire and ability to form and sustain relationships, to grasp others' perspectives, and to manage conflict). The consequence is the associated **risk of harm** to self or others together with the breadth of functional impairment (ICD-11 CDDR). The rater asks

how pervasively these are disturbed, across how many domains of life, and with what danger attached. That single graded judgement then does the work the ten separate type-diagnoses used to do. The empirical case, built by Tyrer and the ICD-11 working group, is that the old categories overlapped so heavily that "type" was unreliable, whereas a simple severity rating tracks concurrent and prospective impairment robustly (New Oxford Textbook of Psychiatry).

PEARL

The reason severity leads is not administrative tidiness but prediction. Across longitudinal data the *severity* of personality dysfunction, more than its stylistic type, forecasts self-harm, suicide risk, service use, relationship breakdown and occupational failure. Rate severity well and you have already said the most prognostically useful thing about the patient.

2.3 The severity gradient: personality difficulty, then mild, moderate and severe

The gradient has a subthreshold rung and three disorder rungs. Personality difficulty (coded QE50.7, and deliberately placed not among the mental disorders but in the chapter on factors influencing health status) is **not a diagnosis of disorder**: it flags pronounced personality features that colour presentation or treatment without reaching the threshold. Above it sit mild personality disorder (6D10.0), moderate personality disorder (6D10.1) and severe personality disorder (6D10.2), separated by how many areas of functioning are affected and how much harm attaches. The table is the object to memorise; the highlighted cell in each row is the feature that fixes that level against its neighbours.

LEVEL (ICD-11 CODE)	SELF AND INTERPERSONAL FUNCTIONING	HARM AND IMPAIRMENT
Personality difficulty (QE50.7)	Pronounced features below the disorder threshold; some relevance to health or treatment	**Not a mental disorder; a health-status qualifier, not a diagnosis**
Mild personality disorder (6D10.0)	**Some areas of functioning affected, others spared; many relationships and expected roles still maintained**	Usually not associated with substantial harm to self or others
Moderate personality disorder (6D10.1)	**Marked problems in most relationships and most expected role functions; most areas of functioning affected**	May be associated with harm to self or others
Severe personality disorder (6D10.2)	**Severe disturbance of the sense of self (identity unstable or incoherent) and of nearly all relationships**	High risk of harm to self or others; severe functional impairment

The ICD-11 severity gradient: the subthreshold rung plus three disorder levels, read by degree of self-and-interpersonal dysfunction and attached risk of harm.

2.4 The five trait-domain qualifiers: describing the style once severity is set

Once severity is rated, one or more **trait-domain qualifiers** (postcoordinated codes 6D11.0 to 6D11.4) describe the prominent style of the disturbance. Each trait domain is a broad dimension,

not a type; a patient may carry several. The five, verbatim in construct, are set out below. Note the mnemonic order and hold them as a closed set: a sixth invented domain, or a missing one, is the classic slip.

Negative affectivity (6D11.0)
A tendency to experience a broad range of negative emotions (anxiety, anger, self-loathing, emotional lability, mistrust).

Detachment (6D11.1)
A tendency to maintain interpersonal and emotional distance: social withdrawal, aloofness, limited emotional expression and experience of pleasure.

Dissociality (6D11.2)
Disregard for the rights and feelings of others; self-centredness and lack of empathy, with grandiosity or callousness.

Disinhibition (6D11.3)
Acting rashly and impulsively on immediate stimuli, without consideration of consequences; recklessness and poor planning.

Anankastia (6D11.4)
A rigid focus on one's own and others' standards, commonly shown as perfectionism and emotional and behavioural constraint.

MNEMONIC

"N, then D-D-D, then A"

The five ICD-11 trait domains in order: **N**egative affectivity, then the three D's, **D**etachment, **D**issociality, **D**isinhibition, and finally **A**nankastia. The three D's are easy to muddle, so anchor them: detachment is *distance*, dissociality is *disregard for others*, disinhibition is *daring impulsivity*. The borderline pattern is a sixth token that sits apart, an optional add-on qualifier, not one of the five domains.

2.5 The borderline pattern qualifier: the one pattern that survived

The single named picture the ICD-11 kept is the borderline pattern qualifier (6D11.5), added for clinical utility and continuity with a large treatment literature (ICD-11 CDDR). It is an **additional qualifier**, not a type and not a trait domain, and it typically overlaps the domains (especially negative affectivity and disinhibition). It marks a pervasive pattern of instability of interpersonal relationships, self-image and affect together with marked impulsivity, defined by **five or more of the nine** features: frantic efforts to avoid abandonment; unstable, intense relationships that swing between idealisation and devaluation; identity disturbance; impulsivity that is potentially self-damaging; recurrent self-harm or suicidal behaviour; affective instability; chronic emptiness; inappropriate intense anger; and transient stress-related paranoid ideation or dissociation (Kaplan & Sadock CTP 2024). The threshold and the nine features are the same set the DSM-5-TR uses for borderline personality disorder, which is why the borderline construct crosses cleanly between the systems while the other types do not. The boundary with complex post-traumatic

stress disorder, a distinction ICD-11 sharpened by introducing both, is drawn in the Anxiety, OCD and trauma-related disorders notes.

GOOD TO REMEMBER

- **ICD-11 personality classification:** no types; rate severity first (personality difficulty, then mild, moderate, severe by self-and-interpersonal dysfunction and risk of harm), then add trait qualifiers.
- **The five trait domains:** negative affectivity, detachment, dissociality, disinhibition, anankastia; they describe style, not severity, and several may co-occur.
- **Borderline pattern qualifier (6D11.5):** the one retained pattern; an add-on qualifier defined by five or more of the nine borderline features; overlaps the domains, not a type.

2.6 Assembling a diagnosis: how the pieces combine in practice

A finished ICD-11 personality diagnosis is a severity level with any qualifiers appended, coded by postcoordination. You never stop at a trait: a qualifier without a rated severity is an incomplete diagnosis. The clinical value is that the same language scales from a screening judgement to a detailed formulation, and that severity, the part that drives the management plan and the risk assessment, is stated up front rather than buried inside a type label. The bipolar-II differential that so often shadows an affectively unstable presentation is worked in the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes; the forensic reading of a prominent dissociality trait belongs to the Mental health legislation and forensic psychiatry notes.

WORKED EXAMPLE

A woman in her twenties has an incoherent sense of who she is, stormy relationships that collapse repeatedly, recurrent self-cutting after perceived abandonment, chronic emptiness and stress-related dissociation. Work the model in order. General criteria met. Severity: the self is severely disturbed and almost all relationships are affected with a high risk of self-harm, so this is severe personality disorder (6D10.2). Trait qualifiers: prominent negative affectivity and disinhibition. Pattern: the picture meets five or more of the nine borderline features, so add the borderline pattern qualifier (6D11.5). The diagnosis is "severe personality disorder with negative affectivity, disinhibition and a borderline pattern", not "borderline personality disorder" as a type.

2.7 Cross-map to DSM-5-TR: the categorical clusters and the AMPD hybrid

DSM-5-TR did not follow the ICD-11 all the way. Its main text **retains the categorical system**: three clusters (A the odd or eccentric, B the dramatic or erratic, C the anxious or fearful) holding ten types. In parallel, Section III offers the **alternative model of personality disorders**, a hybrid that mirrors the ICD-11 logic: Criterion A rates self and interpersonal functioning on the Level of Personality Functioning Scale (self as identity and self-direction; interpersonal as empathy and intimacy), and Criterion B specifies five pathological trait domains with 25 facets (Kaplan & Sadock CTP 2024). The two dimensional systems are close cousins but their trait sets are not identical, and the mismatch is examinable. The grid below is the discriminator to hold.

ICD-11 TRAIT DOMAIN	DSM-5-TR AMPD COUNTERPART	NOTE
Negative affectivity	Negative affectivity	Shared construct
Detachment	Detachment	Shared construct
Dissociality	Antagonism	**Same construct, different name**
Disinhibition	Disinhibition	Shared construct
Anankastia	(no AMPD domain)	**ICD-11 only; a constraint pole absent from the AMPD**
(no ICD-11 domain)	Psychoticism	**DSM only; ICD-11 places schizotypal with the psychoses, so it has no psychoticism domain**

The two dimensional trait sets: four align, but ICD-11 carries anankastia and the AMPD carries psychoticism; the highlighted rows are where they part.

TRAP **Do not equate the ICD-11 five with the DSM-5 AMPD five.** Anankastia is ICD-11-only and psychoticism is DSM-only; the schizotypal-versus-schizophrenia placement is set out in the Schizophrenia: aetiology, phenomenology, classification and course notes.

2.8 The legacy ICD-10 box: what changed and why the old names still get tested

The break from ICD-10 is total, which is exactly why the categorical vocabulary refuses to die. Knowing what was removed is itself the exam point.

ICD-10 TO ICD-11: WHAT CHANGED

ICD-10 (F60) **kept the categorical specific types**: paranoid, schizoid, dissocial, emotionally unstable (impulsive and borderline subtypes), histrionic, anankastic, anxious or avoidant, and dependent personality disorder, with schizotypal sitting separately under the schizophrenia grouping. ICD-11 **removed all of these named types** and rebuilt the diagnosis as a severity level plus trait-domain qualifiers, keeping only the borderline pattern as an optional qualifier. Exams still test the categorical names because DSM-5-TR retains them in its main text and clinicians still speak in them, so you must read fluently in both the dimensional and the categorical languages.

COMMON TRAP

Rating a trait qualifier while skipping severity, or naming "borderline personality disorder" as an ICD-11 type. In ICD-11 borderline is a *pattern qualifier* appended to a rated severity, never a standalone type; and no trait domain is a diagnosis on its own.

2.9 India and the cultural frame

Two India-specific cautions attach to this model. The first is **under-recognition**: personality disorders are diagnosed far less often in Indian clinical practice than Western prevalence would predict, an under-detection documented in Indian samples (Gupta & Mattoo, on personality-disorder prevalence and demography). A severity-led system that begins with a graded judgement of self-and-interpersonal dysfunction, rather than demanding a full type match, is well suited to

catching the milder end that Indian services routinely miss. The second is the **cultural expression of pathology**: the general criteria require deviation from what the person's own culture expects, so a self that is deeply embedded in family and community, or a deference and interdependence that would look like dependence through a Western lens, must not be read as disorder. The medico-legal weight of a prominent dissociality trait, which surfaces most sharply in offender assessment, is handled in the Mental health legislation and forensic psychiatry notes.

INDIA

Access to the structured psychotherapies that this severity framing points toward is uneven. Dialectical behaviour therapy and schema therapy are available and being culturally adapted in Indian metros and academic centres but remain scarce elsewhere, so a severe rating that mandates intensive structured therapy can outrun what a given service can deliver. Rate honestly, then match the plan to what is actually accessible, and never read collectivist family-embeddedness as a personality disorder.

5	3	5+	3 / 10
ICD-11 TRAIT DOMAINS	SEVERITY LEVELS (MILD, MODERATE, SEVERE)	OF NINE BORDERLINE-PATTERN FEATURES	DSM-5-TR CLUSTERS / TYPES (RETAINED)

HOLD THIS

ICD-11 has no personality-disorder types: rate severity first (personality difficulty, then mild, moderate, severe by self-and-interpersonal dysfunction and risk of harm), then add any of the five trait domains, negative affectivity, detachment, dissociality, disinhibition, anankastia, and the borderline pattern qualifier.

3 · DSM-5 categorical clusters and the alternative model

Two classifications of personality live side by side inside one manual. **dsm-5-tr** keeps, in its official Section II, the familiar **categorical clusters** and the **ten types** inherited almost unchanged from DSM-IV; and it offers, in its research Section III, an **alternative model**, a dimensional-categorical **hybrid model** (the **ampd**) that scores how badly the personality functions and profiles the traits that colour it. Knowing both, and being able to cross-map them onto the ICD-11 dimensional system, is the single highest-yield task on the personality-disorders paper.

Why it matters, and what this note owns. This note owns the DSM-5-TR side of the nosology: the three **categorical clusters** and their ten types with each type under its correct cluster, and the Section III **alternative model** in full, its Criterion A **level of personality functioning** scale and its Criterion B **pathological trait domains**. The ICD-11 dimensional model (the severity gradient and the five trait qualifiers) is taught forward in its own sibling note and only cross-mapped here; the deeper per-disorder phenomenology of each type lives in the cluster notes, and the general diagnostic criteria that gate any personality-disorder diagnosis are stated here only as the framing rule. The accompanying figure maps the ten types under the three clusters; a second figure alongside it lays the DSM-5 alternative model against the ICD-11 domains.

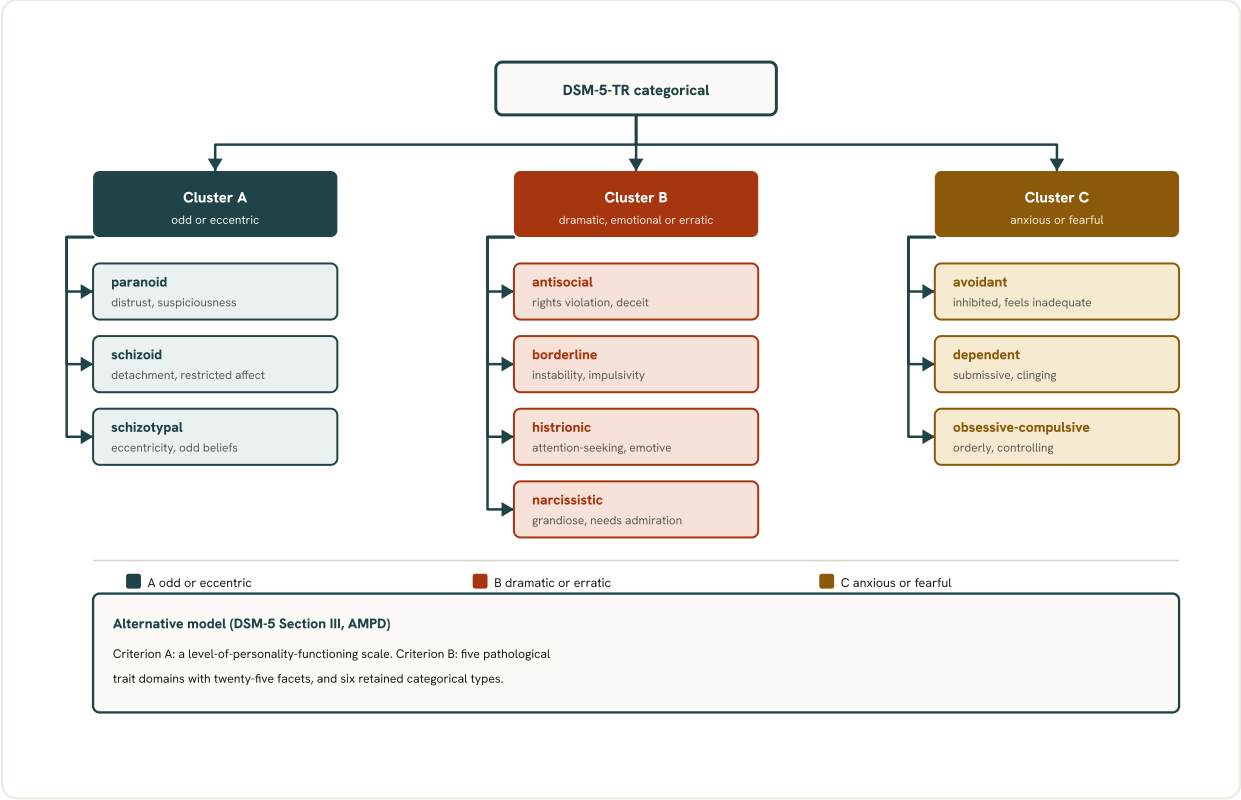

Fig 16.3 The DSM-5-TR keeps the ten categorical types in three clusters, A odd or eccentric, B dramatic or erratic, C anxious or fearful, with the Section III alternative model (a functioning scale plus pathological trait domains) alongside; ICD-10 kept these categories, which is why exams still test them.

3.1 Two systems in one manual: Section II categorical, Section III alternative

The structural fact to state first. dsm-5-tr carries *both* a categorical and a dimensional account of personality disorder. Section II, the official classification for routine clinical use, retains the ten categorical types grouped into three **categorical clusters**, virtually unchanged from DSM-IV-TR (DSM-5-TR 2022). Section III, "Emerging Measures and Models", houses the alternative model (also called the **hybrid model** or **ampd**, the Alternative **dsm-5** Model for Personality Disorders), placed there for further study rather than official use. The APA Board of Trustees kept both deliberately: the categorical set to preserve continuity with clinical practice, and the hybrid model to answer the categorical system's well-known failings (excessive comorbidity between types, and "other specified" being the commonest and least informative diagnosis).

Why the split is examinable. The examiner wants you to be fluent in the official categorical vocabulary (paranoid, borderline, and the rest) *and* able to explain the model that is expected to replace it. That is the through-line of the whole chapter: teach the dimensional direction of travel (ICD-11 has already abolished the categorical types entirely), but master the categorical names because Section II, everyday communication and most examinations still run on them.

GOOD TO REMEMBER

- **DSM-5-TR dual structure:** Section II retains the official categorical system, three clusters and ten types unchanged from DSM-IV-TR; Section III offers the alternative (hybrid AMPD) model for further study; both are printed in the same manual by deliberate APA decision, the categorical for continuity, the dimensional to fix comorbidity and the uninformative "unspecified" default.

3.2 The gate before any label: the general criteria for a personality disorder

The pattern precedes the type. No cluster and no type may be assigned until the general criteria for a personality disorder are met: an enduring, pervasive, inflexible pattern of inner experience and behaviour that *deviates markedly from the expectations of the individual's culture*, is stable over time, traceable to **adolescence or early adulthood**, and leads to distress or impairment, and is not better explained by another mental disorder, a substance, or a medical condition (DSM-5-TR 2022). The same seven general criteria (A to G) sit at the head of the Section III model, where Criterion A is reframed as moderate or greater impairment in personality functioning and Criterion B as one or more pathological traits, but the enduring, pervasive, culturally-deviant, early-onset spine is identical.

Deviation is judged against the person's own culture. The cultural clause is not decorative; the pattern must deviate from the norms of the individual's *own* cultural, ethnic and social reference group, and manifest across cognition, affectivity, interpersonal functioning and impulse control. Reading a migrant's habits, a subculture's mores, or a life-stage's turbulence as personality pathology is the classic misdiagnosis this criterion exists to block.

RULE **The enduring pattern before the label.** Establish the general personality-disorder criteria first, an inflexible, pervasive, culturally-deviant pattern stable since adolescence or early adulthood with distress or impairment, and only then place the cluster and the type; the cluster or the AMPD trait profile is meaningless without that gate.

TRAP **State mistaken for trait.** Do not label situational or episodic features a personality disorder: calling a passing affective lability "borderline" without the enduring identity disturbance and abandonment features, or reading a cultural or developmental norm as pathology, breaks the general criteria and is the commonest error on this topic.

3.3 Cluster A, the odd or eccentric cluster

The cluster and its three types. **cluster a** groups the personality disorders whose sufferers "often appear odd or eccentric" (DSM-5-TR 2022): paranoid personality disorder (a pervasive distrust and suspiciousness, reading others' motives as malevolent), schizoid personality disorder (detachment from social relationships with a restricted, flattened emotional range, the person is a genuine loner who does not want closeness), and schizotypal personality disorder (acute social discomfort with cognitive and perceptual distortions and eccentricities, ideas of reference, odd beliefs and magical thinking, unusual perceptions). The cluster's phenomenology shades toward the schizophrenia spectrum.

The boundary that is tested. Schizotypal is the one to place carefully: its cognitive-perceptual eccentricities are attenuated, not frank psychosis, so it stays a personality disorder in DSM-5-TR (though it is cross-listed with the schizophrenia spectrum), and mislabelling it as schizophrenia is a standard error, developed in the Schizophrenia: aetiology, phenomenology, classification and course notes.

GOOD TO REMEMBER

- **Cluster A (odd or eccentric):** paranoid (pervasive distrust and suspiciousness), schizoid (detachment with restricted emotion, a contented loner), schizotypal (social discomfort plus cognitive-perceptual distortions, ideas of reference, magical thinking); the discriminator from the schizophrenia spectrum is that the distortions are attenuated, not frankly psychotic.

3.4 Cluster B, the dramatic, emotional or erratic cluster

The cluster and its four types. **cluster b** groups those who "often appear dramatic, emotional, or erratic" (DSM-5-TR 2022): antisocial personality disorder (a pervasive disregard for and violation of the rights of others, deceit, impulsivity, aggression and lack of remorse, requiring evidence of conduct disorder before the age of fifteen years), borderline personality disorder (instability of relationships, self-image and affect with marked impulsivity), histrionic personality disorder (pervasive excessive emotionality and attention seeking), and narcissistic personality disorder (grandiosity, need for admiration and lack of empathy). This is the cluster that dominates the clinic and the examination, borderline above all.

Two exam anchors. Antisocial personality disorder is the one type DSM-5-TR will not diagnose before the age of eighteen years and only with a documented childhood conduct disorder, and it carries the forensic weight of the chapter (offender assessment, court reports), developed in the Mental health legislation and forensic psychiatry notes. Borderline is the flagship carried in detail below and across the day.

GOOD TO REMEMBER

- **Cluster B (dramatic, emotional or erratic):** antisocial (disregard for and violation of others' rights; needs conduct disorder before age fifteen and diagnosis only from age eighteen), borderline (instability of relationships, self-image and affect with impulsivity), histrionic (excessive emotionality and attention seeking), narcissistic (grandiosity, need for admiration, lack of empathy); it is the highest-yield cluster.

3.5 Cluster C, the anxious or fearful cluster, and the full ten-type map

The cluster and its three types. **cluster c** groups those who "often appear anxious or fearful" (DSM-5-TR 2022): avoidant personality disorder (social inhibition, feelings of inadequacy and hypersensitivity to negative evaluation, the person wants closeness but is too afraid of rejection to risk it), dependent personality disorder (a pervasive, excessive need to be taken care of, submissive and clinging behaviour, fear of separation), and obsessive-compulsive personality disorder (a preoccupation with orderliness, perfectionism and control at the expense of flexibility and efficiency). Avoidant is separated from social anxiety disorder by its pervasive, trait-level character, and obsessive-compulsive personality disorder is separated from OCD by the absence of true obsessions and compulsions, the confusion of the anankastic character with the anxiety disorder being a stock trap.

The ten under the three. The mapping to reproduce cold, three **categorical clusters** holding **ten types**, is set out in the table and the accompanying figure. DSM-5-TR itself warns that the clustering, though useful for teaching and research, "has serious limitations and has not been

consistently validated": types from different clusters co-occur freely, which is exactly the comorbidity problem the alternative model was built to solve.

CLUSTER	CHARACTER	TYPE	ONE-LINE SIGNATURE
Cluster A	**Odd or eccentric**	Paranoid	Pervasive distrust and suspiciousness; reads motives as malevolent
Cluster A	Odd or eccentric	Schizoid	Detachment from relationships; restricted emotion; a contented loner
Cluster A	Odd or eccentric	Schizotypal	**Social discomfort plus cognitive-perceptual distortions and eccentricity**
Cluster B	**Dramatic, emotional or erratic**	Antisocial	Disregard for and violation of others' rights; deceit, impulsivity, no remorse
Cluster B	Dramatic, emotional or erratic	Borderline	**Instability of relationships, self-image and affect; marked impulsivity**
Cluster B	Dramatic, emotional or erratic	Histrionic	Excessive emotionality and attention seeking
Cluster B	Dramatic, emotional or erratic	Narcissistic	Grandiosity, need for admiration, lack of empathy
Cluster C	**Anxious or fearful**	Avoidant	Social inhibition, feelings of inadequacy, fear of negative evaluation
Cluster C	Anxious or fearful	Dependent	Excessive need to be cared for; submissive, clinging; fear of separation
Cluster C	Anxious or fearful	Obsessive-compulsive	**Preoccupation with order, perfectionism and control; not OCD**

The DSM-5-TR Section II categorical system: three clusters holding ten types; the discriminator cells flag the boundaries most often tested (schizotypal versus schizophrenia, borderline as the flagship, obsessive-compulsive personality versus OCD) (DSM-5-TR 2022).

MNEMONIC

Weird, Wild, Worried

The three clusters by feel. **Cluster A** is **Weird** (odd or eccentric: Paranoid, Schizoid, Schizotypal, the three "P-S-S" types). **Cluster B** is **Wild** (dramatic, emotional or erratic: Antisocial, Borderline, Histrionic, Narcissistic). **Cluster C** is **Worried** (anxious or fearful: Avoidant, Dependent, Obsessive-compulsive). Three, four, three, adding to the ten types.

GOOD TO REMEMBER

- **Cluster C (anxious or fearful):** avoidant (social inhibition and fear of negative evaluation; wants but fears closeness), dependent (excessive need to be cared for, clinging, fear of separation), obsessive-compulsive personality (orderliness, perfectionism and control without true obsessions or compulsions); the whole set is three clusters and ten types, a clustering DSM-5-TR itself flags as weakly validated.

ICD-10 LEGACY: WHAT CHANGED

The old ICD-10 KEPT a categorical list of personality disorders largely paralleling the DSM types (paranoid, schizoid, dissocial for antisocial, emotionally unstable with an impulsive and a borderline type, histrionic, anankastic for obsessive-compulsive, anxious for avoidant, and dependent), with two familiar divergences: narcissistic sat only under "other specific personality disorder", and schizotypal was placed in the schizophrenia and delusional-disorders grouping, not among the personality disorders. ICD-11 then made the sharpest break of all: it *abolished* every one of these discrete categorical types, replacing them with a single personality-disorder diagnosis rated by severity (personality difficulty, then mild, moderate or severe) plus five trait qualifiers and a borderline pattern qualifier. Examinations still test the categorical names because DSM-5-TR Section II retains them, decades of literature and clinical communication use them, and the dimensional transition is recent, so the vocabulary of clusters and types remains the shared currency even where the official classification has moved on.

3.6 Borderline personality disorder: the flagship type and the five-of-nine threshold

The criterion to state cold. borderline personality disorder is "a pervasive pattern of instability of interpersonal relationships, self-image, and affects, and marked impulsivity, beginning by early adulthood", diagnosed when **five or more of the nine** criteria are present (DSM-5-TR 2022). The nine are: frantic efforts to avoid abandonment; a pattern of unstable, intense relationships alternating between idealisation and devaluation; identity disturbance; impulsivity in at least two potentially self-damaging areas; recurrent suicidal or self-mutilating behaviour; affective instability due to marked reactivity of mood; chronic feelings of emptiness; inappropriate, intense anger; and transient, stress-related paranoid ideation or severe dissociative symptoms.

Why the threshold is worth memorising. The **five or more of the nine** rule is the count most likely to be asked, and it is the reason a polythetic categorical system produces so many symptom combinations: two people can each carry the borderline label while sharing only one of the nine features. That combinatorial sprawl is the empirical case for the dimensional models. The borderline-versus-bipolar-II discrimination (do not start a mood stabiliser for personality-based

instability) and the biosocial and psychotherapeutic detail are developed elsewhere in the day and in the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes.

GOOD TO REMEMBER

- **Borderline personality disorder:** a pervasive pattern of instability of relationships, self-image and affect with marked impulsivity from early adulthood; diagnosed on five or more of the nine criteria (abandonment fears, idealisation-devaluation, identity disturbance, impulsivity, recurrent self-harm or suicidality, affective instability, chronic emptiness, intense anger, transient paranoia or dissociation); the first diagnostic step is the enduring pattern, and the five-of-nine polythetic threshold is why the same label covers very different presentations.

3.7 The alternative model (AMPD): a dimensional-categorical hybrid

What the hybrid does. The Section III alternative model for personality disorders redefines a personality disorder as the combination of two things: *impairment in personality functioning* (Criterion A) and one or more *pathological personality traits* (Criterion B) (DSM-5-TR 2022). It is a **hybrid model** because it fuses a dimensional severity axis (how impaired the personality is) with a dimensional trait profile (which traits are elevated), then still allows six named categorical diagnoses to be reconstructed from those dimensions. The general criteria C to G (inflexible and pervasive, stable since adolescence or early adulthood, not better explained by another disorder, a substance or a developmental or cultural norm) carry over unchanged.

The two determinations. Diagnosing under the **ampd** requires two assessments in order: first rate the level of impairment in personality functioning (Criterion A) on the Level of Personality Functioning Scale, then evaluate the pathological personality traits (Criterion B) across the trait domains. A *moderate* or greater impairment in personality functioning is the entry threshold; below it, no personality disorder is diagnosed however the traits fall.

GOOD TO REMEMBER

- **Alternative model (AMPD):** the DSM-5 Section III dimensional-categorical hybrid; a personality disorder is impairment in personality functioning (Criterion A) plus one or more pathological personality traits (Criterion B), retaining general criteria C to G; diagnosis runs A then B, with moderate or greater functional impairment the required entry threshold; it exists to cure the categorical system's comorbidity and its uninformative "unspecified" default.

3.8 Criterion A: the Level of Personality Functioning scale (self and interpersonal)

The self and interpersonal axes. Criterion A grades disturbance in *self* and *interpersonal* functioning on the Level of Personality Functioning Scale (DSM-5-TR 2022). Self functioning has two elements, identity and self-direction; interpersonal functioning has two, empathy and intimacy. The scale differentiates five levels of impairment, from little or no impairment (healthy) through some, moderate and severe to extreme; moderate impairment is the threshold that a personality disorder must reach. The severity of impairment also predicts whether the person has more than one personality disorder or one of the more severe types, which is why the **level of personality functioning** is rated first and leads.

Identity (self)

A stable, bounded sense of self; regulated self-esteem and accurate self-appraisal; capacity to experience and modulate a range of emotion.

Self-direction (self)
Pursuit of coherent short-term and life goals; constructive, prosocial internal standards; the ability to self-reflect productively.

Empathy (interpersonal)
Comprehension of others' experiences and motives; tolerance of differing perspectives; awareness of one's effect on others.

Intimacy (interpersonal)
Depth and duration of connection; the desire and capacity for closeness; mutuality of regard in relationships.

The four elements of personality functioning that anchor Criterion A of the alternative model; two are self elements, two interpersonal, graded across five severity levels with moderate impairment the diagnostic threshold (DSM-5-TR 2022).

GOOD TO REMEMBER

- **Criterion A (Level of Personality Functioning):** the AMPD severity axis, self functioning (identity, self-direction) and interpersonal functioning (empathy, intimacy) across five levels from little-or-no to extreme; moderate or greater impairment is required to diagnose any personality disorder, and severity predicts multiplicity and the more severe types, so it is rated first.

3.9 Criterion B: the five pathological trait domains, and the ICD-11 cross-map

The five domains and their facets. Criterion B profiles the personality across five broad pathological trait domains: **negative affectivity**, **detachment**, **antagonism**, **disinhibition** and **psychoticism**, which subdivide into twenty-five specific trait facets (DSM-5-TR 2022). Each named disorder's B criterion is a defined subset of those facets, for example antisocial personality disorder draws on Antagonism and Disinhibition, avoidant on Negative Affectivity and Detachment. The five domains are the maladaptive-range extensions of the Big Five personality dimensions.

The cross-map to ICD-11, the point examiners love. The ICD-11 dimensional model, taught forward in its own note, uses its own five trait qualifiers, and four broadly correspond to the DSM-5 **pathological trait domains**: negative affectivity, detachment, dissociality (aligning with DSM-5 Antagonism) and disinhibition are shared. The fifth is where they part: DSM-5 has **psychoticism** (which ICD-11 has no equivalent domain for), while ICD-11 has **anankastia** (which DSM-5 folds into low Disinhibition rather than naming). ICD-11 then adds a borderline pattern qualifier on top of its domains, a feature the DSM-5 trait set does not carry.

DSM-5 ALTERNATIVE-MODEL DOMAIN	ICD-11 TRAIT QUALIFIER	WHAT IT CAPTURES
Negative affectivity	Negative affectivity	Frequent, intense negative emotions (anxiety, insecurity, emotional lability)
Detachment	Detachment	Social and emotional withdrawal, avoidance of intimacy, restricted emotion
Antagonism	**Dissociality**	Disregard for others; grandiosity, deceit, callousness, manipulation
Disinhibition	Disinhibition	Impulsivity, irresponsibility, recklessness, distractibility
Psychoticism (no ICD-11 domain)	**Anankastia (no DSM-5 domain)**	DSM-5: odd beliefs, unusual perceptions, eccentricity. ICD-11: rigidity, perfectionism, constraint

Cross-mapping the two dimensional trait systems: four domains broadly correspond, but the fifth differs, DSM-5 names Psychoticism where ICD-11 names Anankastia, and ICD-11 adds a borderline pattern qualifier the DSM-5 set lacks (DSM-5-TR 2022; ICD-11 CDDR).

COMMON TRAP

Do not treat the two dimensional systems as identical five-domain sets. Four domains align (negative affectivity, detachment, antagonism as ICD-11 dissociality, disinhibition), but the fifth is different in each: the DSM-5 alternative model has *psychoticism* and no anankastia domain, whereas ICD-11 has *anankastia* and no psychoticism domain. Naming psychoticism as an ICD-11 domain, or anankastia as a DSM-5 domain, is a straight error.

GOOD TO REMEMBER

- **Criterion B (pathological trait domains):** five domains, negative affectivity, detachment, antagonism, disinhibition and psychoticism, with twenty-five facets, each disorder's B criterion a defined subset; four align with the ICD-11 qualifiers (antagonism maps to dissociality), but DSM-5's fifth is psychoticism while ICD-11's is anankastia, and only ICD-11 adds a borderline pattern qualifier.

3.10 The six retained types and the trait-specified diagnosis

Ten collapse to six, plus a residual. Where the categorical system names ten types, the **alternative model** retains only six that can be diagnosed by their own criteria sets: antisocial, avoidant, borderline, narcissistic, obsessive-compulsive and schizotypal personality disorders (DSM-5-TR 2022). Each is defined by a characteristic Criterion A functioning impairment plus a specified Criterion B trait subset. The four categorical types dropped from the named list (paranoid, schizoid, histrionic, dependent) are not lost: when a personality disorder is present but no specific set is met, it is diagnosed as *personality disorder, trait specified* (PD-TS), recording the impairment level and the elevated trait domains directly.

How a diagnosis is built. To diagnose, say, avoidant personality disorder under the hybrid model, the clinician confirms moderate or greater impairment across the relevant functioning elements (Criterion A) and the specified maladaptive traits, here in Negative Affectivity and Detachment (Criterion B), then checks the general criteria C to G. The system's promise is that the profile itself, the severity level and the domain scores, carries the clinical information even when no tidy category fits, which is precisely the case in most real patients.

GOOD TO REMEMBER

- **The six AMPD types and PD-TS:** the alternative model diagnoses six specific types, antisocial, avoidant, borderline, narcissistic, obsessive-compulsive and schizotypal, each an A-functioning impairment plus a B-trait subset; the other cases (including the dropped paranoid, schizoid, histrionic and dependent) become personality disorder, trait specified, recorded by severity level and trait domains.

