Three distinct interventions are gathered under this heading, and the first discipline is to keep them apart, because they carry different legal answers. **Seclusion** is the confinement of a person alone in a room or space they cannot freely leave; its extreme form, **solitary confinement**, isolates the person from all meaningful human contact. **Physical restraint** is the use of manual force or a mechanical device to restrict free movement. A third and quieter category is **chemical restraint**, the administration of medication whose purpose is to control behaviour or movement rather than to treat the underlying condition. Distinct again is **involuntary treatment**, the delivery of a medical intervention to a person who has not consented, or who has refused.

What unites them is that each is an exception to a legal default. The default is that an adult of sound understanding may not be confined, touched, or medicated without agreement; departing from that default requires positive legal authority, and the law grants that authority narrowly and conditionally. This is why coercion is examined as law and not merely as good practice: a restraint that is clinically understandable but legally unauthorised is still a battery, and a confinement that felt safe on the ward is still a false imprisonment if the conditions the statute demands were not met.

23.2 The least restrictive alternative as the governing legal principle

The single organising idea across the whole of coercive care is the **least-restrictive alternative**. It holds that where an aim can be achieved by more than one means, the law requires the means that intrudes least on the person's liberty, dignity and bodily integrity. It is not a counsel of perfection but a legal test with teeth: it makes the more restrictive option unlawful whenever a

less restrictive one would have worked. In practice it forces an ordered climb - environmental change, de-escalation and verbal engagement, offered medication, then, only if these genuinely fail, physical measures - and it treats each higher rung as justifiable only by the failure or inadequacy of the ones below it.

Its companion is **proportionality**: the degree and duration of any coercion must be matched to the seriousness and immediacy of the risk it answers, and no more. Proportionality is what stops the least restrictive option from being applied too hard or too long. Together they convert a vague clinical instinct into something a court can review after the fact: not "was the ward safer" but "was this the least intrusive step that would have contained the specific danger, and was it kept to the shortest span that danger required."

RULE **Coercion is lawful only as the least restrictive, proportionate means, and each form answers to its own threshold: physical restraint to a real and immediate risk, involuntary treatment to the conditions of the statutory pathway relied on.** Every coercive act must be justified twice over: that a less intrusive alternative was tried or genuinely unavailable, and that the intensity and duration were no greater than the danger demanded. A step that skips the ladder, or outlasts the risk, forfeits its lawfulness even if it was well intentioned.

Least	Nil	Exception
RESTRICTIVE ALTERNATIVE IS THE LEGAL DEFAULT	LAWFUL SECLUSION OR SOLITARY CONFINEMENT	INVOLUNTARY CARE DISPLACES CONSENT, NEVER RIGHTS

23.3 The rights and safeguards frame

The law does not simply permit coercion and walk away; it wraps every permitted instance in procedural safeguards whose function is to keep the intervention honest. These safeguards recur, in one form or another, across every jurisdiction and every code, and a candidate who can recite the frame can reconstruct almost any specific provision from first principles. The core safeguards are:

- **Necessity** - a lawful ground exists only on the test the governing provision itself sets: for physical restraint, that coercion is the sole realistic way to prevent serious, imminent harm; for involuntary treatment, the necessity written into the pathway relied on.
- **Proper authorisation** - the decision rests with a defined clinician, not with whoever is nearest or most senior on the floor.
- **Time-limitation** - the measure lasts no longer than the risk that justified it, with active review built in rather than a fixed licence.
- **Documentation** - the reasons, the alternatives tried, and the timing are recorded contemporaneously, because an unrecorded safeguard is indistinguishable from an absent one.
- **Notification** - the person's representative is told, so that coercion is never invisible to those outside the treating team.
- **External oversight** - instances are reported to an independent review body, moving accountability beyond the establishment that imposed the measure.

Reading down that list, the interventions sort themselves onto a continuum from tolerable-under-conditions to never-permitted, and the same axes explain why.

INTERVENTION	LEGAL STATUS	GOVERNING SAFEGUARD
Seclusion / solitary confinement	Prohibited outright	No condition can make it lawful
Physical restraint	Conditionally permitted	Necessity, authorisation, strict time-limit
Chemical restraint	A clinical description; its statutory position is not settled by the grounded text of the restraints and seclusion provision	The consent and involuntary-treatment rules governing the medication itself
Involuntary medication or treatment	Only under statutory authority	Applicable statutory pathway and decision-specific capacity; Board review where prescribed

IN INDIA

The Indian embodiment of this frame is the Mental Healthcare Act, whose restraints-and-seclusion provision is section **97**: it prohibits seclusion and solitary confinement absolutely, and permits physical restraint only conditionally. The full machinery of that section - who authorises, for how long, whom to inform, and to which body instances are reported - together with the Act's definitions, capacity provisions, advance directive, admission pathways and review boards, is set out in the Mental health legislation and forensic psychiatry notes and is named here rather than restated. The point to carry is structural: Indian statute encodes the continuum above, drawing the hard line at seclusion and hedging restraint with cumulative conditions.

23.4 Involuntary treatment as an exception to consent

Involuntary treatment raises a different legal question from restraint, because it engages the doctrine of consent directly. The starting position is that valid treatment requires the patient's informed agreement; the elements of that agreement - capacity, adequate disclosure, and voluntariness - are set out in this chapter's account of consent in psychiatry and are not re-derived here. Treatment without consent is lawful only where a specific legal authority displaces the ordinary requirement, and that authority depends on the applicable statutory pathway and on the patient's decision-making capacity, not on the diagnosis or the setting alone.

Two errors follow from losing sight of this. The first is to treat a mental illness as if it were itself the authority to override refusal; it is not, because many patients with serious illness retain capacity for the particular decision in front of them. The second is to assume that a lawful involuntary admission is a blanket warrant for any and all treatment. Admission answers the question of where the person may be kept; it does not by itself answer whether a given intervention may be imposed over refusal, which is a separate determination with its own conditions. The capacity standard, the advance directive that may speak for the patient's earlier wishes, and the admission categories themselves belong to the Mental health legislation and

forensic psychiatry notes; the legal principle to hold here is that involuntary treatment is a conditional exception and never a default that admission switches on.

PITFALL

The common clinical error is to read an involuntary admission as consent to everything that follows, and to medicate over refusal without a fresh, decision-specific capacity assessment. Admission and treatment authority are distinct legal questions; conflating them exposes the clinician to a claim of treatment without lawful authority even where the detention itself was sound.

23.5 Chemical restraint and the discriminations candidates miss

Chemical restraint is the category that most often escapes the frame, precisely because it looks like ordinary prescribing. A dose of a sedative can be a legitimate treatment of an underlying illness or a device to subdue difficult behaviour; the same drug, the same route, and only the purpose distinguishes them. Ethically the purpose matters more than the pharmacology: medication given to control behaviour rather than to treat is coercion in substance, and the safeguards that keep restraint honest - necessity, authorisation, time-limitation, documentation and review - are the right discipline to hold it to. Its legal authority is a separate question, because the statute's restraints-and-seclusion provision is written for physical restraint; medication over refusal has to be justified under the consent, capacity and involuntary-treatment rules that govern giving the drug at all. Calling it a "PRN" or writing it up as routine does not remove it from either frame.

The discriminations worth rehearsing are therefore three. Restraint answers an immediate danger, whereas treatment answers an illness over time. Restraint is measured against the least restrictive alternative and must climb the ladder of de-escalation first, whereas ordinary treatment is measured against consent and clinical indication. And restraint is time-limited by the risk, whereas a treatment course is governed by the condition. Blur these and a control measure is dressed up as care, which is both a legal exposure and, on the wards, a route to overuse.

TRAP **Treating sedation-for-behaviour as though it were outside the restraint safeguards.** Candidates and clinicians alike assume that because a drug is a treatment in other contexts, giving it here is treatment too. Purpose is what makes the label chemical restraint apt, and it is what the ethical safeguards attach to; the legal authority for giving the drug still has to be found in the consent, capacity and involuntary-treatment rules, however the dose is documented.

23.6 Documentation, oversight and liability

The safeguards frame is only as real as the record that proves it was followed, which is why documentation is the practical hinge of this whole topic. When a coercive act is later questioned - by a review body, a representative, or a court - the contemporaneous note of what danger was faced, what less restrictive steps were tried, who authorised the measure, and when it ended is the evidence that separates a lawful intervention from an actionable one. A coercive act that was in fact necessary and proportionate but was never recorded is, for the purposes of any later scrutiny, an act without a justification.

Liability flows along familiar channels. Coercion applied without a lawful ground can found a claim in the ordinary law of professional negligence, the standard-of-care analysis for which is developed in this chapter's treatment of professional negligence and is not restated here; coercion that is disproportionate or prolonged can breach the person's rights independently of any question of clinical skill. The rights lens that applies with particular force in prisons and custodial settings is taken up separately in this chapter. The through-line is that oversight is not an administrative afterthought but the mechanism by which the least restrictive principle is enforced after the event, when the clinical urgency that prompted the act has passed and only the record remains.

GOOD TO REMEMBER

Before any restraint, and while it is in force, write the ladder down: the danger, the less restrictive steps attempted, the authorising clinician, and the intended and actual end-point. This single habit satisfies the safeguards frame, shortens the intervention by keeping its end in view, and is the strongest protection against a later claim that coercion was imposed without lawful justification.

Every coercive intervention in psychiatry is lawful only as the least restrictive, proportionate, authorised and reviewable response to a genuine necessity; physical restraint answers a real and immediate risk while involuntary treatment runs through its own statutory conditions, and seclusion and solitary confinement have no lawful place at all.

Cross-cutting synthesis

24 · Cross-cutting synthesis

Every topic in this chapter is one question asked over and over. A patient says something in a consulting room. What happens to that sentence next - whether it is guarded, revealed to protect someone, spoken aloud in a witness box, or written into a record an inspector may later read - is not decided by the sentence. It is decided by who the psychiatrist is at that moment, and by what makes the telling lawful. Learn each of this chapter's topics on its own and you have a shelf of separate rules. See that they answer a single recurring question and you have the chapter, because the ethics, the consent, the confidentiality, the liability and the forensic role are not neighbours on a syllabus; they **interlock**, and the joint that holds them together is disclosure governed by role.

The marks for this synthesis are earned in the transitions, not in any one rule. An examiner who wants to separate a candidate who has memorised from a candidate who has understood gives a vignette that crosses roles: the treating doctor who is later summoned to court, the consent that turns out to be a capacity problem, the confidence that collides with a threat to a third person, the complaint that becomes a consumer matter, the accused a magistrate has ordered assessed. In every one of these, the facts do not change; the psychiatrist's relationship to them does, and with it the answer. This account owns that shared logic only. It names each rule in a clause and sends

you to the topic that teaches it in full; if it starts restating a section or a test, it has wandered into a sibling's territory.

Patient	Third party	Court	Regulator
CONFIDENTIAL BY DEFAULT, THE CLINICIAN'S OWN DUTY	A PROPORTIONATE DISCLOSURE THAT IS PERMITTED, NOT COMMANDED	A DISCLOSURE THE COURT'S OWN PROCESS CAN COMPEL	A RECORD REACHABLE ONLY UNDER A LAWFUL ORDER OR AN EXPRESS STATUTORY POWER

24.1 The two roles that decide everything

The organising fact of forensic ethics is that a psychiatrist can stand in one of two fundamentally different relationships to the same person, and the primary allegiance and much of what is owed change between them. In the first, the **treating clinician** owes their duties to the patient: to act for that person's welfare, to hold their confidences, to obtain their consent, to keep faithful records of their care. In the second, the **forensic evaluator** owes their primary duty not to the person in the chair but to the court that has asked for an opinion: to be objective, to serve the process of justice, to tell the tribunal what the clinical findings are even when they do not help the person being examined. This **dual role** is the spine of the whole chapter, and almost every discrimination the examination tests is a consequence of it.

The two roles pull in opposite directions on the one thing both handle, which is information. The treating role's instinct is to protect and withhold; the forensic role's obligation is to examine and report. That is why the same clinical detail is not one fact with one rule but a single fact whose governance shifts as the psychiatrist's relationship to the person shifts. The chapter's individual topics each sit on one side of this divide or describe a crossing between the sides, and the account of the expert witness elsewhere in this chapter, which separates the treating role from the expert role, is the place where the divide is drawn most sharply.

RULE **Ask the role before you answer the question.** No rule in this chapter can be applied until you have fixed which relationship the psychiatrist stands in. The role sets the duty, the duty sets what may be disclosed, and the same information carries a different answer depending on which of the two hats the psychiatrist is wearing when the question arrives.

24.2 One fact, several governances

Take a single piece of clinical information and watch how differently the law treats it as the setting changes. In the consulting room it is confidential, and the default duty not to reveal it is the clinician's own, owed to the patient. If that same information reveals a serious and specific danger to an identifiable other, it becomes something the clinician is permitted to reveal to avert the harm, a permitted **disclosure** that the Indian position allows without ever commanding; the full working of confidentiality and its recognised exceptions is taught in this chapter's account of confidentiality and its limits. Put the same clinician in a witness box under an order of the court, and the information can be compelled from them, because the authority over the telling has passed to the court's own process; being compelled makes them a witness, and the expert's duty to the tribunal arises only where that role has been separately defined. Written into the clinical file, that information becomes a record whose standards of keeping, and whose openness to

inspection by a regulator or a court, are the subject of this chapter's account of medical records and certification.

Nothing about the information itself changed across those four settings; the authority governing it did. This is the single most useful table to carry into the examination, because it turns a set of separate topics into one grid, and a vignette into a question of which column applies.

SETTING	WHO THE PSYCHIATRIST IS	WHAT GOVERNS THE INFORMATION	ON WHOSE AUTHORITY IT MAY BE DISCLOSED
THE CONSULTING ROOM	Treating clinician	The default duty of confidentiality	No one: it is kept, unless a recognised ground arises
A THREAT TO AN IDENTIFIABLE OTHER	Treating clinician exercising judgement	A permission to make a proportionate protective disclosure	The clinician's own bounded discretion, not a command
THE WITNESS BOX	Expert or compellable witness	The rules of evidence and the court's order	The court, which can compel the telling
THE CLINICAL RECORD	Record-keeper and certifier	Documentation and certification standards	The patient's consent, a lawful order, or an express statutory power of inspection
ANY OF THE ABOVE	Either role	Valid consent, where it can be and has been obtained	The patient, whose consent makes an otherwise closed disclosure lawful

24.3 Consent is the hinge, and capacity is the question under it

Running underneath the whole grid is **consent**, because a valid consent is the cleanest authority of all: within the scope of what the patient has actually authorised it can make lawful a disclosure that would otherwise be a breach, and it is the ground on which the treating relationship is built in the first place. This chapter teaches consent in full in its account of informed consent in psychiatry, with its elements and its special situations. The synthesis point is narrower and sharper: consent is not a signature, it is a state of the patient, and the moment you probe it you may find yourself asking a different question altogether.