3.11 The India lens: under-recognition, cultural expression and the medico-legal frame

An under-recognised group read through the wrong culture. Personality disorders are markedly under-recognised in routine Indian practice: they present through their comorbidities (a mood or anxiety disorder, a substance problem, repeated self-harm) rather than as a personality diagnosis, they are under-coded, and the personality label is often avoided for fear of stigma. The cultural clause in the general criteria matters acutely here, deviation must be judged against the patient's own cultural, familial and social norms, so that collectivist family embeddedness is not misread as dependent personality, culturally sanctioned religious or ritual practice is not misread as schizotypal eccentricity, and gendered social scripts are not misread as histrionic or avoidant traits. The cultural expression of personality pathology is genuine and must be weighed before any type is fixed.

Where the label carries force. Antisocial personality disorder is the type with the sharpest medico-legal edge in Indian practice, surfacing in offender assessment, fitness and court reports, where a careful, non-pejorative formulation matters, and it is developed in the Mental health legislation and forensic psychiatry notes. On the treatment side, the structured psychotherapies that the borderline diagnosis calls for, dialectical behaviour therapy and schema therapy, are available only patchily outside the metros and are being culturally adapted for Indian settings; that availability gap, not the classification, is usually what limits care once the diagnosis is correctly made.

INDIA

Personality disorders are under-recognised in Indian practice, surfacing through comorbid mood, anxiety, substance or self-harm presentations and often left uncoded for fear of stigma. The general criteria's cultural clause is the safeguard: judge deviation against the patient's own cultural and social norms, so family embeddedness is not scored as dependency, religious practice not as schizotypal eccentricity, and social scripts not as histrionic or avoidant pathology. Antisocial personality disorder carries the medico-legal weight (offender and court work, cross-referenced to the forensic notes), and the structured psychotherapies borderline needs, dialectical behaviour therapy and schema therapy, are unevenly available and still being culturally adapted for India.

3	10	5	five
CATEGORICAL CLUSTERS (A ODD, B DRAMATIC, C ANXIOUS)	CATEGORICAL PERSONALITY-DISORDER TYPES ACROSS THE CLUSTERS	PATHOLOGICAL TRAIT DOMAINS IN THE DSM-5 ALTERNATIVE MODEL	OF THE NINE CRITERIA NEEDED TO DIAGNOSE BORDERLINE PERSONALITY DISORDER

HOLD THIS

DSM-5-TR keeps the categorical clusters in Section II (Cluster A odd or eccentric: paranoid, schizoid, schizotypal; Cluster B dramatic, emotional or erratic: antisocial, borderline, histrionic, narcissistic; Cluster C anxious or fearful: avoidant, dependent, obsessive-compulsive, ten types in all) and offers, in Section III, the alternative hybrid model (AMPD): Criterion A the Level of Personality Functioning scale (self: identity, self-direction; interpersonal: empathy, intimacy) plus Criterion B the five pathological trait domains (negative affectivity, detachment, antagonism, disinhibition, psychoticism), diagnosing six specific types; ICD-11 has abolished the categorical types for a severity-led dimensional model whose fifth domain is anankastia, not psychoticism, yet the categorical names remain the examinable vocabulary.

4 · Categorical versus dimensional approaches

Why this matters. This is the conceptual hinge of the whole personality-disorders chapter, and it is the stem an examiner reaches for when a single question has to test understanding rather than recall. The sibling notes teach the two live classifications in full, the DSM-5-TR categorical clusters and the ICD-11 dimensional model; this note owns the argument *between* them. The **categorical versus dimensional** debate asks a prior question: is a personality disorder a distinct kind of thing that you either have or do not, or a position on a set of continua that shade imperceptibly into ordinary personality? Answer that, and you can explain every failing of the old system and every design choice of the new one.

Held tightly, the **comparison of approaches** is a small object: two definitions, a short list of **strengths and weaknesses** on each side, and the reason the evidence tilted one way. The categorical approach trades validity for familiarity; the dimensional approach trades familiarity for validity and coverage; and the modern manuals split the difference, ICD-11 committing fully to dimensions while DSM-5-TR keeps the categories in front and files the dimensional model behind them for study. The accompanying figure lays the two approaches out as one grid, discrete boxes on one side against graded continua on the other, and it is the single image to carry for this

topic. The detailed severity gradient, the trait domains and the cluster map are developed in the sibling framework notes and only invoked here as evidence.

Feature	Categorical (DSM-5-TR, ICD-10)	Dimensional (ICD-11, DSM-5 AMPD)
Unit	Discrete named types	Severity and trait continua
Comorbidity and thresholds	Excessive comorbidity, arbitrary cut-offs	Handled on continua
Communicability	Familiar, easy to convey in a word	Less familiar, harder to convey
Validity and coverage	Within-type heterogeneity, a large not-otherwise-specified group	Covers the subthreshold majority, better validity
Exam bottom line	Still tested and clinically familiar	The direction the field moved

Paradigm header Deciding contrast for the row

Fig 16.4 Categorical classification names discrete types (familiar, but with excessive comorbidity, arbitrary thresholds and a large residual group), while dimensional classification grades severity and traits on continua (better validity and coverage of the subthreshold majority); the field moved dimensional, though the categories are still examined.

4.1 Two ways to carve personality: kinds versus degrees

The distinction to state first. The categorical approach holds that personality disorders are *qualitatively distinct clinical syndromes*, discrete kinds that a person either meets or does not, sorted into named types (DSM-5-TR 2022). The dimensional approach holds the opposite: that personality pathology represents *maladaptive variants of personality traits that merge imperceptibly into normality and into one another*, so that difference from health is one of degree, not of kind (DSM-5-TR 2022). One view draws boundaries and puts patients in boxes; the other places them on continua of severity and trait and reads their position. Everything else in the debate follows from this single fork, kinds against degrees.

Why the fork is not merely philosophical. The choice determines what the diagnosis can say. A category returns a name; a dimension returns a profile. Where a categorical system must decide a threshold above which a person "has" the disorder, a dimensional system can describe exactly how far along each continuum the person sits, and can keep describing the many people who fall below any categorical cut-off. The five-factor model of normal personality supplies the trait scaffolding the dimensional side builds on, its maladaptive poles becoming the pathological trait domains of the modern models (New Oxford Textbook of Psychiatry).

RULE **Kinds versus degrees is the whole debate.** The categorical approach treats a personality disorder as a discrete type you have or lack; the dimensional approach treats it as a position on continua of severity and trait that grade smoothly into normal personality. Every strength and weakness on either side is a consequence of this one choice.

4.2 The categorical approach: where it is strong

Familiarity and communicability are its real assets. The categorical approach is the default of clinical medicine: a diagnosis is a name, and a name is fast to assign, easy to record, and instantly communicable to another clinician in a single phrase (Tasman Psychiatry). Saying "borderline personality disorder" transmits a rich prototype in two words; there is a century of description, a large treatment literature and an examination vocabulary all built on the named types. The explicit operational criteria introduced from DSM-III onward gave the categories a further, genuine payoff: they let the field *document* substantial community and clinical prevalence, high rates of social and occupational impairment, and a more chronic course for co-occurring disorders (New Oxford Textbook of Psychiatry). These are not trivial gains, and they are why the categories have survived every attempt to retire them.

The prototype is the mechanism. Clinicians reason by pattern-matching a patient to a remembered exemplar, and the categorical types are ready-made prototypes. That cognitive fit, not evidence of natural boundaries, is the categorical system's durable strength: it maps onto how doctors actually think and talk.

PEARL

The categorical system persists because of its *communicative* value, not its scientific validity. The single most defensible thing to say for it is that a type name carries a whole clinical picture in one phrase, which is exactly what a busy clinic and a shared record need. Hold that as its strength, and its weaknesses become easier to name honestly.

4.3 The categorical approach: where it fails

Four failings, and they are examinable as a set. The problems are the mirror image of the discrete-kinds assumption, and the New Oxford Textbook lists them cleanly: *extensive co-occurrence of personality disorders* (excessive comorbidity, patients routinely meeting several type criteria at once), *considerable heterogeneity within categories* (two people can share a diagnosis while sharing almost none of its features), *arbitrary diagnostic thresholds without empirical bases* (the cut-off between disorder and no-disorder is a convention, not a natural join), and *incomplete coverage of the full range of personality pathology* (the many patients whose difficulty is real but does not match any single type). Temporal instability of the categories and their limited validity and clinical utility round out the indictment (New Oxford Textbook of Psychiatry).

Borderline is the worked case of heterogeneity. Because borderline personality disorder is polythetic, diagnosed on **five or more of the nine** criteria, two patients can each carry the label while overlapping on only one feature. That combinatorial sprawl is the categorical system's within-category heterogeneity made concrete, and it is the empirical case the dimensional models

were built to answer. The unstable, affectively reactive presentation also blurs into bipolar-II, a boundary drawn in the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes.

The residual category tells the story. The clearest sign of incomplete coverage is that the residual not-otherwise-specified diagnosis (personality disorder not otherwise specified in DSM-IV, and the "other specified" and "unspecified" categories in DSM-5-TR) has been among the most frequently assigned of all the personality-disorder diagnoses, and is also the least informative one (DSM-5-TR 2022; New Oxford Textbook of Psychiatry). A system whose commonest verdict is "a personality disorder, but none of the ones we named" is telling you its named types do not cover the territory.

TRAP **Reading the types as non-overlapping natural kinds.** The categorical model implies the types are distinct and separable, but they co-occur freely and blur at every edge; treating a tidy single-type label as the natural truth of a patient, rather than a convenient summary, is the error the dimensional case exists to correct.

COMMON TRAP

Mistaking the frequency of the not-otherwise-specified diagnosis for clinician laziness. It is a structural signal, not a shortcut: the residual category is common *because* most real personality pathology is subthreshold or mixed and falls between the named types. That is the coverage problem, not a documentation problem.

4.4 The dimensional approach: its strengths

It fixes what the categories broke. By placing severity and traits on continua, the dimensional approach retains the information a category discards: a profile records how impaired the personality is and which traits are elevated, so two patients who would share one categorical label are told apart, and a patient who matches no type is still fully described (Tasman Psychiatry). This is why the empirical structure favours it: a meta-analytic review of many latent-structure studies found little persuasive evidence for discrete taxa underlying the personality disorders, with schizotypal the only possible partial exception (New Oxford Textbook of Psychiatry). If the underlying reality is continuous, a continuous model has better *validity* and, crucially, covers the subthreshold majority that the categorical cut-offs leave out.

Severity leads because severity predicts. The single most useful dimension is overall severity of personality dysfunction, which forecasts self-harm, service use, relationship breakdown and occupational failure better than any type label; rating it first is the design principle both modern dimensional systems adopt. The schizotypal exception, the one construct with some categorical support, sits at the schizophrenia-spectrum edge and is developed in the Schizophrenia: aetiology, phenomenology, classification and course notes.

4.5 The dimensional approach: its price

Validity is bought with unfamiliarity. The dimensional model's weaknesses are the reciprocal of its strengths. It is *less familiar* and harder to communicate: a severity level plus a set of trait

qualifiers does not compress into a single memorable phrase the way "narcissistic personality disorder" does, and clinicians trained on the types find the profiles unintuitive at first (New Oxford Textbook of Psychiatry). There has also been decades of *controversy over the best dimensional representation*, how many domains, which ones, how to set the severity anchors, though considerable consensus has now settled on a small set of core trait domains. Notably, once clinicians use the dimensional models they tend to find them *more* clinically useful than the categories, so the unfamiliarity is a transitional cost rather than a permanent defect (New Oxford Textbook of Psychiatry).

GOOD TO REMEMBER

- **Categorical approach:** personality disorders as qualitatively distinct kinds sorted into named types; strengths are clinical familiarity and one-phrase communicability plus documented prevalence, impairment and course; weaknesses are excessive comorbidity, within-category heterogeneity, arbitrary thresholds, temporal instability, limited validity, and incomplete coverage of the subthreshold majority (a large not-otherwise-specified group).
- **Dimensional approach:** personality pathology as maladaptive variants of traits on continua of severity and trait that merge into normality; strengths are better validity, retention of individual profile information and coverage of the subthreshold majority; weaknesses are unfamiliarity, harder single-phrase communication, and past controversy over the best representation.
- **The discriminator to state:** kinds versus degrees; every strength and weakness on each side follows from that one assumption.

4.6 The comparison of approaches, side by side

The object to reproduce cold. The **comparison of approaches** is best held as a two-column ledger of matched trade-offs; the highlighted cells are the points most often tested. Read across each row and the reciprocal structure is obvious: what one approach gains, the other loses.

DIMENSION OF COMPARISON	CATEGORICAL APPROACH	DIMENSIONAL APPROACH
Core claim	Distinct kinds; a disorder you have or lack	**Degrees; maladaptive variants merging into normality**
Diagnosis returns	A type name	A severity level plus a trait profile
Communicability	**High; one phrase carries a prototype**	Lower; a profile is harder to state briefly
Clinical familiarity	**High; the default of medicine, a century of use**	Low; newer and initially unintuitive
Comorbidity	**Excessive; types co-occur freely**	Dissolved; overlap is expected on shared traits
Within-category variation	Large; polythetic criteria yield heterogeneous cases	**Captured; the profile separates similar-looking patients**
Thresholds	Arbitrary, without empirical basis	Graded; the cut is a chosen point on a continuum
Coverage of subthreshold pathology	Poor; a large not-otherwise-specified residual	**Good; the subthreshold majority is still described**

DIMENSION OF COMPARISON	CATEGORICAL APPROACH	DIMENSIONAL APPROACH
Empirical validity	Limited; little evidence for discrete taxa	**Better; matches the continuous latent structure**

The categorical and dimensional approaches as matched trade-offs; the highlighted cells mark each side's decisive advantage, and every row is a consequence of the kinds-versus-degrees choice.

MNEMONIC

Categories COMMUNICATE, dimensions VALIDATE

The one-line split. The **categorical** approach wins on **C**ommunicability and **C**linical familiarity but is **C**omorbidity-ridden and **C**rudely-thresholded. The **dimensional** approach wins on **V**alidity, **V**ariation captured and coverage, but is unfamiliar and hard to state in a phrase. Communicate versus validate is the trade-off, and the field has decided validity should lead.

4.7 Why the field moved to dimensional

The evidence tilted, then the manuals followed. The reason for the shift is not fashion but data. Latent-structure research found little support for discrete personality-disorder taxa, and by a 2007 survey a large majority of personality-disorder experts, some **eighty-seven per cent**, judged that personality pathology was dimensional in nature (New Oxford Textbook of Psychiatry). The verdict in the literature is that the classification of personality pathology has been "slowly but inexorably moving from a categorical to a dimensional model", because a dimensional model better reflects the continuous phenomena and better describes both the distance from normal personality and the degree of severity. That, in a phrase, is **why the field moved to dimensional**: the discrete kinds the categories assume do not appear to exist, and continua describe the reality and predict the outcomes better.

Two manuals, two speeds of change. ICD-11 made the full commitment: it abolished the categorical types outright and rebuilt the diagnosis as a severity rating (personality difficulty, then mild, moderate or severe) followed by the trait-domain qualifiers and an optional borderline pattern, the model taught forward in the ICD-11 dimensional-classification note. DSM-5-TR was more cautious, and its caution is itself the examinable compromise: it kept the familiar categorical clusters and ten types in Section II for everyday use, and placed the alternative model of personality disorders (the AMPD, a dimensional-categorical hybrid built on the Level of Personality Functioning Scale plus five trait domains) in Section III for further study, developed in the DSM-5 categorical-clusters note. The hybrid is the evidence-driven middle path: it scores personality functioning and traits dimensionally, yet still lets a handful of named types be reconstructed, so the field can move toward dimensions without discarding a century of clinical vocabulary at once.

ICD-10 TO ICD-11: WHAT CHANGED

ICD-10 (F60) **kept the categorical types**, paranoid, schizoid, dissocial, emotionally unstable, histrionic, anankastic, anxious and dependent, in step with the DSM tradition. ICD-11 **removed every one of them** and replaced the list with a severity-led dimensional diagnosis plus trait qualifiers and a borderline pattern qualifier. This is the field moving to dimensional in its purest form. Examinations still test the categorical names because DSM-5-TR Section II retains them, because decades of literature and clinical communication run on them, and because the transition is recent, so a candidate must read fluently in both the categorical and the dimensional languages.

WORKED EXAMPLE

Take the same patient through both approaches. A man in his thirties has rigid perfectionism and interpersonal coldness, plus marked suspiciousness, but does not fully meet any single type. The *categorical approach* stalls: he has features of obsessive-compulsive, paranoid and schizoid personality disorder, meets none cleanly, and is filed as a personality disorder, unspecified, a label that says almost nothing. The *dimensional approach* succeeds: rate moderate personality dysfunction and note prominent anankastia and detachment with some negative affectivity, and the profile describes him precisely and guides the plan. The contrast is the whole argument in one case: the category returns a shrug, the dimensions return a description.

4.8 The India lens and the cultural frame

Under-recognition meets a severity-led model. Personality disorders are markedly under-recognised in routine Indian practice: they surface through comorbid mood, anxiety, substance or self-harm presentations rather than as a personality diagnosis, and the personality label is often avoided for fear of stigma (Gupta and Mattoo, on Indian personality-disorder prevalence and demography). A severity-led dimensional system, which begins with a graded judgement of self-and-interpersonal dysfunction rather than demanding a full type match, is well suited to catching the milder and mixed presentations that categorical thresholds cause Indian services to miss. The categorical versus dimensional choice is therefore not only academic here; the dimensional route may materially improve detection.

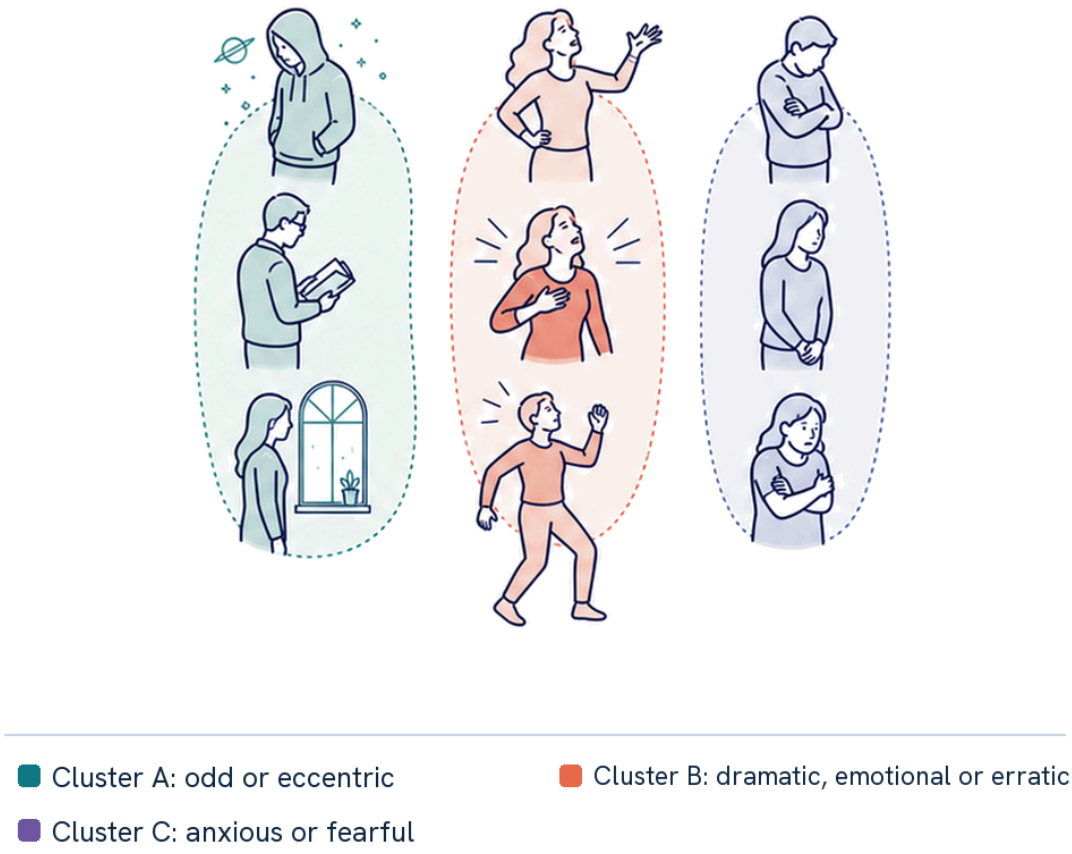

Fig 16.5 The legacy DSM categorical model groups personality disorders into Cluster A, odd or eccentric; Cluster B, dramatic, emotional or erratic; and Cluster C, anxious or fearful. ICD-11 instead prioritises severity and trait domains.

The cultural expression of pathology cuts across both. Whichever approach is used, the general criteria require deviation from what the person's *own* culture expects, so a self deeply embedded in family and community, or a deference and interdependence that would read as dependence through a Western lens, must not be scored as disorder; personality pathology must not be read through a single culture's norms. On the treatment side, the structured psychotherapies a dimensional severity rating points toward, dialectical behaviour therapy and schema therapy, are available and being culturally adapted in Indian metros and academic centres but remain scarce elsewhere, so a severe rating can outrun what a service can deliver. Antisocial personality disorder carries the sharpest medico-legal edge in Indian practice, and its offender and court framing is handled in the Mental health legislation and forensic psychiatry notes; the wider technique of the psychological therapies belongs to the Psychotherapies, clinical assessment, MSE and nosology notes.

INDIA

Personality disorders are under-recognised in Indian practice, presenting through their comorbidities and often left uncoded for fear of stigma; a dimensional, severity-first reading is better at catching the subthreshold and mixed cases that categorical cut-offs miss. Judge deviation against the patient's own cultural and social norms, so collectivist family-embeddedness is not scored as dependency and religiously framed experience not as schizotypal oddness. The structured psychotherapies that the dimensional model points to, dialectical behaviour therapy and schema therapy, are available and being culturally adapted in the metros and academic centres but unevenly accessible elsewhere; and antisocial personality disorder carries the medico-legal weight, cross-referenced to the forensic notes.

3 / 10	5	5+	87%
DSM-5-TR CATEGORICAL CLUSTERS / TYPES	DIMENSIONAL TRAIT DOMAINS (ICD-11 AND AMPD)	OF NINE BORDERLINE CRITERIA (THE POLYTHETIC THRESHOLD)	OF PD EXPERTS JUDGED PATHOLOGY DIMENSIONAL (2007 SURVEY)

HOLD THIS

The categorical approach treats a personality disorder as a discrete type (familiar and communicable, but comorbid, heterogeneous, arbitrarily thresholded and poor at covering the subthreshold majority); the dimensional approach treats it as severity plus traits on continua (better validity and coverage, but less familiar); the field moved to dimensional because the discrete kinds do not appear to exist, and ICD-11 abolished the types while DSM-5-TR keeps them in front with the AMPD hybrid behind as the evidence-driven compromise.

The personality disorders by cluster

5 . Cluster A: paranoid, schizoid and schizotypal

Why this cluster is worth its marks. **cluster a** is the **odd or eccentric** group, and it rewards a candidate who can do two things: give the one-line essential feature of each of its three types cold, and defend the boundaries that separate them from one another and from frank psychosis. The three are paranoid personality disorder (a pervasive distrust and suspiciousness in which others' motives are read as malevolent), schizoid personality disorder (detachment from social relationships with a restricted range of emotional expression), and schizotypal personality disorder (acute discomfort in close relationships together with cognitive or perceptual distortions and eccentricities of behaviour) (DSM-5-TR). The thread that ties them is a retreat from, or a distortion of, ordinary social relatedness, and at the schizotypal end that thread runs into the **schizophrenia spectrum**.

This fragment first frames the cluster on one grid, then takes each type through its defining criterion and the discriminator an examiner rewards, and finally isolates the single highest-yield boundary of the group, schizotypal versus schizophrenia, with the nosological twist that schizotypal is the one member that both manuals place, wholly or partly, among the psychotic disorders rather than the personality disorders. Two prior cautions carry over from the

framework topics of this chapter and are assumed throughout: the general personality-disorder criteria (an enduring, pervasive, inflexible pattern, culturally deviant, with onset by adolescence, causing impairment, and not better explained otherwise) must be cleared before any of these types is named; and ICD-11 has abolished the categorical types, so "paranoid" and "schizoid" as labels survive only in DSM-5-TR and in clinical shorthand. The deep pharmacology sits in the Schizophrenia: management, antipsychotics and adverse effects notes, the schizophrenia boundary in the Schizophrenia: aetiology, phenomenology, classification and course notes, and the wider psychotherapy technique in the Psychotherapies, clinical assessment, MSE and nosology notes.

5.1 The cluster on one frame

Three types, one thread, graded by how far from reality they drift. DSM-5-TR groups the three types whose sufferers "often appear odd or eccentric" (DSM-5-TR). Read the cluster as a gradient of departure from normal relatedness: paranoid personality disorder distrusts other people but keeps a firm hold on reality; schizoid personality disorder withdraws from other people without distorting them; schizotypal personality disorder adds to that withdrawal a layer of cognitive and perceptual oddness that shades toward, but never reaches, frank psychosis. Learning the three essential features and their thresholds as one block is the fastest route to every cluster A question.

TYPE	ESSENTIAL FEATURE (DSM-5-TR)	THRESHOLD	CORE DISCRIMINATOR
Paranoid	A pervasive distrust and suspiciousness such that others' motives are interpreted as malevolent	Four or more of the seven features	**Suspiciousness with reality intact; no cognitive-perceptual distortion**
Schizoid	Detachment from social relationships with a restricted range of emotional expression	Four or more of the seven features	**A contented loner: no desire for closeness at all**
Schizotypal	Acute discomfort in close relationships, plus cognitive or perceptual distortions and eccentricities of behaviour	Five or more of the nine features	**Odd cognition and perception; the schizophrenia-spectrum edge**

The three DSM-5-TR Cluster A types with their essential features, criterion thresholds and core discriminators; the accompanying figure lays the same three on a distrust-to-distortion gradient.

PEARL

A one-word tag per type keeps them apart under pressure: paranoid is *distrust*, schizoid is *detachment*, and schizotypal is *distortion* laid on top of detachment. The suspiciousness of paranoid and the aloofness of schizoid can both appear in schizotypal, but only schizotypal carries the odd beliefs, perceptions and speech; that added layer is the whole diagnosis.

5.2 Paranoid personality disorder

Malevolent motives read into a neutral world. The essential feature of paranoid personality disorder is a pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent, beginning by early adulthood and present across contexts, shown by **four or more of the seven** features (DSM-5-TR). The seven are: unjustified suspicion that others are exploiting, harming or deceiving them; preoccupation with doubts about the loyalty or trustworthiness of associates; reluctance to confide for fear the information will be used against them; reading hidden demeaning or threatening meaning into benign remarks or events; persistently bearing grudges; perceiving attacks on their character that are not apparent to others, with a quick angry counterattack; and recurrent unjustified suspicions about a partner's fidelity. The interpersonal signature is a person who scrutinises every action for hostile intent and cannot accept loyalty when it is shown. Crucially the beliefs are held with suspicion, not with delusional conviction: the patient can, at least in principle, acknowledge an alternative reading, which is exactly what separates this from a persecutory delusion (Companion).

GOOD TO REMEMBER

- **Paranoid personality disorder:** defining criterion is a pervasive distrust and suspiciousness in which others' motives are read as malevolent, four or more of the seven features present, from early adulthood. Discriminator upward from psychosis: the suspicions are not of delusional intensity and alternatives can be acknowledged (from delusional disorder and schizophrenia). Discriminator within the cluster: no cognitive-perceptual distortion or eccentricity, which would move it to schizotypal. First step: confirm the general personality-disorder criteria, then that the suspiciousness is pervasive and reality-based, not a fixed delusion.

5.3 Schizoid personality disorder

The genuine loner, not the frightened one. The essential feature of schizoid personality disorder is a pervasive pattern of detachment from social relationships and a restricted range of emotional expression in interpersonal settings, from early adulthood, shown by **four or more of the seven** features (DSM-5-TR). The seven are: neither desiring nor enjoying close relationships, including being part of a family; almost always choosing solitary activities; little interest in sexual experiences with another person; taking pleasure in few activities; lacking close friends or confidants other than first-degree relatives; indifference to praise or criticism; and emotional coldness, detachment or flattened affect. The person is a contented loner who does not want closeness, presenting a bland exterior with little visible emotional reactivity. The examiner's favourite contrast is with avoidant personality disorder: the avoidant person longs for relationships but is held back by fear of rejection, whereas the schizoid person has no desire for them in the first place. That single question, "do they want closeness?", separates the two.

GOOD TO REMEMBER

- **Schizoid personality disorder:** defining criterion is detachment from social relationships with a restricted, flattened range of emotional expression, four or more of the seven features, from early adulthood. Discriminator from avoidant: absence of any desire for closeness (avoidant desires it but fears rejection). Discriminator from schizotypal: detachment without cognitive-perceptual distortion or eccentricity. First step: establish that solitariness is preferred and pervasive, not a secondary retreat from anxiety, depression or psychosis.

5.4 Schizotypal personality disorder

Attenuated oddness, not frank psychosis. The essential feature of schizotypal personality disorder is a pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships, together with cognitive or perceptual distortions and eccentricities of behaviour, shown by **five or more of the nine** features (DSM-5-TR). The nine are: ideas of reference (incorrect readings of casual events as having special personal meaning, but short of delusional conviction); odd beliefs or magical thinking influencing behaviour (superstition, belief in clairvoyance, telepathy or a "sixth sense"); unusual perceptual experiences including bodily illusions; odd thinking and speech (vague, digressive or over-elaborate, but without derailment or incoherence); suspiciousness or paranoid ideation; inappropriate or constricted affect; behaviour or appearance that is odd, eccentric or peculiar; lack of close friends other than first-degree relatives; and excessive social anxiety that does not ease with familiarity and is tied to paranoid fears rather than to negative self-judgement. Two distinctions matter. Ideas of reference are not delusions of reference: the difference is conviction. And the social anxiety, unlike the avoidant type's, does not settle as the person gets to know the setting, because it is driven by suspiciousness. Under stress these patients may have transient psychotic-like episodes lasting minutes to hours, usually too brief to meet the threshold for a brief psychotic disorder.

GOOD TO REMEMBER

- **Schizotypal personality disorder:** defining criterion is social and interpersonal deficits plus cognitive or perceptual distortions and eccentricity, five or more of the nine features, from early adulthood. Discriminator within the cluster: it is paranoid plus schizoid plus the distortion layer (odd beliefs, unusual perceptions, odd speech, eccentricity), which neither of the others has. Discriminator upward: the distortions are attenuated, ideas of reference not delusions, no sustained frank psychosis. First step: demonstrate the cognitive-perceptual oddness is enduring and trait-level, then that it never crosses into frank, sustained psychosis.

5.5 Schizotypal versus schizophrenia, and the schizophrenia-spectrum placement

The one member that belongs to the psychosis family. Schizotypal is the boundary the day is built to test. It is characterised by an enduring pattern of unusual speech, perceptions, beliefs and behaviours that resemble *attenuated* forms of the defining symptoms of schizophrenia (ICD-11 CDDR). The line from schizophrenia is drawn on intensity alone: schizophrenia is diagnosed when the symptoms are severe and sustained enough to meet its own threshold, and until then the presentation stays eccentric or peculiar rather than overtly psychotic. The familial evidence backs the kinship: schizotypal aggregates in the first-degree biological relatives of people with

schizophrenia and is regarded as part of the schizophrenia-related spectrum of psychopathology. This is why the classification treats it as a half-member of the personality-disorder family. DSM-5-TR lists it in the personality-disorders chapter but cross-lists it in the Schizophrenia Spectrum and Other Psychotic Disorders chapter and codes it F21. ICD-11 goes further and places schizotypal disorder (6A22) squarely within the schizophrenia and other primary psychotic disorders grouping, not among the personality disorders at all, continuing what ICD-10 did with F21. So while ICD-11 abolished paranoid and schizoid as categories, it kept schizotypal, but moved it out of the personality chapter entirely.

BOUNDARY	CLUSTER A SIDE	THE OTHER SIDE	DISCRIMINATOR
Schizotypal vs schizophrenia	Attenuated distortions; eccentric or peculiar; transient stress-related psychosis of minutes to hours	Frank, sustained delusions or hallucinations meeting threshold	**Intensity alone: attenuation versus frank sustained psychosis**
Schizotypal vs paranoid or schizoid	Cognitive-perceptual distortions and marked eccentricity present	Suspiciousness alone (paranoid) or detachment alone (schizoid)	Presence of the distortion and eccentricity layer
Schizoid vs avoidant	No desire for relationships; content in solitude	Desires relationships but fears rejection	Whether closeness is wanted at all
Paranoid vs delusional disorder	Suspicion not of delusional intensity; alternatives can be acknowledged	Fixed persecutory delusion held with conviction	Delusional conviction and intensity

The four boundaries most often tested around Cluster A; the highlighted cell is the single discriminator that decides schizotypal versus schizophrenia. The schizophrenia side is developed in the Schizophrenia: aetiology, phenomenology, classification and course notes.

RULE **Schizotypal is schizophrenia-spectrum, and the line is intensity.** ICD-11 codes schizotypal disorder 6A22 with the primary psychotic disorders, not the personality disorders; it is separated from schizophrenia by the attenuation of its symptoms alone, not by a different set of symptoms.

TRAP **Calling attenuated schizotypal features schizophrenia.** Ideas of reference, magical thinking, odd speech and eccentricity that never reach frank, sustained delusions or hallucinations are schizotypal, not schizophrenia; upgrading them to a psychotic diagnosis on their oddness alone is the classic error.

WORKED EXAMPLE

A man in his late twenties is referred as "possible schizophrenia". He has always been a fringe figure: he believes he can sense events before they happen, dresses in a way that does not quite fit together, speaks in a vague, over-elaborate way, and keeps to himself because he suspects colleagues mean him harm. There are no sustained delusions and no hallucinations; under stress he has had brief spells of feeling watched that pass within an hour or two. This is schizotypal personality disorder (or ICD-11 schizotypal disorder), not schizophrenia: the cognitive-perceptual features are attenuated and enduring, never crossing into frank, sustained psychosis. The label you avoid saves him a lifelong psychotic diagnosis and its treatment.

5.6 Management in outline, and the cultural reading

Engagement is the treatment; drugs are narrow and symptom-targeted. Cluster A is managed, not cured, and the deep detail is cross-referenced. No drug is disorder-specific for any of the three. The working mode is a structured, supportive psychotherapy delivered with a reliable, low-intensity, non-intrusive stance: for the paranoid and schizoid patient the whole difficulty is engagement, because suspiciousness or a genuine preference for solitude makes them slow to enter therapy and quick to leave it, and over-warmth or forced intimacy can rupture the alliance. For schizotypal personality disorder, a low-dose second-generation antipsychotic (for example, risperidone) can be used in a symptom-targeted, adjunctive way for the cognitive-perceptual features, with the dosing and adverse-effect detail carried in the Schizophrenia: management, antipsychotics and adverse effects notes rather than re-taught here. The broader psychotherapy technique sits in the Psychotherapies, clinical assessment, MSE and nosology notes.