That different question is **capacity**. A consent form is only as good as the decision-making ability of the person who signed it, so a consent question in a patient whose illness clouds judgement quietly becomes a capacity question, and a capacity finding is what determines whether the treating role can proceed on the patient's own authority or must fall back on the substituted machinery. The capacity determination itself, and the statutory scheme of advance directives, nominated representatives and admission that surrounds it, belong to the Mental health legislation and forensic psychiatry notes and are named here, not reworked. The seam to hold is the slide: an autonomy question about what the patient wants becomes a capacity question about whether they can decide, and only after that is answered does the disclosure or the treatment have a lawful footing.

GOOD TO REMEMBER

When a consent feels shaky, stop treating it as a consent problem and test it as a capacity problem. The two are asked in the same breath but answered by different tools, and the whole lawfulness of what follows - the treatment, the admission, the release of information to a family member - rests on getting that second question right rather than accepting the first answer at face value.

24.4 The handoffs a real case crosses

A single patient can walk the psychiatrist through most of this chapter. Real forensic difficulty comes not from any one rule but from the crossings between them, when a case moves from one role or forum to the next and the governing rule changes at the boundary. The recurring handoffs are these.

- **Treating clinician is summoned as a witness.** The doctor who has cared for a patient is called to speak about them in court. A summons does not by itself turn the treating clinician into the forensic expert: they ordinarily give evidence of fact and of the treatment they provided, and a separate expert role must be defined explicitly rather than assumed at the courtroom door. Keeping the two roles distinct is the discipline taught in this chapter's account of the expert witness.
- **A consent becomes a capacity question.** The autonomy the treating role respects turns out to depend on a decision-making ability the illness has compromised, and the answer moves from what the patient wants to whether they can decide, as above.
- **A confidentiality duty meets a duty to a third party.** The promise to the patient collides with the safety of an identifiable other, and the clinician must decide whether a permitted protective disclosure is warranted and how far it may go, a decision governed by proportionality and taught in this chapter's account of confidentiality.
- **A negligence claim becomes a consumer matter.** A grievance about care crosses from the language of professional negligence into a specific statutory forum with its own remedy, so the same allegation is litigated in a different place under a different frame; the standard of care and the forum are taught in this chapter's accounts of negligence and of the consumer-protection route.
- **An accused becomes a psychiatric subject by order.** A person facing trial is sent for assessment not by their own consent but by a court's direction, which converts a clinical encounter into a court-authorised examination whose procedural pathway this chapter teaches, while the substantive test of criminal responsibility belongs to the Mental health legislation and forensic psychiatry notes.

Notice that every handoff is a change in the authority over information or over the person: a duty owed to one party is joined, and to that extent limited, by a duty owed to another. That is why disclosure, and not any single doctrine, is the thread the chapter is strung on.

24.5 The forum, the code and the currency behind every answer

Two further layers sit behind the grid and quietly decide answers. The first is the forum: the place a dispute is heard shapes the remedy available, so a claim about deficient care is one thing framed as professional negligence and another routed into the consumer-protection forum, and an opinion is received under one set of rules in a courtroom that this chapter's account of the court and the rules of evidence sets out. The second is currency, and it is the trap that most often turns a correct-sounding answer wrong. The rules cited must be the ones actually in force. The professional-conduct code that governs a psychiatrist's ethics, taught in this chapter's account of the codes, is the operative one and not the later edition that was notified but held in abeyance. The substantive criminal law changed, and the framework and its savings rule are taught in this chapter's account of the penal-code transition; naming the superseded statutes as current is a currency error, not a substantive one, and it is caught all the same.

These two layers are why the synthesis is more than a tidy diagram. A candidate can identify the right role, the right duty and the right disclosure and still lose the mark by citing the wrong forum for the remedy or the wrong edition of the code for the duty. The frame tells you what the answer is about; the forum and the currency tell you whether the answer you have written is still the law.

IN INDIA

The Indian shape of this chapter is specific and examinable. Protective disclosure is a permission and not the positive duty of the American case law. The professional-conduct code in force is the earlier statutory edition, the later one being notified but not operative. Deficient medical service reaches a defined consumer forum. The criminal statutes have been recast, and the savings rule decides which version governs: the older penal law still governs offences committed before the change, while proceedings already pending at the change continue under the old procedure and evidence law. The child-protection and juvenile framework, and the general mental-health machinery, sit in the Child psychiatry: assessment, treatment, services and protection notes and the Mental health legislation and forensic psychiatry notes respectively; this chapter points to them rather than restating them.

PITFALL

The commonest real-world slip is not a wrong rule but a blurred role. A treating psychiatrist, asked casually by a lawyer or a relative, writes a forensic-sounding opinion about fitness or responsibility into a discharge summary, without a court's referral or any other properly defined retaining authority, and without flagging that they are no longer speaking as the treating doctor. The opinion then carries the weight of an expert's while resting on none of an expert's safeguards, and the confidences of treatment leak into a quasi-legal document. Fix the role in writing before you offer the opinion, or decline until the proper role and authority are in place.

24.6 How it interlocks: the master frame

Assemble the pieces and the chapter resolves into a single decision procedure that fits every vignette it can throw at you. Fix the role. Identify the information at stake. Ask what may be told,

to whom, and on whose authority. Check that the code, the statute and the forum you are relying on are the ones currently in force. Where a rule belongs to a sibling topic, apply it by name and reason from it rather than restating it. The reason this works is that the whole chapter was built on one seam: the psychiatrist's two roles and the single question of disclosure they govern between them.

MNEMONIC

Two hats, three questions

The master frame for any forensic-ethics vignette. First the **two hats**: is the psychiatrist the treating clinician, who owes duties to the patient, or the forensic evaluator, who owes candour to the court? Then, of the information in play, the **three questions**: **What** may be told, **to Whom**, and on **Whose authority** - the patient's consent, the clinician's bounded discretion, a court's order, or a regulator's power. Fix the hat, run the three questions, and every rule in this chapter falls into its place.

Fix the role first: it decides the duty, the duty decides what may be disclosed, and the same fact carries a different lawful answer under each hat.

TRAP **Answering a role-crossing vignette with a single rule.** Candidates read the clinical detail, reach for the one doctrine it looks like - confidentiality, or consent, or negligence - and answer as though the setting were fixed. The examiner wrote the vignette precisely because the setting moves, and the mark is for tracking the information across the crossing: what was confidential becomes compellable, what looked like consent was a capacity question, what began as negligence is heard as a consumer complaint. Name the role at each stage and the moving answer becomes visible; assume one role throughout and you answer only the first frame.

Apply and consolidate

25 · Applying the chapter

Why worked vignettes earn their marks. The examiner rarely asks you to recite a rule; they hand you a short case in which two rules pull in opposite directions and watch how you reason to a defensible answer. A vignette is therefore a test of judgement under a stated constraint, not of recall, and the candidate who has only memorised isolated provisions freezes precisely where the marks are. The cases below are deliberately built at the seams this chapter has been teaching, so that each one forces the same first move: work out which role the psychiatrist is in, then work out on whose authority anything may be done or disclosed. Everything else follows from those two questions.

These vignettes assert no new rule of their own. Each reuses only what the chapter has already established and cross-refers, by name, to the material owned elsewhere. Read each one as a rehearsal: cover the answer, decide what you would do and why, then check your reasoning

against the model. Between them the four cases span the four families of question this chapter can throw at you, and the closing case draws them back into a single frame.

25.1 How to read a medico-legal vignette

Before the individual cases, fix the method, because the same skeleton unlocks every vignette in this territory. The first and decisive move is to name the psychiatrist's **dual role**: are you the treating clinician, who owes duties of care, confidence and consent to the patient in front of you, or the forensic evaluator, who owes an impartial opinion to a court and owes the person examined no therapeutic loyalty? Almost every trap in this domain is baited by a scenario that quietly switches your role halfway through, or asks you to act in one role using the duties of the other.

With the role fixed, the rest of the reasoning is a short, ordered checklist you can run on any case:

- What exactly is the decision point, and who is asking for the decision - the patient, the family, an employer, a court?
- Which duty is in tension with which, and is one of them a default that may yield rather than an absolute?
- What is the governing authority - the patient's own valid consent, a statutory permission, or a court order - and is that authority actually present here?
- What is the least intrusive action that discharges the duty, and how will you record the reasoning so a later reviewer can follow it?

MNEMONIC

The four C's - Consent, Confidentiality, Conduct, Court

Every question this chapter can set falls into one of four families, and the four C's name them in the order the chapter taught them: **C**onsent and capacity; **C**onfidentiality and its limits; professional **C**onduct, negligence and boundaries; and the **C**ourt, where the psychiatrist becomes an expert and an accused is assessed. Under all four sits the one recurring question - what may be disclosed, to whom, and on whose authority. Place the case in its C, answer that question, and the vignette resolves.

RULE **Name your role before you answer.** Whether you are the treating clinician or the forensic evaluator determines every duty that follows, so it is the first line of any good answer, not an afterthought. A candidate who states the role explicitly has already earned marks and has protected themselves from the commonest way these vignettes are lost, which is answering in the wrong hat.

25.2 Vignette: consent and capacity in a special situation

A man in his thirties is brought to the emergency department by his family after a deliberate act of self-harm. He is now medically stable. He is drowsy, his attention drifts, and he is refusing admission and any further care, saying he wants to leave. The family are divided: some insist he

be kept, one pleads that he be allowed home. The decision point is sharp - may he be allowed to refuse, and if not, on whose authority is he held?

The reasoning a candidate must show turns on **capacity**, and the key insight is that capacity is decision-specific and time-specific, not a fixed property of the person. The task is to assess, at this moment and for this decision, whether he meets the statutory test of decision-making capacity, a test set out in the mental health legislation and taught in the Mental health legislation and forensic psychiatry notes, applied here rather than restated. A fluctuating sensorium immediately after an overdose is a classic special situation, but clouded consciousness does not by itself settle the question: the legislation starts from a presumption of capacity, so the refusal stands unless an immediate, documented assessment against that statutory test shows the required abilities are absent, and the correct response is not to override him permanently but to treat what is immediately necessary, protect him from foreseeable harm, and reassess capacity when he is lucid. The second thread is **voluntariness**: a decision squeezed by family pressure in either direction is not fully free, and that too must be weighed. Where capacity is genuinely absent and the risk is high, the lawful route is the involuntary pathway set out in the mental health legislation, not an open-ended clinical override; the machinery of admission, the capacity provisions and the safeguards belong to the Mental health legislation and forensic psychiatry notes and are applied, not reinvented, here.

The answer, then, is layered: give emergency treatment to the extent necessary to prevent serious harm; do not accept a refusal made without capacity as though it were valid; reassess capacity as the clinical picture clears and honour a capacitous refusal if one emerges; and, if involuntary care is needed, use the statutory pathway and its safeguards rather than force alone. One further point earns marks and protects the patient: the man and his nominated representative have a right to information they can actually understand about the nature of the illness and what the treatment involves, a right set out in the mental health legislation and owned by the Mental health legislation and forensic psychiatry notes; the explanation is pitched in plain terms he can take in - his risk, his current confusion and what the treatment is for - rather than left as unexplained clinical jargon.

25.3 Vignette: confidentiality and the duty to warn

A patient in ongoing treatment discloses persistent, detailed thoughts of seriously harming a named colleague, describing a specific and plausible plan. The colleague is identifiable. The decision point is one candidates reliably mishandle: must the psychiatrist warn the colleague, may they, or must they say nothing?

The reasoning must begin from the default, which is that **confidentiality** is owed, and then locate the edge at which it yields. The chapter's teaching on the **limits of confidentiality** is that what the law permits is the disclosure necessary to protect another person from harm, and even then it must be proportionate and minimal - enough to avert the harm, no more; the seriousness and specificity of the threat guide how far a proportionate disclosure may reasonably go. The distinctively Indian move, and the one the examiner is testing, is that this is a permission, not an American-style blanket mandate to warn: the mental health legislation permits a proportionate

disclosure in the interest of protecting a third party rather than imposing an automatic positive duty, and the exact statutory permission sits in the Mental health legislation and forensic psychiatry notes. Before breaching anything, the candidate should show they considered the alternatives that avert the danger without disclosure at all - intensifying treatment, or arranging admission so the risk is contained clinically.

The defensible answer is graded rather than reflexive: assess the seriousness and specificity of the threat; reduce the risk within the therapeutic frame where you can, and where disclosure is necessary to protect the person threatened from harm, make the narrowest disclosure that will do it, to those who can act on it, without delaying a protective disclosure the danger has already made necessary; and document the reasoning at every step, because the justification for the breach is itself examinable and later reviewable. Taking no reasonable protective step in the face of a credible, specific threat may expose the clinician to criticism, though the Indian position frames this as a permission to disclose rather than a positive command to warn; warning reflexively at the first hostile thought needlessly destroys the alliance and exceeds the permission.

GOOD TO REMEMBER

When you decide a disclosure is justified, disclose to the person who can actually reduce the risk and tell them only what they need to act - not the case history. Proportionality is measured by what averts the harm, and a breach wider than that is itself a fresh wrong, however good the original reason.

25.4 Vignette: professional conduct, negligence and boundaries

A psychiatrist volunteers at a free mental health camp and gives advice to an attendee who, months later, alleges she was harmed by that advice. Separately, over the same period, the psychiatrist has accepted a personal gift from a regular patient, begun exchanging friendly messages outside sessions, and drifted into a relationship that is no longer purely clinical. Two decision points sit in one vignette: is a free service beyond the reach of a consumer complaint, and has the psychiatrist crossed a professional line?

On the first, the reasoning must resist a tempting shortcut. Whether the encounter grounds a claim in **negligence** turns on whether a duty of care arose, whether the conduct fell below the standard expected of a reasonable practitioner, and whether that shortfall actually caused the harm alleged. Whether the consumer-protection forum is even available turns on how the service was charged for: a service given free to every attendee falls outside it, whereas free treatment given at an establishment that charges the patients who can afford to pay is within its reach - so the shortcut that a service given without a fee is always outside, and the opposite assumption that it is always inside, are both wrong, and an ordinary negligence action may lie regardless; the reach of that forum is taught with its own case law elsewhere in this chapter. On the second, the issue is a **boundary violation**, and whether these facts have already become one: gifts, out-of-session contact and dual roles mark the slow slide from a therapeutic relationship into a personal one, and how far along that slide a case has travelled is judged against the test taught in this chapter's account of boundaries, applied here rather than assumed. The reasoning to show is that

boundaries are protective of the patient, not merely proprieties, and that the earliest crossings are the ones to name.

TRAP **Treating the four-D mnemonic as the legal test of negligence.** The familiar teaching list - duty, dereliction of that duty, damage, and direct causation - is a memory aid, not the courts' formulation. The Supreme Court's own statement is tighter: it asks for a duty, a breach of that duty, and resulting damage, with causation embedded in the last, and it holds that criminal negligence needs more still - gross negligence coupled with a guilty mind. Reciting the D's as though they were the ratio, or blurring civil and criminal thresholds, loses the mark.

PITFALL

The recurring real-world error in conduct cases is citing the wrong professional code. The operative code a disciplinary body actually applies is the long-standing Medical Council of India professional-conduct regulations; the successor National Medical Commission practitioner-conduct regulations, though formally notified, were held in abeyance and are not in force. Answering, or worse advising, from the newer notified rules treats notification as though it were commencement, and it is confidently wrong.

25.5 Vignette: the forensic role, the expert and the accused

A psychiatrist has been treating a patient for some months. The patient is now charged with an offence, and the family asks the treating psychiatrist to appear in court and give an opinion on the patient's mental state at the time of the alleged act. The decision point is whether the treating clinician can, or should, also serve as the forensic evaluator in the same case.

The reasoning must foreground the dual-role conflict this whole chapter has been building toward. As the treating clinician the psychiatrist is an advocate for the patient's clinical welfare, bound by the alliance and by confidentiality; as an **expert witness** the same psychiatrist would owe an impartial opinion to the court, must set therapeutic loyalty aside, and gives opinion evidence that is distinct from the fact evidence a witness ordinarily offers. Holding both roles compromises each: the court cannot fully trust an opinion coloured by therapeutic allegiance, and the patient's trust is betrayed if their doctor becomes the instrument of their examination. Best practice is to separate the roles, so that an independent evaluator conducts the forensic assessment. The question the family poses - the patient's mental state at the time of the alleged act - is one of criminal responsibility, whose insanity-defence test and burden of proof are owned by and cross-referred to the Mental health legislation and forensic psychiatry notes, named, not restated, here. It is distinct from fitness to stand trial, which turns on the accused's present capacity to defend; the court-referral procedure for assessing an accused is taught in this chapter, and it is engaged by that present-capacity question alone, never by the question of the mental state at the time of the act. The rules of evidence that govern how the opinion is received are the court's, and the substantive criminal law now runs on the recodified penal, procedure and evidence statutes, with a savings rule deciding which regime applies to a given case - taught in full within this chapter's statute material.

The answer is to decline the conflated role, or at least to make the conflict explicit and let the court decide, and in any event to confine any opinion given to what is within competence and to disclose its limits. A treating psychiatrist dragged into the witness box against their own patient is the sharpest instance of the two hats colliding, and naming the conflict is itself the mark-worthy move.

IN INDIA

The forensic vignette is answered from Indian primary sources, and their currency is itself examinable. The older penal, procedural and evidence codes have been superseded by their successors, so an answer that names the historical statutes as current law is wrong; the offence date governs which penal code applies, while pendency at the point of transition governs procedure and evidence. Where a child is the survivor or the accused, the child-sexual-offences and juvenile-justice framework is not this chapter's to apply - it belongs to the Child psychiatry: assessment, treatment, services and protection notes.

25.6 The common thread across the four cases

One skeleton, four skins. Set side by side, the four vignettes are the same reasoning wearing different clothes. Each opens by fixing the role, each turns on a duty that is a default rather than an absolute, each is decided by locating the governing authority, and each is lost in the same way - by importing a foreign rule, a stale statute or the wrong hat. The table below lays the four domains on shared axes so the pattern is visible at a glance.

DOMAIN	THE DECISION POINT	THE GOVERNING FRAME	THE CLASSIC TRAP
Consent and capacity	May this refusal or agreement stand?	Capacity, voluntariness, and the statutory pathway when capacity is absent	Treating a clouded refusal as valid, or overriding without the lawful route
Confidentiality	May I, or must I, disclose?	A default of confidence, with a proportionate permission at its edge	Importing a foreign mandatory duty to warn instead of a permitted disclosure
Conduct and negligence	Did the conduct fall below what was owed?	Duty, breach and resulting damage; the current professional-conduct code	Reciting the four-D mnemonic as law, or citing the code held in abeyance
Court and the accused	In which role am I answering?	Treating role separated from the impartial expert opinion to the court	Serving as expert for one's own patient, or naming superseded statutes

Notice that the right-hand column is a single family of mistakes: each is a rule applied from the wrong place - the wrong country, the wrong version of a statute, or the wrong role. That is why the method in this closer leads with role and authority. Get those two right and the specific rule usually falls out; get them wrong and even a correctly remembered rule is deployed in the wrong case.

Every forensic-ethics vignette resolves to the same two questions - which role you are in, and on whose authority you may act or disclose - and naming both is the first mark of a defensible answer.

26 · Consolidation

A chapter you have read is not a chapter you can retrieve. This closing section is a self-test, and it works only if you use it as one. The prompts below are questions with no answers printed beside them, and that is deliberate: **active recall** - forcing an answer out of memory before you look it up - is what fixes material for an examination, and an answer sitting next to the question quietly converts the exercise back into rereading, which feels productive and teaches almost nothing. Cover the notes, work down the list, say or write your answer in full, and only then turn back to the topic that owns it to check yourself.

Everything asked here was taught earlier in this chapter; nothing new is introduced and no prompt reaches for a fact the chapter never covered. The questions are grouped into the three sub-areas the chapter is built from - professional ethics with consent and confidentiality, the special settings of disaster, prisoners and custody, and the forensic statutes with legal procedure - and each group ends where the material ends, so that a blank you draw is a topic to revisit, not a trick.

26.1 How to use this list

Before the questions, fix the frame that answers most of them. Two facts run under this whole chapter. The first is the **dual role**: at any moment the psychiatrist is either the **treating clinician**, who owes duties to the patient, or the **forensic evaluator**, whose duty runs to the court. The second is that almost every rule is really a rule about **disclosure** - what may be told, to whom, and on whose authority. Run each prompt through those two facts before you reach for a specific rule, and the specific rule will usually announce itself.

RULE **Retrieve first, review second.** The value of this list is destroyed the instant you read an answer before you have tried to produce one. Attempt every prompt from memory, out loud or on paper, and treat the checking as the reward for the attempt, not a substitute for it. A prompt you cannot answer marks the exact topic to reopen.

26.2 Sub-area one: professional ethics, consent and confidentiality

These prompts sweep the ethical foundations and the two constructs the chapter stresses hardest - consent and disclosure. Answer each fully before checking the owning topic.

1. Name the principles of biomedical ethics, and say what a clinician actually does when two of them pull in opposite directions in a psychiatric decision.
2. State the essential elements of a valid informed consent and name the Indian judgment that anchors them; then explain the moment a consent question quietly becomes a capacity question.

3. Recall the grounds on which the duty of confidentiality may be lifted, and state precisely how the Indian position on disclosing to protect an endangered third party differs from the American doctrine; name the leading Indian judgment on breaching confidentiality to protect an identifiable person at risk, and be clear about what it did and did not decide.
4. Give the teaching mnemonic for the components of negligence, then state the components in the Supreme Court's own formulation, and say what criminal negligence adds to the civil standard.
5. Name the test that fixes the standard of care and the later gloss that qualified it, and explain vicarious liability in a single sentence.
6. Identify the current statute under which a patient pursues a claim for deficient medical service, what it replaced, the landmark that brought medical service within it, and when a free service falls outside it.
7. Separate the treating role from the expert role - to whom does each owe its primary duty - and say why the expert is the courtroom's exception to the bar on opinion evidence.
8. State which edition of the professional-conduct code is operative and which was notified but held in abeyance, and which of the two carries the graduated levels of professional misconduct; then name the profession's own code of ethics and the meeting that adopted it.
9. Distinguish a boundary crossing from a boundary violation, describe the slippery slope between them, and say what makes a clinical record defensible and its certification truthful.

26.3 Sub-area two: disaster, prisoners and custody

Here the vulnerable population meets the coercive institution, and the answers are Indian statutes and Indian judgments. The clinical management of substance use in these settings is not asked, because it belongs to the Substance use disorders notes.

1. Describe the tiered command structure the disaster-management statute creates, and identify the tier a psychiatrist most often works within.
2. State what that Act means by disaster management, and name what is conspicuously absent from its scheme.
3. Explain the two mechanisms by which imprisonment both generates and worsens psychiatric disorder.
4. Say what the principal Indian prisons statute provides for mental health care, and why its position is a problem.
5. State the principle of equivalence of care and the problem of dual loyalty as they arise behind the wall.
6. Name the provision that authorises the transfer of a mentally ill prisoner for treatment, and the two doors it opens.
7. Recall the judgment holding that the non-criminal mentally ill do not belong in jail, and state its practical consequence.

8. Describe the custodial duty around self-harm and suicide, and how consent and confidentiality actually operate for a detained patient.

26.4 Sub-area three: forensic statutes and legal procedure

These prompts cover the recodified criminal-legal interface. Two doctrines the chapter deliberately does not teach - the insanity-defence test with its burden of proof, and the child-sexual-offences framework - are cross-referred, and the prompts respect that boundary.

1. State the savings rule that decides which criminal regime governs a case after the recodification: what governs the penal question, and what governs procedure and evidence?
2. The insanity-defence test itself, and the burden of proof, are taught in the Mental health legislation and forensic psychiatry notes; state only the correction this chapter makes - in which code does the defence now sit, and in which separate code does the burden sit?
3. Distinguish the legal meaning of consent in sexual-offences law from clinical informed consent, and outline the psychiatrist's role with a survivor; the child framework belongs to the Child psychiatry: assessment, treatment, services and protection notes and is only named.
4. Trace the procedural pathway by which an accused is sent for psychiatric assessment: which recodified statute now houses it, what happens at referral and report, and what follows a finding of incapacity - with the fitness criteria themselves left to the Mental health legislation and forensic psychiatry notes.
5. Say what makes a dying declaration relevant and admissible, and how the Indian rule departs from the common-law requirement of a settled expectation of death.
6. Admissibility is not reliability: state what the psychiatrist must assess about a declarant's mind, and the conditions that can cloud it.
7. Recall the statutory ladder of the criminal courts, and the rule of evidence that admits an expert's opinion at all.
8. Explain why the expert's opinion is a relevant fact and not a verdict, and the currency check you must run before testifying after the codes changed.

> **GOOD TO REMEMBER**
>
> Do not run this list once the night before. Retrieval strengthens memory most when it is spaced and repeated - sweep the three groups now, mark the prompts you missed, and return to those alone after a gap of some days. The prompts you answer cleanly need no revisiting; your time belongs to the blanks.

26.5 The currency check that flips answers

A right rule stated as the wrong version is a wrong answer. More marks are lost on this chapter to stale law than to genuine ignorance, because the ground has shifted twice and the superseded answers still read as natural. Before you accept any answer you have retrieved, ask whether the code or statute you named is the one actually in force. The grid below is the coverage map: read across each row to confirm you can answer the recurring question, name the currency or limit

that most often flips it, and place the neighbouring doctrine you must cross-refer rather than re-teach.

SUB-AREA	THE RECURRING QUESTION TO ANSWER FROM MEMORY	THE CURRENCY OR LIMIT THAT FLIPS THE ANSWER	THE NEIGHBOUR TO NAME, NOT RE-TEACH
ETHICS, CONSENT, CONFIDENTIALITY	Whose is the information, and on whose authority may it be disclosed?	Which conduct code is operative, and is protective disclosure a permission or a command?	the Mental health legislation and forensic psychiatry notes (capacity, advance directives, admission)
DISASTER, PRISONERS, CUSTODY	Who owes care to a detained person, and to what standard?	The principal prisons statute's want of a substantive care standard, and the authority that permits transfer	the Substance use disorders notes (substance use in custodial settings)
STATUTES AND PROCEDURE	In which role, and under which code now in force, is the opinion given?	Are you citing the recodified statutes or the superseded ones - and what does the savings rule say?	the Mental health legislation and forensic psychiatry notes (insanity test, burden) and the Child psychiatry: assessment, treatment, services and protection notes (the child framework)

PITFALL

The recurring real-world error this chapter exists to correct is a currency error. Treating the notified-but-suspended successor professional-conduct regulations as the operative code, or citing the superseded criminal, procedure and evidence statutes as current after the recodification, is confidently wrong in exactly the way that reads as right. A disclosure permitted under the Indian regime is also misremembered as a positive duty to warn imported from foreign case law. If a prompt above returns one of these, that is the topic to reopen first.

IN INDIA

Every answer on this list is an Indian primary-source answer, and most of them differ from the Western textbook default: protective disclosure that is permitted rather than commanded, an earlier statutory conduct code still in force while its successor waits in abeyance, a consumer forum that reaches into medical practice, and a criminal law recently recast with a savings rule. When a prompt tempts you toward the familiar Western answer, that temptation is itself the signal to recall the Indian position instead.

26.6 The master frame to run on any vignette

The whole chapter collapses into one short procedure you can run against any question it throws at you. It is not new content; it is the chapter's own spine, gathered into four moves so that a vignette becomes a sequence of decisions rather than a scramble for the one rule it resembles.

MNEMONIC

HATS

The master frame for any forensic-ethics question. **H**at: fix the role first - is the psychiatrist the treating clinician who owes duties to the patient, or the forensic evaluator who owes candour to the court? **A**uthority over the information: of what is in play, ask what may be told, to whom, and on whose authority - the patient's consent, the clinician's bounded discretion, a court's order, or a regulator's power. **T**est the currency: is the conduct code the operative one and not the suspended successor, and is the criminal, procedure or evidence code the version in force under the savings rule? **S**ource and sibling: read the primary source, and where a doctrine belongs to another chapter, name it and reason from it rather than restating it. Fix the hat, run the three, and every rule in this chapter falls into place.

TRAP **Recognition mistaken for recall.** Reading an answer and thinking "yes, of course" feels identical to knowing it, and it is not - recognising a stated answer is a far weaker trace than producing one unprompted. The candidate who reviews by rereading walks into the hall confident and empties out under a blank page. Cover the answer, force the retrieval, and let the failures on this list, not the successes, direct your last days of revision.