GOOD TO REMEMBER

- **Structured supportive psychotherapy (Cluster A):** mechanism is a reliable, low-intensity working alliance that reduces isolation and reality-tests suspicion without forcing intimacy; indication is all three Cluster A types, chosen because they rarely tolerate intensive, emotionally demanding therapy; signature caution is that engagement itself is the obstacle, so over-familiarity or a pushed pace ruptures the alliance in the paranoid and schizoid patient. For schizotypal, a low-dose second-generation antipsychotic is adjunctive and symptom-targeted only, never disorder-specific.

INDIA

Two genuine India angles converge on Cluster A. First, under-recognition: these are the quietest personality disorders, ego-syntonic and rarely self-referred, so the paranoid and schizoid patient reaches services only through a comorbidity or a family crisis, and the diagnosis is made only when it is actively sought. Second, and more testable, the cultural reading of schizotypal features. Both DSM-5-TR and the ICD-11 CDDR warn explicitly that culturally sanctioned beliefs and practices, belief in the evil eye, a sixth sense, spirit visitation of a deceased relative, shamanic or trance experience, speaking in tongues, magical beliefs about health and illness, can look schizotypal to an uninformed clinician and must not be scored as cognitive-perceptual distortion when they are normative for the person's community. The cultural expression of personality pathology has to be weighed against the patient's own milieu, with an informant where needed, before any Cluster A type is fixed. Structured psychotherapy is available unevenly and mostly at tertiary and private centres.

5.7 The countable skeleton

One line rebuilds the cluster. Three types, two thresholds and one spectrum placement are the whole of Cluster A worth carrying into the hall. Hook them once and each type unpacks from the tag.

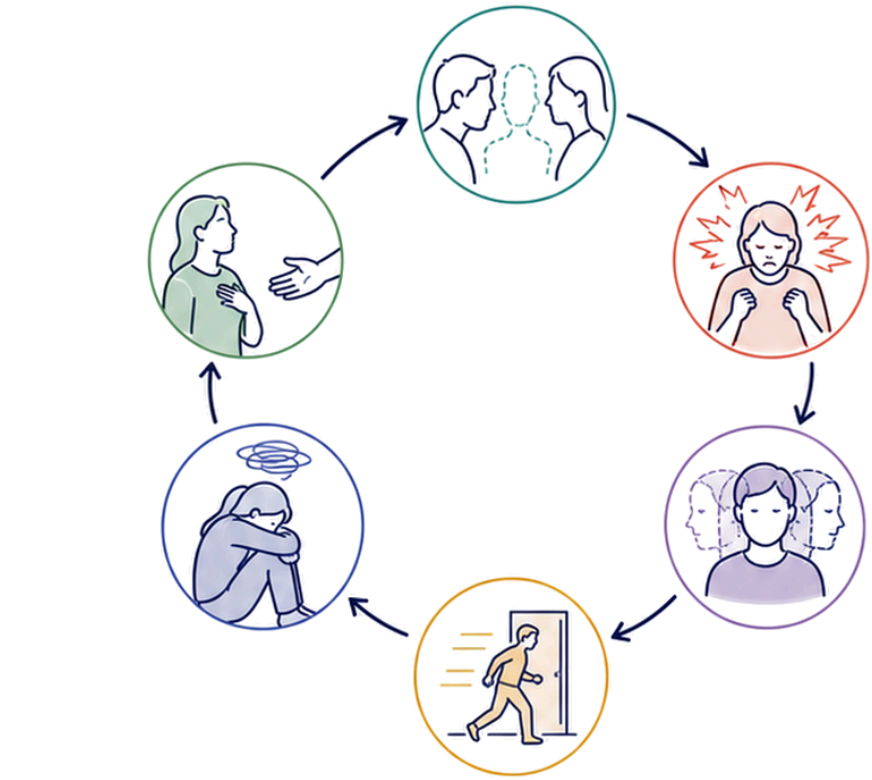

Fig 16.6 A common borderline personality dynamic links perceived attachment threat to rapid affective escalation, unstable self-other representations, impulsive action, shame or emptiness and renewed interpersonal sensitivity.

MNEMONIC

DISTRUST, DETACH, DISTORT

The three Cluster A types by their one-word core. **DISTRUST** is paranoid personality disorder (suspiciousness, motives read as malevolent, four or more of the seven, reality intact). **DETACH** is schizoid personality disorder (a contented loner, restricted emotion, four or more of the seven, no desire for closeness). **DISTORT** is schizotypal personality disorder (detachment plus cognitive-perceptual oddness and eccentricity, five or more of the nine, the schizophrenia-spectrum edge). Distrust keeps reality; detachment leaves it alone; distortion bends it, but never breaks it.

3 CLUSTER A TYPES (ODD OR ECCENTRIC)	**4** OF SEVEN FEATURES: PARANOID OR SCHIZOID THRESHOLD	**5** OF NINE FEATURES: SCHIZOTYPAL THRESHOLD	**6A22** ICD-11 SCHIZOTYPAL, IN THE SCHIZOPHRENIA SPECTRUM

HOLD THIS

Cluster A is odd or eccentric: paranoid is distrust with reality intact (four or more of the seven), schizoid is detachment with no wish for closeness (four or more of the seven), schizotypal is both plus cognitive-perceptual distortion (five or more of the nine); and schizotypal alone sits on the schizophrenia spectrum (ICD-11 schizotypal disorder 6A22), separated from schizophrenia by attenuation, not by a different symptom.

6 . Borderline personality disorder

The type every examiner returns to. Of the ten categorical types, borderline personality disorder (BPD) is the single highest-yield entity of the chapter: it carries as many criteria as any type, the most differentials, and the only personality-disorder treatment literature dense enough to examine on its own. The whole picture reduces to one **pervasive pattern of instability**, of interpersonal relationships, of self-image and of affect, welded to marked impulsivity, beginning by early adulthood and present across a variety of contexts. Learn it as a polythetic set of nine features from which **five or more of the nine criteria** must be present, and you can both make the diagnosis and defend it against the two presentations that most often masquerade as it, bipolar II disorder and complex post-traumatic stress disorder.

This fragment walks the nine criteria one by one, spells the threshold, teaches the **course** and the **complications**, and closes on the ICD-11 borderline pattern qualifier as the dimensional equivalent of the same construct. The **affective instability** boundary with the bipolar-II side is cross-referenced to the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes; the trauma boundary to the Anxiety, OCD and trauma-related disorders notes; and the depth of the disorder-specific psychotherapies (dialectical behaviour therapy, schema therapy, mentalisation-based treatment) to their own topics in this chapter. Everything here sits downstream of the general personality-disorder criteria, which must be cleared before the count begins.

6.1 The essential feature: instability across three domains plus impulsivity

Instability is the signature, in relationships, in the self and in affect. The essential feature of borderline personality disorder is a pervasive pattern of instability of interpersonal relationships, self-image and affects, together with marked **impulsivity**, that begins by early adulthood and is present in a variety of contexts (DSM-5-TR). Three domains are unstable, relationships, self and mood, and a fourth behavioural strand, impulsivity, cuts across all of them; the nine diagnostic criteria are simply these four strands unpacked. Holding the four-strand skeleton first is what stops BPD collapsing into a list to be memorised blind: abandonment and idealisation-devaluation are the *relationship* strand; identity disturbance and chronic emptiness are the *self* strand; reactive mood and inappropriate anger are the *affect* strand; and self-damaging impulsivity, recurrent self-harm and transient stress-related paranoia or dissociation are the *behaviour-under-load* strand. The instability is not situational turbulence but a lifelong, ego-syntonic pattern that the general criteria have already certified as enduring, pervasive and inflexible.

6.2 The nine criteria in full

Reproduce all nine; the count depends on it. The DSM-5-TR criteria (F60.3) are the cleanest form of the construct, and the ICD-11 borderline pattern list mirrors them almost word for word. Carry the block as one table, because a defensible diagnosis names *which* criteria are met, not merely that the patient "seems borderline".

NO.	CRITERION	WHAT IT REQUIRES
1	Abandonment	Frantic efforts to avoid real or imagined **abandonment** (self-harm and suicidal acts are counted separately, under criterion five)
2	Unstable relationships	A pattern of unstable and intense interpersonal relationships alternating between extremes of idealisation and devaluation
3	Identity disturbance	**Identity disturbance**: a markedly and persistently unstable self-image or sense of self
4	Impulsivity	Impulsivity in at least two areas that are potentially self-damaging (spending, sex, substance use, reckless driving, binge eating)
5	Self-harm / suicidality	Recurrent suicidal behaviour, gestures or threats, or self-mutilating behaviour
6	Affective instability	**Affective instability due to a marked reactivity of mood (episodic dysphoria, irritability or anxiety usually lasting a few hours and only rarely more than a few days)**
7	Chronic emptiness	Chronic feelings of emptiness
8	Inappropriate anger	Inappropriate, intense anger or difficulty controlling anger (frequent temper, constant anger, recurrent physical fights)
9	Paranoia / dissociation	Transient, stress-related paranoid ideation or severe dissociative symptoms

The nine DSM-5-TR borderline personality disorder criteria; the highlighted reactivity clause of criterion six is the pivot on which the bipolar-II discrimination turns. The ICD-11 borderline pattern list is materially identical.

6.3 The threshold, and why the disorder is heterogeneous

Five or more of the nine, in any combination. Borderline personality disorder is diagnosed when a pervasive pattern of instability and impulsivity is present, as shown by **five or more of**

the nine criteria. Because any five will do, the set is polythetic: two patients can both carry the diagnosis while sharing only one criterion between them, which is why the presentation ranges so widely, from the quietly empty and self-harming to the floridly angry and quasi-psychotic. The count is not the first step, though; the general personality-disorder criteria (enduring, pervasive and inflexible, onset by adolescence, not better explained by another disorder or a substance) are cleared first, and only then are the nine tallied. This is also why heterogeneity is examinable: naming the five you have counted forces the discipline that a pattern-matched label lacks.

MNEMONIC

AM SUICIDE

The nine criteria, one letter each: **A**bandonment fears; **M**ood instability (reactive affect); **S**uicidal or self-mutilating behaviour; **U**nstable, intense relationships (idealisation to devaluation); **I**mpulsivity in two or more self-damaging areas; **C**ontrol of anger poor (inappropriate intense anger); **I**dentity disturbance; **D**issociation or paranoia that is transient and stress-related; **E**mptiness (chronic). Nine letters, nine criteria, threshold five.

9	5	2
BORDERLINE CRITERIA (DSM-5-TR)	MINIMUM MET, OF THE NINE, TO DIAGNOSE	SELF-DAMAGING AREAS FOR THE IMPULSIVITY CRITERION

WORKED EXAMPLE

A woman in her early twenties presents after an overdose following a break-up. On history she describes terror of being left (one), relationships that swing from "he is perfect" to "he is cruel" within days (two), never knowing who she really is (three), recurrent cutting and this overdose (five), moods that flip within an afternoon in response to a text going unanswered (six), and a background sense of emptiness (seven). That is five of the nine met with room to spare, on an enduring pattern predating the current crisis. The diagnosis is defensible not because she "looks borderline" but because you can name the criteria and show they are trait, not a fresh state.

6.4 Abandonment, and the idealisation-devaluation of relationships

The relationship strand is driven by intolerance of aloneness. The frantic efforts to avoid real or imagined **abandonment** (criterion one) are cued by the mere perception of impending separation or the loss of external structure, so that a clinician ending a session on time or arriving a few minutes late can trigger panic or fury out of all proportion. The same sensitivity produces the unstable, intense relationships of criterion two: the patient idealises a new caregiver or lover at the first meeting, demands closeness, then switches abruptly to devaluation when the other is felt not to give or care enough. These sudden reversals in the view of another person, from all-good to all-bad, are the surface of the classical defence of splitting, in which contradictory images of self and other cannot be held together, so they alternate instead.

PEARL

Splitting is the mechanism the object-relations tradition (Otto Kernberg) places at the centre of the borderline structure: the inability to integrate good and bad representations of the same person, so that idealisation and devaluation swing back and forth rather than blending into a whole, ambivalent view. Naming splitting explains criterion two and the "you are the only one who understands me / you are just like all the others" whiplash that clinicians feel in the room.

6.5 Identity disturbance and chronic emptiness

The self strand is a self that will not hold still. **Identity disturbance** (criterion three) is a markedly and persistently unstable self-image or sense of self: values, goals, career direction, sexual identity and even the felt sense of existing can shift suddenly, and the person may report at times a feeling that they do not exist at all. It is worst in unstructured settings, where there is no external scaffold to borrow an identity from, which is why performance can collapse in open-ended work or study while holding up under close direction. Running underneath it is criterion seven, chronic feelings of emptiness, a persistent hollowness distinct from the sadness of depression: not "I feel low" but "there is nothing inside". The two together are the self-strand that the disorder-specific psychotherapies target most directly, and they are also the features most easily overlooked when attention fixes on the dramatic behaviours.

6.6 Affective instability and inappropriate anger, and the bipolar-II line

The affect is reactive, fast and interpersonally cued. **Affective instability** (criterion six) is defined by a marked reactivity of mood: episodic dysphoria, irritability or anxiety that is triggered, most often by an interpersonal event, and that usually lasts a few hours and only rarely more than a few days. Criterion eight, inappropriate and intense anger, belongs to the same strand: disproportionate temper, sustained anger, sometimes physical fights, frequently aimed at the very person whose closeness is most wanted. This is the criterion pair that collides with bipolar II disorder, and the collision is the highest-yield discrimination on the topic. Bipolar mood runs as sustained, autonomous episodes lasting days to weeks, carrying change in sleep, energy and goal-directed activity; borderline mood is reactive, brief and settles when the trigger resolves. The full grid sits on the bipolar-II topic; here, hold the discriminator.

RULE **Read the clock and the trigger on the mood.** Borderline affective instability is reactive, interpersonally cued and settles in hours; a mood that runs autonomously for days to weeks with change in sleep, energy and goal-direction is a bipolar episode, not a personality trait.

TRAP **Starting a mood stabiliser for personality-based instability.** Missing the borderline-versus-bipolar-II distinction and reading reactive, hours-long lability as bipolar II disorder medicalises a pattern whose primary treatment is structured psychotherapy; the drug then follows the misdiagnosis rather than the illness.

6.7 Impulsivity, recurrent self-harm and suicidality

The behaviour-under-load strand is where the risk lives. Criterion four requires **impulsivity** in at least two potentially self-damaging areas, spending, sex, substance use, reckless driving or

binge eating, and it is counted separately from the self-directed acts. Those acts are criterion five: **recurrent self-harm** and **suicidality**, which is to say recurrent suicidal behaviour, gestures or threats, or self-mutilating behaviour. Self-harm in borderline personality disorder frequently functions to regulate unbearable affect or to end dissociation rather than to end life, but the two intentions coexist and the mortality is real, so the presence of a regulatory function never downgrades the risk assessment. Chronic recurrent self-harm and acute suicidality must be held apart in the moment: the enduring pattern is expected, while a change from baseline, a new plan or a fresh stressor, is what escalates management.

6.8 Transient stress-related paranoia and dissociation

The quasi-psychotic criterion is transient and stress-bound. Criterion nine is **transient stress-related paranoia** (paranoid ideation) or severe **dissociation**, arising in states of high affective arousal, most often under the threat of abandonment, and resolving as the arousal subsides. The qualifiers are load-bearing: *transient* and *stress-related* separate these micro-psychotic experiences from the sustained, autonomous psychosis of a schizophrenia-spectrum disorder, and from the enduring cognitive-perceptual oddness of schizotypal personality. They are brief, reactive, and the patient usually retains some distance from them once calm. This criterion is also the one that overlaps most with the dissociative and hyperarousal features of complex post-traumatic stress disorder, which is the second great mimic of the syndrome.

> **COMMON TRAP**
>
> Collapsing complex post-traumatic stress disorder into borderline personality disorder. Both follow early adversity and share affect dysregulation, dissociation and unstable relationships, but complex post-traumatic stress disorder is built on the trauma triad (re-experiencing, avoidance, hyperarousal) plus disturbances in self-organisation, and its instability is trauma-cued rather than the enduring, abandonment-driven identity pathology of borderline personality disorder. The boundary and its therapeutic consequences are developed in the Anxiety, OCD and trauma-related disorders notes.

6.9 The course: waxing and waning, remission that outpaces recovery

The symptoms remit long before function returns. The **course** of borderline personality disorder is a waxing and waning one that trends, over years, toward **symptomatic remission**: in long-term prospective follow-up (the McLean Study of Adult Development led by Zanarini, and the Collaborative Longitudinal Personality Disorders Study), the majority of patients no longer meet full criteria after several years, and the acute, impulsive features, self-harm, quasi-psychotic episodes, stormy relationships, tend to attenuate earliest. The catch is that *functional* recovery, stable work and durable relationships, lags well behind symptomatic remission; a patient can stop meeting criteria yet remain vocationally and interpersonally disabled. This dissociation between symptom remission and functional recovery is the examinable heart of the prognosis, and it reframes the disorder as more remitting than its acute presentation suggests, while cautioning against calling a symptomatic remission a cure.

6.10 The complications, and the management orientation

The morbidity clusters in four places. The **complications** of borderline personality disorder are, first, repeated self-harm; second, completed suicide, whose lifetime rate is substantial and highest in the early acute years; third, comorbid substance use, mood and eating disorders that both worsen impulsivity and confound the diagnosis; and fourth, the corrosive impact on relationships and on work, which is the burden that outlasts the symptoms. The management orientation follows directly from the course: structured psychological therapy is the primary treatment, the disorder-specific models (dialectical behaviour therapy, schema therapy, mentalisation-based treatment) are taught on their own topics, and pharmacotherapy is symptom-targeted, adjunctive and time-limited rather than a treatment for the disorder itself; the deep drug detail sits in the Mood disorders: pharmacotherapy notes. Crucially, a diagnosis of borderline personality disorder is never grounds to exclude a patient from care.

INDIA

Borderline personality disorder is markedly under-recognised in Indian practice. Patients reach services through the self-harm or the overdose, which is coded as the attempt rather than the pattern, so the underlying disorder is captured only when it is deliberately sought. Two adaptations matter. First, cultural expression: transient dissociative and possession-trance presentations are normative idioms of distress in many Indian settings and must not be over-read as the criterion-nine dissociation, just as family interdependence must not be read as pathological abandonment fear; judge every criterion against the person's own culture. Second, access: dialectical behaviour therapy and schema therapy are being delivered and culturally adapted at Indian tertiary and private centres rather than being widely available, which is what a realistic management plan must reckon with.

6.11 The ICD-11 borderline pattern qualifier: the dimensional equivalent

The same construct, carried forward into the dimensional model. ICD-11 abolished the categorical types, but it did not abolish borderline; it preserved the construct as an optional *borderline pattern* specifier (6D11.5), applied on top of a rated severity level and the trait-domain qualifiers. A complete ICD-11 formulation reads, for example, "moderate personality disorder with negative affectivity, dissociality and disinhibition, borderline pattern": severity first, trait domains next, borderline pattern last. The specifier is defined by the same list of features, a pervasive pattern of instability of relationships, self-image and affects with marked impulsivity, and the CDDR applies the *same* formal threshold as DSM-5-TR, five or more of nine features, so the count is not a DSM-only device; it overlaps most with the negative affectivity, dissociality and disinhibition domains. It was retained for a frankly pragmatic reason, which examiners like: to flag the patients who respond to the established borderline-specific psychotherapies. The categorical name therefore survives inside the dimensional system, which is why both are testable.

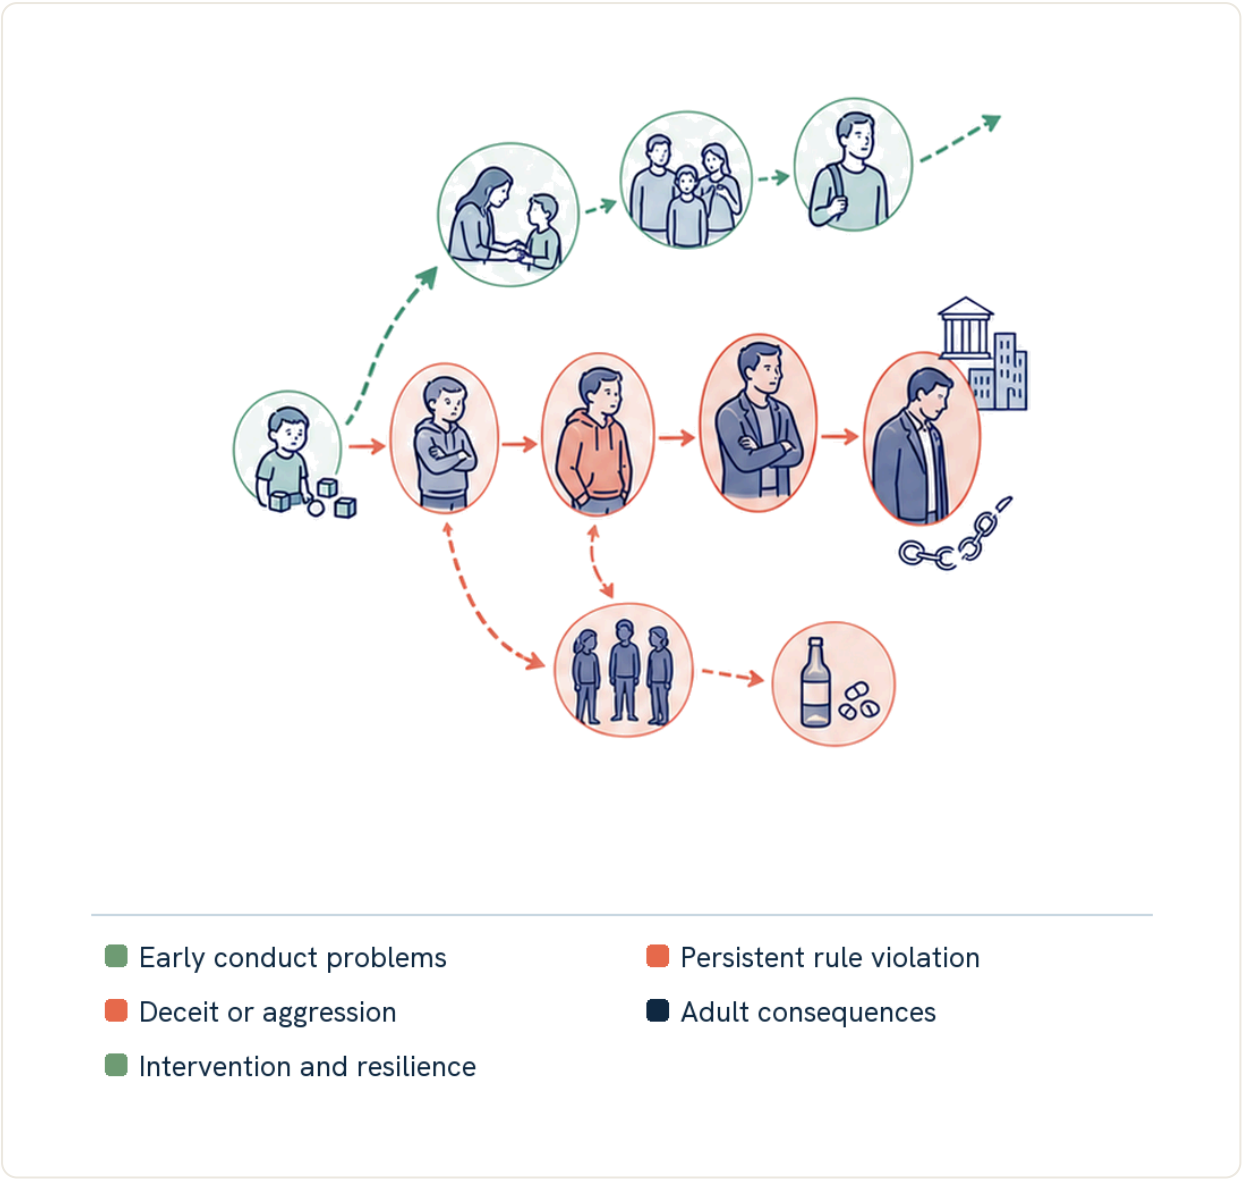

Fig 16.7 Antisocial personality disorder is developmentally anchored in earlier conduct problems, but progression is not inevitable; social context, comorbidity, intervention and resilience shape the adult pathway.

GOOD TO REMEMBER

- **Borderline personality disorder:** defining requirement is a pervasive pattern of instability of relationships, self-image and affect with marked impulsivity, meeting five or more of the nine criteria (abandonment, unstable idealising-devaluing relationships, identity disturbance, self-damaging impulsivity in at least two areas, recurrent self-harm or suicidality, reactive affective instability, chronic emptiness, inappropriate anger, transient stress-related paranoia or dissociation). Discriminator: the affect is rapidly reactive and interpersonally triggered and lasts hours, versus the sustained autonomous episodes of bipolar II disorder. First diagnostic step: clear the general personality-disorder criteria, then count the nine. ICD-11 keeps the construct as the optional borderline pattern qualifier on the dimensional model.

HOLD THIS

Borderline personality disorder is five or more of the nine, on a pervasive base of unstable relationships, unstable identity and reactive affect with impulsivity; the affect swings in hours and tracks interpersonal triggers, which is exactly what separates it from the sustained, autonomous episodes of bipolar II disorder.

7 . Antisocial personality disorder and forensic implications

The type the courts ask about. antisocial personality disorder (**aspd**; dissocial personality disorder in the older ICD terms) is the Cluster B type defined by a pervasive **disregard for and violation of the rights of others**, and it is the one personality disorder the examination reliably pushes into the medico-legal arena. Two features make it examinable beyond the criteria list. First, it is the only personality disorder with a hard developmental gate: it may not be diagnosed without evidence of conduct disorder before adolescence and it may not be diagnosed before adulthood, so the **age criterion** is part of the definition rather than a footnote. Second, it carries the **forensic implications** of the chapter, offending, the assessment of dangerousness, and the court report, and it forces the candidate to hold apart three things that are constantly conflated: the disorder, the construct of psychopathy, and criminality itself.

This fragment states the essential feature and walks the seven adult criteria, fixes the conduct-disorder precursor and the two ages, separates **aspd** from psychopathy and its **pcl-r** construct, cross-maps the categorical name onto the ICD-11 dimensional model, and then develops the two forensic tasks the psychiatrist is actually asked to perform, the structured assessment of dangerousness and the court report. The deep offender-management and legislative detail is carried in the Mental health legislation and forensic psychiatry notes; the general psychotherapy technique in the Psychotherapies, clinical assessment, MSE and nosology notes; and any symptom-targeted pharmacology in the Mood disorders: pharmacotherapy notes and the Schizophrenia: management, antipsychotics and adverse effects notes. Everything here sits downstream of the general personality-disorder criteria, which must be cleared before the count begins.

7.1 The essential feature: a pervasive disregard for the rights of others

The pattern violates the rights of others, and it began in childhood. The essential feature of antisocial personality disorder is a pervasive pattern of disregard for, and violation of, the rights of others, occurring since the age of fifteen years and continuing into adulthood (DSM-5-TR, F60.2). The manual notes in the same breath that this pattern has also been called **psychopathy**, sociopathy or dyssocial personality disorder, which is precisely the overlap the topic exists to disentangle. The behaviour is not a run of bad choices but an enduring, ego-syntonic trait structure: callous unconcern for others' feelings, a readiness to deceive and exploit, impulsive action without forethought, irritable aggression, reckless indifference to safety, chronic irresponsibility, and an absence of guilt. Because deceit and manipulation are central to the presentation, DSM-5-TR advises explicitly that the clinical account be corroborated from collateral and documentary sources rather than taken on the patient's word, a caution that matters even more when the assessment is destined for a court.

7.2 The seven adult criteria, and the three-of-seven threshold

Three or more of the seven, on the enduring pattern. Criterion A is met by **three or more of the seven** features below, present since the age of fifteen years (DSM-5-TR). Carry the block as one table, because a defensible antisocial diagnosis names which features are met, and the

affective item, **lack of remorse**, is the one that later separates the disorder from the narrower construct of psychopathy.

NO.	CRITERION (DSM-5-TR)	WHAT IT REQUIRES
1	Failure to conform to law	Failure to conform to social norms with respect to lawful behaviour, repeatedly performing acts that are grounds for arrest (whether or not arrest follows)
2	Deceitfulness	**deceitfulness**: repeated lying, use of aliases, or conning others for personal profit or pleasure
3	Impulsivity	Impulsivity or failure to plan ahead; decisions made on the spur of the moment without regard for consequences
4	Irritability and aggressiveness	Irritability and aggressiveness, indicated by repeated physical fights or assaults (acts in self-defence do not count)
5	Reckless disregard for safety	Reckless disregard for the safety of self or others (dangerous driving, high-risk behaviour, endangering a dependent)
6	Consistent irresponsibility	Consistent **irresponsibility**: repeated failure to sustain work or to honour financial obligations
7	Lack of remorse	**lack of remorse: being indifferent to, or rationalising, having hurt, mistreated or stolen from another**

The seven DSM-5-TR antisocial personality disorder criteria, of which three or more must be present; the highlighted affective item, lack of remorse, is the feature that most nearly touches the psychopathy construct and is the least likely to be present in ordinary offending.

MNEMONIC

CORRUPT

The seven criteria, one letter each. **C**onformity to law lacking (acts that are grounds for arrest); **O**bligations ignored (consistent irresponsibility, work and money); **R**eckless disregard for safety; **R**emorselessness (lack of remorse); **U**nderhandedness (deceitfulness, lying and conning); **P**lanning absent (impulsivity, failure to plan ahead); **T**emper (irritability and aggressiveness, repeated fights). Seven letters, seven criteria, threshold three.

Two exclusions close the definition. Two further clauses complete Criterion A's scaffolding. The individual must be at least eighteen years old (Criterion B) and must have shown evidence of conduct disorder with onset before fifteen years (Criterion C); and the antisocial behaviour must

not occur exclusively during the course of schizophrenia or a bipolar disorder (Criterion D), so that antisociality driven by mania or by psychosis is excluded from the personality diagnosis.

GOOD TO REMEMBER

- **Antisocial personality disorder:** defining requirement is a pervasive pattern of disregard for and violation of the rights of others since age fifteen, meeting three or more of the seven criteria (failure to conform to law, deceitfulness, impulsivity, irritability and aggressiveness, reckless disregard for safety, consistent irresponsibility, lack of remorse), with the individual at least eighteen and with documented conduct disorder before fifteen, and the behaviour not confined to schizophrenia or bipolar disorder. Discriminator: it is a trait pattern with a childhood-conduct-disorder precursor, not a synonym for a criminal record. First diagnostic step: clear the general personality-disorder criteria, confirm the conduct-disorder history and the age, then count the seven.

7.3 The conduct-disorder precursor and the age criterion

The developmental spine: oppositional to conduct to antisocial. The **age criterion** is what makes this a developmental diagnosis. The disorder cannot be given before eighteen years, and it cannot be given at all without evidence of conduct disorder with onset before fifteen years (DSM-5-TR). Conduct disorder is itself a repetitive, persistent violation of the basic rights of others or of major age-appropriate norms, and its behaviours fall into four groups, aggression to people and animals, destruction of property, deceitfulness or theft, and serious violation of rules; oppositional defiant disorder is a frequent earlier precursor of the childhood-onset type. The line runs, in the minority who progress, from oppositional through conduct disorder into the adult antisocial pattern, and the childhood-onset conduct disorder carries the worse prognosis. Most children with conduct disorder do not become antisocial adults, but essentially every antisocial adult has a conduct-disordered childhood, which is exactly why the history is a mandatory gate and not an optional descriptor. The developmental trajectory is laid out in the accompanying figure.

RULE **No conduct disorder before fifteen, no antisocial personality disorder.** Evidence of childhood conduct disorder and an age of at least eighteen are hard gates in the criteria; the antisocial diagnosis is a developmental one and cannot be built from an adult offending history alone.

TRAP **Reading a criminal record as antisocial personality disorder.** Offending, gang membership or survival-driven rule-breaking is not the disorder without the enduring, pervasive trait pattern and the conduct-disorder precursor; and antisociality seen only during mania or psychosis is excluded by Criterion D. Crime is neither necessary nor sufficient for the diagnosis.

7.4 Antisocial personality disorder versus psychopathy: the affective-interpersonal core and the PCL-R

Psychopathy is the narrower, affect-defined construct. psychopathy overlaps with antisocial personality disorder but is not the same thing, and treating them as interchangeable is the classic error. The categorical diagnosis is defined largely by observable antisocial *behaviour*; psychopathy is defined by an affective-interpersonal *core*, the glib superficial charm, grandiosity, pathological lying, callousness and, above all, the absence of guilt, remorse or empathy that Hervey Cleckley

described in *The Mask of Sanity* (1941). The construct has been dropped from the formal classifications but survives in forensic psychology and the prison service, where it is assessed with the Hare Psychopathy Checklist-Revised (the **pcl-r**; Robert Hare, 1991), a rater-scored instrument of twenty items, each scored zero to two, to a maximum of forty. The items load onto two factors: an interpersonal-affective factor (the charm, callousness and exploitation, the true psychopathic core) and a lifestyle-antisocial factor (the impulsive, irresponsible and violent behaviour that overlaps heavily with the antisocial criteria). Most people who meet the antisocial criteria do *not* reach a high psychopathy score; psychopathy is the smaller, affect-defined subset carrying the interpersonal-affective factor, and it is that factor, not the criminal record, that predicts the most instrumental and remorseless offending. The overlap and the nesting are shown in the figure alongside.

PEARL

Karpman, paralleling Cleckley's clinical description, distinguished *primary* from *secondary* psychopathy: the primary psychopath acts without anxiety, guilt or autonomic arousal, the mark of the affective deficit, while the secondary psychopath reports guilt and fear but offends through poor impulse control and emotional lability. The distinction maps loosely onto the two PCL-R factors, and it is why "psychopathy" is best reserved for the affective-interpersonal core and, as the general-psychiatry texts advise, largely avoided as a loose synonym for antisocial personality disorder.

GOOD TO REMEMBER

- **Psychopathy and the PCL-R:** the defining feature is the affective-interpersonal core, callousness and the absence of guilt, remorse and empathy (Cleckley), which the behaviour-based antisocial criteria do not require; the instrument is the Hare Psychopathy Checklist-Revised, twenty items scored zero to two to a maximum of forty, with an interpersonal-affective factor and a lifestyle-antisocial factor. Discriminator from antisocial personality disorder: psychopathy is the smaller, affect-defined subset, so most antisocial patients are not psychopathic; the two terms are not interchangeable, and psychopathy is not a diagnostic category in DSM-5-TR or ICD-11.

7.5 The classification frame: DSM-5-TR categorical, ICD-10 dissocial, ICD-11 dissociality

The same construct across three systems. In DSM-5-TR Section II the disorder is the antisocial type in Cluster B (the dramatic, emotional or erratic cluster). ICD-10 kept an almost identical categorical entity under the name dissocial personality disorder, requiring at least three of six traits, callous unconcern for others' feelings, gross and persistent irresponsibility and disregard for social norms, incapacity to maintain enduring relationships, very low frustration tolerance with a low threshold for aggression, incapacity to experience guilt or to profit from experience or punishment, and a marked proneness to blame others, with a childhood conduct-disorder history offered as supporting evidence. ICD-11 then abolished the categorical types altogether: there is now a single personality-disorder diagnosis rated first by severity (personality difficulty, then mild, moderate or severe) and qualified by the five trait domains. The antisocial construct is captured dimensionally by prominent **dissociality** (the ICD-11 domain 6D11.2, whose core feature is a disregard for the rights and feelings of others, self-centredness and lack of empathy),

usually together with **disinhibition** (impulsivity, irresponsibility, recklessness), at a moderate or severe level. The forward teaching of the ICD-11 dimensional model, its severity gradient and its five domains, is developed on the framework topics; here, hold the cross-map. The categorical names still dominate the examination and the courtroom because DSM-5-TR retains them and the case-law is written in them, which is why "antisocial" and "dissocial" remain testable even after ICD-11 has moved on.

7.6 Forensic implications: offending and the assessment of dangerousness

The task is a structured, defensible estimate of future risk. The **forensic implications** begin with offending: antisocial personality disorder is far commoner in men and is markedly over-represented in prison populations, and it frequently co-occurs with substance misuse, which amplifies impulsive aggression. The recurring clinical demand is the **assessment of dangerousness**, an estimate of the risk of future violence. Three approaches exist, and the examinable point is which is preferred. Unstructured clinical judgement is variable and biased; purely actuarial scoring is reliable but ignores the individual's own risk and protective factors; the recommended middle path is **structured professional judgement**, in which the clinician rates empirically derived risk factors systematically and then integrates them with the individual case (Clinical Methods in Psychiatry, AIIMS 2024). The most researched such instrument is the HCR-20, a twenty-item scheme across three scales, ten Historical (static) factors including past violence, young age at first violence, psychopathy and personality disorder, five Clinical (dynamic) factors, and five Risk-Management (dynamic) factors; each item is scored absent, partial or present, and the clinician then makes a summary rating of low, moderate or high, which is deliberately *not* a mechanical sum of ticks. A high PCL-R psychopathy score is itself one of the strongest single predictors of violent recidivism, which is why the two instruments are used together. Whenever risk is judged to be directed at an identifiable person, the duty to protect can override confidentiality. The three approaches are contrasted in the accompanying figure.

RULE **Structure the risk estimate, then judge it; never tick and total.** Dangerousness is assessed by structured professional judgement, empirically derived factors rated systematically and then weighed for the individual, ending in a reasoned low, moderate or high rating, not by the raw count on any checklist.

7.7 Forensic implications: court reports and the medico-legal frame

Antisocial personality disorder is a matter of disposal, not of exculpation. The second forensic task is the court report, and its central caution is that the antisocial diagnosis rarely excuses a crime. The insanity defence turns on a defect of reason from unsoundness of mind such that the accused did not know the nature of the act or that it was wrong, and the courts distinguish this *legal* insanity sharply from any *medical* diagnosis; a personality disorder, being a stable trait pattern rather than a disorder that clouds the knowledge of nature or wrongfulness, seldom meets that test. Psychiatric evidence is treated as relevant, not determinative. So the forensic weight of antisocial personality disorder falls on the assessment of dangerousness, on fitness to stand trial, and on disposal and sentencing, and on the psychiatric prediction of future dangerousness that the law can demand before an insanity-acquitted person is discharged, rather

than on culpability itself. In the report the clinician is an expert assisting the court: the opinion must be evidence-based, non-pejorative, carefully recorded (what is not written is treated as not done), and explicit about the limits of prediction. This medico-legal frame, the statutes, the fitness assessment, the disposal pathways and the report structure, is developed in the Mental health legislation and forensic psychiatry notes.

Criminal responsibility (insanity defence)
Whether unsoundness of mind prevented the accused knowing the nature of the act or that it was wrong; a legal test, judged against medical evidence, that antisocial personality disorder rarely satisfies.

Fitness to stand trial
Whether the accused can understand the charge and proceedings and instruct a defence; assessed before culpability is considered.

Assessment of dangerousness
A structured, professionally judged estimate of the risk of future violence, informing bail, disposal, discharge and management, not guilt.

The expert witness / court report
The psychiatrist assists the court with an impartial, evidence-based, well-documented opinion; relevant to the court's decision but never determinative of it.

The four medico-legal points where antisocial personality disorder meets the court; note that all four concern process, risk and disposal, not the excusing of the offence, whose statutory detail sits in the Mental health legislation and forensic psychiatry notes.

WORKED EXAMPLE

A man in his thirties is remanded after a violent robbery and referred for a court report and a "diagnosis of psychopathy". The history shows truanting, cruelty and theft from before the age of twelve, expulsions, repeated adult convictions, a chaotic work record, unpaid debts, and a flat indifference to the people he has hurt. He meets the antisocial criteria comfortably, with conduct disorder well before fifteen. The report says three things and no more than it can defend: the diagnosis is antisocial personality disorder (not, on this assessment, formally psychopathy, which would need a rated PCL-R); the disorder does not amount to the unsoundness of mind that founds an insanity defence, so it does not reduce his responsibility for the act; and his risk of future violence, assessed by structured professional judgement, is high and should guide disposal. The value of the report lies in what it declines to claim as much as in what it asserts.

RULE **Antisocial personality disorder is not an insanity defence.** As a stable trait pattern it seldom meets the legal test of unsoundness of mind; its forensic relevance is to dangerousness, fitness and disposal, not to exculpation, and the psychiatric opinion is relevant to the court, never determinative.

7.8 Management: guideline-anchored, psychological-first, and drug-sparing

Structured psychological work leads; no drug treats the personality. Management is modest and guideline-anchored, and the deep detail is cross-referenced. NICE recommends offering people with antisocial personality disorder group-based cognitive and behavioural interventions, involving the person in choosing their duration and intensity, and delivered where relevant in

criminal-justice as well as health settings, and it stresses a structured clinical assessment to make the diagnosis in the first place (NICE 2015). No drug is recommended or licensed for the antisocial personality itself; pharmacotherapy is reserved for a comorbid mental disorder, and where impulsive aggression is a treatment target it is addressed adjunctively and off-licence, for example with a mood stabiliser such as divalproex (Valprol, Encorate) or a second-generation antipsychotic, with the dosing and adverse-effect detail carried in the Mood disorders: pharmacotherapy notes and the Schizophrenia: management, antipsychotics and adverse effects notes rather than re-taught here. Engagement is the perennial obstacle: the condition is ego-syntonic, motivation is external, and manipulation of the therapeutic frame is expected, so treatment leans on structure, clear limits and realistic goals. Mentalisation-based treatment, adapted for antisocial personality disorder (Bateman and Fonagy), is an emerging structured option under trial; its general technique sits in the Psychotherapies, clinical assessment, MSE and nosology notes.

GOOD TO REMEMBER

- **Group cognitive-behavioural therapy for antisocial personality disorder:** mechanism is a structured, skills-based group intervention targeting the cognitions and behaviours that drive offending, delivered with firm limits; indication is antisocial personality disorder, especially with an offending history, and it is the NICE-recommended mainstay (NICE 2015), the person sharing the choice of duration and intensity; signature caution is that no drug is recommended for the personality itself, that medication is only for a comorbid disorder or, adjunctively and off-licence, for impulsive aggression, and that poor engagement and manipulation of the frame are the rule, not the exception.

INDIA

Three genuine India angles converge on antisocial personality disorder. First, under-recognition: personality disorders are markedly under-recognised in routine Indian practice, and the antisocial pattern in particular surfaces through its comorbidities, a substance-use disorder, repeated violence, or a legal referral, rather than as a personality diagnosis, so it is captured only when actively sought and a corroborated developmental history is taken. Second, the medico-legal frame is where the label carries the most force in India: the insanity defence rests on the unsoundness-of-mind test derived into the Indian Penal Code, which antisocial personality disorder rarely satisfies, so the psychiatrist's work is court reports, fitness assessment and the prediction of dangerousness rather than exculpation, and the dedicated forensic and secure-service infrastructure to support it is thin, developed in the Mental health legislation and forensic psychiatry notes. Third, the cultural expression of personality pathology: deviation must be judged against the person's own cultural, social and economic milieu, so that survival-driven or subcultural offending, or antisociality confined to a substance-use context, is not scored as trait pathology, and the diagnosis is not read through a single culture's norms. Structured group and mentalisation-based programmes for the disorder are scarcely available outside a few tertiary and forensic centres.

COMMON TRAP

Collapsing psychopathy into antisocial personality disorder and treating the two as one label. The antisocial criteria are behaviour-based and are met by a large, heterogeneous group, most of whom are not psychopathic; psychopathy is the narrower affective-interpersonal construct measured by the PCL-R, and it, not the criminal record, drives the most instrumental and remorseless offending. Writing "psychopath" where the assessment supports only antisocial personality disorder, or vice versa, is a straight error, and in a court report it is a consequential one.

3	15	18	20
OF THE SEVEN CRITERIA TO DIAGNOSE ANTISOCIAL PERSONALITY DISORDER	AGE (YEARS) BEFORE WHICH CONDUCT DISORDER MUST BE EVIDENT	MINIMUM AGE (YEARS) FOR THE ANTISOCIAL DIAGNOSIS	ITEMS ON THE HARE PSYCHOPATHY CHECKLIST-REVISED (PCL-R)

HOLD THIS

Antisocial personality disorder is a pervasive disregard for the rights of others, three or more of the seven criteria (failure to conform to law, deceitfulness, impulsivity, irritability and aggressiveness, reckless disregard for safety, consistent irresponsibility, lack of remorse), gated by conduct disorder before fifteen and an age of at least eighteen; it is not a synonym for psychopathy (the narrower affective-interpersonal PCL-R construct) nor for criminality, and its forensic weight is in the structured assessment of dangerousness and the court report, not in the insanity defence.

8 . Histrionic and narcissistic personality disorders

Why these two share a page. Both sit in **cluster b**, the dramatic, emotional or erratic group, and both are built around a hunger for the regard of others, so the examiner tests them together and rewards the candidate who can separate them cleanly. histrionic personality disorder is a pervasive pattern of excessive emotionality and **attention-seeking** (DSM-5-TR), and narcissistic personality disorder is a pervasive pattern of grandiosity, a **need for admiration** and a lack of empathy (DSM-5-TR). They look alike from a distance, two people who must be regarded, but the object of the wanting differs: the histrionic person needs to be the centre of attention and will take any role to get there, while the narcissistic person needs admiration for a superiority they believe is real.

This fragment frames the pair on one grid, takes each through its essential feature and criterion threshold, then isolates the single modern high-yield point, the split within narcissism between **grandiose narcissism** and **vulnerable narcissism**, the overt entitled presentation and the covert, hypersensitive, shame-prone one. Two cautions carry over and are assumed throughout: the general personality-disorder criteria (an enduring, pervasive, inflexible pattern, deviant from the person's own culture, with onset by adolescence or early adulthood, causing impairment, and not better explained otherwise) must be cleared before either type is named; and ICD-11 has abolished both as categories, so histrionic and narcissistic survive as labels only in DSM-5-TR and in clinical shorthand. The fully taught structured psychotherapies of this chapter and the general technique sit in the Psychotherapies, clinical assessment, MSE and nosology notes; the

borderline neighbour that both are most often confused with is developed elsewhere in this chapter.

8.1 The two on one frame

Both crave regard; the object of the craving divides them. Read the pair as a single question asked two ways. The histrionic patient organises a whole personality around being noticed, with emotion as the currency; the narcissistic patient organises it around being admired as superior, with a fragile self-esteem underneath. Learn the essential feature, the threshold and the one discriminator for each as a block, and most stems fall out of it.

TYPE	ESSENTIAL FEATURE (DSM-5-TR)	THRESHOLD	CORE DISCRIMINATOR
Histrionic	Pervasive and excessive emotionality and attention-seeking; discomfort when not the centre of attention	Five or more of the eight features	**Wants attention itself; will be fragile, seductive or dependent, whatever draws the eye**
Narcissistic	Grandiosity (in fantasy or behaviour), need for admiration, and lack of empathy	Five or more of the nine features	**Wants admiration for a believed superiority; entitlement and empathy failure, over a fragile self-esteem**

The two Cluster B attention-oriented types with their essential features, criterion thresholds and the single dividing discriminator; the accompanying figure sets attention-seeking against need for admiration on one axis.

PEARL

One question separates them at the bedside: *what does the attention buy?* For histrionic personality disorder attention is the goal in itself, and the person will happily be seen as fragile, ill or dependent if that is what turns heads. For narcissistic personality disorder attention must come as admiration of superiority; being pitied or seen as needy is intolerable, because it threatens the grandiose self.

8.2 Histrionic personality disorder

Emotion as performance, staged to be watched. The essential feature of histrionic personality disorder is a pervasive pattern of excessive emotionality and attention-seeking behaviour, beginning by early adulthood and present across contexts, shown by **five or more of the eight** features (DSM-5-TR). The eight are: discomfort in situations where they are not the centre of attention; interaction often marked by inappropriate sexually seductive or provocative behaviour; rapidly shifting and shallow expression of emotions; consistent use of physical appearance to draw attention to the self; a style of speech that is excessively impressionistic and lacking in detail; self-dramatisation, theatricality and exaggerated expression of emotion; suggestibility, being easily influenced by others or by circumstances; and considering relationships to be more intimate than they actually are. The signature is a person who is lively, charming and flirtatious on first meeting but whose emotions seem turned on and off too quickly to be deeply felt, whose strong opinions come with dramatic flair but no supporting detail, and

who becomes uncomfortable or aggrieved the moment the spotlight moves. Impairment tends to be milder than in the other Cluster B types and is chiefly interpersonal, with romantic and same-sex friendships strained by the demand for constant attention and the provocative style.

GOOD TO REMEMBER

- **Histrionic personality disorder:** defining criterion is pervasive excessive emotionality and attention-seeking, five or more of the eight features, from early adulthood, with discomfort when not the centre of attention as the anchoring item. Discriminator from narcissistic: it wants attention as such and will accept a fragile or dependent role to get it, where narcissistic wants admiration for superiority. Discriminator from borderline: no chronic emptiness, identity disturbance, self-destructiveness or angry abandonment ruptures. Discriminator from dependent: the flamboyant, theatrical, exaggerated emotionality that dependent lacks. First step: confirm the general personality-disorder criteria, then that the emotionality and attention-seeking are trait-level and pervasive, not a phase or a state.

8.3 Narcissistic personality disorder

Grandiosity above, fragility below. The essential feature of narcissistic personality disorder is a pervasive pattern of grandiosity in fantasy or behaviour, a need for admiration and a lack of empathy, beginning by early adulthood and present across contexts, shown by **five or more of the nine** features (DSM-5-TR). The nine are: a grandiose sense of self-importance; preoccupation with fantasies of unlimited success, power, brilliance, beauty or ideal love; a belief in being special and unique, understood only by, or fit to associate only with, other special or high-status people or institutions; a requirement for excessive admiration; a sense of entitlement, meaning unreasonable expectations of especially favourable treatment or automatic compliance; interpersonal exploitativeness, taking advantage of others to reach one's own ends; a lack of empathy, an unwillingness to recognise or identify with the feelings and needs of others; envy of others or a belief that others envy oneself; and arrogant, haughty behaviours or attitudes. The clinically important addition, spelled out in the DSM-5-TR text, is that the self-esteem beneath the grandiosity is almost always fragile: criticism or defeat can leave the person feeling ashamed, humiliated, hollow and empty, reacting with disdain, rage, or a withdrawal that masks the grandiosity rather than removing it. Empathy is typically cognitive but not emotional, they can read another's perspective yet do not feel with them.

GOOD TO REMEMBER

- **Narcissistic personality disorder:** defining criterion is grandiosity, a need for admiration and a lack of empathy, five or more of the nine features, from early adulthood. Discriminator from histrionic: admiration must be for a believed superiority, and a needy or fragile role is intolerable. Discriminator from antisocial: narcissistic lacks the impulsivity, aggression, deceit and childhood conduct-disorder history, and exploits to enhance the self rather than for material gain. Discriminator from borderline: relatively stable self-image and far less physical self-destructiveness and abandonment terror. First step: confirm the general criteria, then look past the grandiose surface for the fragile self-esteem that the presentation is defending.

8.4 Grandiose versus vulnerable narcissism

One disorder, two faces. The highest-yield modern point is that narcissism presents along two phenotypes rather than one. grandiose narcissism is the overt, textbook picture: openly entitled,

arrogant, exhibitionistic, admiration-demanding, thick-skinned. vulnerable narcissism is the covert picture: hypersensitive, shame-prone, anxiously self-conscious, socially withdrawn, quietly nursing the same grandiose fantasies but defending them behind apparent humility or complaint. DSM-5-TR anchors both in its own text and in its alternative model: it describes narcissistic self-esteem as "variable and vulnerable," regulated through approval-seeking, with grandiosity that may be "either overt or covert," and it records the more vulnerable presentations by adding negative-affectivity traits such as depressivity and anxiousness. The two are not different disorders but different surfaces over a shared core of fragile self-worth; many patients oscillate between them, showing grandiosity when supplied with admiration and collapsing into the vulnerable state when it is withheld. The examiner's trap is to recognise only the loud, grandiose form and miss the quiet, shame-driven one, which is easily mistaken at face value for depression or social anxiety.

FACET	GRANDIOSE (OVERT)	VULNERABLE (COVERT)
Surface presentation	Entitled, arrogant, exhibitionistic, self-assured	**Hypersensitive, shy, self-effacing, complaining**
Self-esteem	Openly inflated, thick-skinned to criticism	Fragile, shame-prone, easily wounded
Response to a slight	Disdain, rage, counterattack	Withdrawal, humiliation, resentment, rumination
Grandiosity	Displayed openly in behaviour	Kept in private fantasy, masked by humility
Common misread	Simple arrogance or a difficult personality	**Depression or social-anxiety disorder**

Grandiose and vulnerable narcissism as two surfaces over one fragile core; the highlighted cells are the covert features most often missed and the diagnosis they are mistaken for.

WORKED EXAMPLE

A man in his thirties presents with low mood, social withdrawal and a sense of being chronically slighted. On the surface this reads as depression. Listening closer, the withdrawal follows a series of perceived humiliations, each one a failure of the world to recognise a talent he privately believes is exceptional; he is exquisitely sensitive to criticism, envious of colleagues he considers his inferiors, and empty when admiration is not forthcoming. There is no overt boastfulness. This is vulnerable narcissism, the covert face of narcissistic personality disorder, not a primary depressive disorder, and treating only the mood while missing the fragile grandiose core underneath is why the presentation keeps returning.

RULE **Attention itself versus admiration for superiority.** The histrionic person wants to be the centre of attention and will take any role, even a fragile or dependent one, to get it; the narcissistic person wants admiration specifically for a superiority they believe is real, and a needy role is intolerable. That is the dividing line.

TRAP **Seeing only the loud narcissist.** Expecting only the grandiose, arrogant presentation and missing vulnerable narcissism, whose covert shame, hypersensitivity and withdrawal are read at face value as depression or social anxiety, leaves the diagnosis and the fragile grandiose core underneath untouched.

8.5 Telling them apart from their neighbours

The confusions the paper actually sets. Both types share features with their Cluster B neighbours, and the marks are in the discriminators, drawn straight from the DSM-5-TR differential text. Hold the grid below and each boundary is a one-line answer.

BOUNDARY	SHARED FEATURE	DISCRIMINATOR
Histrionic vs narcissistic	Both crave attention from others	**Histrionic wants attention as such and accepts a fragile role; narcissistic wants praise for superiority and emphasises status**
Histrionic vs borderline	Attention-seeking, manipulative behaviour, rapidly shifting emotions	Borderline adds self-destructiveness, angry relationship ruptures, chronic emptiness and identity disturbance
Histrionic vs antisocial	Impulsive, superficial, seductive, manipulative	Histrionic manipulates for nurturance and is more exaggerated in emotion; antisocial manipulates for material gain
Histrionic vs dependent	Reliance on others for reassurance	Dependent lacks the flamboyant, exaggerated, theatrical emotionality of histrionic
Narcissistic vs antisocial	Exploitative, lacking empathy	Narcissistic lacks impulsivity, aggression, deceit and a conduct-disorder history; exploits to enhance the self, not for profit
Narcissistic vs borderline	Anger to minor slights	Narcissistic keeps a relatively stable self-image with little physical self-destructiveness or abandonment terror

The six boundaries most often tested around the two types; the highlighted cell is the single discriminator that decides histrionic from narcissistic. The borderline side is developed elsewhere in this chapter.

8.6 The classification shift: ICD-11 and the alternative model

Both categories are gone, but the vocabulary survives. This is where the day's headline nosology point lands on these two types. ICD-11 abolished the categorical personality-disorder types entirely: there is no ICD-11 code for histrionic or narcissistic personality disorder. A histrionic-like presentation is now captured by rating **severity** first (personality difficulty, then mild, moderate or severe) and adding the trait qualifier of negative affectivity for the dramatic, labile emotionality, with the attention-seeking element falling under dissociality. A narcissistic-like presentation is captured by severity plus dissociality, whose text explicitly names self-

centredness, a sense of entitlement, expectation of others' admiration and attention-seeking to remain the centre of focus, with the vulnerable, shame-prone features added under negative affectivity (ICD-11 CDDR). The DSM-5-TR alternative hybrid model treats the two unequally: narcissistic personality disorder is one of the six specific types it retains, defined by impairment plus the antagonism traits of grandiosity and attention-seeking, whereas histrionic is one of the four categorical types it drops, becoming personality disorder, trait specified when the general criteria are met without a named set.

ICD-10 TO ICD-11: WHAT CHANGED

ICD-10 (F60) kept histrionic personality disorder (F60.4) as a named categorical type, but narcissistic never had its own ICD-10 category at all, sitting only under "other specific personality disorder" (F60.8). ICD-11 then removed every categorical type, rebuilding the diagnosis as a severity level plus trait-domain qualifiers, so both histrionic and narcissistic now exist only as descriptive patterns within that dimensional frame. Exams still test the categorical names because DSM-5-TR retains them in its main text and clinicians still speak in them, so read fluently in both languages.

8.7 Management in outline, and the cultural reading

Psychotherapy is the frame; drugs are for comorbidity only. Neither type has a disorder-specific drug, and neither is a receptor problem to be medicated. The working approach is a structured, long-term psychotherapy, with the transference-focused and schema-based models the ones with the most traction for narcissistic pathology (their mechanism and indication are taught in full in their own topics of this chapter). The narcissistic patient tests the alliance hardest, because the very grandiosity that brings collapse also resists the therapist's help, and the vulnerable, shame-prone presentation must be handled without either colluding with the grandiosity or shaming the fragile self beneath it. Medication is reserved for a comorbid depressive or anxiety disorder, or a short crisis, never for the personality itself, and the deep pharmacology is cross-referenced to the Mood disorders: pharmacotherapy notes and the Schizophrenia: management, antipsychotics and adverse effects notes rather than re-taught here.

INDIA

Three genuine India angles converge here. First, under-recognition: personality disorders are diagnosed far less often in routine Indian practice than Western prevalence would predict, and these two surface through their comorbidities, a mood or anxiety disorder, a relational crisis, rather than as a personality label that clinicians often avoid for fear of stigma. Second, the cultural expression of pathology: the general criteria require deviation from the person's *own* culture, so narcissistic-looking traits inflate in individualistic settings and warrant less clinical weight where they are normative, while a warm, expressive, family-embedded emotional style must not be scored as histrionic through a colder cultural lens, and the historical over-diagnosis of histrionic personality disorder in women along gendered social scripts is a bias to guard against actively. Third, availability: the structured psychotherapies these patients need, transference-focused and schema therapy, are unevenly available and still being culturally adapted for India, concentrated at tertiary and private centres. The medico-legal weight of personality pathology attaches to antisocial personality disorder, handled in the Mental health legislation and forensic psychiatry notes, not to these two.

8.8 The countable skeleton

Two essential features, two thresholds, one split. Everything worth carrying into the hall about these two types hooks onto a handful of counts and one distinction. Anchor the mnemonics and each criterion set unpacks.

MNEMONIC

PRAISE ME · GRANDIOSE

PRAISE ME for the eight histrionic criteria: **P**rovocative or seductive; **R**elationships thought more intimate than they are; **A**ttention (uncomfortable when not its centre); **I**nfluenced easily (suggestible); **S**tyle of speech impressionistic and vague; **E**motions shallow and rapidly shifting; **M**ade-up appearance used to draw the eye; **E**xaggerated, theatrical emotional display.
GRANDIOSE for the nine narcissistic criteria: **G**randiose self-importance; **R**equires excessive admiration; **A**rrogant and haughty; **N**eeds to be seen as special and unique; **D**reams of unlimited success, power, brilliance, beauty or ideal love; **I**nterpersonally exploitative; **O**btuse to others' feelings (lacks empathy); **S**ense of entitlement; **E**nvious of others or believes others envy them.

8	9	4	5
HISTRIONIC CRITERIA; FIVE OR MORE NEEDED	NARCISSISTIC CRITERIA; FIVE OR MORE NEEDED	CLUSTER B DRAMATIC TYPES	ICD-11 TRAIT DOMAINS; BOTH TYPES ABOLISHED

HOLD THIS

Histrionic personality disorder is excessive emotionality and attention-seeking (five or more of the eight, uncomfortable when not the centre of attention); narcissistic personality disorder is grandiosity, a need for admiration and a lack of empathy (five or more of the nine); and grandiose and vulnerable narcissism are one disorder's two faces, the overt entitled and the covert shame-prone, over a shared core of fragile self-esteem.

9 . Cluster C: avoidant, dependent and anankastic

Why the anxious cluster earns its marks. **cluster c** is the **anxious or fearful** group, and it rewards the candidate who can give the one-line essential feature of each type cold and then defend the two boundaries an examiner reaches for first: avoidant personality disorder against a genuine loner and against social anxiety disorder, and anankastic personality disorder against obsessive-compulsive disorder. The three types are avoidant personality disorder (social inhibition, feelings of inadequacy and hypersensitivity to negative evaluation, with avoidance of activities involving interpersonal contact), dependent personality disorder (a pervasive and excessive need to be taken care of leading to submissive and clinging behaviour and fears of separation), and obsessive-compulsive personality disorder, the anankastic type (a preoccupation with orderliness, perfectionism and mental and interpersonal control at the expense of flexibility, openness and efficiency) (DSM-5-TR 2022). The thread that ties them is that fear, not oddness and not drama, is the organising affect: fear of rejection, fear of being left, and fear of losing control.

This fragment frames the cluster on one grid, takes each type through its defining criterion and the discriminator that decides it, then isolates the single highest-yield boundary of the group, the anankastic character against the anxiety disorder that shares its name. Two cautions from the framework topics of this chapter are assumed throughout: the general personality-disorder criteria (an enduring, pervasive, inflexible pattern, from early adulthood, causing impairment and not better explained otherwise) must be cleared before any type is named; and ICD-11 has abolished the categorical types, so "avoidant", "dependent" and "anankastic" survive as labels only in the legacy classifications and in clinical shorthand, with the dimensional model taught on the framework topics. The OCD side sits in the Anxiety, OCD and trauma-related disorders notes and the wider psychotherapy technique in the Psychotherapies, clinical assessment, MSE and nosology notes.

9.1 The cluster on one frame

Three types, one affect, three fears. DSM-5-TR groups the three types whose sufferers "often appear anxious or fearful" (DSM-5-TR 2022). Read the cluster by what each type is afraid of and what it does about the fear: the avoidant person wants closeness but withdraws from it for fear of criticism and rejection; the dependent person clings to a caretaker for fear of being left to cope alone; the anankastic person controls and orders the world for fear of anything going wrong. Learning the three essential features with their exact thresholds as one block is the fastest route to every cluster C question, because the thresholds differ across the three and are a favourite trip-wire.

TYPE	ESSENTIAL FEATURE (DSM-5-TR)	THRESHOLD	CORE DISCRIMINATOR
Avoidant	Social inhibition, feelings of inadequacy and hypersensitivity to negative evaluation, with avoidance of interpersonal contact	Four or more of the seven features	**Wants closeness but fears rejection (vs schizoid, who has no desire)**
Dependent	A pervasive, excessive need to be taken care of, leading to submissive, clinging behaviour and fears of separation	Five or more of the eight features	**Appeasement and a replacement caretaker, not rage (vs borderline)**
Anankastic (obsessive-compulsive)	Preoccupation with orderliness, perfectionism and mental and interpersonal control, at the expense of flexibility, openness and efficiency	Four or more of the eight features	**Ego-syntonic traits; no true obsessions or compulsions (vs OCD)**

The three DSM-5-TR Cluster C types with their essential features, criterion thresholds and core discriminators; the accompanying figure lays the same three on a fear-and-response map (fear of rejection, of separation, of loss of control).

PEARL

Tag each type by the fear that drives it: avoidant fears *rejection*, dependent fears *separation*, anankastic fears *loss of control*. Then hold the three thresholds apart, because they are not the same number: avoidant is **four or more of the seven**, dependent is **five or more of the eight**, and anankastic is **four or more of the eight**. Dependent is the odd one out that needs five.

9.2 Avoidant personality disorder

The person who longs for closeness and flees it. The essential feature of avoidant personality disorder is a pervasive pattern of social inhibition, feelings of inadequacy and hypersensitivity to negative evaluation, beginning by early adulthood and present across contexts, shown by **four or more of the seven** features (DSM-5-TR 2022). The seven are: avoiding occupational activities that involve significant interpersonal contact for fear of criticism, disapproval or rejection; being unwilling to get involved with people unless certain of being liked; showing restraint within intimate relationships for fear of being shamed or ridiculed; being preoccupied with being criticised or rejected in social situations; being inhibited in new interpersonal situations because of feelings of inadequacy; viewing the self as socially inept, unappealing or inferior; and being unusually reluctant to take personal risks or try new activities for fear of embarrassment. The signature is a person who deeply wants relationships and feels the loneliness of their absence, but assumes others are critical until stringently proven otherwise. Two contrasts do most of the work. Against schizoid personality disorder, the single question is whether closeness is wanted at all: the avoidant person wants it and fears rejection, the schizoid person has no desire for it. Against social anxiety disorder, the difference is pervasiveness and self-concept: avoidant personality disorder is a trait-level pattern with an entrenched sense of inferiority, present even without the

anxiety disorder, whereas social anxiety may be more situational, though the two overlap heavily and some regard avoidant personality disorder as a more severe form.

GOOD TO REMEMBER

- **Avoidant personality disorder:** defining criterion is pervasive social inhibition, feelings of inadequacy and hypersensitivity to negative evaluation, four or more of the seven features, from early adulthood. Discriminator from schizoid: closeness is wanted but feared (schizoid does not want it). Discriminator from social anxiety disorder: trait-level and pervasive with an entrenched inferiority, present even without the anxiety disorder. First step: confirm the general personality-disorder criteria, then that the avoidance is pervasive and character-level, not confined to circumscribed performance situations.

9.3 Dependent personality disorder

The excessive need to be cared for. The essential feature of dependent personality disorder is a pervasive and excessive need to be taken care of that leads to submissive and clinging behaviour and fears of separation, from early adulthood, shown by **five or more of the eight** features (DSM-5-TR 2022). The eight are: difficulty making everyday decisions without excessive advice and reassurance; needing others to assume responsibility for most major areas of life; difficulty expressing disagreement for fear of losing support or approval; difficulty initiating projects or doing things alone from a lack of self-confidence; going to excessive lengths to obtain nurturance and support, even volunteering for unpleasant tasks; feeling uncomfortable or helpless when alone from exaggerated fears of being unable to cope; urgently seeking another relationship as a source of care when a close one ends; and being unrealistically preoccupied with fears of being left to care for oneself. The behaviours are designed to elicit caregiving and arise from a self-perception of being unable to function alone. The examiner's favoured contrast is with borderline personality disorder: both fear abandonment, but the person with dependent personality disorder responds with increasing appeasement and submissiveness and urgently seeks a replacement caretaker, whereas the person with borderline personality disorder responds with rage, emptiness and demands, against a background of unstable and intense relationships. From avoidant personality disorder it is separated by direction: the dependent person seeks proximity, the avoidant person avoids it, though both share feelings of inadequacy.

GOOD TO REMEMBER

- **Dependent personality disorder:** defining criterion is a pervasive, excessive need to be taken care of leading to submissive, clinging behaviour and fears of separation, five or more of the eight features (the only cluster C type that needs five), from early adulthood. Discriminator from borderline: appeasement and a replacement caretaker, not rage and emptiness; relationships stable-clinging, not unstable-intense. Discriminator from avoidant: proximity-seeking, not proximity-avoiding. First step: confirm the general criteria, then that the dependence is excessive and unrealistic beyond situational and cultural norms, not normative interdependence.

9.4 Anankastic (obsessive-compulsive) personality disorder

Control at the cost of flexibility. The essential feature of obsessive-compulsive personality disorder, the anankastic type, is a preoccupation with orderliness, perfectionism and mental and interpersonal control, at the expense of flexibility, openness and efficiency, from early adulthood,

shown by **four or more of the eight** features (DSM-5-TR 2022). The eight are: preoccupation with details, rules, lists, order, organisation or schedules to the point that the major purpose is lost; perfectionism that interferes with task completion; excessive devotion to work and productivity to the exclusion of leisure and friendships, not explained by economic necessity; over-conscientiousness, scrupulousness and inflexibility about matters of morality, ethics or values, not explained by culture or religion; inability to discard worn-out or worthless objects even when they have no sentimental value; reluctance to delegate unless others submit to exactly one's own way; a miserly spending style, money hoarded against future catastrophe; and rigidity and stubbornness. The core is control: the perfectionism is so complete that projects are never finished and time is poorly allocated, and the rigidity holds even when compromise would clearly serve the person's own interest. The whole pattern is **ego-syntonic**, experienced as reasonable and correct, which is exactly what sets up the marquee trap of the topic.

GOOD TO REMEMBER

- **Anankastic (obsessive-compulsive) personality disorder:** defining criterion is a pervasive preoccupation with orderliness, perfectionism and mental and interpersonal control at the expense of flexibility, openness and efficiency, four or more of the eight features, from early adulthood. Discriminator from OCD: the traits are ego-syntonic character, with no true obsessions and no compulsions. First step: confirm the general criteria and that the perfectionism and control are a pervasive, ego-syntonic trait, then search for (and either exclude or separately co-diagnose) the true obsessions and compulsions of OCD.

9.5 Anankastic versus OCD: ego-syntonic character against ego-dystonic illness

Similar names, different animals. This is the boundary the topic is built to test. Despite the shared name, obsessive-compulsive personality disorder and obsessive-compulsive disorder are clinically quite different (DSM-5-TR 2022). The anankastic personality is not characterised by intrusive thoughts, images or urges, nor by repetitive behaviours performed in response to them; it is an enduring, pervasive maladaptive pattern of excessive perfectionism and rigid control, and it is **ego-syntonic**, the person sees the traits as sensible and right and is not distressed by them, though the people around them often are. Obsessive-compulsive disorder is defined by true **obsessions** (intrusive, unwanted thoughts, images or urges) and **compulsions** (repetitive acts performed to neutralise the distress), and it is **ego-dystonic**, the symptoms are experienced as alien, unwanted and resisted. The presence or absence of true obsessions and compulsions is the line. The two are not mutually exclusive: when the criteria for both are met, both are diagnosed, and comorbid anankastic personality is found in roughly a quarter to a third of people with OCD in longitudinal cohorts. The obsessive-compulsive disorder side, its phenomenology and its treatment, is developed in the Anxiety, OCD and trauma-related disorders notes.