Fix the hat, ask what may be disclosed and on whose authority, and check that the code you cite is the one in force - and you can reason through any forensic-ethics vignette this chapter can set.

Previously asked

There is no indexed past-question bank for this chapter, so nothing in the table below is a catalogued past question and no board or year is claimed for any of them. Attributing a paper the index does not hold would be a fabrication, so in place of a board of origin each row is marked Representative, and the questions are written in the register an examiner uses. Forensic ethics, consent and legal procedure are examined heavily and in every form the paper allows, as long answers, as short notes and in the viva, so the list maps the examined spine of this chapter rather than one board's recent record. Read it as a high-yield revision map, not as a set of questions on record.

QUESTION	MARKS	ASKED
Enumerate the four principles of biomedical ethics and discuss how they come into conflict in a psychiatric decision, with an example of how such a conflict is resolved.	10	Representative
Discuss informed consent in psychiatric practice: its essential elements, the assessment of capacity to consent, and the special situations that complicate it.	10	Representative
Confidentiality and its limits in psychiatry. Discuss the duty to warn, the position under the Mental Healthcare Act, and the relevance of Tarasoff and of Mr X v Hospital Z.	10	Representative
Professional negligence and medical malpractice. Explain the four Ds, the standard of care, and the distinction between civil and criminal medical negligence in Indian law.	10	Representative
Medical services under the Consumer Protection Act. Short note.	*5*	Representative
The psychiatrist as an expert witness: the role, the distinction between opinion and fact evidence, and the conduct expected in court.	*5*	Representative
Boundary violations in the therapeutic relationship. Short note.	*5*	Representative
The Indian Psychiatric Society code of ethics and the current statutory professional-conduct code. Short note.	*5*	Representative
The insanity defence and the burden of proving it under the current criminal law, and the transition from the earlier codes on the first of July 2024.	10	Representative

QUESTION	MARKS	ASKED
Describe the procedure for the psychiatric assessment of an accused person, from the court's referral to the report and its consequences.	10	Representative
Sexual offences law and the psychiatric assessment of a survivor. Discuss the legal meaning of consent.	*5*	Representative
Mental health of prisoners: the transfer and treatment of a prisoner with mental illness, and the human-rights safe-guards in custodial psychiatry.	*5*	Representative
The legal aspects of seclusion, restraint and involuntary treatment, and the least-re-strictive principle. Short note.	*5*	Representative

The shape of these questions is worth reading before their content. A ten-mark question that opens with enumerate or describe wants a structured map rather than a definition, and the marks are won on the discriminations this chapter turns on: the difference between a permission to disclose and a positive duty to warn, the difference between the insanity defence and the burden of proving it, the difference between civil and criminal negligence, and the difference between the treating role and the forensic role. A short note carries fewer marks but the same demand for the exact provision and the exact modal verb, because a permission and a duty are not interchangeable and an answer that names a repealed code as the current law reads as one that has not opened the statute. This is the one part of the paper whose answer is checkable against a primary text, which is precisely why the examiner rewards the candidate who cites the current provision and marks down the one who cites the old one by reflex.

The quick review

One table, read down the left column and cover the right. Every line is taught in full somewhere above and nothing here is new: each is that provision's single must-hold line, the rule lifted from the passage that teaches it, so a line you cannot recover is a section to reread rather than a fact to memorise here. Modal verbs are load-bearing: an exception that permits disclosure is not a command to disclose, and where the statute says shall it is kept as shall. Currency is this chapter's spine. The operative professional-conduct code is the Medical Council of India (Professional Conduct, Etiquette and Ethics) Regulations 2002; the National Medical Commission RMP Regulations 2023 were notified, then held in abeyance, and are not operative. The criminal codes are the Bharatiya Nyaya Sanhita, the Bharatiya Nagarik Suraksha Sanhita and the Bharatiya Sakshya Adhiniyam, in force from 1 July 2024, with the

Indian Penal Code, the Code of Criminal Procedure and the Indian Evidence Act as their historical predecessors; the offence date governs the penal code and pendency governs procedure and evidence.

ASK	HOLD
PROFESSIONAL ETHICS, CONSENT AND CONFIDENTIALITY	
THE FOUR PRINCIPLES OF BIOMEDICAL ETHICS	Respect for autonomy, beneficence, non-maleficence and justice, developed by Beauchamp and Childress; each is a prima facie obligation to be balanced against the others when they conflict.
INFORMED CONSENT, THE THREE ELEMENTS (SAMIRA KOHLI)	Consent to treatment must be real and valid, which the Court defines by three elements: the patient must have the capacity to consent, the consent must be voluntary, and it must rest on adequate information about the nature of the treatment.
CONSENT SCOPE AND THE DISCLOSURE STANDARD (SAMIRA KOHLI)	Consent is confined to the specific procedure consented to, so consent for a diagnostic procedure is not consent for therapeutic treatment, and that unauthorised additional surgery benefited the patient is no defence; the disclosure standard adopted is the Bolam real-consent standard, not the higher Canterbury prudent-patient test.
CONFIDENTIALITY, THE RIGHT AND ITS LIMITS (MHCA S.23)	The person has a right to confidentiality and all health professionals a duty to keep the information confidential; the enumerated exceptions (to protect another from harm, to prevent a threat to life, on the order of the Board or a court, for public safety) permit disclosure, they do not command it.
DUTY TO WARN OR PROTECT, THE US ORIGIN (TARASOFF, 1976)	A therapist who determines, or under professional standards should determine, that a patient presents a serious danger of violence to another incurs an obligation to use reasonable care to protect the intended victim; the protective privilege ends where the public peril begins.
CONFIDENTIALITY AGAINST AN IDENTIFIABLE THIRD PARTY (MR X V HOSPITAL Z, 1998)	The Indian analogue: disclosure of the patient's HIV-positive status to the woman he was about to marry was held not to violate confidentiality or the right to privacy, because an identifiable person was saved from a real risk; the right to privacy is not absolute.
THE IPS CODE AND THE OPERATIVE CONDUCT CODE	The Indian Psychiatric Society code of ethics was approved at its Cuttack conference in 1989, the foundational Indian psychiatry-specific code; the operative professional-conduct code for doctors is the MCI 2002 Regulations, because the NMC RMP 2023 Regulations were notified, then held in abeyance, and are not operative.
NEGLIGENCE, THE FOUR DS AND THE COMPONENTS (JACOB MATHEW)	The teaching mnemonic is the four Ds (duty, dereliction, damage, direct causation); the operative law is Jacob Mathew's three essential components, duty, breach and resulting damage, with causation as the fourth element (the plaintiff must prove the breach caused the injury, from Bolitho).

ASK	HOLD
THE STANDARD OF CARE, BOLAM QUALIFIED BY BOLITHO	Bolam: a professional is not negligent if he acts in accordance with a practice accepted as proper by a responsible body of professional opinion (adopted in India via Jacob Mathew); Bolitho qualifies it, so that opinion protects only if it can withstand logical analysis.
CRIMINAL MEDICAL NEGLIGENCE (JACOB MATHEW)	Far higher than the civil bar: mens rea must be shown and the negligence must be gross or of a very high degree; the words rash or negligent act are read as qualified by grossly, and negligence that is neither gross nor of a high degree may ground a civil action but cannot found a prosecution.
CONSUMER PROTECTION ACT 2019 AND IMA V V.P. SHANTHA	The 2019 Act repealed the 1986 Act; service (s.2(42)) excludes any service rendered free of charge or under a contract of personal service, and deficiency (s.2(11)) includes any act of negligence causing loss or injury; IMA v V.P. Shantha holds paid medical service is service, while service rendered free of charge to everybody is not.
THE EXPERT WITNESS, OPINION VERSUS FACT (RAMESH CHANDRA AGRAWAL)	An expert is not a witness of fact; his evidence is of an advisory character, his duty being to furnish the court with the scientific criteria to test the conclusions so the judge can form an independent judgment; the court is not bound by the expert's opinion.
BOUNDARY CROSSING VERSUS BOUNDARY VIOLATION	A crossing is a minor, non-exploitative, discussable departure from the frame that may even help the patient; a violation is an exploitative, harmful departure that serves the clinician and betrays the fiduciary duty; the slippery slope carries one into the other, and sexual contact with a current patient is the paradigm violation, absolutely prohibited and never excused by apparent consent, because responsibility for the boundary rests always with the clinician.
RESEARCH, RECORDS AND TELEPSYCHIATRY ETHICS	Under the NMC 2023 framework (notified, then held in abeyance; the operative code is the MCI 2002): research on patients or volunteers must comply with ICMR guidelines and the New Drugs and Clinical Trials Rules 2018; a self-employed RMP keeps inpatient records for three years from the last contact and supplies them on request within five working days; telepsychiatry follows the Telemedicine Practice Guidelines.
DISASTER, PRISONERS AND FORENSIC SPECIAL TOPICS	
DISASTER MANAGEMENT ACT 2005 STRUCTURE	A three-tier ladder: the National Disaster Management Authority (s.3, Prime Minister ex officio Chairperson), a State Disaster Management Authority in every State (s.14, Chief Minister ex officio Chairperson) and a District Disaster Management Authority in every district (s.25, Collector or District Magistrate or Deputy Commissioner ex officio Chairperson); the Act's own definition does not name psychosocial or mental-health support as an express limb.

ASK	HOLD
PRISONERS WITH MENTAL ILLNESS (MHCA S.103)	An order directing admission of a prisoner with mental illness is sufficient authority; transfer to the psychiatric ward in the medical wing of the prison is the first option and suffices, and only where there is no such ward may the prisoner be transferred to a mental health establishment, with the prior permission of the Board.
THE REMOVAL WARRANT (PRISONERS ACT 1900 S.30)	Where a detained or imprisoned person appears to be of unsound mind, the State Government may, by a warrant setting forth the grounds, order his removal to a lunatic asylum or other place of safe custody for the remainder of the term; this is the provision MHCA s.103 cross-refers.
CUSTODIAL HUMAN RIGHTS (SHEELA BARSE)	The Supreme Court strictly prohibited confining non-criminal mentally ill persons in jails, treating such confinement as a violation of constitutional rights.
FORENSIC STATUTES AND LEGAL PROCEDURE	
SEXUAL OFFENCES, RAPE AND ITS PUNISHMENT (BNS S.63, S.64)	BNS s.63 (successor to IPC s.375) defines rape by four act-types under seven circumstances, the capacity circumstances including consent given when, by reason of unsoundness of mind or intoxication, she is unable to understand the nature and consequences, being under eighteen, and being unable to communicate consent, with a marital exception where the wife is not under eighteen; s.64 punishes rape with rigorous imprisonment of not less than ten years, extendable to life, and fine.
CONSENT IN SEXUAL-OFFENCES LAW (BNS S.63, EXPLANATION 2)	Consent means an unequivocal voluntary agreement, communicated by words, gestures or any verbal or non-verbal communication, of willingness to the specific sexual act; a woman who does not physically resist is not, by that fact alone, to be regarded as consenting.
THE PENAL TRANSITION, SECTION 22 VERSUS SECTION 108 (THE CORRECTION)	The insanity defence is BNS s.22 (formerly IPC s.84); the burden of proving it is BSA s.108 (formerly IEA s.105); they are separate sections in separate codes, so section 105 BSA is not the successor to s.84; the penal code follows the offence date, procedure and evidence follow whether the matter was pending at the transition.
PROCEDURE FOR ASSESSING AN ACCUSED (BNSS S.367 TO S.369)	Where the accused appears of unsound mind and incapable of making his defence, the court shall first try that fact on medical and other evidence and postpone proceedings, at the inquiry stage (s.367) or at trial (s.368); s.369 governs disposal, release on bail where a relative undertakes out-patient treatment, else kept where regular psychiatric treatment can be provided, with the action reported to the State Government. Successors to CrPC s.328 to s.330.

ASK	HOLD
THE DYING DECLARATION (BSA S.26)	A statement by a person as to the cause of his death, or the circumstances of the transaction that resulted in it, is a relevant fact when the cause of that person's death comes into question, and is relevant whether or not the maker was, at the time, under expectation of death (successor to IEA s.32(1)).
COURT STRUCTURE (BNSS S.6)	Besides the High Courts, every State has Courts of Session, Judicial Magistrates of the first class, Judicial Magistrates of the second class and Executive Magistrates; the Supreme Court is the constitutional apex above them.
EXPERT-OPINION EVIDENCE (BSA S.39)	When the court has to form an opinion on a point of science, art, foreign law or any other field, the opinions of persons specially skilled in that field are relevant facts and such persons are called experts; Illustration (b) covers the question of unsoundness of mind (successor to IEA s.45).
SECLUSION AND RESTRAINT, THE LEGAL ASPECTS (MHCA S.97)	Seclusion and solitary confinement are absolutely prohibited; physical restraint may only be used when it is the only means available to prevent imminent and immediate harm and is authorised by the psychiatrist in charge, kept no longer than absolutely necessary, never as punishment or for staff shortage, the nominated representative informed within twenty-four hours and every instance reported monthly to the Board (the least-restrictive principle).

References

Every specific in this chapter is bound to one of the sources below, and the count is the number of claim rows each carried. The statutory and case-law rows were read at the primary Act on India Code, at the primary judgment on Indian Kanoon, or at the primary notification of the National Medical Commission and the Gazette of India, rather than from any textbook summary, because a stale or paraphrased section changes what a clinician is legally obliged to do. Three currency positions were read at their current form and are load-bearing for this chapter: the operative professional-conduct code is the Medical Council of India Regulations of 2002, because the National Medical Commission Registered Medical Practitioner Regulations of 2023 were notified and then held in abeyance, so the 2023 code is named as drafted but not yet in force; the substantive criminal law was read at the Bharatiya Nyaya Sanhita, the Bharatiya Nagarik Suraksha Sanhita and the Bharatiya Sakshya Adhiniyam, in force from the first of July 2024, with the Indian Penal Code, the Code of Criminal Procedure and the Indian Evidence Act named as the superseded predecessors; and the consumer-protection route was read at the 2019 Act, not the 1986 Act. Of the 61 claim rows, 58 are recorded at verified confidence and 3 at partial, the latter authored from established ethical and clinical knowledge and checked by the adversarial content pass rather than bound to a single primary quote; 14 further specifics were declared as gaps and taught around rather than supplied from memory. The must-have-papers cross-check was NOT performed for this Paper III chapter, because the paper lists do not yet exist in the intel index; for Paper III the topic

bank plus the syllabus scaffolding is the completeness authority. This table records provenance, not proof: it says where each specific came from, not that the chapter's prose uses it correctly, which the content pass and the ship review test.

PAPER III

ECT and neurostimulation

Six bands . one complete notes document

Orientation: the induced seizure and the stimulated brain

1 · Orientation: the induced seizure and the stimulated brain

Electroconvulsive therapy is the most effective acute treatment available in severe mood and catatonic states, and its price is measured in cognition. A brief electrical stimulus crosses the skull of an anaesthetised and relaxed patient, a generalised cerebral seizure follows, and an illness unshifted by weeks of drug treatment can shift within days. From that standing and that price follows everything the chapter teaches: what the treatment is for, how it is delivered, what it costs, and who may lawfully have it.

This opening section is the chapter's **advance organizer**. It asserts no specific of its own: no dose, charge, threshold multiple, percentage or session count appears, because each belongs to its owner. What it owns is the shape: the standing of the treatment, the sequence in which the chapter delivers it, the non-ECT techniques read against it, and the Indian legal frame. The accompanying figure lays the same architecture out visually.

Most effective	No single law	Modified only
THE STANDING OF THIS TREATMENT IN SEVERE MOOD AND CATATONIC STATES	THE TRADES DIFFER BY PARAMETER AND BY PLACEMENT, SO NONE IS INHERITED	THE INDIAN LEGAL FRAME THE WHOLE CHAPTER SITS INSIDE

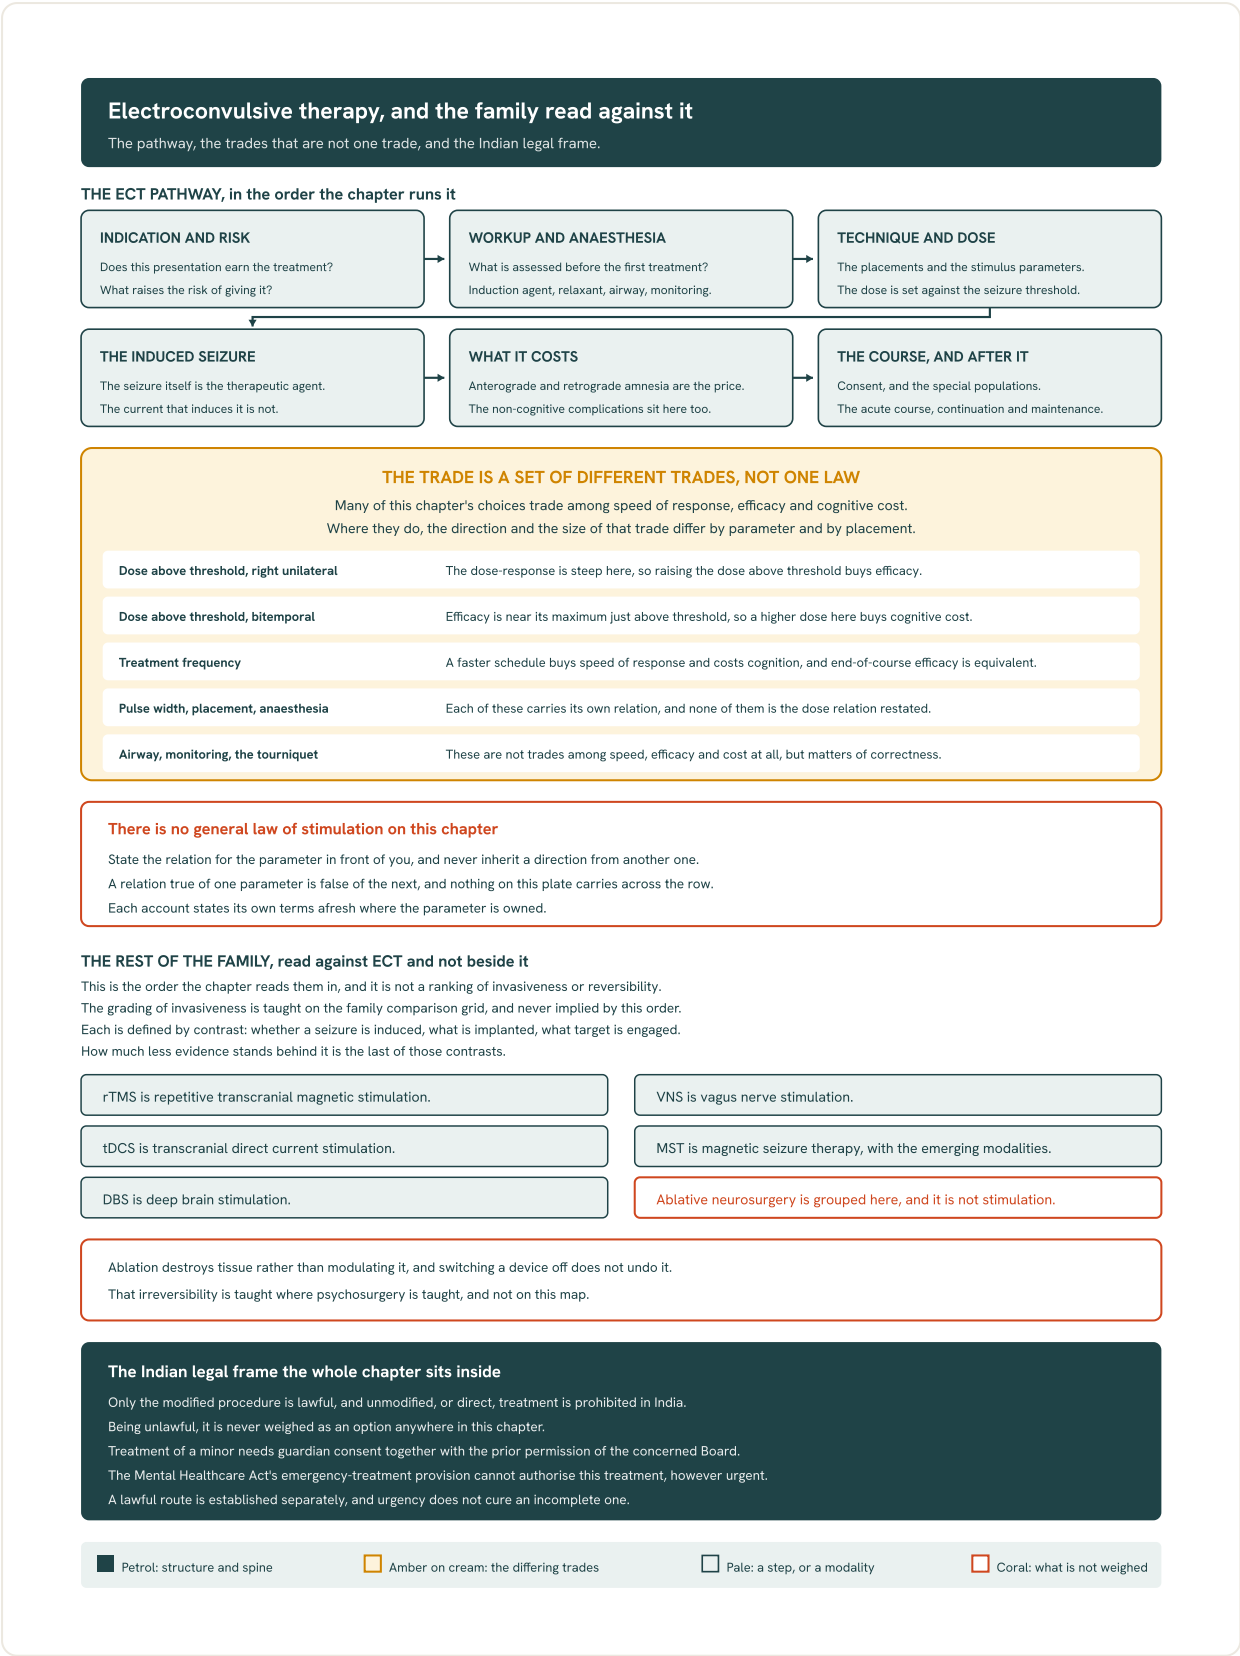

Fig 27.1. The chapter's architecture: the ECT pathway from indication through workup, technique, the induced seizure and its costs to the course and its maintenance; the trades that differ by parameter and by placement rather than following any single law; the rest of the neuromodulation family in a reading order that ranks nothing, with ablative neurosurgery grouped there but not stimulation; and the Indian legal frame the whole chapter sits inside.

1.1 What the treatment is, and where its power lies

The therapeutic agent is the **induced seizure**, not the current that induces it and not the convulsion once visible at the bedside. Modification abolishes the motor convulsion and leaves

the cerebral seizure untouched, so a treated patient lies still. Its power concentrates where illness is severe or immovable: severe depression, above all with psychotic features, food refusal or acute suicidal risk; catatonia, which responds better than almost anything in psychiatry responds to anything; acute and refractory mania; and defined presentations of schizophrenia, including the clozapine non-responder. The evidence under each belongs to the indications account.

The counterpart is a real and measurable effect on memory, and a smaller burden of non-cognitive complication, principally cardiovascular. Neither is a reason to withhold the treatment from a patient who needs it.

1.2 The structural fact the chapter turns on

Many of the choices in this chapter trade among speed of response, efficacy and cognitive cost, and where they do, the direction and the size of that trade differ by parameter and by placement. That is a structural fact, not a directional law. The chapter asserts no law covering all of these choices, because not every choice is such a trade at all: airway management, physiological monitoring and the tourniquet that isolates one limb from the relaxant are not purchases of efficacy at a cognitive price.

Its terms are stated afresh by the topic owning the parameter. The table below is not a rule but a demonstration that no rule applies across the row.

PARAMETER	WHAT THE RELATION ACTUALLY IS	STATED IN FULL BY
STIMULUS DOSE ABOVE THRESHOLD, RIGHT UNILATERAL PLACEMENT	The dose-response is steep, so raising the dose above the seizure threshold buys efficacy.	Stimulus dosing, and the placement comparison.
STIMULUS DOSE ABOVE THRESHOLD, BITEMPORAL PLACEMENT	Efficacy is already near-maximal at a low multiple of threshold, so a higher dose here largely buys cognitive cost alone.	The same accounts, stating it as differing by placement.
TREATMENT FREQUENCY	Buys speed of response and costs cognition. End-of-course efficacy is equivalent between the schedules, so a faster schedule is never listed among the choices that buy efficacy.	The acute course and its frequency.
PULSE WIDTH, ELECTRODE PLACEMENT, ANAESTHETIC CONDUCT	Each carries its own relation, none the dose relation restated.	Technique, and the workup and anaesthesia.
AIRWAY, MONITORING, THE TOURNIQUET	Not a trade among speed, efficacy and cognitive cost. Correctness, not currency.	The workup and anaesthesia.

RULE **State the relation for the parameter in front of you, and never inherit a general direction from a different parameter.** There is no general law of stimulation here. A sentence coupling how hard a treatment is made to work to what it costs in memory is never written on this chapter, however qualified, because a relation true of one parameter is false of the next, and the reader who carries it across will dose a patient on it.

MNEMONIC

DECIDE, DELIVER, LIVE WITH IT, LOOK OUTSIDE

Decide whether this patient should have the treatment at all. **Deliver** it: workup and anaesthesia, technique and dose, and the seizure that results. **Live with it**: what it costs, how consent is lawfully established, and how the course is sustained. **Look outside** to the non-ECT family, defined by contrast with what you have just read. Every section sits inside one of those movements.

1.3 The ECT pathway, in the order the chapter runs it

The ECT sections follow the sequence a resident moves through, and examiners ask about its joints.

- **Indication and risk.** Where the treatment came from and how it became modified; the competing accounts of how it works; the indications and their evidence; and the conditions that raise risk without barring it.
- **Workup and anaesthesia.** What is assessed before the first treatment, what is not routinely needed, and the anaesthetic conduct: induction agent, relaxant, airway and monitoring.
- **Technique and dose.** The placements and what distinguishes them; the parameters that define a stimulus; the threshold and the dose as a multiple of it; the placement comparison as a function of that multiple; and the modified procedure against the unmodified one.
- **The induced seizure.** What makes a seizure adequate, what to do when none follows, and what to do when one does not stop.
- **What it costs.** The anterograde and retrograde amnesias, how they are monitored and how they behave; and the non-cognitive complications.
- **The course, and life after it.** Consent as a lawful route; pregnancy, old age and adolescence; the acute course and its frequency; continuation and maintenance; and the drugs that move the threshold.

1.4 The rest of the family, read against ECT and not beside it

The chapter then reads the remaining modalities in this order: repetitive transcranial magnetic stimulation, transcranial direct current stimulation, deep brain stimulation, vagus nerve stimulation, magnetic seizure therapy with the emerging modalities, and ablative neurosurgery. That is a reading order and not a ranking of invasiveness or reversibility; the grading is taught on the comparison grid the cross-cutting synthesis owns.

Every device in this **neuromodulation** family is defined by contrast with what you have just read: whether a seizure is induced, what is implanted if anything, what target is engaged, and how

much less evidence stands behind it.

One member is not a member. The bank groups **ablative neurosurgery** with the stimulation modalities and this chapter follows it, but ablation is not stimulation. It destroys tissue rather than modulating it, and switching a device off does not undo it. That irreversibility is taught where psychosurgery is.

1.5 The Indian legal frame the whole chapter sits inside

A short list of statutory positions governs practice, each named in words, never renumbered. First, only the modified procedure is lawful. Unmodified, or direct, electroconvulsive therapy is prohibited in India. It is not the older technique, not the resource-limited compromise and not the weaker option: it is unlawful, and is never weighed as an option in this chapter. Second, treatment of a minor is gated: it requires guardian consent together with the prior permission of the concerned Board, sought in advance. Third, the Act's emergency-treatment provision cannot authorise this treatment, however urgent the clinical picture.

That third position is the trap most often examined. A patient can be in a state where the treatment is the correct and urgent answer while the emergency provision still cannot authorise it, so a **lawful route** is established separately and urgency does not cure an incomplete one. This is a point about treatment authority and not admission authority: a capacitous adult can consent to this treatment with no admission at all.

> **IN INDIA**
>
> The Indian frame is not a stricter version of a Western one but different in kind. A prohibition that elsewhere would be a professional standard is here a statutory bar, a treatment decision for a minor passes through a statutory body, and the urgency that would settle the question elsewhere settles nothing. Where a topic has an Indian answer, that is the answer.

1.6 The edges of the map: named here, taught elsewhere

An advance organizer is as much about what sits outside the frame as inside. Several bodies of material touched constantly here are owned by others, and are named rather than re-taught.