FEATURE	ANANKASTIC (OBSESSIVE-COMPULSIVE) PERSONALITY DISORDER	OBSESSIVE-COMPULSIVE DISORDER (OCD)
Relation to self	Ego-syntonic: traits seen as reasonable, right and desirable	Ego-dystonic: symptoms alien, unwanted, resisted
Core content	A pervasive character style of perfectionism, orderliness and rigid control	Discrete intrusive symptoms sitting on the background personality
Obsessions and compulsions	**Absent: no true obsessions and no compulsions**	Present and defining
Distress	Little distress about the traits themselves; others carry the frustration	Marked distress and active resistance to the symptoms
If both present	When the criteria for both are met, both diagnoses are recorded	

The anankastic-versus-OCD discrimination; the highlighted cell is the single feature that decides it, the absence of true obsessions and compulsions in the personality disorder. The OCD side is developed in the Anxiety, OCD and trauma-related disorders notes.

RULE **The line is true obsessions and compulsions, and ego-tone.** Anankastic personality is an ego-syntonic character of perfectionism and control with no true obsessions or compulsions; OCD is defined by ego-dystonic, resisted obsessions and compulsions. Their presence or absence, not the shared name, decides the diagnosis.

TRAP **Calling a rigid perfectionist "OCD".** Orderliness, perfectionism, hoarding of worthless items and inability to delegate, experienced by the person as simply being thorough and correct, are anankastic personality, not OCD, unless there are genuine intrusive obsessions and neutralising compulsions the person resists.

WORKED EXAMPLE

An accountant in his forties is referred as "OCD". He is a relentless perfectionist who cannot discard years of worn-out paperwork, refuses to delegate, and misses deadlines because he rechecks his work endlessly; he regards all of this as ordinary diligence and is untroubled by it, though his family and colleagues are worn down. He describes no intrusive unwanted thoughts and performs no rituals to neutralise anxiety. This is obsessive-compulsive personality disorder, the anankastic type, not OCD: the pattern is ego-syntonic character without true obsessions or compulsions. Had he also described intrusive contamination fears and washing rituals he resisted, both diagnoses would stand together.

9.6 How cluster C maps onto the dimensional and legacy systems

The categorical names decoded into traits. The framework topics of this chapter teach the dimensional model in full; three cluster-C-specific facts are worth carrying. First, the ICD-11 anankastia trait domain, a narrow focus on a rigid standard of perfection and on controlling oneself, others and situations to enforce it, is essentially the OCPD phenotype re-cast as a dimension, and it is the domain with no counterpart in the DSM-5 alternative model. Second, the avoidant and dependent phenotypes load mainly on negative affectivity with detachment, the

anxious-fearful traits. Third, and high-yield, the DSM-5-TR alternative model of personality disorders retains only six categorical types, antisocial, avoidant, borderline, narcissistic, obsessive-compulsive and schizotypal: avoidant and obsessive-compulsive survive the cut, but dependent personality disorder is one of the four types dropped. In the legacy ICD-10, the same phenotypes carried different names, anankastic for obsessive-compulsive and anxious for avoidant, with dependent kept as it is; exams still test these categorical names because DSM-5-TR retains them and the literature is written in them.

PEARL

Two cluster C facts examiners like: the ICD-11 fifth domain is *anankastia* (the OCPD phenotype), where the DSM-5 alternative model instead has psychoticism; and the alternative model keeps avoidant and obsessive-compulsive but drops dependent, so "which cluster C type is not in the DSM-5 alternative model?" has a clean answer, dependent.

9.7 Management in outline, and the cultural reading

Psychological therapy leads; drugs treat comorbidity only. Cluster C is managed, not cured, and no drug is disorder-specific for any of the three. The primary mode is structured psychological therapy: graded exposure to the avoided or feared situation with cognitive restructuring of the beliefs of inadequacy for avoidant personality disorder (the technique overlaps with the treatment of social anxiety disorder), assertiveness and autonomy-building for dependent personality disorder, and work on rigidity and control for the anankastic patient. The schema-mode and dialectical approaches, and the deeper psychotherapy technique, are developed on the psychotherapy topics of this chapter and in the Psychotherapies, clinical assessment, MSE and nosology notes. Pharmacotherapy stays narrow: where avoidant personality disorder carries a comorbid social anxiety disorder, a serotonin reuptake inhibitor may help that comorbidity, with the agents, Indian brands and dosing carried in the Anxiety, OCD and trauma-related disorders notes rather than re-taught here.

GOOD TO REMEMBER

- **Structured cognitive-behavioural therapy (Cluster C):** mechanism is graded exposure to avoided or feared situations plus cognitive restructuring of the core beliefs (inadequacy in avoidant, helplessness in dependent, the need for control in anankastic), with assertiveness and autonomy skills; indication is all three cluster C types, and it engages fastest in avoidant and dependent personality disorder, where the anxious behaviour is distressing to the person; signature caution is the alliance and pace, shame drives drop-out in the avoidant patient, the anankastic patient resists surrendering control, and the dependent patient can transfer their dependence onto the therapist. Medication is for a comorbidity only, never disorder-specific.

INDIA

Two genuine India angles meet on cluster C. First, under-recognition: the anankastic patient is ego-syntonic and almost never self-refers, reaching services only through burnout, a comorbid depression or a family complaint, while the avoidant and dependent patient usually presents for a comorbid anxiety or depressive disorder rather than for the personality itself, so the diagnosis is made only when it is actively sought. Second, and the more testable, is the cultural reading of dependent personality disorder. In collectivist Indian family life, interdependence, deference to elders, and decisions made jointly or by the family (about marriage, work or money) are normative, not pathological; scoring them as dependent personality disorder through a single culture's autonomy norms is a straight error, and DSM-5-TR itself requires that dependence be judged excessive relative to the person's own cultural and situational context, weighed with an informant. The same caution applies to over-conscientiousness read as anankastic when it reflects religious or cultural observance. Structured psychotherapy for these disorders is available unevenly and mostly at tertiary and private centres.

9.8 The countable skeleton

One line rebuilds the cluster. Three types, three fears, three thresholds and one marquee boundary are the whole of cluster C worth carrying into the hall. Hook them once and each type unpacks from its fear.

MNEMONIC

FLEE, CLING, CONTROL

The three cluster C types by the fear they answer. **FLEE** is avoidant personality disorder (wants closeness, flees it for fear of rejection, four or more of the seven). **CLING** is dependent personality disorder (needs to be cared for, clings for fear of separation, five or more of the eight). **CONTROL** is anankastic or obsessive-compulsive personality disorder (orders the world for fear of anything going wrong, ego-syntonic, no true obsessions or compulsions, four or more of the eight). Flee from people, cling to a person, control the world.

3	5	6
CLUSTER C TYPES (ANXIOUS OR FEARFUL)	ICD-11 TRAIT DOMAINS (ANANKASTIA IS THE CLUSTER C ONE)	DSM-5 ALTERNATIVE-MODEL TYPES KEPT (DEPENDENT DROPPED)

HOLD THIS

Cluster C is anxious or fearful: avoidant wants closeness but fears rejection (four or more of the seven), dependent needs to be cared for and clings for fear of separation (five or more of the eight), anankastic controls and perfects the world (four or more of the eight); and the marquee line is anankastic personality (ego-syntonic character, no true obsessions or compulsions) against OCD (ego-dystonic, resisted obsessions and compulsions).

10 · Borderline personality disorder versus bipolar II

The discriminator the whole chapter builds toward. Two conditions share a surface, mood that will not hold still and behaviour that runs ahead of judgement, and the examiner exploits the overlap: is this borderline personality disorder or is this bipolar II disorder? Getting **borderline**

versus bipolar right is not a fine academic point but the fork on which the management plan turns, because one answer sends the patient to a structured psychotherapy and the other to a mood stabiliser. This note owns that **discrimination**. The bipolar-II side of the picture, the hypomanic and depressive syndromes and their neurobiology, is developed in the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes; here the two are held side by side and pulled apart.

The trick is to resist matching on the shared symptom and instead read **one discriminator** at a time, each of which points reliably to one diagnosis. The **bipolar ii differential** reduces to a small grid of these discriminators, the tempo and trigger of the mood change, the duration of a shift, the presence of an unstable identity and chronic emptiness, the character of the self-harm and impulsivity, the family history, and the response to a mood stabiliser. Read across the grid and the answer usually declares itself. The accompanying figure lays the same discriminators out as a two-column contrast, and it is the single image to carry for this topic.

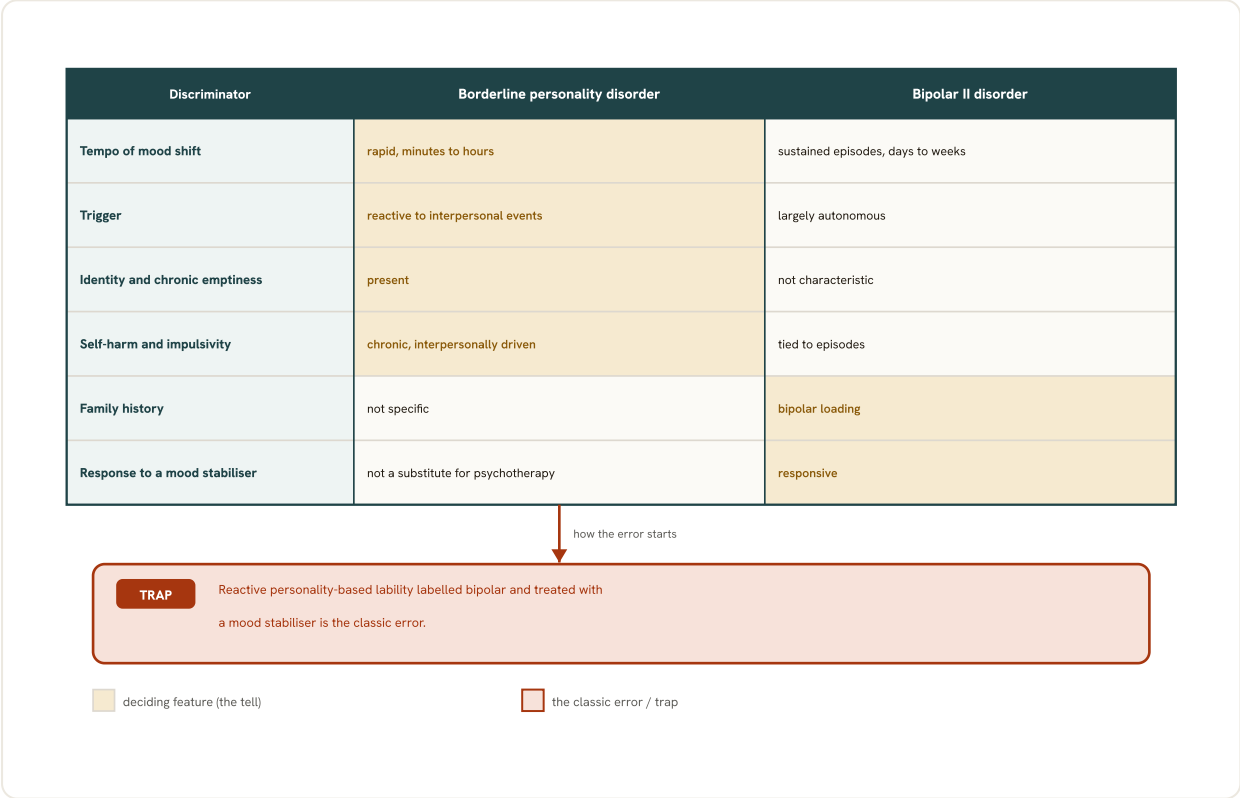

Fig 16.8 Borderline mood instability is rapid and reactive to interpersonal triggers, with identity disturbance and chronic emptiness; bipolar II episodes are sustained and autonomous with a bipolar family history and a mood-stabiliser response. The bipolar syndromes are taught in the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes.

10.1 The shared surface, and why the misdiagnosis is easy

Both present with mood lability and impulsivity, so the overlap is real. A patient who describes moods that flip, relationships that combust and impulsive acts they regret can fit either label on first telling, and the temptation is to hear "unstable mood" and reach for bipolar II disorder. The overlap is genuine: affective instability and impulsivity are cardinal in borderline personality disorder and are also the texture of the hypomanic and depressive swings of bipolar II. But the two instabilities have a different *form*, and the discipline of this topic is to describe the

mood change rather than name it, then let its tempo, its trigger and its duration decide. The discrimination fails only when the clinician pattern-matches on the shared word and stops looking.

RULE **Read the mood, do not name it.** Discriminate borderline from bipolar II on the tempo, the trigger and the duration of the affective change: reactive, interpersonally cued shifts over minutes to hours are borderline; autonomous, sustained episodes over days to weeks are bipolar.

10.2 The discriminator grid: one discriminator per row

The object to reproduce cold. Hold the differential as a grid in which each row turns on a single discriminator, and each discriminator points to one side. The highlighted cell in every row is the one that settles that row; read the whole column on either side and the diagnosis emerges as a pattern, not a single sign. This is the same grid drawn in the figure alongside.

DISCRIMINATOR	BORDERLINE PERSONALITY DISORDER	BIPOLAR II DISORDER
Tempo of affective instability	**Rapid shifts over minutes to hours, often several within one day**	Sustained episodes evolving over days to weeks
Trigger of the mood change	**Reactive, cued by an interpersonal event (rejection, criticism, a threat of abandonment)**	Largely autonomous; episodes arise and remit on their own timetable, frequently unprovoked
Duration of a mood shift	Dysphoria, irritability or anxiety usually lasting a few hours and only rarely more than a few days	**Hypomania at least four consecutive days; a depressive episode at least two weeks**
Baseline between shifts	Chronic dysphoria and emptiness; rarely a settled euthymic baseline	**Return to a euthymic baseline between discrete episodes**
Identity and emptiness	**Identity disturbance and chronic emptiness are core and enduring**	Identity is stable; emptiness is not a defining feature
Self-harm and impulsivity	**Self-harm is recurrent and affect-regulating, interpersonally cued; impulsivity is a pervasive lifelong trait**	Risk-taking and impulsivity are state-bound to the hypomanic phase; self-harm clusters in depressive episodes
Family history	Loads toward cluster B traits, trauma, mood and substance problems	**A strong loading for bipolar disorder points toward bipolar**
Response to a mood stabiliser	Modest and symptom-targeted at best; never a substitute for structured psychotherapy	**Often clearly effective; the mainstay of treatment**

The borderline-versus-bipolar-II discriminator grid; each row turns on one discriminator, and the highlighted cell is the one that decides it. No single row is definitive alone; the diagnosis is the whole pattern read across the columns.

5+	4	5
OF NINE BORDERLINE CRITERIA TO DIAGNOSE	DBT SKILLS MODULES (THE THERAPY BORDERLINE RESPONDS TO)	ICD-11 TRAIT DOMAINS (THE DIMENSIONAL CROSS-MAP)

10.3 The affective instability tempo, and the duration of mood shifts

The clock is the first and best discriminator. The **affective instability tempo** in borderline personality disorder is fast: mood swings over minutes to hours, sometimes several times within an afternoon, and it settles as quickly as it flared. The DSM-5-TR criterion says as much, episodic dysphoria, irritability or anxiety usually lasting a few hours and only rarely more than a few days. The **duration of mood shifts** in bipolar II disorder is categorically longer: hypomania requires a distinct period of persistently elevated or irritable mood lasting **at least four consecutive days**, and a major depressive episode lasts **at least two weeks**. Between those episodes the bipolar patient typically returns to a euthymic baseline, whereas the borderline patient rarely does, sitting instead on a floor of chronic dysphoria. So the two questions to ask are: how long does a low or an irritable spell last, and where does the mood return to when it passes.

10.4 The trigger: reactivity to interpersonal triggers versus autonomy

Ask what set the mood off. The second discriminator is the **reactivity to interpersonal triggers**. Borderline affective instability is characteristically reactive: a text left unanswered, a perceived slight, a looming separation, and the mood collapses or the anger flares, then eases when the relationship is repaired. Bipolar mood is largely autonomous; a hypomanic or depressive episode arrives and departs on its own timetable, often with no proportionate external cause, and it does not switch off the moment an interpersonal rupture is mended. This is why the history should chase the antecedent of every mood change: a mood that tracks the state of a relationship minute by minute is borderline reactivity, whereas a mood that runs for a week regardless of what is happening around the person is a bipolar episode. Rejection sensitivity, the exquisite reactivity to perceived abandonment, is the borderline signature that has no bipolar counterpart.

WORKED EXAMPLE

A woman in her twenties is referred as "query bipolar II, mood swings". On history the swings last two to three hours, always follow a fight with her partner or a fear he is pulling away, and lift the moment he reassures her; she describes never knowing who she is and a constant hollow emptiness, and she cuts when the distress peaks. Nothing here is a sustained, autonomous, days-long episode with a euthymic return. Read one discriminator at a time, the hours-long tempo, the interpersonal trigger, the identity disturbance and emptiness, and the picture is borderline personality disorder, not bipolar II. The label matters: it points to a structured psychotherapy, not to a mood stabiliser prescribed for a bipolarity she does not have.

10.5 Identity, chronic emptiness, and the character of self-harm and impulsivity

Look for the features bipolar II simply does not carry. The **identity and self-harm** row is decisive because these features belong to borderline personality disorder and are not part of bipolar II at all. Identity disturbance, a markedly and persistently unstable self-image, and chronic emptiness, a persistent hollowness distinct from depressive sadness, are core borderline criteria

with no bipolar equivalent; a genuinely stable sense of self between episodes argues strongly against borderline. The *character* of the self-harm and impulsivity discriminates too. In borderline personality disorder self-harm is recurrent, interpersonally cued and typically functions to regulate unbearable affect or to end dissociation, and the impulsivity is a pervasive, lifelong trait present between crises. In bipolar II the risk-taking and impulsivity are state-bound, confined to the hypomanic phase and absent when euthymic, and the self-harm clusters within depressive episodes. So the same behaviour, cutting or reckless spending, discriminates by *when* it happens: pervasive and trigger-linked in borderline, phasic and episode-linked in bipolar.

PEARL

Impulsivity that is present *between* episodes is a personality trait; impulsivity that appears only *during* an elevated mood and vanishes when the mood settles is a state. Trait impulsivity, chronic emptiness and an unstable identity together pull hard toward borderline; state-bound impulsivity on a euthymic baseline pulls toward bipolar II. The discriminator is not the behaviour but its timing against the mood.

10.6 Family history, and the response to a mood stabiliser

Two corroborating discriminators, held as support rather than proof. The **family history** is a genuine pointer because bipolar disorder is among the most heritable of psychiatric conditions: a strong, well-documented bipolar loading in first-degree relatives raises the prior for bipolar II, whereas a family picture weighted toward trauma, cluster B traits, mood and substance problems fits borderline better. Treat it as corroboration, not verdict, since both loadings can coexist. The **response to a mood stabiliser** is the other corroborating discriminator, and it is where the error becomes consequential. In bipolar II a mood stabiliser (lithium, valproate, or lamotrigine (Lamitor, Lametec) for the depressive pole) is foundational and often clearly effective; the deep pharmacology sits in the Mood disorders: pharmacotherapy notes. In borderline personality disorder the same drugs have at best a modest, symptom-targeted effect and are never a substitute for structured psychotherapy, which is the primary treatment. A patient whose "mood swings" do not respond to an adequate mood-stabiliser trial was very likely never bipolar; the non-response is itself a discriminator.

GOOD TO REMEMBER

- **Borderline personality disorder:** a pervasive pattern of instability of relationships, self-image and affect with marked impulsivity, five or more of the nine criteria; the affect is rapidly reactive, interpersonally triggered and lasts hours, on a floor of chronic emptiness and an unstable identity. First discriminating step in this differential: read the tempo, the trigger and the baseline of the mood change.
- **Bipolar II disorder:** at least one hypomanic episode (elevated or irritable mood, at least four consecutive days) plus at least one major depressive episode (at least two weeks), with a euthymic baseline between discrete, largely autonomous episodes and no full manic episode. Discriminator: sustained, autonomous, days-to-weeks episodes, not minutes-to-hours interpersonal reactivity.
- **Dialectical behaviour therapy:** the structured psychotherapy the borderline side responds to; it targets emotion dysregulation and self-harm through four skills modules (mindfulness, distress tolerance, emotion regulation, interpersonal effectiveness). Indication is recurrent self-harm and affective instability in borderline personality disorder, not the mood episodes of bipolar II. Caution: it treats the personality pathology, not a coexisting bipolar illness, which still needs its mood stabiliser.

10.7 The classic trap, and holding both diagnoses when they co-occur

The error and its correction. The classic trap is to hear reactive, hours-long, interpersonally driven lability, label it bipolar II, and start a mood stabiliser, medicalising a personality-based instability whose primary treatment is a structured psychotherapy. The drug then chases a misdiagnosis rather than an illness, the patient does not improve, and the failure is read as treatment resistance rather than as the wrong target. The correction is the grid: apply the discriminators before the label. Equally, the two are not mutually exclusive, and a comorbid bipolar II disorder is not rare in patients with borderline personality disorder; when a genuine, sustained, autonomous episode with a euthymic baseline is documented alongside the pervasive reactive pattern, both diagnoses stand and both treatments are needed, the mood stabiliser for the episodes and the structured psychotherapy for the personality pathology. The boundary with complex post-traumatic stress disorder, the other great mimic of borderline instability, is drawn in the Anxiety, OCD and trauma-related disorders notes.

TRAP **Labelling reactive instability "bipolar" and starting a mood stabiliser.** Reading minutes-to-hours, interpersonally cued lability as bipolar II and prescribing a mood stabiliser treats a personality-based instability with the wrong tool and delays the structured psychotherapy that is its actual primary treatment.

COMMON TRAP

Assuming the diagnosis is either-or. A strong bipolar family history or a documented autonomous episode does not exclude borderline personality disorder, and a clear borderline pattern does not exclude a genuine comorbid bipolar II. Diagnose each on its own evidence: the pervasive reactive pattern for borderline, a discrete sustained autonomous episode with a euthymic return for bipolar II. Where both are truly present, treat both.

10.8 The India lens: under-recognition, cultural expression, and access to therapy

The trap is amplified in Indian practice. Borderline personality disorder is markedly under-recognised in India: patients reach services through the overdose or the self-harm, which is coded as the act rather than the pattern, so the reactive lability underneath is repeatedly mislabelled as a mood disorder and medicated as bipolar. Two adaptations matter for this discrimination. First, cultural expression: affective display, transient dissociative or possession-trance presentations, and intense family-embedded reactions are normative idioms of distress in many Indian settings and must be judged against the person's own cultural and social norms before they are read as either borderline reactivity or a bipolar episode; personality pathology must not be read through a single culture's norms. Second, access: the structured psychotherapies the borderline side points to, dialectical behaviour therapy and schema therapy, are being delivered and culturally adapted at Indian tertiary and private centres rather than being widely available, so recognising that a patient needs psychotherapy rather than a mood stabiliser is only the first step, and a realistic plan must reckon with what the local service can actually deliver.

INDIA

Because borderline personality disorder is under-recognised in Indian practice, reactive interpersonal lability is disproportionately mislabelled bipolar and treated with a mood stabiliser, the exact trap of this topic. Judge every mood change against the patient's own cultural norms before scoring it, so that culturally sanctioned emotional expression and dissociative or possession-form idioms are not read as either a borderline criterion or a hypomanic episode. And recognise that catching the borderline diagnosis only helps if dialectical behaviour therapy or schema therapy is reachable; both are available and being adapted in the metros and academic centres but scarce elsewhere, which the plan must accommodate.

MNEMONIC

REACTIVE and RAPID versus AUTONOMOUS and SUSTAINED

The one-line split. Borderline instability is **REACTIVE** (interpersonally triggered) and **RAPID** (minutes to hours, on a floor of emptiness with an unstable identity); bipolar II mood is **AUTONOMOUS** (arises unprovoked) and **SUSTAINED** (days to weeks, with a euthymic baseline). Trigger and tempo first, then the corroborating family history and mood-stabiliser response.

HOLD THIS

Borderline affective instability is reactive, interpersonally triggered and lasts minutes to hours on a floor of chronic emptiness and unstable identity; bipolar II mood is autonomous and sustained over days to weeks (hypomania at least four consecutive days, depression at least two weeks) with a euthymic baseline; the mood stabiliser helps bipolar, while structured psychotherapy is primary for borderline, and mislabelling the first as the second is the classic, consequential error.

Aetiology, assessment and treatment

11 . Aetiology of personality disorders

Ask the question at three levels, then name one model. The **aetiology of personality disorders** is examined the same way every time: at the **genetic** level (what is heritable), the **neurobiological** level (the circuitry and neurochemistry that carry the trait), and the **developmental** level (attachment, trauma, temperament and the environment that shapes the trait into a disorder), all knitted together by a **gene-environment** transaction rather than a single cause. What is inherited is never a diagnostic category; it is a set of continuous personality trait dimensions whose extreme configurations, transacting with a formative environment, become the inflexible patterns the classification then labels.

This fragment walks the three levels in turn, states the integrating gene-environment principle, and then teaches the one disorder-specific aetiological model examiners expect by name, the Marsha Linehan biosocial theory of borderline personality disorder: a biologically heightened **emotional vulnerability** transacting reciprocally, across development, with a pervasively **invalidating environment**. The accompanying figure lays the transaction out schematically. The bipolar-II side of the affective-instability spectrum is cross-referenced to the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes; the complex-PTSD boundary to the Anxiety, OCD and trauma-related disorders notes; the deep serotonergic and mood-stabiliser pharmacology to the Mood disorders: pharmacotherapy notes; and attachment-based technique to the Psychotherapies, clinical assessment, MSE and nosology notes.

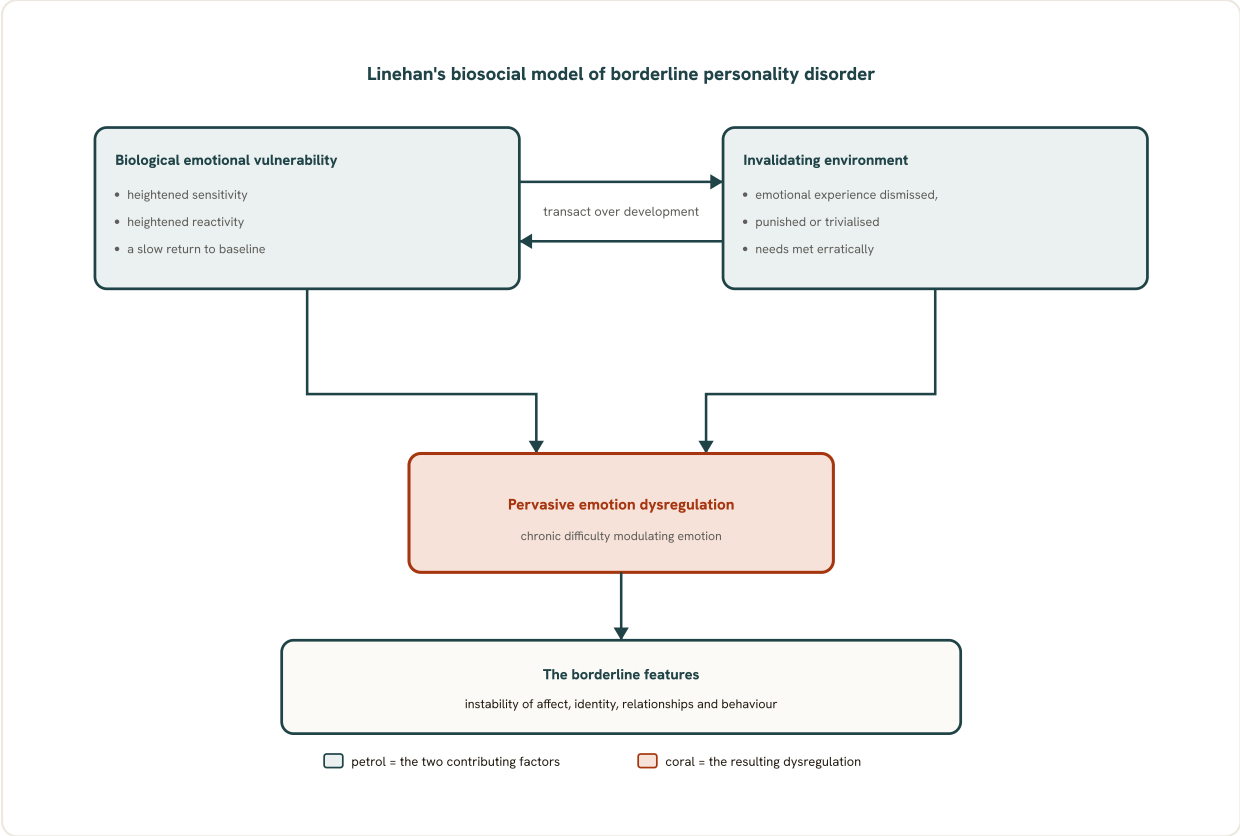

Fig 16.9 Linehan's biosocial model holds that a biological emotional vulnerability (heightened sensitivity and reactivity with a slow return to baseline) transacts reciprocally over development with a pervasively invalidating environment, and the transaction produces the pervasive emotion dysregulation that underlies the borderline features.

11.1 The three-level frame and the diathesis-stress spine

No personality disorder has a single cause. The stable finding across every type is that a heritable trait diathesis is necessary but not sufficient; the disorder emerges only when that diathesis meets a formative environment, and the two do not simply add but transact. Hold the three levels as a scaffold, the **genetic** (heritable trait dimensions), the **neurobiological** (the amygdala-prefrontal emotion circuitry and the serotonergic substrate of impulsive aggression) and the **developmental** (attachment disruption, childhood maltreatment, temperament), and read them not as competing explanations but as three windows on one process. This diathesis-stress spine, sharpened into a reciprocal transaction, is what the Linehan model makes concrete for borderline personality disorder, and it is the frame an examiner is testing when the question simply says "discuss the aetiology".

11.2 The genetic level: heritable dimensions, not heritable categories

Personality disorder is moderately heritable, and inherited as continuous traits. Twin, family and adoption studies agree that liability to personality pathology varies quantitatively and is moderately heritable, with estimates for normal and abnormal personality traits clustering in the roughly 40 to 60 per cent band. Crucially, personality disorders are not transmitted as discrete entities; what is inherited is a spread of trait dimensions, and the disorders are unusual configurations of the same traits that vary across the general population. The heritable loading is shared across spectra rather than tidy per-category packages: an **impulsivity and externalising** spectrum and an **affective-instability** spectrum load onto borderline and antisocial pathology

together, which is why comorbidity among the types is the rule. Most of the heritability sits in complex gene-gene interaction (epistasis) rather than in the average effect of single variants, so that individual common genes explain very little variance even in samples of tens of thousands, the so-called missing-heritability problem; the variants that are found tend to regulate neural development and neuroplasticity.

ENTITY	HERITABILITY ESTIMATE	WHAT IT TELLS YOU
Personality traits (normal + abnormal)	Moderate, roughly 40 to 60 per cent	Inherited as continuous dimensions, not discrete categories; mostly via epistasis (gene-gene interaction)
Any personality disorder	**Broad heritability about 44 per cent (Torgersen twins: MZ concordance 58, DZ 36 per cent)**	The anchor twin figure; DZ correlations well under half of MZ point to gene-environment interaction
Clusters A, B and C	Moderate, 40 to 60 per cent each	Separate heritable influences further differentiate the three clusters
Antisocial personality (symptom count)	The most heritable type, around 38 per cent	Best-studied; adoption and twin data converge; an unstable, hostile home acts synergistically
Paranoid personality (symptom count)	The least, around 28 per cent	Weak-to-moderate range across the ten categorical types

Heritability of personality pathology (Torgersen SCID-II twin data and DSM symptom-count studies). The highlighted any-disorder figure is the number to carry; the message is moderate, dimensional, and gene-environment dependent.

11.3 The neurobiological level: an amygdala-prefrontal imbalance and a serotonergic floor

Emotion dysregulation and impulsive aggression have a shared circuitry. At the **neurobiological** level the recurring finding is an imbalance in the **amygdala-prefrontal** emotion-regulation circuit: a hyperreactive amygdala that responds fast and hard to emotionally salient and socially threatening cues, paired with hypofunction of the prefrontal regions (orbitofrontal cortex and anterior cingulate) that would normally exert top-down inhibitory control. The net effect is intense, poorly braked affect, exactly the reactivity that shows up clinically as affective instability and as anger that outruns its trigger; imaging of individuals with impulsive aggression (Emil Coccaro and colleagues) shows just this exaggerated amygdala and blunted orbitofrontal response to social threat. Beneath the circuit sits a neurochemical dimension: reduced central **serotonergic** function correlates with **impulsive aggression** and with self-directed violence, the endophenotype Larry Siever placed at the centre of the borderline and antisocial impulsive-aggressive spectrum. That serotonergic floor is the rationale, cross-referenced to the Mood disorders: pharmacotherapy notes, for the symptom-targeted use of serotonin reuptake inhibitors against impulsive aggression, and it is a dimensional trait marker, not a disorder-specific lesion.

11.4 The developmental level: attachment, trauma and temperament

Early relationships and adversity shape the trait, but do not simply cause the disorder. Three **developmental** strands recur. First, **attachment disruption**: disorganised early attachment and a caregiving environment that fails to help the child read and regulate internal states leave a fragile capacity to mentalise (to hold minds in mind), which Peter Fonagy places at the heart of the borderline vulnerability. Second, **childhood trauma and maltreatment**: histories of sexual and physical abuse, neglect and pervasive family adversity are over-represented, and childhood sexual abuse is reported by a large minority to a majority of borderline patients (roughly 40 to 70 per cent). Third, **temperament**: early-emerging, procedurally learned dispositions (high negative emotionality, effortful-control deficits, novelty seeking) are the behavioural face of the heritable diathesis and are visible long before a disorder can be diagnosed. The developmental level is the environment that the genetic diathesis meets, and it is where the therapeutic leverage lies; the complex-PTSD-versus-borderline boundary that this trauma strand raises is developed in the Anxiety, OCD and trauma-related disorders notes.

TRAP **Reading childhood abuse as the cause of borderline personality disorder.** Childhood sexual abuse is reported by roughly 40 to 70 per cent of borderline patients, yet the association is only moderate (a meta-analytic effect size of about r = 0.28) and is neither necessary nor sufficient; trauma is a powerful risk factor that transacts with the diathesis, not the single cause.

11.5 The integrating principle: the gene-environment transaction

Diathesis and environment do not add, they transact. The three levels are bound by **gene-environment** interplay operating in both directions. Genes moderate how strongly a child reacts to adversity (gene-environment interaction), and a child's heritable temperament also shapes and selects the very environment it meets: an irritable, emotionally intense infant evokes harsher, more inconsistent caregiving (evocative gene-environment correlation) and later seeks out environments that amplify the trait (active correlation). The consequence is a feedback loop rather than a sum, in which a heritable diathesis and a formative environment escalate one another over years. This is precisely why the same adversity produces a personality disorder in one child and resilience in another, and why heritability estimates that ignore this transaction over-read the genetic share. The transactional reading is the modern successor to plain diathesis-stress, and it is the exact logic the Linehan model applies to borderline personality disorder.