- Every Mental Healthcare Act provision touching this treatment and psychosurgery, the bar on the unmodified procedure, the minor's guardian-consent and Board-permission gate, the psychosurgery restriction and the emergency-treatment bar, belongs to the Mental health legislation and forensic psychiatry notes, each named here in words.
- The catatonia entity, the lorazepam challenge, malignant catatonia against neuroleptic malignant syndrome and the Bush-Francis rating belong to the Other psychotic disorders, delusional syndromes and catatonia notes.
- The mood-disorder algorithms, the staging of treatment resistance and the pharmacology of continued agents belong to the Mood disorders: pharmacotherapy notes.
- The schizophrenia resistance algorithm, clozapine and the antipsychotic adverse-effect burden belong to the Schizophrenia notes, which assign the clozapine-resistant evidence here.

Many of this chapter's choices trade among speed of response, efficacy and cognitive cost, and where they do the direction and size of that trade differ by parameter and by placement, so each account states its own relation; some are not such trades at all. It sits inside an Indian legal frame in which only the modified procedure is lawful, treatment of a minor is gated behind guardian consent and prior Board permission, and the emergency-treatment provision cannot authorise the treatment.

Electroconvulsive therapy: foundations and indications

2 · History and evolution of ECT

Electroconvulsive therapy is one of the few treatments in current psychiatric practice that was invented out of a therapeutic premise which was not borne out, fell into disrepute it had partly earned, and came back on evidence gathered decades later. It is also the shortest route to understanding the modern procedure: the anaesthetic, the relaxant, the monitored seizure and the documented consent were each added to answer a specific failure of what came before. Names and dates carry marks in this paper, so they are given with their attributions.

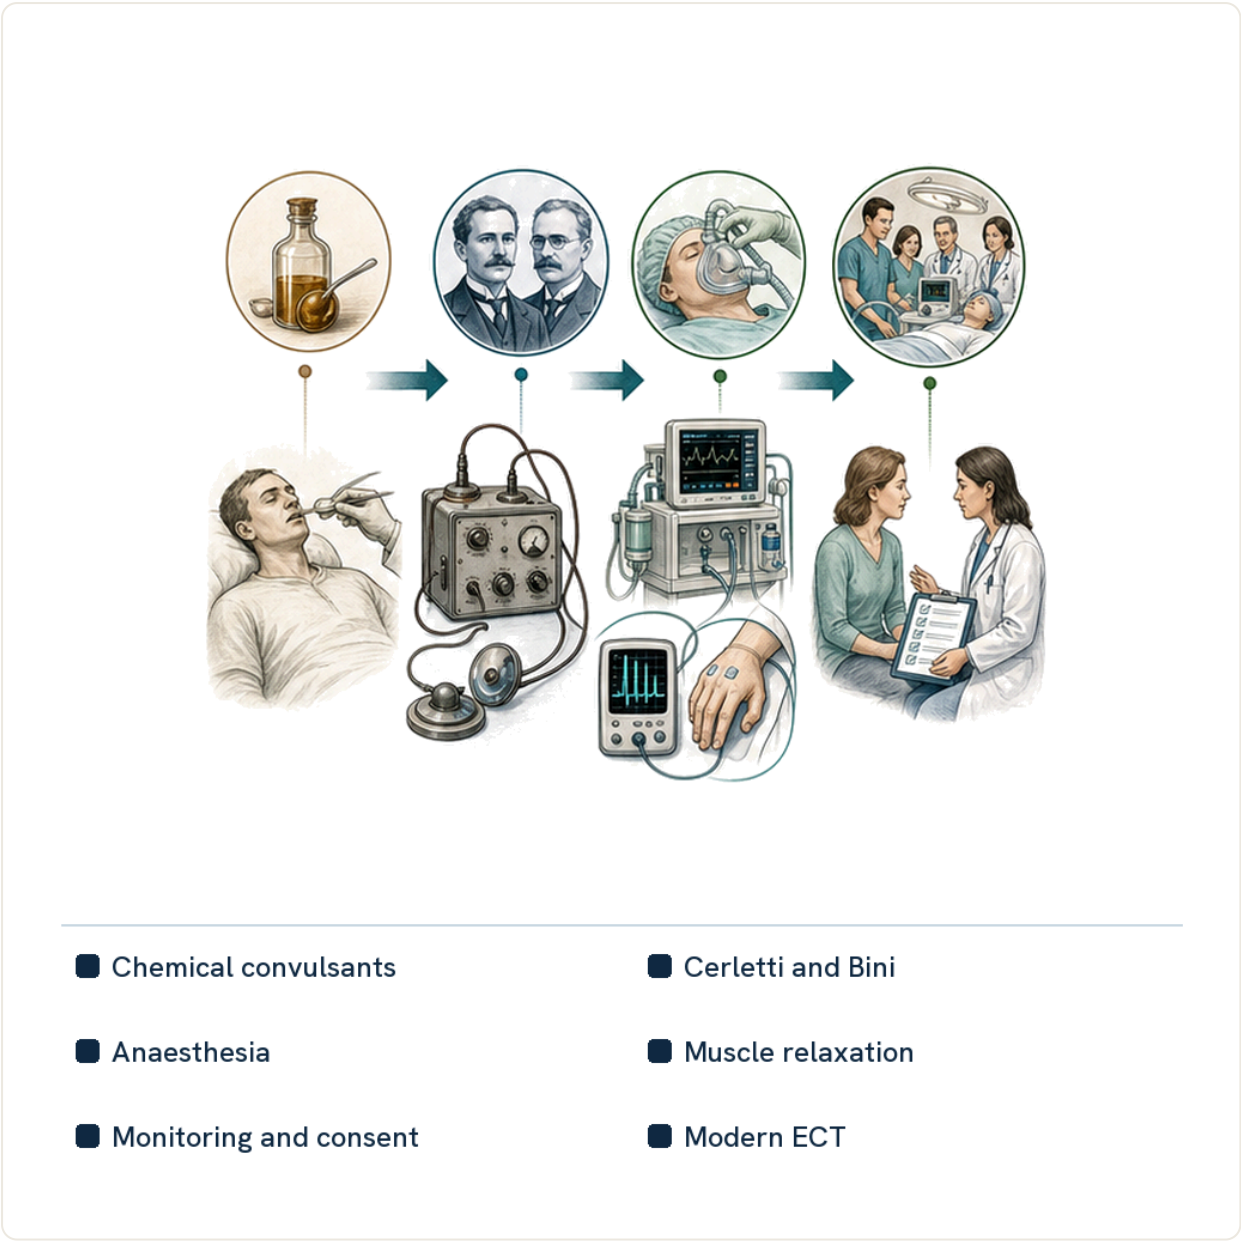

Fig 27.2 The evolution of electroconvulsive therapy runs from chemical convulsants and the work of Cerletti and Bini to anaesthesia, muscle relaxation, physiological monitoring and documented consent. Each addition answered a limitation of the earlier procedure.

This account owns the origin and evolution of convulsive therapy: the antagonism hypothesis, the chemical convulsants, Cerletti and Bini, the introduction of anaesthesia and muscle relaxation, the mid century decline, the modern reappraisal and the Indian arc. It does not teach why an induced seizure helps; the competing neurobiological theories, none of them settled, belong to this chapter's account of the mechanism of action and neurobiological theories of electroconvulsive therapy. It does not teach the technique contrast between modified and unmodified (direct) ECT, nor the Indian legal position on the unmodified form; both belong to this chapter's account of modified against unmodified (direct) ECT. It does not narrate the leucotomy story, which belongs to this chapter's account of psychosurgery, its history, current indications and ethics. Modern stimulus parameters and electrode placements appear nowhere in this account.

1934	1938	1943
THE FIRST DELIBERATE THERAPEUTIC CONVULSION IN A HUMAN BEING, PRODUCED CHEMICALLY	THE FIRST THERAPEUTIC SEIZURE INDUCED ELECTRICALLY, IN ROME	ELECTROCONVULSIVE THERAPY AT THE CENTRAL INSTITUTE OF PSYCHIATRY, RANCHI

2.1 The convulsion as a treatment, long before there was a device

Convulsive therapy is older than psychiatry's capacity to measure a convulsion, and a candidate who begins the story in the twentieth century has already misplaced it. Camphor given by mouth to induce convulsions and cure lunacy is attributed to the Swiss alchemist Paracelsus in the sixteenth century, and convulsions induced by chemical means, specifically camphor in oil, are documented in the eighteenth and nineteenth centuries. The idea that a seizure could relieve mental illness was inherited, not invented; what the twentieth century added was the deliberate production of one, in a named patient, for a named condition, on a stated rationale. That rationale is where the modern history begins, and it is where it first goes wrong.

2.2 Meduna and the schizophrenia and epilepsy antagonism hypothesis

In 1934 Ladislaw Meduna, a Hungarian psychiatrist, investigated a hypothetical inverse relationship between seizures and schizophrenia, drawing on neuropathological studies and on a review of a century of earlier work, and postulated a relationship between a lack of glial cells in people with schizophrenia and an overgrowth of those cells in people with epilepsy. The forename is written Ladislaw because that is how the source quoted here spells it; two other peer reviewed histories write Ladislas von Meduna, which is the form to expect in an answer, and the difference is a transliteration rather than a different person. This is the **schizophrenia and epilepsy antagonism hypothesis**, the founding premise of the entire treatment family this chapter teaches.

It did not rest on neuropathology alone. A dedicated history of the treatment in schizophrenia attributes to Gyula Nyiro, in 1929, the clinical observation from which the antagonism hypothesis followed. Different histories state what Nyiro actually reported in different ways, so the observation is attributed here without asserting any one version of its content.

The therapeutic premise was not borne out, and the two things that happened to it should be kept apart. Meduna's original theory of an antagonism between epilepsy and schizophrenia has been replaced by hypotheses about the mechanism of action of the treatment. Replaced is what the source says, and it is not the same as disproved: the same paper adds that subsequent research could not confirm the antagonism hypothesis, which is a failure to confirm rather than a refutation, and a 2022 position still argues the biological question is open on shared genetic and network findings. So the premise stopped being the reason to give the treatment, while whether epilepsy and schizophrenia stand in any antagonistic relation at all remains unsettled. Those hypotheses, none presented as settled, belong to this chapter's account of the mechanism of action and neurobiological theories of electroconvulsive therapy.

RULE **The hypothesis that produced convulsive therapy was mistaken, and that does not make the treatment mistaken.** Whether a treatment works is settled by trials of it; why it works is a question about mechanism; and the accuracy of the guess that led somebody to try it bears on neither. Convulsive therapy is psychiatry's cleanest example of a wrong reason producing a right treatment, which is why the origin story is worth knowing rather than skipping.

2.3 The chemical era, and why it ended

Meduna moved from hypothesis to patient quickly. The eightieth anniversary review dates the first human experiment, involving intramuscular camphor injections, to 2 January 1934; other histories give the day differently, and one dates the first camphor injections to the November of the preceding year, so not even the year is undisputed and that winter, rather than a day or a year, is the honest unit. Attribute the date rather than asserting it, and note that any interval measured from the start of this work inherits the same disagreement. Camphor in oil was injected into a patient with catatonic schizophrenia, causing a 60 second grand mal seizure; the patient recovered fully after a short series of such treatments, and five more patients were treated by the end of that year. Catatonia was therefore present at the origin of the treatment and remains among its strongest indications, taught in this chapter's account of the indications for electroconvulsive therapy.

Camphor was not the agent that carried the era. After about two months the intramuscular camphor injections were replaced by pentylenetetrazol, better known as **cardiazol** and marketed elsewhere as metrazol, which was less painful and had a lower latency of seizure induction. The chemical era ended for a reason a candidate should be able to state in one clause: the interval between the injection and the seizure remained unpredictable and frightening for the patient, and it is that latency which sent Cerletti looking for an electrical alternative. Electricity did not offer a better seizure. It offered a seizure whose timing the operator controlled.

2.4 Cerletti and Bini, Rome, 1938

Ugo Cerletti and Lucio Bini performed the first electrical induction of a seizure in a psychotic patient in Rome in April 1938, after animal studies in which they defined the parameters of an electrical stimulus they judged safe. The animal work is not decoration; it is the reason the pair could argue the stimulus was survivable before applying it to a person. One history dates the first stimulation to 11 April 1938, records that it did not produce an epileptic seizure, and dates a tonic clonic seizure at a higher voltage to 20 April. The year is agreed by every source opened for this chapter; the exact date is not, a useful marker that historical detail drifts where the substance does not.

The drift is visible in the patient too. A second independent history gives the same month and year and describes the patient as a 39 year old man treated at the Clinic for Mental and Nervous Diseases in Rome. The two accounts differ on how he came to the clinic. The discovery was reported publicly in August 1939, at the Third International Neurological Congress in Copenhagen, by Professor Lucio Bini, and that record is also the reason to write the forename as Lucio, since at least one contemporary peer reviewed source writes Luigi.

The stimulus of that first treatment is worth carrying for one reason only, which is contrast. It is recorded that no anaesthesia was used and that a first shock was delivered at 80 volts for one tenth of a second. Those are historical figures from the first treatment ever given, and they describe no device in use anywhere today. What happened after that first shock is deliberately not printed: the sources disagree not only on the DAY of these events but on their STRUCTURE, one account giving a failed attempt followed by a seizure some days later and another a single session of escalating shocks, and the number and escalation of the shocks lie in sentences no row here quotes. Both disagreements are declared as gaps rather than resolved into a sequence neither source describes.

TRAP **Quoting the figures of the first treatment as though they described a modern stimulus.** They record what was applied in Rome before anaesthesia, muscle relaxation, brief pulse waveforms, seizure monitoring or dosing against a measured threshold existed. Everything a candidate is examined on regarding the modern stimulus belongs to this chapter's accounts of electroconvulsive therapy technique and electrode placement and of stimulus dosing, the seizure threshold and adequate seizure criteria. A history figure written into a technique answer is a wrong answer, not an erudite one.

2.5 The modification: a relaxant first, then anaesthesia

What separates the treatment of 1938 from the treatment given today is not the electricity but what is given alongside it. Curare came first, introduced to stop the fracture and dislocation injuries of the unmodified convulsion, and muscle relaxation and anaesthesia were both in place by the early 1950s. Sources differ on the precise years, so the decade is the honest unit and a false precision is worse than none. The result is the treatment current Indian guidance defines: **modified ECT** is the modern form of electroconvulsive therapy in which the electrical stimulus is given under general anaesthesia and muscle relaxation.

This account stops there. How the modified and **unmodified (direct)** techniques differ in injury and in patient experience, and why the unmodified form was historically used, belong to this chapter's account of modified against unmodified (direct) ECT, as does the settled Indian position that the unmodified form is unlawful, its prohibition sitting in the Mental health legislation and forensic psychiatry notes' provision on treatment without anaesthesia and muscle relaxants. Here the unmodified technique is a historical stage and nothing else. The anaesthetic agents and the relaxant themselves belong to this chapter's account of the pre-ECT workup and anaesthesia.

AXIS	CHEMICAL CONVULSIVE THERAPY	THE FIRST ELECTRICAL ERA	MODIFIED ECT
BEGAN	1934	1938	the early 1950s
HOW THE CONVULSION WAS PRODUCED	Camphor by injection, then pentylenetetrazol	An electrical stimulus applied to the scalp	An electrical stimulus applied to the scalp
GIVEN ALONGSIDE	Nothing	No anaesthesia	General anaesthesia and muscle relaxation
WHAT FORCED THE NEXT STEP	An unpredictable and frightening latency to the seizure	Fracture and dislocation injuries of the convulsion	The current form
STATUS TODAY	Abandoned	Historical only, and unlawful in India	The standard technique

2.6 The mid century decline, and how much of it was earned

The decline is the part of this history a candidate is most often asked to explain, and the honest explanation has an earned half and an unearned half. The earned half is stated best by the American national consensus statement, in its own words. In the United States in the 1940s and 1950s the treatment was often given to the most severely disturbed patients in large mental institutions; as often occurs with new therapies it was used for a variety of disorders, frequently in high doses and for long periods; many of those efforts proved ineffective and some even harmful; and its use as a means of managing unruly patients, for whom other treatments were not then available, contributed to the perception of an abusive instrument of behavioural control.

Some of the disrepute attaches to identifiable practices, and naming them is the honest way to teach this. In **regressive ECT**, sessions were performed several times a day until the deliberate onset of an acute brain syndrome, with memory loss, confusion, disorientation, apathy and dysarthria. That was the point of the technique, not its complication. It is abandoned, and it is the sharpest available contrast with a modern course, taught in this chapter's account of the course, frequency and number of sessions.

The unearned half is that the fall in use ran well past the abuses that provoked it. Three forces drove the decline together: effective psychopharmacological medication arriving from 1952, the development of judicial and regulatory restriction, and public protest. Use was widespread during the 1950s and 1960s, with approximately 300,000 people a year receiving the treatment in the United States, dwindled significantly during the 1970s and early 1980s under the ascendancy of pharmacological approaches and increased public protest, and recovered in the late 1980s and 1990s once it became apparent that medication was not a panacea. Those figures are United States figures and must be labelled as such; no Indian utilisation figure is carried in this account.

Attitude, not evidence, did much of the work. Negative media portrayal and the earlier misuse contributed to the negative professional and public perceptions that attitude surveys record repeatedly, and that attitude has played an important role in decreasing use of the treatment in the developed world and in reducing access to it, which constitutes a violation of psychiatric

patients' right to an effective treatment. A candidate who can say that last clause out loud has understood why the history is taught at all.

2.7 The evidence led reappraisal, and why it is not finished

The turn back towards evidence has a datable institutional marker. Because research had intensified on effectiveness, indications, mechanism, adverse effects and optimum technique while remaining outside the mainstream of mental health research, the National Institutes of Health, together with the National Institute of Mental Health, convened a Consensus Development Conference on Electroconvulsive Therapy from 10 to 12 June 1985. That conference is where the treatment stopped being defended by assertion and started being assessed in public against data.

The evidence anchor came later. The 2003 systematic review and meta-analysis of electroconvulsive therapy in depressive disorders concluded that it is an effective short term treatment for depression, and probably more effective than drug therapy. This account carries the milestone only; the magnitudes and the cognitive costs belong to the items that own them.

The story has not closed. Despite that evidence base, global trends show a paradoxical decline in utilisation across the United States, Europe and Italy itself, where the procedure originated. The history therefore lands in the present rather than in an archive: the gap between what the evidence supports and what services deliver is the live problem, which is why stigma belongs in a clinical chapter at all.

2.8 The Indian arc

India did not receive this treatment late, and an Indian candidate should be able to say so with a date. The Central Institute of Psychiatry, Ranchi, was one of the first centres outside Europe to start cardiazol induced seizure treatment, in 1938, and electroconvulsive therapy in 1943. Two things follow:

- cardiazol treatment began at Ranchi in the same year as the first electrical induction in Rome;
- India took up the chemical era and not only the electrical one, so the Indian story has the same phases as the international one.

A second institution corroborates the decade without fixing a year. An institutional history of the Government Mental Hospital, Madras, places the arrival of electroconvulsive therapy and of insulin coma therapy, including modified insulin coma therapy, in the years 1939 to 1948, and attributes the lag to the emergence of the Second World War, which held over changes that were long overdue. This is why the Ranchi record carries the date here and the Madras record the corroboration.

What followed was not passive adoption. Over the past five decades Indian research on electroconvulsive therapy has produced more than 250 publications, with a notable increase following the 1989 national workshop. The country has been a producer of the evidence base it applies, and the workshop is the turning point a candidate can name.

MNEMONIC

CAMPHOR, CARDIAZOL, CERLETTI, CURARE, CRITICISM, CONSENSUS

The arc in order. **Camphor**, the first deliberate therapeutic convulsion, on a mistaken premise. **Cardiazol**, whose unpredictable latency ended the chemical era. **Cerletti**, with Bini, the first electrical induction. **Curare**, the relaxant that began the modification anaesthesia completed. **Criticism**, the mid century decline. **Consensus**, the evidence led reappraisal that has still not restored utilisation.

Convulsive therapy began from a false premise about antagonism between epilepsy and schizophrenia, was produced first chemically by Meduna and then electrically by Cerletti and Bini in Rome, and became the modern procedure only when a muscle relaxant and then general anaesthesia were added by the early 1950s; it fell out of use for reasons partly earned by overuse and practices such as regressive ECT, partly imposed by new drugs, regulation, protest and stigma; and the reappraisal that followed left an evidence base strong enough to expose a decline in use that continues in spite of it. India entered the story at the beginning, at Ranchi, and has generated evidence about the treatment ever since.

3 · Mechanism of action and neurobiological theories of ECT

Electroconvulsive therapy is among the most effective treatments in psychiatry, and nobody has established how it works. That is the state of the evidence, not a gap in the resident's reading, and the field says so: a review of the neurobiology concludes that the cause and effect relationship between the findings and the therapeutic effects could not be established with absolute certainty, and it is not very prudent to assume a single mechanism that can explain the therapeutic effect. The examinable answer is therefore not a mechanism but a set of competing accounts, each with the observations behind it and the observation it cannot reach, none promoted to a fact.

Owned here in full: why the induced seizure helps, across the anticonvulsant and seizure-threshold, neuroendocrine and hypothalamic, monoamine and receptor-sensitivity, neurotrophic and neuroplastic, and network and connectivity accounts. Named and not re-derived, each with its own account in this chapter: the seizure threshold and how the stimulus is set against it; the placements; the cognitive adverse effects; the indications outside depression; and magnetic seizure induction. The division is strict: the seizure appears here only as a candidate therapeutic mechanism, never as a dosed event.

five	unclear	62 patients
COMPETING ACCOUNTS, OF WHICH THE NETWORK ACCOUNT IS THE NEWEST	THE EXACT NEUROBIOLOGICAL MECHANISMS, IN A REVIEW'S OWN WORD	IN THE TITRATION STUDY THAT SPLIT THE ANTICONVULSANT EFFECT FROM RESPONSE

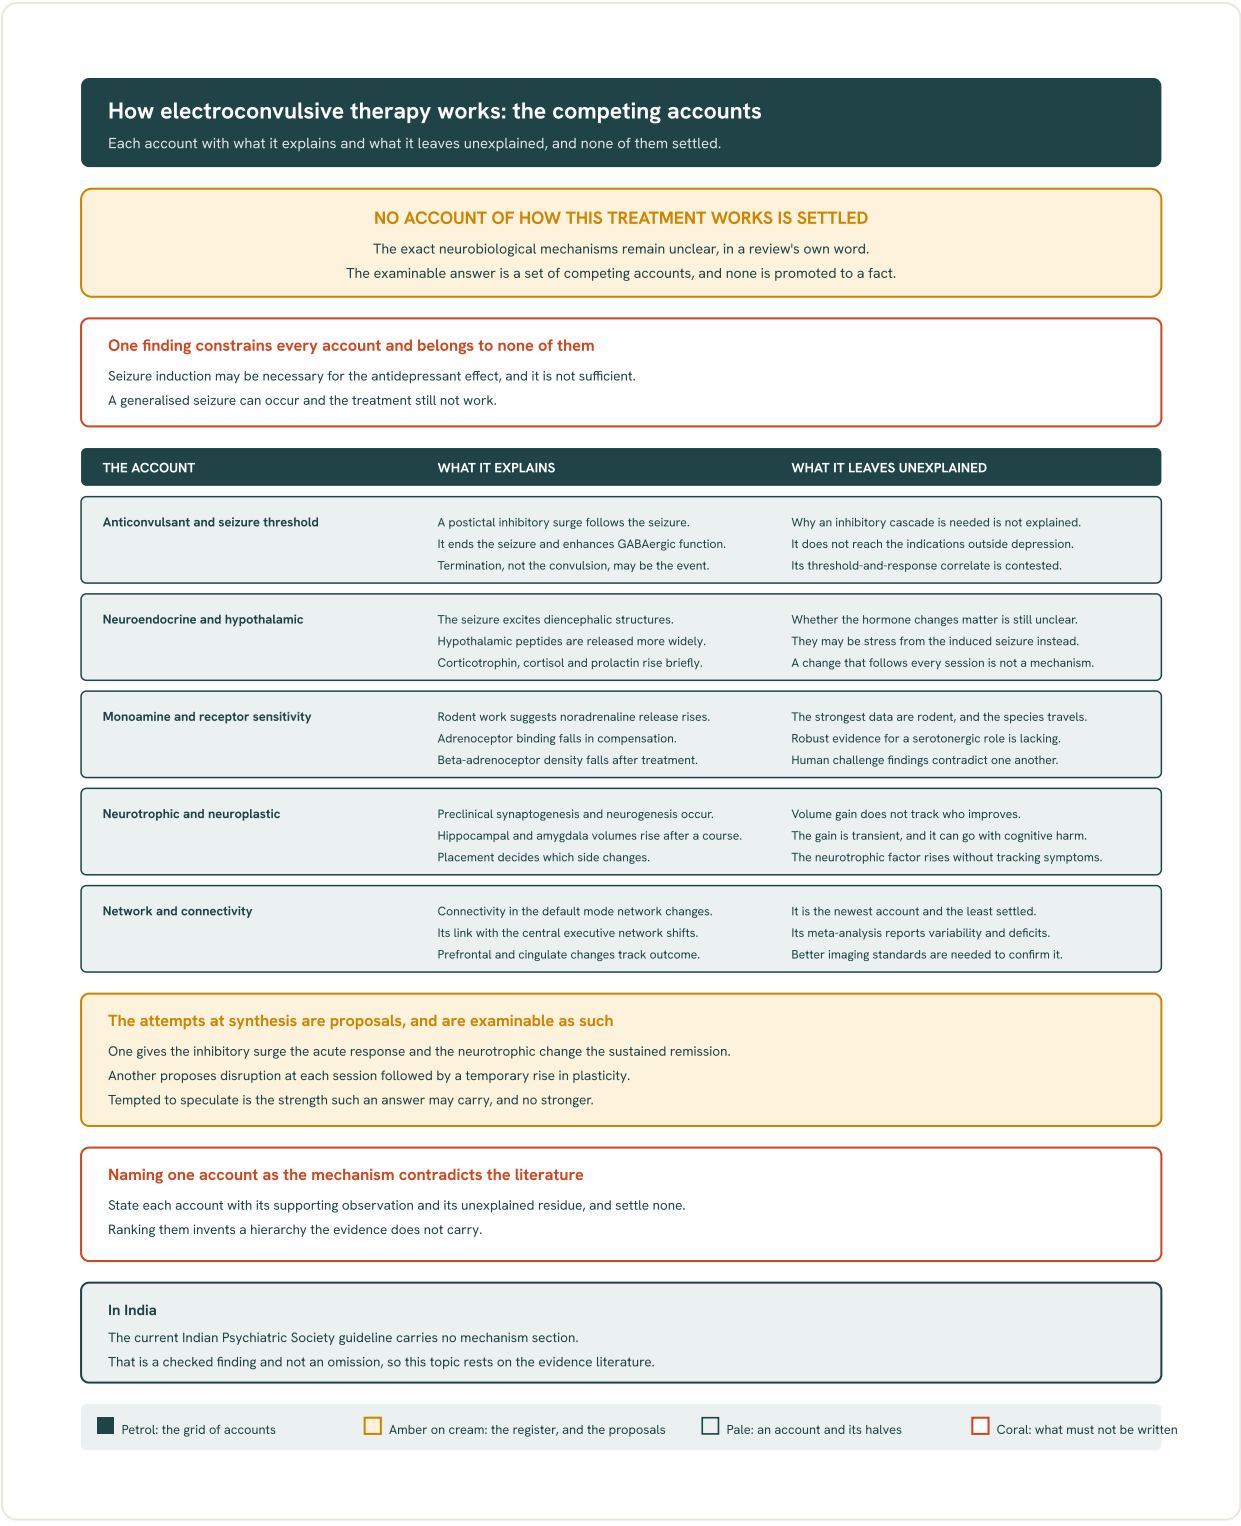

Fig 27.3. The competing neurobiological accounts of how electroconvulsive therapy works, each set beside the observation that supports it and the residue it leaves unexplained, with the finding that seizure induction may be necessary and is not sufficient constraining all of them, the attempts at synthesis stated as proposals, and no account marked as settled.

3.1 The register this topic is written in

The confidence available to every account is fixed first: the commonest error is not naming the wrong theory but naming a real one in the wrong voice. An independent review reaches the same place: the exact neurobiological mechanisms underlying the efficacy of the treatment remain unclear. A candidate who writes that the mechanism of action is the anticonvulsant hypothesis has contradicted the literature, whatever else the answer contains.

One structural finding constrains every account and belongs to none of them. Seizures induced by low-dose right unilateral stimulation lacked antidepressant efficacy, so seizure induction may be necessary but insufficient for antidepressant effects. A generalised seizure occurred and the treatment did not work. Any account that treats the bare occurrence of a seizure as the therapeutic event is under-determined, and the question becomes what kind of seizure, where it began and what followed it. The dose that makes right unilateral stimulation effective, and the placement comparison, belong to this chapter's accounts of stimulus dosing and of the placements.