RULE **A heritable trait becomes a disorder only in transaction with development.** Inherited trait dimensions set the diathesis; the disorder emerges through their reciprocal gene-environment transaction with attachment, trauma and the family environment, never from heredity or adversity alone.

11.6 The Linehan biosocial model: the disorder-specific synthesis

Borderline personality disorder is fundamentally a disorder of the emotion-regulation system. The Linehan **biosocial model** is the aetiological theory to name for borderline personality disorder, and it is simply the gene-environment transaction made concrete. In the **Linehan biosocial** account, the pervasive emotion dysregulation that underlies the borderline features results from continuous, reciprocal transactions among three components: a biological

emotional vulnerability, a pervasively **invalidating environment**, and the emotion dysregulation the two of them generate. None of the three is the cause on its own; the causal force is the transaction between them, running back and forth across development, and the figure alongside sets out that reciprocal loop. Because the model locates borderline pathology in emotion regulation rather than in character or manipulation, it is also non-pejorative and directly treatment-guiding, which is why it, and not the older object-relations account alone, is the model expected in an examination answer.

3	3	5	44
COMPONENTS OF THE LINEHAN BIOSOCIAL TRANSACTION	FEATURES OF THE EMOTIONAL VULNERABILITY	ICD-11 DIMENSIONAL TRAIT DOMAINS	BROAD HERITABILITY OF ANY PERSONALITY DISORDER, PER CENT (TORGERSEN TWINS)

11.7 The biological emotional vulnerability

Fast up, hard hit, slow down. The first arm of the model is a biologically mediated **emotional vulnerability**: a predisposition to affective instability arising from genetic, intrauterine and temperamental factors, and defined by three properties. The person is emotionally over-sensitive (a low threshold, so a wide range of ordinary stimuli triggers a response), over-reactive (a high magnitude of physiological arousal once triggered), and slow to return to baseline. The third property is the engine of the disorder: because arousal decays slowly, each subsequent event lands on top of incompletely settled arousal, making extreme responses ever more likely, the emotional equivalent of a burn victim feeling the wind. This vulnerability is the biological diathesis of the transaction, and it is what a treatment such as dialectical behaviour therapy targets with emotion-regulation and distress-tolerance skills.

Heightened sensitivity

A low threshold for emotional response; a wide range of everyday cues sets emotion off.

Heightened reactivity

A high magnitude of physiological arousal once a response is triggered.

Slow return to baseline

Arousal decays slowly, so successive events compound and escalate; the property that drives the instability.

11.8 The pervasively invalidating environment

An environment that teaches the child not to trust its own experience. The second arm is the **invalidating environment**: one that pervasively criticises, minimises, trivialises, punishes or only erratically reinforces the communication of internal experience, and that over-simplifies how easy problems are to solve ("you're not really upset", "you don't know what you want"). Two consequences follow. The child learns that its own thoughts and feelings are wrong, unimportant or shameful, and so comes to rely excessively on the social surround for cues on how to feel, producing the interpersonal hypersensitivity that marks the disorder. And because ordinary emotional displays are dismissed while extreme ones are intermittently attended to, the environment shapes escalation: the child who is ignored until it threatens self-harm, and then receives soothing, is taught that only extreme distress works. Childhood sexual and physical

abuse are the prototypical severe instances, but the invalidation need not be abusive; a well-meaning but poorly matched caregiver of a highly vulnerable child can invalidate inadvertently.

PEARL

The most examinable mechanism inside the invalidating environment is *intermittent reinforcement of extreme emotional displays*. When calm requests are ignored and only crisis behaviour (self-harm, threats) draws a caring response, the environment inadvertently trains the very high-amplitude behaviour it then finds intolerable. Naming this loop explains why borderline self-harm is so resistant to simple reassurance and why dialectical behaviour therapy works to break the contingency rather than to scold the behaviour.

11.9 The transaction, its product, and the treatment it points to

The two arms amplify each other; emotion dysregulation is the product. The force of the model is reciprocal. A highly emotionally vulnerable child is harder to soothe and so makes an environment more invalidating, even when caregivers mean well; and a more invalidating environment, by punishing and confusing emotional learning, further worsens the vulnerability. Round the loop turns, and its cumulative product is a pervasive **emotion dysregulation** that expresses itself across the borderline domains, the unstable relationships, the identity disturbance, the reactive affect, the impulsivity and the self-harm, all of them re-read as failures of emotion regulation rather than as separate symptoms. Because the model names a mechanism, it names a treatment: dialectical behaviour therapy was built directly on it to teach the emotion-regulation skills the transaction never allowed to develop, and schema therapy targets the same developmental deficits through the maladaptive schema modes; both are developed on their own topics in this chapter.

INDIA

Three India-specific points are genuine here. First, under-recognition: personality disorders are markedly under-diagnosed in Indian practice because patients reach services through the self-harm, the overdose or a comorbid depression, which is coded as the event rather than the enduring pattern, so the aetiological formulation is rarely made. Second, cultural expression: judge every trait and every "invalidation" against the person's own cultural and family norms, because collectivist family interdependence must not be misread as pathological dependence or as an invalidating environment, and possession-trance and dissociative idioms are normative in many settings. Third, access and forensic framing: dialectical behaviour therapy and schema therapy are being delivered and culturally adapted at Indian tertiary and private centres rather than being widely available, and antisocial personality disorder in particular carries a medico-legal frame (offender assessment, court reports) developed in the Mental health legislation and forensic psychiatry notes.

GOOD TO REMEMBER

- **Borderline personality disorder (aetiology):** the model to name is the Linehan biosocial theory, a biologically heightened emotional vulnerability (heightened sensitivity, heightened reactivity, slow return to baseline) transacting reciprocally over development with a pervasively invalidating environment, the transaction producing the pervasive emotion dysregulation that underlies the borderline features. Discriminator from a purely genetic or purely trauma account: the cause is the reciprocal transaction, not either arm alone. The diagnosis still rests on five or more of the nine criteria, developed on its own topic; the first aetiological step is to think transaction, not single cause.

GOOD TO REMEMBER

- **Dialectical behaviour therapy (from the model):** mechanism is to correct the emotion dysregulation the biosocial model places at the core, teaching skills across mindfulness, distress tolerance, emotion regulation and interpersonal effectiveness, delivered through its four treatment modes (individual therapy, the skills group, intersession phone coaching, and the therapist consultation team). Indication is borderline personality disorder, especially where reducing recurrent self-harm is the priority (NICE, Indian Psychiatric Society). Signature caution: it is a comprehensive structured programme, not a brief "DBT-informed" add-on, and delivering truncated fragments is not delivering dialectical behaviour therapy.

HOLD THIS

Borderline personality disorder is neither purely inborn temperament nor purely childhood damage: it is the product of a biologically heightened emotional vulnerability transacting reciprocally, across development, with a pervasively invalidating environment, and it is that gene-environment transaction, not either half alone, that generates the pervasive emotion dysregulation underlying the borderline features.

12 · Assessment of personality

Why this matters. The **assessment of personality** is the step that turns a clinical impression into a defensible diagnosis, and it is examined as a set of named instruments plus two governing principles. The instruments split cleanly into two families: clinician-administered **structured interviews** that confirm a diagnosis against the general criteria, and self-report questionnaires that screen for it. The two principles are the ones a stem is built to catch: a self-report screen identifies, an interview confirms, and personality is a trait, not a state, so it must never be diagnosed from the affect of an acute episode. Learn the instruments as their structure, not their item wording, and hold the two principles as the reasoning frame.

Fig 16.10 Personality assessment integrates longitudinal history, clinical interview, collateral information, dimensional trait and severity measures, developmental context and the effects of the current mental state.

This note typesets the working toolkit: the International Personality Disorder Examination (IPDE) and the Structured Clinical Interview for DSM-5 Personality Disorders (SCID-5-PD) as the categorical confirming interviews; the Personality Inventory for DSM-5 (PID-5) as the dimensional self-report of the trait model; the Zanarini Rating Scale for Borderline Personality Disorder (ZAN-BPD) as a symptom-severity and change measure; and the **ICD-11 severity anchors** as the graded frame that a modern, severity-led assessment records first. The general diagnostic criteria that open the chapter are assumed here; this note owns the measurement, the screen-then-confirm logic, and the state-versus-trait caution. The wider technique of clinical assessment and the mental state examination belong to the Psychotherapies, clinical assessment, MSE and nosology notes.

12.1 Two families of instrument: interviews that confirm, questionnaires that screen

Map the toolkit before the details. Every personality instrument is either an interview or a self-report, and either categorical (does the patient meet the criteria of a named type) or dimensional (how severe and along which trait continua). The four workhorses populate the grid: the IPDE

and the SCID-5-PD are clinician interviews that yield categorical diagnoses; the PID-5 is a self-report that yields a dimensional trait profile; the ZAN-BPD is a clinician scale that quantifies borderline severity for tracking change. Sitting over all of them is the ICD-11 severity judgement, which is not a questionnaire at all but a clinical grading of impairment recorded first. Fix that two-by-two picture and each instrument slots into place.

The prior gate still governs. No instrument replaces the general threshold: an enduring, pervasive, inflexible, culturally deviant pattern with onset by adolescence and clinically significant impairment, not better explained by another disorder. The instruments operationalise that judgement; they do not bypass it. A structured interview is, in effect, the general criteria and the type criteria administered as a disciplined, replicable schedule.

12.2 Self-report versus interview: screen wide, confirm narrow

The single most testable design principle. The **self-report versus interview** distinction is the logic that ties the instruments together. Self-report questionnaires (the IPDE screening questionnaire, the SCID-5 Personality Questionnaire, the PID-5) are quick, patient-completed and deliberately over-inclusive: they are sensitive but not specific, so they *screen* and over-identify. The clinician-administered **structured interview** (the IPDE, the SCID-5-PD) then probes only what screened positive and *confirms* the diagnosis, distinguishing a genuine enduring trait from an endorsed item. A positive screen is a prompt to interview, never a diagnosis in itself. This screen-then-confirm architecture is why the interview instruments each ship with a matched self-report front end.

RULE **Screen wide, confirm narrow.** A self-report questionnaire (the IPDE-SQ, the 106-item SCID-5-SPQ, the PID-5) screens and over-identifies; the structured interview (the IPDE, the SCID-5-PD) confirms against the criteria. A screen that is positive earns an interview; it does not earn a label.

PEARL

Read the self-report and interview as a sensitivity-then-specificity pair. The questionnaire is tuned to miss few cases (high sensitivity, low specificity), so its job is to decide which criteria are worth a clinician's time; the interview is tuned to confirm (specificity), so its job is to decide whether the endorsed pattern is real, enduring and impairing. Getting the order wrong, confirming from a questionnaire, is the commonest measurement error in the personality field.

12.3 The instruments, typeset

The object to hold cold. The instruments are learned as their structure and scoring with a citation, not as their items. The table gathers the four workhorse instruments and their matched screeners; the highlighted cells are the structural facts an examiner reaches for.

INSTRUMENT	ADMINISTRATION	STRUCTURE AND COVERAGE	SCORING	SOURCE
IPDE	Clinician semi-structured interview	**Two modules, an ICD-10 and a DSM-IV module, usable alone or together; questions grouped by six life areas (work; self; interpersonal relationships; affects; reality testing; impulse control), not by disorder**	Each relevant criterion rated 0 absent, 1 subthreshold, 2 criterion level; trait present at least the past five years, one criterion before the age of twenty-five; output both dimensional and categorical (definite or probable)	Loranger, Janca, Sartorius; WHO / Cambridge UP (Loranger et al. 1994)
IPDE-SQ	Self-report screener (true or false)	First-pass filter flagging which disorders to probe in the full interview	A positive screen prompts the interview; not diagnostic	IPDE screening questionnaire
SCID-5-PD	Clinician structured interview	Covers the ten DSM-5 (Section II) personality disorders plus other-specified personality disorder; the DSM-5 successor to the SCID-II	**Each criterion rated 1 absent, 2 subthreshold, 3 threshold; the DSM-5 required criterion counts then decide each diagnosis**	First, Williams, Benjamin, Spitzer 2016 (APPI)
SCID-5-SPQ	Self-report screener (yes or no)	A 106-item questionnaire the patient completes first, so the interview probes only criteria that screened positive	Screening only; not itself diagnostic	SCID-5 Personality Questionnaire
PID-5 (and PID-5-BF)	Self-report dimensional trait measure	**Five higher-order trait domains over twenty-five lower-order facets; full form 220 items, Brief Form 25 items (domain level); operationalises the DSM-5 Section III alternative model Criterion B**	Items scored 0 to 3; domain and facet scores as item means (higher is more maladaptive); no single categorical cut-off	Krueger, Derringer, Markon, Watson, Skodol 2012 (APA)

INSTRUMENT	ADMINISTRATION	STRUCTURE AND COVERAGE	SCORING	SOURCE
ZAN-BPD	Clinician-rated severity and change scale	Nine items, one per DSM borderline criterion, spanning the affective, cognitive, impulsive and interpersonal domains; rated over the prior week	**Each item 0 to 4; total on the 0 to 36 scale; higher is greater severity; tracks change, not a diagnostic cut-off**	Zanarini et al. 2003

The four workhorse personality instruments and their matched self-report screeners, typeset as structure and scoring with a citation; the highlighted cells mark the single fact most often tested for each. Item wording is not reproduced.

GOOD TO REMEMBER

- **IPDE:** a WHO semi-structured interview in two modules (ICD-10 and DSM-IV) organised by six life areas, criteria scored 0, 1 or 2, giving both a dimensional and a categorical output, paired with the IPDE-SQ self-report screener.
- **SCID-5-PD:** the DSM-5 structured interview over the ten Section II personality disorders, criteria rated 1, 2 or 3, fronted by the 106-item SCID-5-SPQ self-report screener; the successor to the SCID-II.
- **PID-5:** the self-report dimensional measure of the five trait domains and twenty-five facets (220-item full form, 25-item brief), the alternative-model Criterion B instrument, with no categorical cut-off.
- **ZAN-BPD:** nine clinician-rated items, one per borderline criterion, each 0 to 4 for a total on the 0 to 36 scale; a severity and change measure, not a diagnostic test.
- **ICD-11 severity anchors:** personality difficulty, mild, moderate and severe on a harm gradient; severity is graded first, before any trait qualifier.

12.4 The categorical confirming interviews: IPDE and SCID-5-PD

Two interviews, one job: confirm a named type against the criteria. The IPDE, developed by Armand Loranger out of the earlier Personality Disorder Examination and adopted under the WHO joint programme, is the international standard. Its distinctive move is to organise questions by life area rather than by disorder, walking the patient through work, self, interpersonal relationships, affects, reality testing and impulse control, so the clinician rates the underlying criteria as they surface across the whole life rather than interrogating one type at a time. Each criterion is scored 0, 1 or 2, and the IPDE builds in a temporal guard against late-onset mimics: a criterion counts only if the trait has run for at least the past five years, with at least one criterion satisfied before the age of twenty-five. It returns both a dimensional score per disorder and a categorical verdict (definite, or probable when one criterion short).

The SCID-5-PD is the DSM-native equivalent. The SCID-5-PD covers the ten DSM-5 Section II personality disorders and rates each criterion on the standard SCID convention of 1 (absent), 2 (subthreshold) or 3 (threshold), with the DSM-5 criterion counts then deciding each diagnosis. Its 106-item self-report questionnaire, the SCID-5-SPQ, is completed first so the interview need only probe the criteria that screened positive, the screen-then-confirm logic in a single package.

Both instruments are copyright and are learned as structure and scoring, not as reproduced items.

GOOD TO REMEMBER

- **IPDE (the discriminator):** the interview organised by six life areas, not by disorder; criteria scored 0, 1 or 2 with the five-year and pre-age-twenty-five temporal guard, yielding a dimensional plus categorical result.
- **SCID-5-PD (the discriminator):** the DSM-5 structured interview over the ten Section II types, criteria rated 1, 2 or 3 to the DSM criterion counts, with the 106-item SCID-5-SPQ as its screen.

12.5 The PID-5 and the dimensional trait map

The self-report that measures the trait model directly. The PID-5 is the self-report operationalisation of the DSM-5 Section III alternative model of personality disorders, specifically its Criterion B maladaptive-trait model. It measures five higher-order trait domains, negative affectivity, detachment, antagonism, disinhibition and psychoticism, resolved into twenty-five lower-order facets. The full form is 220 items on a four-point scale from 0 to 3, scored at domain and facet level; the 25-item Brief Form (PID-5-BF), five items per domain, gives a domain-level profile only. Being dimensional, it has no categorical cut-off: an elevated domain or facet mean flags maladaptive trait expression, to be read alongside the Criterion A judgement of how impaired personality functioning is.

The trait domains almost, but not exactly, match ICD-11. The high-yield trap is that the two dimensional systems share four domains and differ on the fifth. Read the table across: the DSM-5 alternative model and ICD-11 both carry negative affectivity, detachment, a callous-antagonistic domain and disinhibition, but ICD-11's fifth domain is anankastia (rigid over-control), whereas the alternative model's fifth is psychoticism (odd, eccentric cognition). ICD-11 also names its antagonistic domain dissociality and adds a borderline pattern qualifier.

TRAIT-DOMAIN THEME	ICD-11 QUALIFIER	DSM-5 ALTERNATIVE MODEL / PID-5 DOMAIN
Negative emotionality	Negative affectivity	Negative affectivity
Social withdrawal	Detachment	Detachment
Callous, antagonistic	Dissociality	Antagonism
Under-control, impulsivity	Disinhibition	Disinhibition
The differing fifth domain	**Anankastia (rigid over-control)**	**Psychoticism (odd, eccentric)**
Optional pattern specifier	Borderline pattern qualifier	A borderline type is reconstructed from the traits

The two dimensional trait systems share four domains; the fifth differs, ICD-11 adding anankastia while the DSM-5 alternative model adds psychoticism. Cross from one to the other by swapping anankastia for psychoticism (and dissociality for antagonism).

MNEMONIC

Three D's, plus N and A

The five ICD-11 trait domains: the three D's, **D**etachment, **D**issociality and **D**isinhibition, plus **N**egative affectivity and **A**nankastia. To convert to the DSM-5 alternative model, keep negative affectivity, detachment and disinhibition, rename dissociality as antagonism, and swap anankastia for psychoticism.

COMMON TRAP

Reading a high PID-5 domain score as a diagnosis. The PID-5 is dimensional and has no categorical cut-off; an elevated negative-affectivity or detachment mean describes trait expression, it does not by itself declare a personality disorder. The diagnosis still needs the level-of-functioning judgement (Criterion A) and the general threshold. A trait score is a profile, not a verdict.

12.6 The ICD-11 severity anchors

Severity is graded first, and it leads the diagnosis. The **ICD-11 severity anchors** are the frame a modern assessment records before anything else: rather than matching a type, the clinician grades how impaired personality functioning is, on a continuum from personality difficulty through mild, moderate and severe. The judgement rests on impairment of the *self* (identity, self-worth, self-direction) and of *interpersonal* functioning (relationships and roles), together with the risk of harm to self or others. There is no numeric cut-off; the harm gradient is the quick discriminator, running from typically none in mild, through sometimes in moderate, to often in severe.

SEVERITY LEVEL (CODE)	SELF AND INTERPERSONAL FUNCTIONING	HARM TO SELF OR OTHERS
Personality difficulty (QE50.7)	Longstanding pronounced traits shown only intermittently (for example under stress) or at low intensity; some but not notable disruption; a health-status factor, not a mental disorder	Minimal
Mild (6D10.0)	Some areas of self-functioning affected, or all areas mildly; problems in many relationships and roles, but some are maintained	Typically none
Moderate (6D10.1)	Multiple areas of self-functioning affected at moderate severity; marked problems in most relationships and most roles compromised; may show mild dissociative or psychotic-like states under stress	**Sometimes**
Severe (6D10.2)	Severe disturbance in the sense of self; virtually all relationships affected and role performance severely compromised or absent; impairment across nearly all of life	**Often**

The ICD-11 severity anchors, graded on self and interpersonal impairment plus harm risk; the harm gradient (minimal, typically none, sometimes, often) is the quick discriminator, and personality difficulty is a health-status factor rather than a disorder. Trait-domain qualifiers may be added at any severity level.

12.7 The ZAN-BPD: a measure of change, not a diagnostic test

Quantify severity, then track it. The ZAN-BPD, derived by Mary Zanarini from the borderline criteria and the revised diagnostic interview for borderlines, is a nine-item clinician-rated scale in which each item maps onto one of the nine DSM borderline criteria, from frantic efforts to avoid abandonment through to transient stress-related paranoia or dissociation. Each item is rated 0 to 4 over the prior week, for a total on the 0 to 36 scale, with higher scores meaning greater severity. Its purpose is to be sensitive to change: it is the instrument used to measure whether borderline symptoms are responding in a treatment trial or over follow-up, not to make the diagnosis. That confirming diagnosis is the job of the general criteria and a structured interview; the ZAN-BPD then meters the severity over time.

GOOD TO REMEMBER

- **ZAN-BPD (the discriminator):** nine clinician-rated items, one per borderline criterion, each 0 to 4 for a 0 to 36 total; a severity and change measure sensitive to treatment response, explicitly not a diagnostic instrument.

12.8 State versus trait: assess personality at baseline, not mid-storm

The caution that governs the whole assessment. The **state versus trait** rule is the reason a personality diagnosis is timed as much as it is measured: a personality disorder is an enduring, pervasive pattern, so it must not be diagnosed from the affect, impulsivity or relational chaos of an acute episode of another disorder. The lability of a mood episode, the disinhibition of intoxication and the reactivity of a fresh crisis all mimic personality pathology while they last. The safeguards are to assess when the patient is at baseline rather than in the acute state, to require that the same pattern predates and outlasts the episode, and to lean on collateral and longitudinal history rather than a single cross-sectional interview. Situational affective lability without the identity disturbance and abandonment fear is not borderline personality; and the reactive, hours-long mood swings of borderline must be separated from the sustained, autonomous episodes drawn out in the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes.

TRAP **Diagnosing a personality disorder mid-episode.** Affective instability, impulsivity and stormy relationships during an acute mood episode, an intoxication or a fresh crisis are state, not trait. Diagnose personality at baseline, against a pattern that is enduring, pervasive and pre-existing, or you will pin a lifelong label on a passing storm.

WORKED EXAMPLE

A woman in her twenties is admitted after self-harm during a depressive relapse, floridly labile and rejecting. The temptation is to record borderline personality disorder from the presentation. The disciplined route is the reverse: quantify the acute picture (a ZAN-BPD can meter current borderline symptoms, but does not diagnose), treat the mood episode, and defer the personality assessment. Reassessed at baseline some weeks later with collateral, a structured interview (the SCID-5-PD or the IPDE) then establishes whether an enduring, pervasive pattern truly predated the episode. Screen if useful, confirm by interview, and grade ICD-11 severity, but do it when the storm has passed.

12.9 The India lens and the cultural frame

Under-recognition makes systematic assessment worth more, not less. Personality disorders are substantially under-recognised in routine Indian practice, surfacing through comorbid mood, substance, anxiety or self-harm presentations rather than as a personality diagnosis, and often left uncoded for fear of stigma. A brief self-report screen embedded in a busy clinic is exactly the low-cost step that raises detection of the mixed and subthreshold cases that a purely impressionistic assessment misses, provided a structured interview then confirms. A severity-led ICD-11 reading, which begins with a graded judgement of dysfunction rather than a full type match, suits this reality well.

Read pathology against the patient's own culture, not a single norm. Every instrument still requires deviation from what the person's *own* culture expects, so joint-family interdependence, deference and religiously framed experience must not be scored as dependent, avoidant or odd pathology; personality must not be read through one culture's norms. On the treatment side, the

structured psychotherapies a severity rating points toward, dialectical behaviour therapy and schema therapy, are available and being culturally adapted at Indian tertiary and private centres but scarce elsewhere, so a severe rating can outrun what a service can deliver; the wider technique of these therapies belongs to the Psychotherapies, clinical assessment, MSE and nosology notes. Antisocial personality disorder carries the sharpest medico-legal weight in the Indian context, where the structured assessment feeds offender and court framing, cross-referenced to the Mental health legislation and forensic psychiatry notes.

INDIA

Personality disorders are under-recognised in Indian practice and present through their comorbidities, so a brief self-report screen followed by a confirming structured interview genuinely raises detection of the subthreshold and mixed cases. Judge deviation against the patient's own cultural norms, so collectivist family-embeddedness is not miscoded as dependency and religiously framed experience not as schizotypal oddness. The structured psychotherapies that a severity rating points to, dialectical behaviour therapy and schema therapy, are available and being culturally adapted in the metros and academic centres but unevenly accessible elsewhere; and antisocial personality disorder carries the medico-legal weight, where the assessment feeds the forensic notes.

5	25	0 to 36	4
ICD-11 AND ALTERNATIVE-MODEL TRAIT DOMAINS	PID-5 LOWER-ORDER TRAIT FACETS (220-ITEM FULL FORM)	ZAN-BPD TOTAL SCORE RANGE (NINE ITEMS)	ICD-11 SEVERITY ANCHORS (DIFFICULTY TO SEVERE)

HOLD THIS

Assessment of personality runs screen-then-confirm: self-report questionnaires (the IPDE-SQ, the 106-item SCID-5-SPQ, the PID-5) screen and over-identify, and a structured interview (the IPDE, organised by six life areas; the SCID-5-PD, over the ten DSM-5 types) confirms against the criteria; grade the ICD-11 severity anchors first (difficulty, mild, moderate, severe on a harm gradient), map the five trait domains and twenty-five PID-5 facets, meter borderline change with the ZAN-BPD, and never fix the diagnosis during an acute episode, because personality is a trait, not a state.

13 . Dialectical behaviour therapy for borderline personality disorder

The first treatment that worked, and the template for all the rest. Dialectical behaviour therapy (DBT) is the psychotherapy that changed the outlook for borderline personality disorder: developed by Marsha Linehan out of failed attempts to treat chronically suicidal women with standard behaviour therapy, it was the first treatment of any kind shown in a randomised trial to reduce self-harm in a group that clinicians had come to regard as untreatable. Examiners return to it because it is comprehensive and highly structured, so it can be dismantled into named parts: a theory of the disorder, an organising philosophy, four skills modules, four treatment modes, a hierarchy of what to treat first, and staged goals across the whole arc of recovery. Learn those parts as a scaffold and the topic answers itself.

This fragment builds DBT from its foundations upward. It sets out the **biosocial theory** that DBT rests on, the central **dialectic** of acceptance and change from which the treatment takes its name, the four skills modules with **mindfulness** as their core, the four modes that together make a comprehensive programme, the target hierarchy that decides what is worked on in any given session, the stages of treatment, and the evidence for the reduction in self-harm and hospitalisation that earned DBT its place at the front of the guidelines. The disorder itself is taught on its own topic; here the pharmacology stays deliberately light and adjunctive, and the deep drug detail is cross-referenced to the Mood disorders: pharmacotherapy notes.

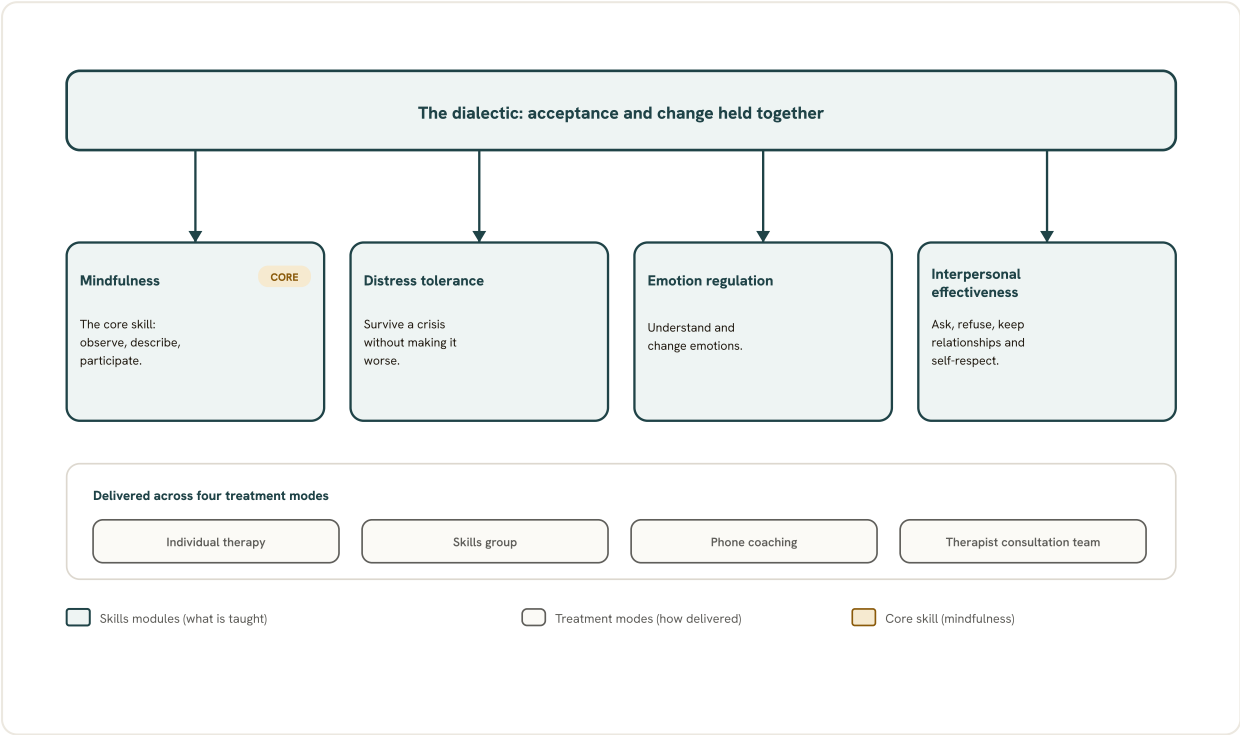

Fig 16.11 Dialectical behaviour therapy holds acceptance and change in dialectic and teaches four skills modules, mindfulness at the core, distress tolerance, emotion regulation and interpersonal effectiveness, delivered across four modes: individual therapy, the skills group, phone coaching and the therapist consultation team.

13.1 Origins and the core proposition

A behaviour therapy rebuilt around emotion dysregulation. Dialectical behaviour therapy grew in the early nineteen-eighties from work on repetitive suicidal and self-harm behaviour. Standard cognitive and behavioural change strategies, applied to chronically suicidal borderline patients, met a wall: pushing for change alone was experienced as invalidating, provoked drop-out and sometimes worsened the very behaviours being targeted. Linehan's solution was to place emotion dysregulation, rather than any single symptom, at the centre of the disorder, and to hold change strategies in constant balance with an equally strong stance of acceptance. The first controlled trial (Linehan and colleagues, published in the Archives of General Psychiatry) tested the new treatment in chronically parasuicidal women and made DBT the first psychotherapy to demonstrate efficacy in borderline personality disorder, opening the era of therapeutic optimism from which schema therapy, mentalisation-based treatment and transference-focused psychotherapy all followed.

4	4	3
SKILLS TRAINING MODULES	TREATMENT MODES IN COMPREHENSIVE DBT	STAGE-ONE TARGET TIERS (LIFE-THREATENING FIRST)

13.2 The biosocial theory of emotion dysregulation

Biology transacting with an invalidating environment. The biosocial theory is DBT's model of how borderline personality disorder arises, and it is the mechanism the whole treatment is built to address. A biological **emotional vulnerability**, meaning heightened sensitivity to emotional stimuli, greater intensity of response, and a slow return to baseline, transacts over development with a pervasively **invalidating environment**, one that dismisses, punishes or responds erratically to the child's inner experience. The transaction is reciprocal: the environment's invalidating responses amplify the biological sensitivity, and the resulting dysregulated behaviour draws further invalidation. The end state is pervasive **emotion dysregulation**, and DBT reads the criterion behaviours of the disorder, self-harm, impulsivity, stormy relationships and identity disturbance, as either the direct consequence of that dysregulation or the person's own attempts to re-regulate an unbearable affective state. Framing self-harm as attempted problem-solving, rather than manipulation, is what makes the theory both compassionate and clinically directive.

PEARL

The biosocial theory is why DBT never treats self-harm as a thing to be simply forbidden. If the behaviour is an attempt to solve the problem of unbearable emotion, then removing it without teaching a replacement skill leaves the person defenceless. Every act on the target list is therefore met with a behavioural chain analysis (what preceded it, what it achieved) and a substitute skill, not merely a safety contract.

13.3 The central dialectic: acceptance and change

Two technologies held in tension. The name of the treatment comes from **dialectics**: the philosophical stance that every position (thesis) calls up its opposite (antithesis) and that truth is found by synthesising the valid kernel of each. The single overarching dialectic in DBT is **acceptance and change**. The therapist must simultaneously accept the patient exactly as they are and relentlessly push for the changes that will build a life worth living, moving fluidly between the two poles rather than settling at either. This resolves the impasse that defeated ordinary behaviour therapy. Practically, DBT fuses two technologies: **behaviourism**, the technology of change (chain analysis, contingency management, skills training, exposure), and mindfulness derived from Zen, the technology of acceptance (validation, and ultimately radical acceptance of reality as it is). The constant motion between accepting and pushing is what gives DBT its characteristic speed and flow, and failures of the treatment are typically dialectical failures, a therapist stuck rigidly at one pole.

RULE **Structured psychotherapy is primary; DBT is the best-evidenced option for self-harm.** In borderline personality disorder the primary treatment is a structured, theory-based psychological therapy, and DBT is the intervention guidelines name first where reducing recurrent self-harm is the priority (NICE 2009, IPS 2023); medication is only adjunctive, symptom-targeted and time-limited.

13.4 The four skills modules, and mindfulness as the core

Four modules, built around a mindfulness centre. DBT teaches concrete behavioural skills in four modules, and Kaplan and Sadock name them exactly: mindfulness, distress tolerance, emotion regulation and interpersonal effectiveness. Mindfulness is the *core*: it is not one module among equals but the foundation, taught first and re-taught recurrently at the start of each of the other three modules. Its skills are the observing, describing and participating "what" skills, and the non-judgmental, one-mindful and effective "how" skills, converging on *wise mind*, the synthesis of emotion mind and reasonable mind. An elegant way to hold the set, shown in the accompanying figure, is that two modules serve *acceptance* (mindfulness and distress tolerance) and two serve *change* (emotion regulation and interpersonal effectiveness), so the four modules themselves mirror the central acceptance-change dialectic. A wrong module is the classic slip; verify the four against this list.

MODULE	POLE	WHAT IT TRAINS	SIGNATURE SKILLS
Mindfulness	**Acceptance (the CORE, re-taught before each module)**	Present-moment, non-judgmental awareness; the ground for all other skills	Observe, describe, participate; non-judgmentally, one-mindfully, effectively; wise mind
Distress tolerance	Acceptance	Surviving a crisis without making it worse; accepting what cannot be changed now	TIP, distraction (ACCEPTS), self-soothe, IMPROVE the moment, radical acceptance
Emotion regulation	Change	Understanding, naming and reducing the intensity of emotions; lowering vulnerability	Check the facts, opposite action, PLEASE (reduce vulnerability), accumulate positives
Interpersonal effectiveness	Change	Asking, refusing and keeping relationships and self-respect intact	DEAR MAN (objectives), GIVE (relationship), FAST (self-respect)

The four DBT skills modules; mindfulness is the core set, taught first and revisited before each of the other three. Two modules serve acceptance, two serve change.

MNEMONIC

DEAR MAN

The interpersonal-effectiveness skill for getting an objective met: **D**escribe the situation, **E**xpress feelings, **A**ssert the ask or the no, **R**einforce (name the benefit to the other), stay **M**indful (broken-record, ignore attacks), **A**ppear confident, **N**egotiate. Its two companions are GIVE (Gentle, Interested, Validate, Easy manner) for keeping the relationship, and FAST (Fair, no Apologies, Stick to values, Truthful) for keeping self-respect.

13.5 Distress tolerance, emotion regulation and interpersonal effectiveness

The three modules that complete the set. **Distress tolerance** is the acceptance-side crisis kit: skills to get through an urge to self-harm or an overwhelming affect without acting on it, from physiological down-regulation (the TIP skills) to distraction, self-soothing and, at its deepest, radical acceptance of a painful reality that cannot be changed in the moment. **Emotion regulation** is the change-side workhorse: it teaches the person to identify and label emotions, to check whether an emotion fits the facts, to act opposite to an unjustified emotion's urge, and to reduce baseline vulnerability by attending to sleep, eating, exercise and mastery. **Interpersonal effectiveness** supplies scripts for asking effectively, refusing without rupture, and preserving both the relationship and self-respect, which directly targets the abandonment sensitivity and the idealisation-devaluation swings of the disorder. The three change-and-tolerance modules are where the biosocial deficits are actively repaired.

TRAP **Calling a stand-alone skills class "DBT".** A weekly skills group on its own is skills training, not comprehensive DBT; the full treatment requires all four modes working together (individual therapy, skills group, phone coaching and a consultation team). Over-relying on distress tolerance while neglecting emotion regulation is the parallel error, since it teaches survival without teaching change.

13.6 The four treatment modes

Four modes, five functions. Comprehensive DBT is delivered through four **modes**, each serving a treatment function. The two that carry the standard trial format are **individual therapy plus skills group**: weekly **individual therapy** (which enhances motivation, uses the diary card and chain analysis, and where the individual therapist bears ultimate responsibility for the target behaviours) and the weekly **skills training group** (which enhances capabilities by teaching the four modules in a psychoeducational, class-like format). Alongside them run between-session phone coaching (which ensures the generalisation of skills into real life, coaching the patient through a crisis in the moment rather than in the next session) and the therapist consultation team (the "therapy for the therapists", which enhances the clinicians' own capability and motivation, guards treatment fidelity, and protects against burnout and dialectical failure). Between them these modes deliver DBT's five functions: enhance capabilities, improve motivation, ensure generalisation, structure the environment, and enhance the therapist. A programme missing any mode is not comprehensive DBT.

MODE	FUNCTION IT SERVES	WHAT HAPPENS IN IT
Individual therapy (weekly)	Improve motivation	One-to-one; diary card review and behavioural chain analysis; the individual therapist holds ultimate responsibility for the targets
Skills training group (weekly)	Enhance capabilities	Class-format teaching of the four modules with homework; a leader and co-leader; opens with a mindfulness exercise
Phone coaching (between sessions)	Ensure generalisation	Brief in-the-moment coaching to apply a skill during a crisis; commonly structured by a rule limiting calls after self-harm
Consultation team	**Enhance the therapist (fidelity and morale)**	Weekly clinician meeting; "therapy for the therapists"; sustains adherence and prevents dialectical failure and burnout

The four modes of comprehensive DBT and the functions they serve. The consultation team, exported into the treatment itself from the trials that use teams to control adherence, is the uniquely DBT mode examiners test.

13.7 The hierarchy of treatment targets

What gets worked on first is fixed, not chosen ad hoc. Because borderline patients typically present with many simultaneous problems, DBT imposes a strict order on what any given individual session addresses. Within the first stage of treatment the targets are ranked: **life-threatening behaviours** first (suicidal and self-harm acts, and credible threats), then **therapy-interfering behaviours** (of the patient or the therapist, such as missing sessions, arriving intoxicated, or a therapist's own drift), and finally **quality-of-life-interfering behaviours** (the substance use, disordered eating, unemployment and relational chaos that seriously destabilise a life). Only once those are in hand does the work turn to increasing behavioural skills. The diary card is scanned against this hierarchy at the top of every session, so a fresh episode of self-harm always pulls the agenda upward regardless of what patient or therapist would rather discuss. This ordering is one of the most reliably examined facts of the topic.

WORKED EXAMPLE

A young woman in comprehensive DBT arrives wanting to talk about a job interview. Her diary card, however, shows a cutting episode three evenings earlier. The target hierarchy decides the agenda: the therapist addresses the life-threatening behaviour first, running a chain analysis of the cutting and rehearsing the distress-tolerance skill that could have replaced it, before any time goes to the interview (a quality-of-life target). The ordering is not coldness; it is the treatment refusing to let the highest-risk behaviour be talked past.

13.8 The DBT stages of treatment

Staged goals across the whole arc of recovery. The **DBT stages** organise the treatment over time, beginning with a distinct pre-treatment phase of orientation and commitment, in which

patient and therapist agree the goals, the mode structure and the working agreements before therapy proper starts. The staged plan then runs from severe behavioural dyscontrol toward a full life, and the target hierarchy above sits inside the first stage.

STAGE	PRESENTING LEVEL	GOAL OF THE STAGE
Pre-treatment	Not yet committed or oriented	Orientation, commitment, agreeing goals, modes and working agreements
Stage one	Severe behavioural dyscontrol	**Behavioural control and stability (the life-threatening, therapy-interfering, quality-of-life target hierarchy)**
Stage two	Quiet desperation; controlled behaviour but emotional suffering	Non-anguished emotional experiencing; processing the past, including trauma and post-traumatic stress
Stage three	Problems in living	Ordinary happiness and unhappiness; self-respect and individual life goals
Stage four	Sense of incompleteness	Capacity for sustained joy, freedom and connection

Pre-treatment plus the four DBT stages. Most suicidal borderline patients enter at stage one, where behavioural control is the priority; trauma processing waits for stage two, after stability is achieved.

13.9 The evidence base: self-harm and hospitalisation

The reductions that earned it the guidelines. The foundational trial (Linehan and colleagues, in chronically parasuicidal women with borderline personality disorder) showed that, compared with treatment as usual, DBT reduced the frequency and medical severity of self-harm, produced fewer psychiatric hospitalisation days, and markedly improved treatment retention by lowering drop-out, even where it did not initially separate on depression or hopelessness. Those two signals, less **self-harm** and less **hospitalisation**, have been the durable core of the DBT evidence base ever since, replicated across later trials and reviews, and DBT remains the most extensively researched and evaluated of all treatments for the disorder (the basis for its Cochrane and guideline standing). Both NICE and the Indian Psychiatric Society recommend DBT specifically to reduce recurrent self-harm and emotion dysregulation, which is exactly the outcome the original trial demonstrated.

13.10 Place among the borderline psychotherapies, and the guideline anchor

One of several structured therapies, first among equals for self-harm. DBT sits alongside schema therapy, mentalisation-based treatment and transference-focused psychotherapy as the evidence-based structured psychotherapies for borderline personality disorder, each with its own mechanism and their own topics in this chapter; DBT is distinguished by its behavioural roots, its skills curriculum, and the strongest evidence base for reducing self-harm. The guideline position is consistent and worth carrying cleanly: structured psychological therapy is the primary treatment, DBT (or an equally comprehensive programme) is offered where recurrent self-harm is

the priority, and pharmacotherapy is not a treatment for the disorder itself but a symptom-targeted, time-limited adjunct for a comorbidity or a crisis. A programme is only DBT if it keeps the biosocial theory, the acceptance-change dialectic, all four modes and the target hierarchy; strip those out and what remains is skills training under a borrowed name. The wider technique of the structured psychotherapies is developed in the Psychotherapies, clinical assessment, MSE and nosology notes.

INDIA

Personality disorders are markedly under-recognised in Indian practice, so the borderline patient usually reaches services coded by the self-harm episode rather than by the pattern, and the structured therapy that would help is rarely offered. Two things temper a realistic plan. First, availability: dialectical behaviour therapy and schema therapy are being delivered and culturally adapted at Indian tertiary and private centres rather than being widely accessible, and few settings can staff a full four-mode programme with a trained consultation team, so pragmatic, skills-focused adaptations are common. Second, cultural fit: the mindfulness and acceptance core of DBT sits naturally with Indian contemplative traditions, an asset when framed in the patient's own idiom, while the interpersonal-effectiveness scripts must be calibrated to family interdependence rather than imported wholesale, since assertiveness norms and the very expression of personality pathology differ by culture and must not be read through a single culture's lens.

GOOD TO REMEMBER

- **Dialectical behaviour therapy (DBT):** core mechanism is the biosocial theory, an emotional vulnerability transacting with an invalidating environment to produce pervasive emotion dysregulation, treated by fusing behavioural change with mindfulness-based acceptance (the acceptance-change dialectic). Structure: four skills modules (mindfulness as the core, plus distress tolerance, emotion regulation and interpersonal effectiveness) delivered through four modes (individual therapy, skills group, phone coaching and consultation team), with a target hierarchy of life-threatening, then therapy-interfering, then quality-of-life-interfering behaviours across staged treatment. Indication: borderline personality disorder with recurrent self-harm, suicidality and chronic emotion dysregulation; it is the first-line structured psychotherapy for self-harm (NICE, IPS). Signature caution: it must be comprehensive and delivered with fidelity, it is resource-intensive, and trauma processing waits for stage two, only after stage-one behavioural control.

HOLD THIS

DBT rests on the biosocial theory of emotion dysregulation and the acceptance-change dialectic, and is delivered as four skills modules (mindfulness at the core, with distress tolerance, emotion regulation and interpersonal effectiveness) through four modes (individual therapy, skills group, phone coaching, consultation team), targeting life-threatening before therapy-interfering before quality-of-life behaviours; its landmark evidence is the reduction in self-harm and hospitalisation.

14 . Schema therapy for personality disorders

The integrative psychotherapy built for the difficult patient. Schema therapy is Jeffrey Young's integrative model, weaving cognitive-behavioural technique together with attachment theory, object relations and the experiential (gestalt) tradition, and designed expressly for the chronic, characterological presentations on which ordinary short-term cognitive-behavioural therapy

stalls. It matters in the examination because it is one of the small handful of structured psychotherapies with a genuine borderline personality disorder evidence base, and because its vocabulary, **early maladaptive schemas**, coping styles, **schema modes** and **limited reparenting**, is asked directly. Learn it as a four-part architecture: the schemas (the enduring self-defeating patterns), the domains that group them, the coping styles that keep them alive, and the modes framework that carries the work with the labile borderline patient.

This fragment teaches the model forward: what a **schema** is and where it comes from, the **five schema domains** holding the **eighteen early maladaptive schemas**, the **three coping styles** (surrender, avoidance, overcompensation), and the mode map that reduces the borderline patient's shifting states to a workable set of parts. It then teaches the two signature techniques, limited reparenting and experiential **mode work**, and closes on the trial evidence and the Indian picture. The wider landscape of psychotherapy models and technique sits in the Psychotherapies, clinical assessment, MSE and nosology notes; the borderline construct itself, and the sibling therapies dialectical behaviour therapy and mentalisation-based treatment, are developed on their own topics in this chapter.

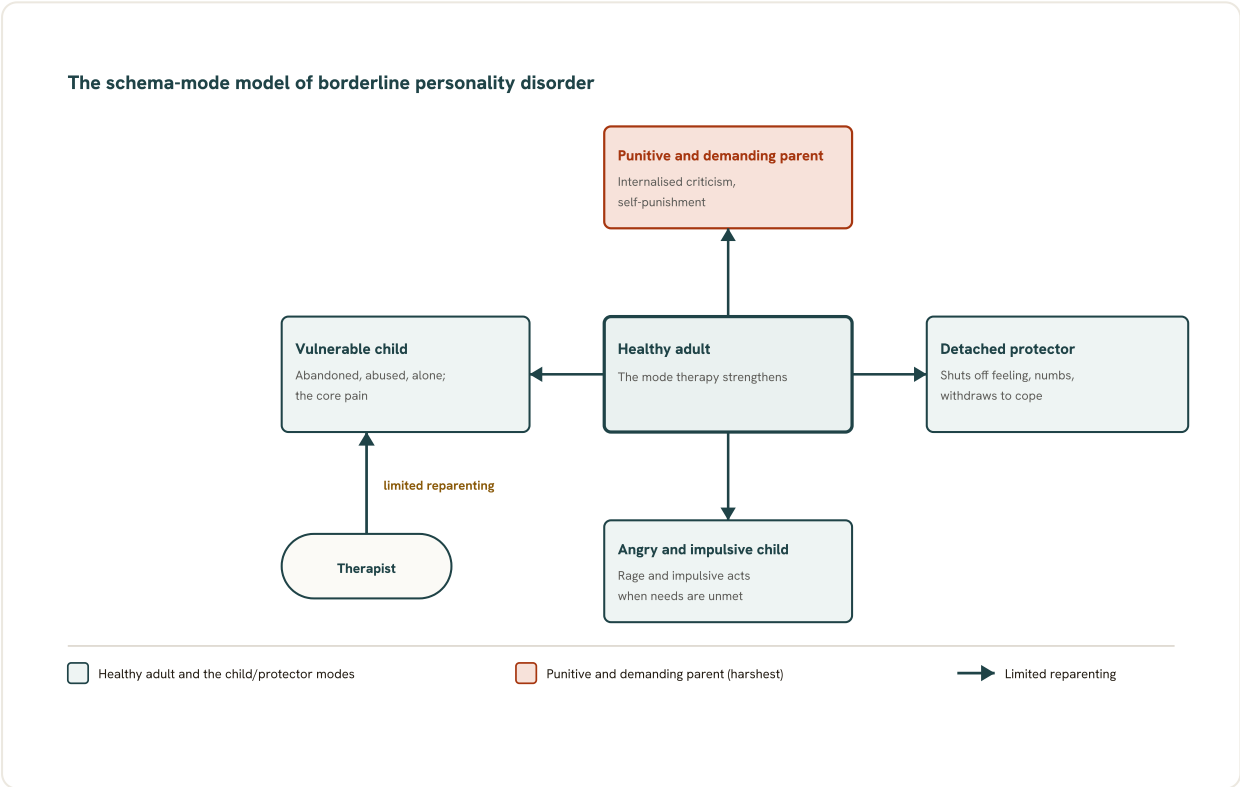

Fig 16.12 Schema therapy formulates borderline personality disorder as shifts between modes, the vulnerable child, the angry and impulsive child, the detached protector and the punitive and demanding parent, and uses limited reparenting to meet the vulnerable child's needs and build up the healthy adult mode.

14.1 What schema therapy is, and who it is for

An integrative model for ego-syntonic, characterological pathology. Standard cognitive-behavioural therapy assumes a patient who forms an alliance quickly, has a stable identity and clear goals, can access and verbalise affect, and can change through logic and homework. The personality-disordered patient breaks every one of those assumptions: the pathology is rigid, ego-syntonic and interpersonal, and it defeats a symptom-focused approach. Schema therapy was

constructed by Young for exactly this population. Its organising idea is that maladaptive personality patterns grow from **unmet core emotional needs** in childhood, five of them, secure attachment, autonomy and competence and a sense of identity, freedom to express valid needs and emotions, spontaneity and play, and realistic limits and self-control. Where these needs go unmet, through aversive experience interacting with temperament, the child lays down self-defeating patterns that harden into personality. The therapy aims to meet those needs, in a bounded therapeutic form, and so to heal the patterns rather than merely manage the symptoms.

14.2 Early maladaptive schemas: the enduring self-defeating pattern

Broad, pervasive, self-perpetuating themes about self and relationships. An early maladaptive schema is a broad, pervasive theme about oneself and one's relationships, comprising memories, emotions, cognitions and bodily sensations, laid down in childhood or adolescence and elaborated across the lifespan, dysfunctional to a significant degree. The examples make it concrete: abandonment, mistrust and abuse, emotional deprivation, defectiveness and shame. A schema begins as a reasonably accurate reading of a harmful early environment and becomes inaccurate as the person grows, yet it fights for survival: the patient assimilates new experience to fit the schema and discounts what would disconfirm it, which is schema perpetuation. This is what makes personality pathology so treatment-resistant, and it is why the schema, not the presenting symptom, is the unit of the work. Schemas are traits: present as a vulnerability, they may or may not be activated at a given moment, and when a schema is triggered the person is flooded with the original affect.

18	5	3	4
EARLY MALADAPTIVE SCHEMAS (YOUNG)	SCHEMA DOMAINS GROUPING THEM	MALADAPTIVE COPING STYLES	DYSFUNCTIONAL BORDERLINE MODES

14.3 The five schema domains and the eighteen schemas

Each domain answers one thwarted childhood need. The **eighteen early maladaptive schemas** are grouped into **five schema domains**, and the domain is the more examinable unit because each maps cleanly onto one of the unmet core emotional needs. Hold the five domains and one or two schemas under each, rather than reciting all eighteen; the domain structure is what the questions test.

DOMAIN	THWARTED CORE NEED	REPRESENTATIVE SCHEMAS WITHIN IT
Disconnection and Rejection	**Secure attachment: safety, stability, nurturance, acceptance**	**Abandonment/Instability; Mistrust/Abuse; Emotional Deprivation; Defectiveness/Shame; Social Isolation**
Impaired Autonomy and Performance	Autonomy, competence, a sense of identity	Dependence/Incompetence; Vulnerability to Harm; Enmeshment/Undeveloped Self; Failure
Impaired Limits	Realistic limits and self-control	Entitlement/Grandiosity; Insufficient Self-Control/Self-Discipline
Other-Directedness	Freedom to express valid needs and emotions	Subjugation; Self-Sacrifice; Approval/Recognition-Seeking
Overvigilance and Inhibition	Spontaneity and play	Negativity/Pessimism; Emotional Inhibition; Unrelenting Standards; Punitiveness

The five schema domains, each anchored to the childhood emotional need it reflects; the highlighted Disconnection and Rejection domain is the one most central to borderline pathology and the main target of limited reparenting.

14.4 The three maladaptive coping styles: surrender, avoidance, overcompensation

How the patient responds when a schema is triggered. A schema is the wound; the coping style is what the person does when it is touched. Young identifies **three coping styles**, and they map onto the innate threat responses. In surrender, the patient yields to the schema, accepts it as true and lives it out, choosing partners and situations that confirm it. In avoidance, the patient arranges life so the schema is never activated, blocking the thoughts and numbing the affect, often through detachment, substance use or workaholism. In overcompensation, the patient fights the schema by acting as though its opposite were true, so a defectiveness schema can drive grandiose perfectionism. All three are adaptive survival responses in childhood that become maladaptive later, because each perpetuates the very schema it was meant to escape.

COPING STYLE	INNATE ANALOGUE	WHAT THE PATIENT DOES
Surrender	Freeze	Yields to the schema, accepts it as true, repeats the schema-driven pattern and confirms it
Avoidance	Flight	Keeps the schema from firing at all: blocks thought and affect, withdraws, self-medicates, disengages from therapy
Overcompensation	**Fight**	**Behaves as though the opposite of the schema were true; counter-attacks, and overshoots into grandiosity or control**

The three maladaptive coping styles and their fight, flight, freeze analogues; a single patient uses different styles with different schemas and at different times.

MNEMONIC

FIGHT, FLIGHT, FREEZE

The three coping styles as the three threat responses: **Fight** is overcompensation (act as if the opposite is true), **Flight** is avoidance (keep the schema from firing), **Freeze** is surrender (yield to it and live it out). Three responses, three coping styles, one schema underneath.

14.5 The schema modes framework: from traits to states

Modes are the workhorse for the labile borderline patient. The original schema model is a trait model, and it fits the more stable personality disorders. It struggles with borderline personality disorder, where patients score high on almost every schema at once and flip between extreme states within minutes, angry, then terrified, then detached, then self-hating. Young answered this with the schema modes concept: a mode is the moment-to-moment state, the cluster of schemas and coping responses that is active right now, in contrast to the schema, which is the enduring trait. Reframing a chaotic patient as a small set of parts that alternate, rather than dozens of simultaneously active schemas, is what makes borderline pathology workable in the room, and it is why the modes framework, not the schema list, is the tool used with these patients. The mode map is shown in the accompanying figure.

RULE **Trait for the stable, state for the labile.** Use the schema (trait) model for the more stable personality disorders and the schema modes (state) model for the borderline patient who shifts between extreme states, because that patient has too many schemas active at once to work with one at a time.

14.6 The borderline modes: the four that shift, and the one that heals

Four dysfunctional modes, alternating around an underdeveloped Healthy Adult. The borderline patient characteristically moves between **four dysfunctional modes**. The **vulnerable child** (the Abandoned Child) carries the raw pain of the schemas, fragile, frightened, alone; the Angry and Impulsive Child erupts in rage or acts out impulsively when needs go unmet; the

detached protector is a coping mode of avoidance, shutting off all feeling and connection to keep the pain out; and the **punitive parent** (the internalised critical, sometimes demanding, parent) attacks the child with self-hatred and punishment, and drives much of the self-harm. Against these stands the fifth mode, the Healthy Adult, which in the borderline patient is weak and which the therapy exists to strengthen: the goal of treatment is to build a Healthy Adult that can nurture the vulnerable child, set limits on the angry child, bypass the detached protector and banish the punitive parent.

WORKED EXAMPLE

A woman in her twenties arrives numb and monosyllabic, saying she feels nothing (the detached protector is in charge). As the therapist gently makes contact, she begins to cry about being unlovable and terrified of being left (the vulnerable child breaks through). Asked about the previous night's cutting, she says flatly that she deserved it and is disgusting (the punitive parent speaks). Minutes later she is furious that the session must end (the angry child). The formulation is not "unstable and manipulative" but a rapid cycling through four modes, each of which is addressed differently: soothe the child, validate but contain the anger, get past the protector, and fight the punitive parent.

14.7 Limited reparenting: the relational engine

The therapist partially meets the unmet childhood needs, within bounds. Limited reparenting is the central relational stance of the therapy and its main active ingredient. Within the ethical and professional limits of the therapeutic frame, the therapist deliberately provides an approximation of the emotional experiences the patient missed in childhood, warmth, stability, containment and, where needed, firm limit-setting, so as to directly address the core emotional needs behind the schemas, above all those in the Disconnection and Rejection domain. It is *limited* precisely because the therapist does not become the parent and does not regress the patient into dependency; the more severe the early deprivation, and the more childlike the borderline patient's needs, the more central this reparenting becomes. It runs alongside empathic confrontation, in which the therapist holds warmth and honest challenge together, confronting the schema-driven behaviour while staying firmly on the patient's side.

PEARL

Limited reparenting is what most sharply distinguishes schema therapy from ordinary cognitive-behavioural therapy, in which the relationship is a vehicle for technique rather than an active ingredient. Here the relationship *is* a treatment: the therapist is a stable, caring figure who models the Healthy Adult the patient will internalise. The word "limited" is load-bearing, and marks the difference between therapeutic reparenting and a boundary violation.

14.8 Experiential mode work: imagery rescripting and chair work

Change is driven at the level of affect, not just cognition. Schema therapy works across four channels, cognitive (testing and reframing the schema), behavioural (pattern-breaking, replacing the coping responses), the therapy relationship (limited reparenting and empathic confrontation), and, most distinctively, the experiential. Experiential **mode work** engages the modes emotionally

rather than by argument. In imagery rescripting, the patient re-enters a painful childhood image; the therapist, and later the patient's own Healthy Adult, enters the scene to protect and comfort the vulnerable child and to confront the offending figure, so the memory is re-scripted with the need met. In chair work, the modes are externalised onto chairs and put into dialogue, so the Healthy Adult can, for instance, be given a voice to answer and expel the punitive parent. These techniques are the engine of schema change, and treating the therapy as cognitive disputation alone forfeits them.

TRAP **Running schema therapy as ordinary CBT.** Reducing it to cognitive disputation and homework, skipping the limited reparenting and the experiential imagery and chair work, strips out its two signature ingredients and leaves the schemas, which are held in affect and memory, untouched.

14.9 The evidence, in borderline and other personality disorders

A real trial base, strongest in borderline personality disorder. The landmark trial is Giesen-Bloo and colleagues' multicentre randomised study in the Netherlands (2006), which ran schema therapy against transference-focused psychotherapy over roughly three years in borderline personality disorder and found schema therapy superior, with a higher recovery rate (about double) and notably lower attrition. Farrell and colleagues (2009) showed a large added benefit from a group form of schema therapy, and Bamelis and colleagues (2014) extended the evidence beyond borderline, with a randomised trial supporting schema therapy across a range of personality disorders (including avoidant, dependent, obsessive-compulsive, paranoid, histrionic and narcissistic types), for which specific mode models have since been mapped. On this base, schema therapy sits, with dialectical behaviour therapy and mentalisation-based treatment, among the structured psychological therapies that are the primary treatment for borderline personality disorder; drug treatment is not first-line, and the deep pharmacology is cross-referenced to the Mood disorders: pharmacotherapy notes.

14.10 Place in management, and the Indian picture

A structured, longer-term psychotherapy delivered by trained, supervised therapists. Schema therapy is a structured, theory-based, longer-term treatment, typically delivered over a couple of years, moving from assessment and schema education, through the experiential and cognitive change work built on the reparenting relationship, to behavioural pattern-breaking and relapse prevention. It is not a brief intervention and, like the other borderline-specific therapies, it should not be delivered outside a supervised, structured service. Where availability is thin, its ideas, the mode formulation and limited reparenting, still usefully inform a general management plan even when the full protocol is out of reach.

INDIA

Personality disorders are markedly under-recognised in Indian practice, so the patients who would benefit from schema therapy are often reached only through a self-harm presentation and never formulated. Access is the second constraint: schema therapy, like dialectical behaviour therapy, is being delivered and adapted at a small number of Indian tertiary and private centres rather than being widely available, and trained, supervised schema therapists are scarce. Cultural calibration matters throughout, both because the schema content is read against family and cultural norms (interdependence and duty to family are not, in themselves, a Subjugation or Self-Sacrifice schema) and because the reparenting relationship must respect local expectations of the therapeutic bond; personality pathology must never be judged through a single culture's norms.

GOOD TO REMEMBER

- **Schema therapy (Young):** mechanism is healing early maladaptive schemas, the enduring self-defeating patterns laid down by unmet core emotional needs, through limited reparenting (the therapist partially and within bounds meets the missed needs) plus experiential mode work (imagery rescripting, chair work) alongside cognitive and behavioural change; the eighteen schemas sit in five domains, the three coping styles are surrender, avoidance and overcompensation, and the borderline patient is worked through the schema modes (vulnerable child, angry and impulsive child, detached protector, punitive parent) toward a strengthened Healthy Adult. Indication is chronic, characterological personality pathology, with the strongest evidence in borderline personality disorder (Giesen-Bloo 2006, superior to transference-focused psychotherapy) and support across other personality disorders (Bamelis 2014). Signature caution: it is a structured, longer-term therapy needing trained, supervised delivery, and stripping out the reparenting and the experiential work turns it into ordinary CBT that leaves the schemas untouched.

HOLD THIS

Schema therapy heals early maladaptive schemas through limited reparenting and experiential mode work; for the borderline patient the workhorse is the schema modes map, four dysfunctional modes (vulnerable child, angry and impulsive child, detached protector, punitive parent) cycling around a Healthy Adult that the therapy exists to strengthen.

15 . Mentalisation-based therapy and transference-focused psychotherapy

Two more borderline-specific therapies, two different engines. Alongside dialectical behaviour therapy and schema therapy, the borderline literature carries two further structured, manualised, evidence-based models, and the examiner wants the *mechanism* of each, not a vague label. Mentalisation-based therapy (**MBT**, also called mentalisation-based treatment, developed by Bateman and Fonagy) reads borderline pathology as a collapse of mentalising, the capacity to understand behaviour in terms of underlying mental states, that occurs under attachment stress; its whole technique is to restore that capacity through a particular therapeutic posture. Transference-focused psychotherapy (**TFP**, developed by Clarkin and Kernberg) reads the same pathology through object relations theory as a set of split, unintegrated internal representations of self and other, and works to integrate them in the live, here-and-now transference.

The high-yield frame is the contrast: both work in the here and now and both use the therapeutic relationship as the instrument, but MBT deliberately does *not* interpret the unconscious (it takes a curious, not-knowing **mentalising stance** to get the patient thinking about minds again), whereas TFP *does* interpret, using the sequence of clarification, confrontation and interpretation to fuse the idealised and persecutory images the patient cannot hold together. This fragment teaches each engine, its indications and its evidence, and closes by placing both alongside dialectical behaviour therapy and schema therapy; those two are taught on their own topics in this chapter, and the wider psychodynamic and general models are cross-referenced to the Psychotherapies, clinical assessment, MSE and nosology notes.

15.1 Mentalising: holding mind in mind

Mentalising is reading behaviour, one's own and others', in terms of mental states.

Mentalising is the social-cognitive ability to make sense of actions, of the self and of other people, in terms of the mental states behind them, thoughts, feelings, wishes, beliefs and desires; in plain language, it is attentiveness to thinking and feeling in oneself and in others. It is an ordinary human capability that underpins everyday interaction, and it runs across four dimensions that can each become unbalanced: automatic versus controlled, self versus other, cognitive versus affective, and internal versus external. In personality disorder these capacities are reduced, and reduced most sharply at moments of interpersonal stress, which is exactly when they are most needed. Bateman and Fonagy argue that many borderline symptoms emerge from this distortion or loss of mentalising: the person loses the felt distinction between their own perspective and external reality, cannot easily coordinate their mind with another's, and is left isolated, since the joining of minds (the so-called we-mode) is the ingredient of ordinary connection that the loss of mentalising obstructs.

15.2 The collapse under attachment stress, and the nonmentalising modes

Rising arousal switches mentalising off, and older, prementalising modes reappear.

Mentalising develops within attachment relationships and is vulnerable within them: high arousal, generated by attachment hyperactivation and disorganised attachment strategies, disrupts the less well-practised, higher cognitive capacity to reflect. As the accompanying figure shows, when interpersonal arousal climbs past a threshold, balanced mentalising drops away and three developmentally earlier, nonmentalising modes take over. The examinable point is that borderline phenomena are not random: each mode is what you get when one dimension of mentalising dominates and the others fail.

NONMENTALISING MODE	EXPERIENCE OF THE MIND	CLINICAL FACE
Psychic equivalence	**Inner states are felt as literally, unquestionably real; thought equals reality, so no alternative perspective is possible ("concreteness of thought")**	Overwhelming certainty ("the therapist hates me", "I am wicked"), the drama and terror that make self-harm feel comprehensible
Teleological	Mental states are believed only if their outcome is physically observable; affection is real only with a touch, care real only with an action	Demands for concrete proof of caring; self-harm or action as the only "real" expression of a state; the automatic pole dominates
Pretend mode	Thoughts and feelings become severed from reality; much is said about mental states with little genuine connection to them	Hypermentalising or pseudo-mentalising, long inconsequential talk about feelings; taken to an extreme, derealisation and dissociation

The three nonmentalising (prementalising) modes that reappear when mentalising collapses under arousal; the highlighted psychic-equivalence cell is the one that makes borderline self-harm and quasi-psychotic certainty intelligible.

MNEMONIC

TOO REAL · ONLY IF SEEN · NOT REAL AT ALL

The three nonmentalising modes in three tags. **Too real** = psychic equivalence (thought is experienced as reality). **Only if seen** = teleological (a state counts only if physically demonstrated). **Not real at all** = pretend mode (talk about feelings cut loose from any real feeling; hypermentalising).

15.3 The mentalising stance: curious, not-knowing, restoring the capacity to think

The stance is the treatment: inquisitive, not-knowing, aimed at reviving mentalising rather than delivering insight. The bedrock clinical principle of MBT is an authentic **mentalising stance**, an inquisitive, "not-knowing" posture that respects the opacity of minds: minds can never be truly known, so the clinician's task is to inquire, to be genuinely curious, and to be willing to be surprised by the patient's answer, with the aim of raising the patient's own awareness of their internal states through a shared process. The work is in the here and now and stays close to preconscious, working-memory experience rather than pursuing unconscious meaning through free association; a session typically settles onto a single focus within the first ten to fifteen minutes and then works around it. Crucially, MBT does not push interpretation while the patient is non-mentalising and highly aroused; the first job is to lower arousal and re-open thinking, because interpreting a mind that has collapsed into psychic equivalence only confirms the concreteness. The secure-base relationship to the therapist is what makes it safe to explore one's own mind and find it reflected in another's.

WORKED EXAMPLE

A patient arrives certain that "you were going to cancel on me, I could tell". A not-knowing MBT response is not a reassurance and not an interpretation of transference; it is a curious inquiry: "I did not know that was in your mind, help me understand what told you that, and what it was like to sit with it." The clinician marks their own not-knowing, slows the moment, and invites the patient back into thinking about the mental states involved, theirs and the clinician's, rather than settling the "fact". The same opening moment in TFP would be handled differently (see below), and that difference is the whole point of the topic.

RULE **Structured, borderline-specific psychotherapy is the treatment; the model is chosen by fit, not by a proven winner.** MBT, TFP, dialectical behaviour therapy and schema therapy are all evidence-based for borderline personality disorder, and head-to-head trials show no single model is reliably superior; choose by patient fit, therapist training and local availability, and deliver it as a structured programme, not as eclectic support.

15.4 MBT: structure, indications and evidence

A structured, time-limited programme of individual plus group work, first proven in a partial-hospitalisation trial. MBT is delivered as a combination of individual and group sessions within a structured, time-limited programme (the original model ran in a day-hospital and partial-hospitalisation setting, with later intensive-outpatient versions), all built around the mentalising stance. Its indications have widened from borderline personality disorder (the primary and best-evidenced target) to antisocial personality disorder (MBT-ASPD), to adolescents with emerging borderline features and self-harm (MBT-A), and to other conditions marked by mentalising failure. The founding evidence is Bateman and Fonagy's randomised trial of partial-hospitalisation MBT against treatment as usual: the MBT group showed significant reductions in depressive symptoms, in suicidal and self-injurious behaviour and in inpatient days, with better social and interpersonal functioning; the gains began to appear after about six months and were maintained after treatment ended, with long-term follow-up showing durable benefit. That "benefit emerges over months, then holds" shape is itself examinable.

PEARL

MBT reframes what a borderline crisis *is*: not primarily a behaviour to be managed but a moment when mentalising has gone offline. This is why the intervention is a stance rather than a technique menu, and why "the therapist not knowing what to say" is treated as useful data, an accurate read of the patient's own collapsed mentalising, rather than a therapist failure.

GOOD TO REMEMBER

- **Mentalisation-based therapy (MBT), Bateman and Fonagy:** mechanism, borderline symptoms arise from a loss of mentalising (understanding behaviour in terms of mental states) under attachment-stress arousal, so the therapy restores mentalising through a curious, not-knowing mentalising stance in the here and now, working close to conscious experience rather than interpreting the unconscious. Indication, borderline personality disorder first-line among structured therapies, extended to antisocial personality disorder and to adolescents; evidence from a partial-hospitalisation RCT versus treatment as usual with gains maintained after termination. Signature caution, do not push interpretation while the patient is non-mentalising and highly aroused, lower arousal and re-open thinking first.

15.5 TFP and the object-relations frame: split, unintegrated representations of self and other

The borderline mind is built of split object dyads that idealise and persecute but never integrate. Transference-focused psychotherapy rests on an ego-psychological and **object relations** framework derived from Melanie Klein and elaborated by Otto Kernberg. Its unit of analysis is the internal *object dyad*: a single mental representation of the self linked to a representation of another person by an affect (for example, a weak, needy self bound to an exploitative but needed other by fear). In health these representations integrate into whole, ambivalent images; in borderline personality organisation (BPO) they do not. Instead the patient relies on splitting, keeping idealised and persecutory representations apart so that the same person is experienced as all-good or all-bad and flips between the two. TFP therefore diagnoses along a *level of personality organisation* axis rather than by categorical criteria, assessing the interrelated domains of identity, object relations, primitive defences, reality testing, aggression and moral values in a structural interview, which the Structured Interview of Personality Organization (STIPO-R) helps to operationalise. The core therapeutic target is **identity diffusion**, the lack of an integrated sense of self, and the goal is identity consolidation.

COMMON TRAP

Reading TFP as "diagnose the DSM type, then treat it". TFP works on borderline personality organisation, a broader structural construct than DSM borderline personality disorder that cuts across many categorical personality diagnoses and also covers narcissistic pathology. Two patients with different DSM labels can share the same borderline-level organisation and the same split object relations, which is exactly what TFP targets; the categorical label is not the treatment axis.

15.6 The TFP technique: integrating the dyads in the here-and-now transference

Contract first, then channel the split into the transference and interpret it into integration. TFP is an individual therapy, tested as a twice-weekly treatment of at least one to two years' duration, and it begins with explicit contracting, goal-setting and limit-setting. The wager is that the patient's split, unintegrated representations of self and other will inevitably be enacted in the relationship with the therapist, the *transference*, where they become available in the room in the here and now rather than only in history. Work follows a priority hierarchy (suicidal and self-destructive behaviour first, then threats to the continuity of the treatment, then the dominant transference theme) and a technical sequence of clarification, then confrontation of contradictions, then interpretation. By naming, for example, that the patient is treating the

therapist as the persecutor of the moment while a needy, idealising self is split off, TFP brings the two poles into contact so they can begin to integrate; as the split dyads fuse into whole-object relations, identity consolidates. Reflective functioning and integration, not symptom management alone, are the intended fruits.

TRAP **Deep transference interpretation into a mind that has already collapsed.** Interpretation only works on a patient who can still mentalise; delivering a Kernberg-style transference interpretation while the patient is in psychic equivalence and high arousal tends to confirm the concreteness and destabilise, which is precisely the failure MBT was built to avoid. Restore mentalising and lower arousal first; interpret when there is a mind available to think with.

3	4	6	2
MBT NONMENTALISING MODES (PSYCHIC EQUIVALENCE, TELEOLOGICAL, PRETEND)	DIMENSIONS OF MENTALISING IN MBT	TFP STRUCTURAL-INTERVIEW DOMAINS OF PERSONALITY ORGANISATION	TFP SESSIONS A WEEK (TWICE WEEKLY, OVER ONE TO TWO YEARS)

15.7 TFP indications and evidence

For borderline and narcissistic pathology in a patient who can tolerate interpretation, with a solid RCT base. TFP is indicated for borderline and narcissistic personality disorders and, more broadly, for patients at a borderline level of organisation who can commit to a long, twice-weekly, interpretation-based treatment and tolerate the affect it raises; the containing contract and limit-setting are what make it usable in a high-risk population. The evidence base is genuinely randomised. Clarkin and colleagues' three-arm trial compared TFP, dialectical behaviour therapy and supportive psychodynamic therapy and found all three efficacious, with TFP producing broad change across domains; Doering and colleagues found TFP superior to treatment by experienced community psychotherapists on borderline symptoms, suicide attempts and dropout; and the Giesen-Bloo multicentre trial comparing schema therapy and TFP showed both producing significant improvement, with schema therapy holding an advantage on recovery and retention. Mechanism-consistent findings (Levy and colleagues) show TFP increasing reflective functioning and shifting attachment toward security, which is the change the object-relations model predicts.

GOOD TO REMEMBER

- **Transference-focused psychotherapy (TFP), Clarkin and Kernberg:** mechanism, an object-relations therapy that treats borderline pathology as split, unintegrated internal representations of self and other (object dyads) held apart by splitting, and integrates them by working the here-and-now transference through clarification, confrontation and interpretation, with identity diffusion as the core target and identity consolidation the goal. Indication, borderline and narcissistic personality disorders (borderline personality organisation) in a patient able to tolerate a long, twice-weekly, interpretive treatment; evidence from several RCTs. Signature caution, it is interpretation-heavy, so it needs a mind that can still mentalise and a firm contract, or the interpretation destabilises.

15.8 Where MBT and TFP sit alongside dialectical behaviour therapy and schema therapy

Four structured models, four different theories of the same disorder. The four borderline-specific psychotherapies are best held as one grid: each names a different core mechanism and a

different signature technique, and no head-to-head trial has crowned one as reliably best, which is why the selection RULE above governs. The two owned on their own topics in this chapter (dialectical behaviour therapy and schema therapy) are set here beside MBT and TFP so the discriminators are visible at a glance.

THERAPY	THEORETICAL MODEL	CORE MECHANISM / TARGET	SIGNATURE TECHNIQUE
Dialectical behaviour therapy (Linehan)	Biosocial: emotional vulnerability plus an invalidating environment	Emotion dysregulation and behavioural dyscontrol	Skills training (mindfulness, distress tolerance, emotion regulation, interpersonal effectiveness) held in dialectic of acceptance and change
Mentalisation-based therapy (Bateman and Fonagy)	Attachment and mentalising deficit	Loss of mentalising under arousal	**Curious, not-knowing mentalising stance that restores thinking about mental states in the here and now**
Transference-focused psychotherapy (Clarkin and Kernberg)	Ego-psychology and object relations (Klein, Kernberg)	Identity diffusion; split, unintegrated self and other representations	**Here-and-now transference interpretation (clarification, confrontation, interpretation) to integrate the split dyads**
Schema therapy (Young)	Early maladaptive schemas and schema modes	Maladaptive schema modes (vulnerable child, detached protector, punitive parent)	Limited reparenting and mode work

The four structured, evidence-based borderline psychotherapies; the two highlighted cells are the discriminator of this topic, MBT restores mentalising through a stance while TFP interprets the transference to integrate split object relations.

INDIA

Personality disorders are markedly under-recognised in Indian practice, and the specialist psychotherapies are scarcer still. Dialectical behaviour therapy has the widest, if uneven, adaptation and delivery at Indian tertiary and private centres; mentalisation-based therapy and transference-focused psychotherapy are far less available, concentrated in a few academic and psychodynamically trained settings, and the binding constraint is the training and supervision pipeline rather than patient demand. Two cautions travel with the models. First, mentalising norms are cultural: the we-mode, joint attention and the expression of affect are read differently across Indian family systems, and interdependence must not be mistaken for a mentalising failure. Second, the object-relations reading of a case must be held against the patient's own cultural idiom, so that a culturally normative deference or a shared family self is not over-interpreted as split or diffuse identity. Judge the mind against its own context, not a single culture's template.

HOLD THIS

MBT (Bateman and Fonagy) restores lost mentalising through a curious, not-knowing stance and does not interpret; TFP (Clarkin and Kernberg) integrates split object-relations dyads by interpreting the here-and-now transference, and does; both work in the present through the therapeutic relationship, and both sit as evidence-based options beside dialectical behaviour therapy and schema therapy.

16 . Pharmacotherapy in personality disorders

The most trapped question on the day: which drug? The examinable truth about **pharmacotherapy in personality disorders** is almost entirely a truth about restraint. There is no medication registered to treat any personality disorder, structured psychological therapy is the primary treatment, and every drug that is used is used **symptom-targeted** and adjunctive, aimed at a defined target symptom or a comorbidity, never at the disorder itself. The single fact worth more than any dose is the NICE position on borderline personality disorder: drug treatment is not first-line, and the candidate who reaches for a mood stabiliser or an antipsychotic as the answer has walked into the classic trap.

This fragment leads with the guideline law, states the NICE rule as both a rule and a trap, then reconciles it with what the wider bodies (the Indian Psychiatric Society CPG and WFSBP) permit at symptom-domain level. It teaches the three psychobiological symptom domains and the agent class attached to each, keeps the pharmacology deliberately light, and cross-references the deep drug detail to the Mood disorders: pharmacotherapy notes and the Schizophrenia: management, antipsychotics and adverse effects notes. The bipolar-II differential that so often triggers a wrong prescription sits in the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes, and the forensic frame for antisocial personality disorder in the Mental health legislation and forensic psychiatry notes.

16.1 The governing principle: adjunctive, symptom-targeted, never disorder-specific

No drug licensed. The organising principle of **pharmacotherapy in personality disorders** is that it is never a disorder-specific registered treatment. **No drug licensed** for any personality disorder exists in any major formulary, and every guideline body, however permissive, agrees that psychotherapy is primary and medication is at most an adjunct. What medication can legitimately do is act on a discrete **symptom-targeted** problem, an aggressive outburst, a run of cognitive-perceptual disturbance, a depressive or anxious swing, or a comorbid Axis-I disorder sitting alongside the personality pathology. It follows that a drug is prescribed against a named, measurable target with a defined review point, and is stopped if that target does not move. The diagnosis itself must be secure before any of this begins: an enduring, pervasive, inflexible pattern with onset by adolescence, not a situational state, and for borderline personality disorder that means the full pattern (five or more of the nine criteria), not a single stormy fortnight.

PEARL

Read every personality-disorder drug question as a question about a target symptom, not about the disorder. "What is the drug treatment for borderline personality disorder?" has no correct drug answer, the correct answer is that structured psychological therapy is the treatment and medication is only a time-limited, symptom-targeted adjunct. Reframing the question this way is what protects you from the trap the stem is usually setting.

16.2 The NICE rule: drug not first-line for borderline

The most tested management fact of the day. NICE (2009, CG78) states that drug treatment should not be used specifically for borderline personality disorder or for the individual symptoms and behaviours associated with it (repeated self-harm, marked emotional instability, risk-taking, transient psychotic symptoms). Structured psychological therapy is primary. Medication is legitimate in only two situations: to treat a diagnosed comorbid condition, or short-term during a crisis (a sedative, usually for no longer than one week). NICE guidance is explicit that antipsychotic drugs should not be used for the medium- and long-term treatment of the disorder. This is the highest-yield line of the topic, and a mis-statement of it is a critical error.

RULE **Drug not first-line for borderline.** In borderline personality disorder, structured psychological therapy is primary; any medication is symptom-targeted, adjunctive and time-limited, for a comorbidity or a crisis only, and antipsychotics are not for medium- or long-term use (NICE 2009).

TRAP **Reaching for a drug first.** Starting a mood stabiliser or antipsychotic as the primary treatment for borderline personality disorder, or for its self-harm and lability directly, is the classic error and contradicts NICE outright; there is no licensed disorder-specific drug to reach for.

0	3	1
DRUGS LICENSED FOR BORDERLINE PERSONALITY DISORDER	SYMPTOM-TARGET DOMAINS FOR ADJUNCTIVE DRUGS	WEEK, USUAL MAXIMUM FOR CRISIS SEDATION (NICE)

16.3 Reconciling the guidelines: NICE, the Indian Psychiatric Society, WFSBP

Same primacy of psychotherapy, differing latitude on adjuncts. The bodies agree that psychological therapy is the primary treatment and that no drug is a registered disorder-specific treatment; they differ in how much symptom-targeted prescribing they permit. NICE is the most restrictive (no drug for the disorder or its symptoms; a crisis sedative or comorbidity treatment only). The Indian Psychiatric Society CPG (IPS 2023) makes psychotherapy central but allows that, in some patients, antipsychotics may reduce hostility, suspiciousness, affect dysregulation and cognitive-perceptual distortions, and that mood stabilisers may reduce impulsivity and aggressiveness. WFSBP (2007) supplies the fullest symptom-domain framework for adjunctive agents. Hold NICE as the safe default answer and the domain framework as the "where is there any evidence" detail.

GUIDELINE (YEAR)	POSITION ON DRUG TREATMENT	WHAT IT PERMITS
NICE, CG78 (2009)	**Do NOT use drugs specifically for borderline personality disorder or its symptoms; no antipsychotic for medium- or long-term use**	Treat a comorbidity; a crisis sedative for usually no longer than one week; review and deprescribe
NICE, personality disorders (2015)	No drug for the personality itself; structured clinical assessment to diagnose	Antipsychotic or sedative only for short-term crisis or a comorbid condition; group cognitive-behavioural therapy for antisocial personality disorder
the Indian Psychiatric Society CPG (2023)	Psychotherapy is central; DBT recommended early	Symptom-targeted antipsychotics and mood stabilisers in some patients; avoid benzodiazepines
WFSBP (2007)	Adjunctive, symptom-targeted only, not a registered treatment	Agent chosen by symptom domain; trial for at least three months against defined targets
APA (2024)	Structured psychotherapy primary; medication adjunctive	Time-limited, single measurable target symptom; reconcile and review medications at least every six months

The guideline hierarchy for these notes: NICE leads and is the safest default, the Indian Psychiatric Society and WFSBP add the symptom-domain latitude, APA supplies the core prescribing principles.

16.4 The three symptom domains and the agent attached to each

The Soloff-style psychobiological domains organise all adjunctive prescribing. When medication is used at all, it is targeted at one of three symptom domains rather than at the disorder, a framework running from Soloff's psychobiological model through the APA and WFSBP schemes. The **cognitive-perceptual** domain (suspiciousness, ideas of reference, transient quasi-psychotic or dissociative experiences) attracts a low-dose antipsychotic; the **impulsive-behavioural dyscontrol** domain (impulsive aggression, self-damaging impulsivity, anger) attracts a mood stabiliser, with a low-dose antipsychotic as an alternative where aggression dominates; and the **affective instability domain** (affective dysregulation, depressive mood swings, anxiety) attracts an SSRI. The mapping is the examinable core, shown in the accompanying figure.

SYMPTOM DOMAIN	TARGET FEATURES	AGENT CLASS WITH ADJUNCTIVE EVIDENCE
Cognitive-perceptual	Suspiciousness, ideas of reference, transient quasi-psychotic and dissociative symptoms	**Low-dose antipsychotic (second-generation)**
Impulsive-behavioural dyscontrol	Impulsive aggression, self-damaging impulsivity, anger and behavioural discontrol	**Mood stabiliser (a low-dose antipsychotic where aggression dominates)**
Affective instability and anxiety	Affective dysregulation, depressive mood swings, rejection sensitivity, anxiety	**SSRI**

The three psychobiological symptom domains and the drug class attached to each; this is the framework the wider guidelines use, always as an adjunct to primary psychotherapy, never as a treatment for the disorder.

16.5 Low-dose antipsychotics: cognitive-perceptual and impulsive domains

Low, short, and for a named target only. A **low-dose antipsychotic**, a second-generation agent such as quetiapine (Qutipin, Seroquel), olanzapine (Oleanz, Zyprexa) or aripiprazole (Arip, Abilify), carries moderate adjunctive evidence in the **cognitive-perceptual** domain and, where impulsivity and aggression dominate, in **impulsive-behavioural dyscontrol** (WFSBP 2007; IPS 2023). The doses used are low and the course is meant to be short and target-defined; the deep pharmacology, receptor profiles and adverse effects belong to the Schizophrenia: management, antipsychotics and adverse effects notes and are not re-taught here. The overriding constraint is the NICE one: an antipsychotic is legitimate short-term, but must not be continued for the medium- and long-term treatment of borderline personality disorder, so a crisis prescription is reviewed and stopped once the crisis resolves.

16.6 Mood stabilisers: impulsive aggression

For impulsive aggression, not for a personality-based "mood swing". A **mood stabiliser**, valproate or divalproex (Valprol, Encorate), lamotrigine (Lamitor, Lametec) or topiramate, has adjunctive evidence for reducing impulsivity and impulsive aggression that antipsychotics have not settled (IPS 2023; WFSBP 2007). The trap this sets is the borderline-versus-bipolar-II confusion: the rapid, reactive affective instability of borderline personality disorder, minutes to hours and triggered by interpersonal events, is not the sustained syndromic mood episode of bipolar II, and starting a mood stabiliser for personality-based lability, mislabelled as bipolarity, is a common and consequential error. That differential is developed in the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes, and the deep drug detail in the Mood disorders: pharmacotherapy notes; here the mood stabiliser stays a targeted adjunct for impulsive aggression.

TRAP **Treating borderline lability as bipolar II.** Rapid, reactive, interpersonally cued affective instability is a borderline feature, not a bipolar mood episode; reflexively starting a mood stabiliser for it medicalises a personality target and misses the primary psychotherapy.

16.7 SSRIs: the affective instability and anxiety domain

Best-shown class for affective dysregulation and anxiety, still adjunctive. Of the drug classes, the SSRI has the clearest evidence for the **affective instability domain**, the depressive mood, mood swings and anxiety of the disorder (WFSBP 2007), and an SSRI such as fluoxetine (Fludac, Prozac) or sertraline (Serlift, Zoloft) is a reasonable adjunct where that domain predominates or where a comorbid depressive or anxiety disorder is present. It also carries the practical advantage of relative safety in overdose, which matters in a population with recurrent self-harm. As always, this is symptom-targeted and adjunctive to psychotherapy, and where an SSRI is used for a comorbidity it is that comorbidity, not the personality disorder, that is being treated; the deep detail sits in the Mood disorders: pharmacotherapy notes.

16.8 The cautions: avoid polypharmacy, deprescribe, and what never to use

The prohibitions are as examinable as the indications. Several cautions run across the guidelines. Avoid benzodiazepines: the Indian Psychiatric Society CPG advises against them in borderline personality disorder because of dependence risk and disinhibition that can worsen impulsive behaviour. Avoid drugs dangerous in overdose: WFSBP counsels against irreversible MAOIs and lithium despite some efficacy, precisely because these patients need agents safe in parasuicidal acts. Above all, **avoid polypharmacy** and long-term prescribing without a clear indication: NICE guidance is to review repeat prescriptions regularly, to discourage polypharmacy, and to withdraw drugs started in a crisis once it resolves, aiming to reduce and stop unnecessary treatment. The maintenance rule that antipsychotics are not for medium- or long-term use in borderline personality disorder belongs here too.

> **COMMON TRAP**
>
> A borderline patient accumulates a low-dose antipsychotic, a mood stabiliser, an SSRI and a "when required" benzodiazepine over successive crises, none reviewed. This is exactly the polypharmacy NICE tells you to unwind: benzodiazepines should be off entirely, the crisis-era drugs deprescribed once the crisis has passed, and the whole regimen reconciled against a single measurable target. Deprescribing is an active clinical act, not neglect.

16.9 Crisis, comorbidity, and antisocial personality disorder

Where a drug is genuinely indicated, and where none is. Two legitimate windows remain. In a crisis, short-term cautious sedation (an antihistamine such as promethazine, or a low-dose antipsychotic) may be considered as part of an overall plan, usually for no longer than one week, alongside risk assessment and a collaborative crisis plan (NICE 2009). For a diagnosed comorbid depression, post-traumatic stress or anxiety disorder, that comorbidity is treated on its own terms within the structured programme. Antisocial personality disorder is the instructive contrast: there is no drug treatment for the antisocial personality itself, the mainstay is a group cognitive-behavioural intervention (often in criminal-justice or health settings), and pharmacotherapy is reserved strictly for a comorbid mental disorder (NICE 2015). The offender-assessment and court-report frame is cross-referenced to the Mental health legislation and forensic psychiatry notes.

WORKED EXAMPLE

A woman in her twenties with borderline personality disorder presents in crisis after an argument, with rising urges to self-harm and transient paranoid ideas. The correct plan is not to "start" a drug for the disorder: assess risk, enhance coping and reflective capacity, agree a crisis plan, and, if sedation is needed, offer it cautiously and briefly (usually no longer than one week), reviewing to stop it as the crisis settles. The definitive treatment is referral to a structured psychological therapy such as dialectical behaviour therapy; any antipsychotic used for the cognitive-perceptual symptoms is short-term and target-defined, never a maintenance prescription.

16.10 Place in the plan, and the Indian picture

Medication sits inside a psychotherapy-led, stepped plan. The management spine holds: outpatient care by default with admission avoided and, when unavoidable, brief and purposeful; short-term focus on crisis and safety, mid-term on the core features through structured psychological therapy, long-term on function and relationships. Within that, pharmacotherapy is a symptom-targeted, time-limited adjunct, layered onto (never in place of) dialectical behaviour therapy, schema therapy, mentalisation-based treatment or transference-focused psychotherapy by availability and fit. The candidate who leads with a drug has inverted the plan.

INDIA

Personality disorders are markedly under-recognised in Indian practice, so many patients reach services only through a self-harm or crisis presentation and are prescribed a symptom drug without ever being formulated or offered the structured therapy that is the actual treatment. Two realities shape a sensible plan. Access: dialectical behaviour therapy and schema therapy are being delivered and culturally adapted at a small number of Indian tertiary and private centres rather than being widely available, so the psychotherapy-first rule can be hard to enact and makes disciplined, minimal prescribing (and active deprescribing) all the more important. Culture: personality pathology must never be read through a single culture's norms, its expression, and the antisocial and medico-legal framing in particular, differs by setting, and the forensic use of an antisocial diagnosis carries weight that belongs with the forensic notes, not with a prescription pad.

GOOD TO REMEMBER

- **Pharmacotherapy overall:** mechanism is symptom-targeted and adjunctive (never disorder-specific; no drug licensed); indication is a defined target symptom, a comorbidity, or short-term crisis sedation; signature caution is that it is not first-line for borderline personality disorder, psychotherapy is primary, and antipsychotics are not for medium- or long-term use (NICE 2009).
- **Low-dose antipsychotic:** targets the cognitive-perceptual domain (and impulsive aggression where it dominates); short-term and low-dose; caution is no medium- or long-term use in borderline personality disorder.
- **Mood stabiliser:** targets impulsive-behavioural dyscontrol and impulsive aggression; caution is not to mistake reactive borderline lability for bipolar II and medicalise a personality target.
- **SSRI:** targets the affective instability and anxiety domain and any comorbid depression or anxiety; advantage is relative safety in overdose; caution is it treats the symptom or comorbidity, not the disorder.
- **Never:** avoid benzodiazepines (dependence, disinhibition), avoid drugs dangerous in overdose (irreversible MAOIs, lithium), and avoid polypharmacy; review and deprescribe.

HOLD THIS

No drug is licensed for a personality disorder; structured psychological therapy is primary and NICE says drug treatment is not first-line for borderline personality disorder, so all pharmacotherapy is symptom-targeted and adjunctive, a low-dose antipsychotic for the cognitive-perceptual domain, a mood stabiliser for impulsive-behavioural dyscontrol, an SSRI for the affective instability and anxiety domain, for a comorbidity or a crisis only, while you avoid benzodiazepines, avoid polypharmacy, and deprescribe.

17 . The integrated management of borderline personality disorder

The treatment block, assembled into one plan. The separate topics teach the disorder and each therapy on its own; this one is the synthesis, the single algorithm an examiner wants when the question is simply "how would you manage this patient". The integrated management of borderline personality disorder is *integrated* in two senses: it braids the strands of care (crisis work, structured psychotherapy, selective medication, care planning and psychoeducation) into one coherent plan, and it reconciles the guideline bodies (NICE, the Indian Psychiatric Society and WFSBP) into one defensible line. The plan is built on a three-part spine, **LOCUS** (where care happens), **FOCUS** (what is targeted, and when) and **MODUS** (by what means), and it is anchored, above everything, on one rule that examiners test relentlessly: a drug is not the first-line treatment for this disorder.

This fragment walks the spine end to end. It fixes the **locus** of care as outpatient and community by default, sets the **focus** by phase from short-term crisis and risk through the mid-term core-feature work to long-term function and remission, and lays out the **modus**, with structured psychological therapy as the primary mode and medication kept symptom-targeted, time-limited and adjunctive. Throughout, the guideline order is NICE first (CG78), then the Indian Psychiatric Society CPG and WFSBP, and the pharmacology stays deliberately light, with the deep drug detail cross-referenced to the Mood disorders: pharmacotherapy notes and the Schizophrenia: management, antipsychotics and adverse effects notes. The integrated algorithm is drawn in the accompanying figure.

4	0	1 wk
STRUCTURED PSYCHOTHERAPIES FOR THE DISORDER (DBT, SCHEMA, MBT, TFP)	DRUGS LICENSED FOR BORDERLINE PERSONALITY DISORDER (NICE)	USUAL CEILING FOR A CRISIS SEDATIVE (NICE)

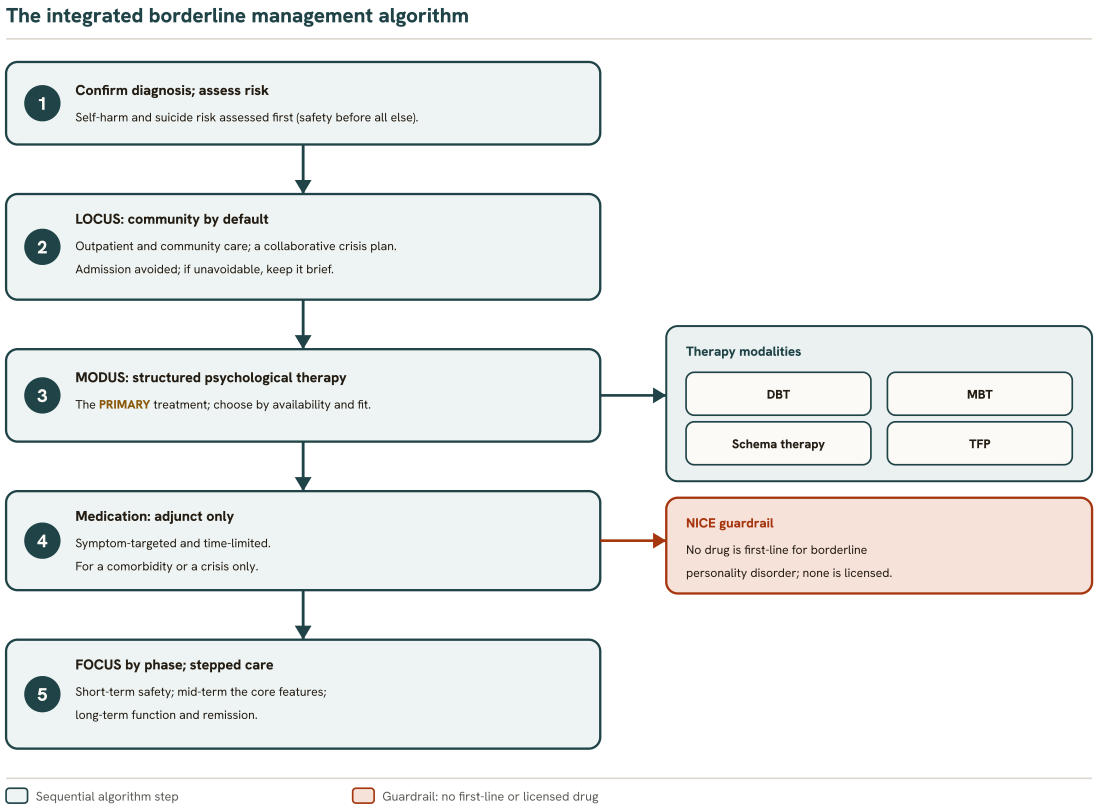

Fig 16.13 The integrated plan treats borderline personality disorder mostly in the community with a crisis plan, makes structured psychological therapy (dialectical behaviour therapy, mentalisation-based therapy, schema therapy or transference-focused psychotherapy) the primary treatment, and uses medication only, symptom-targeted and time-limited, for a comorbidity or a crisis, because no drug is first-line or licensed for the disorder.

17.1 The integrated frame, and the one rule that governs it

One plan, one governing rule. Before the spine, fix the principle that shapes every branch of it. NICE (2009, CG78) states that drug treatment should not be used specifically for borderline personality disorder or for its individual symptoms (repeated self-harm, marked emotional instability, risk-taking, transient psychotic symptoms), that no drug is licensed for the disorder, and that structured psychological therapy is the primary treatment; medication is reserved for a comorbid condition or short-term use in a crisis. The Indian Psychiatric Society (IPS 2023) agrees, making psychotherapeutic methods the central treatment and permitting only symptom-targeted adjuncts; WFSBP (2007) frames any drug as adjunctive and symptom-domain-targeted rather than disorder-specific. The three bodies differ only in how much room they leave for adjunctive medication, NICE the most restrictive, IPS and WFSBP allowing symptom-targeted agents, and they are unanimous that psychotherapy is primary. The whole integrated plan is therefore a psychotherapy-led plan into which crisis care, selective medication and care planning are fitted.

RULE **Structured psychological therapy is primary; any medication is adjunctive.** In borderline personality disorder the first-line treatment is a comprehensive, structured, theory-based psychotherapy delivered by trained supervised practitioners; medication is only ever symptom-targeted, time-limited and reserved for a comorbidity or a crisis (NICE 2009, IPS 2023, WFSBP 2007).

TRAP **Reaching for a drug first-line for the disorder itself.** Starting an antipsychotic or a mood stabiliser as the primary treatment for borderline instability, or continuing antipsychotics for medium- and long-term management, runs directly against NICE (which recommends no drug for the disorder and no antipsychotic for its longer-term treatment). A wrong first-line for borderline personality disorder is a critical error.

17.2 LOCUS, where the care happens

Outpatient and community by default; admission avoided, and when unavoidable, brief and purposeful. The **locus** of care is the community. Borderline personality disorder is managed in outpatient and community settings within a stepped care framework, matching intensity to need and stepping up only as required. Inpatient admission is actively avoided, because prolonged admission tends to entrench regression, reinforce crisis behaviour and disrupt the very relationships and roles that recovery depends on; NICE is explicit that admission should be avoided unless there is a serious risk to self or others that cannot be managed any other way, and that when it does happen it should be brief and for an agreed, specific purpose (typically the containment of acute risk), not open-ended asylum. The **service frame** matters as much as the setting: people with the disorder must not be excluded from any health or social care service because of the diagnosis or because they have self-harmed, and any planned change or withdrawal of a service is agreed with the person through a structured, phased plan rather than an abrupt discharge. Community continuity, not the ward, is the therapeutic base.

COMMON TRAP

Admitting the recurrently self-harming borderline patient to a general ward for safety, and keeping them. Beyond the brief, purposeful containment of an unmanageable acute risk, prolonged admission is not protective; it interrupts the outpatient therapy that actually reduces self-harm, models the crisis as the route to care, and is where iatrogenic regression sets in. The default is to manage the crisis in the community and return the person to their structured programme.

17.3 FOCUS, the target shifts by phase

Three phases, three different jobs. The **focus** of the work is not static; it moves as the patient stabilises. In the *short term* the target is safety, the job is crisis management and **risk** (containing self-harm and suicidality, and building a collaboratively agreed crisis plan). In the *mid term* the target is the core disorder itself, the emotion dysregulation, identity disturbance, abandonment sensitivity and unstable relationships, addressed through a sustained course of structured psychological therapy. In the *long term* the target is life beyond symptoms, function, relationships, work or study, and consolidated remission, which for many patients is a realistic goal given that borderline personality disorder has a substantially remitting long-term course. Sequencing

matters: trauma processing and deep character work wait until behavioural safety is established, so a plan that opens with intensive trauma exposure while the patient is still cutting weekly has the phases in the wrong order.

PHASE	PRIMARY TARGET (THE FOCUS)	THE MAIN WORK
Short-term	**Safety, risk and the acute crisis**	Risk assessment, crisis management, a collaboratively agreed crisis plan with identified triggers; brief, purposeful containment only if risk is otherwise unmanageable
Mid-term	The core disorder features	A sustained course of structured psychological therapy (the emotion dysregulation, identity, abandonment and relational instability)
Long-term	Function, relationships and remission	Rehabilitation into role and relationship, relapse prevention, and consolidation of gains toward remission

The focus of the integrated plan shifts by phase; safety is secured before core-feature therapy, and function follows.

17.4 The short-term focus, crisis management, risk and self-harm

Assess the risk, hold the person, agree a plan, avoid the ward. When a patient presents in crisis, the sequence is concrete. Assess the current **risk** to self and others; ask what has happened before and what helped then; help the person manage the surge of anxiety by enhancing coping and reflective capacity rather than simply removing them from their life; and avoid hospital admission unless there is a serious risk that cannot be managed otherwise (NICE 2009). The durable output of a crisis contact is a crisis plan, agreed collaboratively and documented, that names the person's individual triggers, the early-warning signs, the self-management steps and skills to use first, and exactly whom to contact and how, so that the next crisis has a rehearsed pathway that is not the emergency department by default (IPS 2023 makes the collaboratively agreed crisis plan central to reducing hospitalisation in acutely suicidal patients). Self-harm is managed within, not outside, this frame: it is understood, taught and responded to inside the structured therapy, and the person is never excluded from care because of it. Where a sedative is genuinely needed to get through an acute crisis, its use is short-term and time-limited (see the medication topic below), and benzodiazepines are avoided.

WORKED EXAMPLE

A woman known to the community team presents at night after superficial cutting following a relationship rupture, distressed but not acutely suicidal on assessment. The integrated response is not admission. The clinician assesses current risk, reviews what helped in previous episodes, helps her down-regulate the immediate arousal, and works with her on the crisis plan, updating the trigger list, rehearsing the distress-tolerance skill to use first, and confirming the daytime contact route back into her structured therapy. If night-time distress is extreme, a short-term sedative for a few days may be considered as part of the plan, not a new standing prescription, and she returns to her outpatient programme rather than to a ward.

17.5 MODUS, structured psychological therapy as the primary mode

The primary means is a structured, theory-based psychotherapy, delivered whole. The **modus** of the plan is led by structured psychological therapy. The question is rarely whether to offer psychotherapy but *which structured psychotherapy*, chosen by availability, patient fit and the dominant problem: dialectical behaviour therapy (DBT, Marsha Linehan), the best-evidenced option where reducing recurrent self-harm is the priority; schema therapy (Jeffrey Young), where enduring maladaptive patterns and identity are central; mentalisation-based treatment (MBT, Bateman and Fonagy), where the loss of mentalising under attachment stress dominates; and transference-focused psychotherapy (TFP, Clarkin and Kernberg), an object-relations treatment for the patient who can tolerate a long interpretive therapy. What matters more than the brand is that whichever is chosen is comprehensive, theory-based, of adequate duration and delivered by trained, supervised practitioners; NICE warns specifically against brief psychological interventions of less than three months offered outside a structured, supervised service. Each modality has its own topic; the wider models and technique are developed in the Psychotherapies, clinical assessment, MSE and nosology notes.

STRUCTURED THERAPY	CORE MECHANISM (WHAT IT TARGETS)	BEST-FIT INDICATION
Dialectical behaviour therapy (DBT)	**Emotion dysregulation from a biosocial deficit; skills plus acceptance-change balance**	Recurrent self-harm and suicidality the priority (the first-line, best-evidenced choice for self-harm)