RULE **State each account with its supporting observation and its unexplained residue, and settle none of them.** These accounts describe changes at different levels of organisation and on different timescales, and several may be describing parts of one process without any having been shown to cause the benefit. Ranking them invents a hierarchy the evidence does not carry.

IN INDIA

There is no Indian guideline position to quote here, and that is a checked finding, not an omission. The current Indian Psychiatric Society clinical practice guideline for electroconvulsive therapy declares its aim as enabling consistent, safe and effective practice in applicable psychiatric disorders; its full text carries no mechanism section and no neurobiological hypothesis, and every hit on the word anticonvulsant is pharmacological. Current Indian guidance controls Indian practice questions; on mechanism it has nothing to control, so this topic rests on the evidence literature.

3.2 The anticonvulsant hypothesis, stated as the hypothesis

The **anticonvulsant hypothesis** is a claim about therapeutic action and must be learnt in that form. It contends that the antidepressant effect is mediated by a postictal inhibitory surge in regions of the prefrontal cortex, which both terminates the immediate seizure and enhances GABAergic function. It derives from the GABA deficit model of affective disorders, so it is a hypothesis about inhibition rather than convulsion.

So read, it explains two things nothing else here explains as neatly: why the therapeutic event might be the **postictal inhibitory surge** and the seizure's termination rather than the convulsion, and why a stimulus initiating seizure activity in prefrontal regions might work when one initiating in motor cortex does not. The word throughout is might.

TRAP **Writing "the anticonvulsant hypothesis is that the rise in seizure threshold across a course correlates with clinical response" as the definition.** That states a contested empirical correlate and calls it a definition, in the one topic where nothing may be presented as settled. The hypothesis is the postictal inhibitory account above; the correlate is a separate observation, taught next, and disputed by the literature of the people who proposed it.

3.3 The contested correlate: does the rise in threshold track response

Across a course the seizure threshold tends to rise, though not in every patient, and the exception matters here because the argument below is built on the size of the rise. That rise, its magnitude

and its clinical consequences belong to this chapter's account of stimulus dosing, the seizure threshold and adequate seizure criteria, and are not restated. What belongs here is the mechanistic question laid on top of it: if the treatment works by being anticonvulsant, the size of the anticonvulsant effect ought to predict who improves. Two literatures answer differently.

AXIS	POSITION A: THE RISE TRACKS OUTCOME	POSITION B: IT DOES NOT
THE CLAIM	The magnitude of the change in seizure threshold over the course is associated with therapeutic outcome, particularly with right unilateral treatment, in the review that advanced the hypothesis	No relation between the rise in threshold and either therapeutic response status or speed of response, in a prospective titration study of 62 depressed patients
ITS AUTHORS' CAVEAT	Evidence associating the anticonvulsant and antidepressant effects has accrued, but critical experiments augmenting and blocking the anticonvulsant action in relation to efficacy should still be conducted	The same study confirms the anticonvulsant effect and concludes only that it is not tightly coupled to therapeutic efficacy
STANDING NOW	Subsequent investigations have not replicated key findings of the anticonvulsant hypothesis, and studies have failed to reproduce the correlation between seizure threshold increases and antidepressant response	

Position B is the more useful record, because it separates what a careless answer welds together: the anticonvulsant effect is real and was confirmed in the same study that refused the correlation, while the coupling of that effect to who improves is what was not found. Two further lines of negative evidence sit beside the failed replications, both at review level: spectroscopy studies of GABA concentration report either no change or increases unrelated to antidepressant outcome, and a study of plasma neuroactive steroids that modulate GABA receptor function found no change. That is what makes the correlate contested rather than merely old.

3.4 What the anticonvulsant account does not explain

Two conceptual limits come from the same review that recorded the failed replications. The account does not provide a rationale for why an inhibitory cascade should be necessary for antidepressant response, and it does not account for the treatment's efficacy in psychiatric disorders other than major depression. The second limb is load-bearing: the indications taught in this chapter's account of the indications and the evidence base include catatonia, mania and treatment-resistant schizophrenia, and a mechanism framed wholly as an antidepressant mechanism cannot carry them. Offering it as the mechanism offers a mechanism for one indication only, which is why the plural in theories is not a hedge.

3.5 The neuroendocrine and hypothalamic hypotheses

The **neuroendocrine hypothesis** is the oldest formal account here, best quoted in its originating form. Its authors postulated in 1980 that the antidepressant efficacy of convulsive therapy results

from the increased release and more widespread cerebral distribution of hypothalamic peptides with behavioural effects. Its base was the observation that neuroendocrine abnormalities characterise endogenous depression and are reversed by convulsive therapy.

What it observes is well established and frequently examined. The treatment has been hypothesised to enhance release of hormones from the hypothalamus into cerebrospinal fluid and blood through excitation of diencephalic structures, and there is a transient and selective increase in secretion of adrenocorticotrophic hormone, cortisol and prolactin that returns to baseline in a few hours. The prolactin surge is the item most residents are asked about, and it is a genuine consequence of the induced seizure.

PITFALL

Offering the prolactin surge as the mechanism. The source that records it declines to: whether these changes in hormone levels have therapeutic implications, or are manifestations of stress related to the induced seizure and secondary to other changes in the brain, is still unclear, and it is not known how changes in hormone levels affect the amelioration of symptoms. A change that follows every treatment is evidence that the treatment was delivered; it becomes a mechanism only when shown to differ with clinical outcome, and that step has not been taken.

3.6 The monoamine and receptor-sensitivity accounts

The **receptor-sensitivity account** reads the treatment as an antidepressant of a familiar kind, acting on monoamine transmission and receptor sensitivity. Its strongest data are preclinical, and the species travels with the claim. Results from studies on rodents suggest that the therapeutic effect may be mediated through an increased release of noradrenaline, indicated by a compensatory reduction in alpha-2 adrenoceptor binding, most marked in frontal cortex regions connected to the amygdala and hippocampus. The classical companion is a controlled rodent experiment in which electroconvulsive shock produced down-regulation of both the cyclic AMP response and beta-adrenoceptor density in rat cortex. Human data in the same literature are observations rather than mechanisms: reduced dopamine transporter binding is reported in major depressive disorder, and a treatment series elevates cerebrospinal fluid metabolites of monoamine neurotransmitters.

The serotonergic limb is where answers most often overreach, and the source is blunt. Robust evidence for the direct involvement of the serotonergic system in electroconvulsive therapy is lacking at this point of time, and further research in this domain might throw light on its implications. The same source calls the rodent receptor-sensitivity data ambiguous and the human challenge findings contradictory. No receptor-subtype direction or binding figure is carried, because none is grounded well enough to print.

3.7 The neurotrophic and neuroplastic account

This is the account a resident is most likely to state as fact, and the one whose caveats are most explicit. **The neurogenesis hypothesis** holds that the therapeutic effects depend on increasing the number of neurons or the connections among neurons, on a preclinical base:

- synaptogenesis markers;
- granule cell and mossy fibre sprouting;
- newborn cells in the dentate gyrus;
- growth factor signalling including brain-derived neurotrophic factor.

One observation inside it speaks to the seizure's standing as the therapeutic agent, and the review draws the inference itself: epileptic seizures induce similar neurogenesis effects in the absence of electrical stimulation, so if neurogenesis drives efficacy, this argues for the seizure, and not the electric field, driving efficacy.

The human test has been indirect, through blood **brain-derived neurotrophic factor**. A systematic review and meta-analysis of the preclinical and clinical literature concluded that electroconvulsive stimulation in rodents and the treatment in humans increase concentrations of this factor, but this is not consistently associated with changes in behaviour; in its human pooling, plasma rose and serum did not. A later review summarised two recent meta-analyses as finding that the factor increases after treatment, but with considerable heterogeneity and no clear relationship between change in the factor and change in depressive symptoms, and across treatment-resistant depression interventions peripheral levels increased overall with no association with depressive symptoms, making peripheral measurements of the total factor inadequate predictors of treatment response. The newest meta-analysis explains the disagreement rather than resolving it: the anaesthetic used and the time the blood sample was taken greatly influence measured levels, and the biological matrix and specific methodological variables affect the measurement, reinforcing the need to standardise future studies.

The structural limb carries the most orderly finding and the sharpest caveat. The largest neuroimaging dataset on this treatment showed a highly significant dose-dependent effect on hippocampal volume scaling with the number of sessions, with lead placement determining laterality: bilateral stimulation changed both hippocampi similarly, while right unilateral stimulation acted more focally on the right. A meta-analysis of limbic structures agrees: both right and left hippocampal and amygdala volumes increased after treatment, and meta-regression found age, the percentage responding and the percentage in remission negatively associated with volume increase in the left hippocampus.

Then the caveat that governs the limb. In the same dataset greater enlargement went with worse outcome, and that negative relation lost significance once session number was controlled for, because non-responders received more sessions. Either reading refuses the assumption the field had carried: this represents a major deviation from the common assumption of a positive association between treatment-induced volume enlargement and clinical improvement, and gross volume increase of the hippocampus by itself is not a meaningful biomarker for positive therapeutic response. The authors' own word for it is epiphenomenon, and the meta-analysis reaches the same caution: the treatment increased brain volume in the limbic structures, and the clinical relevance of that increase needs further investigation.

The change also does not last: follow-up imaging at six months showed hippocampal volumes had decreased back to pre-treatment levels, and the change was unrelated to antidepressant or cognitive outcomes. And it does not run in one clinical direction: two studies have shown that increases in hippocampal volume with treatment correlated with adverse cognitive effects, the mechanism-side counterpart of this chapter's account of the cognitive adverse effects. A change that is real, orderly, reversible, unrelated to benefit and sometimes associated with harm is a poor candidate for what makes the treatment work.

3.8 The network and connectivity accounts

The **network and connectivity account** is the newest and least settled, and its observations are functional rather than structural. Whole-brain analysis revealed significant effects on functional connectivity in various networks, including the default mode network, the central executive network, the sensorimotor network and the cerebellar posterior lobe, with connectivity increased within the default mode network and between it and the central executive network, aligning with previous reports that the treatment can normalise the connectivity between them. Its outcome linkage is regional rather than global: specific prefrontal and cingulate connectivity changes have been linked to therapeutic outcomes.

Its meta-analysis states its limits before its findings. There was considerable variability as well as a few key deficits in the preprocessing and analysis of the neuroimages and in the reporting of results across the included studies. What it reports is bounded in the same breath: the brain regions noted are reasonably specific and distinguished and had significant changes in resting-state functional connectivity after a course for depression, and more studies with better neuroimaging standards should be conducted to confirm these results.

One trial supplies the dissociation that earns the account its place. Right hippocampal connectivity increased, or normalised, after the series and correlated with depressive symptom reduction, while the hippocampal subfields were unchanged relative to the comparison group. Read the second half precisely, because it is not a claim that the volumes stayed still: the subfield volumes rose but did not separate the patients from the comparison group, so what failed was the discrimination and not the change. Function moved with the illness where structure, having moved, did not distinguish anyone. The conclusion those authors drew carries its later fate with it: they suggested that increased hippocampal functional connectivity and volumes may be biomarkers for response, and the volume part of that suggestion is what the larger dataset above did not support.

3.9 Holding the accounts together without settling them

The attempts at synthesis are proposals, and are examinable as such. Abbott and colleagues argue for integrating the anticonvulsant and neurogenesis hypotheses, and the shape of the integration is temporal: they contend that a frontal inhibitory surge and subsequent reductions in metabolism and perfusion are key to an acute response, but that neurotrophic changes in the medial temporal lobes are required for sustained remission. That gives each account a phase rather than a verdict.

A second model runs the same logic across the whole course. In response to the disruptive effects of each session, the brain exhibits a temporary enhancement of neuroplasticity, leading to increased brain tissue volume and enhanced connectivity, and the combination of disruption and neuroplastic effects leads to a rewiring of neural circuits associated with depressive symptoms. Its own review reports it as a proposed model, and it is written here in that voice; its corollary about electric field dosing belongs to this chapter's accounts of stimulus dosing and of the placements.

The register the field chose for its own synthesis is worth copying. Integrating the evidence, one review writes that it is tempted to speculate that the treatment may have neuroplastic effects resulting in the modulation of connectivity between and among specific large-scale networks that are altered in depression. Tempted to speculate is the strength an answer may carry, and no stronger.

MNEMONIC

A NEW MAN NEEDS NETWORKS

Anticonvulsant, **NEW**roendocrine, **MAN**oamine, **NEE**urotrophic, **NETWORK**. A sound-alike, not an initialism; the order is the order in which they are taught here, not of date and not of merit. Note in particular that the anticonvulsant account heads the mnemonic while the neuroendocrine hypothesis is the oldest formal account carried on this page, so the sequence is not chronological.

No account of how electroconvulsive therapy works is established, and the field says so in its own words; the seizure may be necessary and is not sufficient; the anticonvulsant hypothesis is the postictal inhibitory account, not the disputed threshold-and-response correlate; the neuroendocrine rise, the rodent receptor changes, the neurotrophic factor and the hippocampal volume gain are real observations not shown to track benefit; and connectivity, the newest account, states its own methodological limits beside its findings, so the strongest register available is that of its reviewers, who were tempted to speculate.

4 · Indications for ECT (depression, mania, catatonia, schizophrenia, emergencies)

An indication for electroconvulsive therapy settles one question only, whether this presentation earns the treatment, and never the second, whether there is a lawful route to give it. The set is short and stable in outline across the major guidelines: severe depression, particularly with psychotic features, food refusal, stupor or acute suicidal risk; catatonia; acute and refractory mania; schizophrenia, where the sources openly disagree; and the psychiatric emergency, where urgency is highest and the statutory position most easily misread.

Owned here in full: why each indication earns ECT, its evidence, and the distinction between a clinical emergency and a statutory route. Named and not re-derived: the risk profile and the contested status of absolute contraindication; the acute course and its schedules; continuation and maintenance treatment; consent as it is taken in Indian practice, where the lawful routes are enumerated; and the special populations. The catatonia entity, its signs and aetiology, the lorazepam challenge, the malignant catatonia against neuroleptic malignant syndrome

differential and the structured rating scale belong to the Other psychotic disorders, delusional syndromes and catatonia notes. The mood ladders are the Mood disorders: pharmacotherapy notes'; the resistance algorithm and clozapine itself the Schizophrenia: management, antipsychotics and adverse effects notes'.

0.91	80 to 100%	Grade B
EFFECT SIZE FAVOURING REAL OVER SIMULATED ECT IN DEPRESSION	RESPONSE ACROSS THE CATATONIA SERIES, THE STRONGEST INDICATION HERE	THE BEST GRADE ANY CLOZAPINE AUGMENTATION STRATEGY REACHES

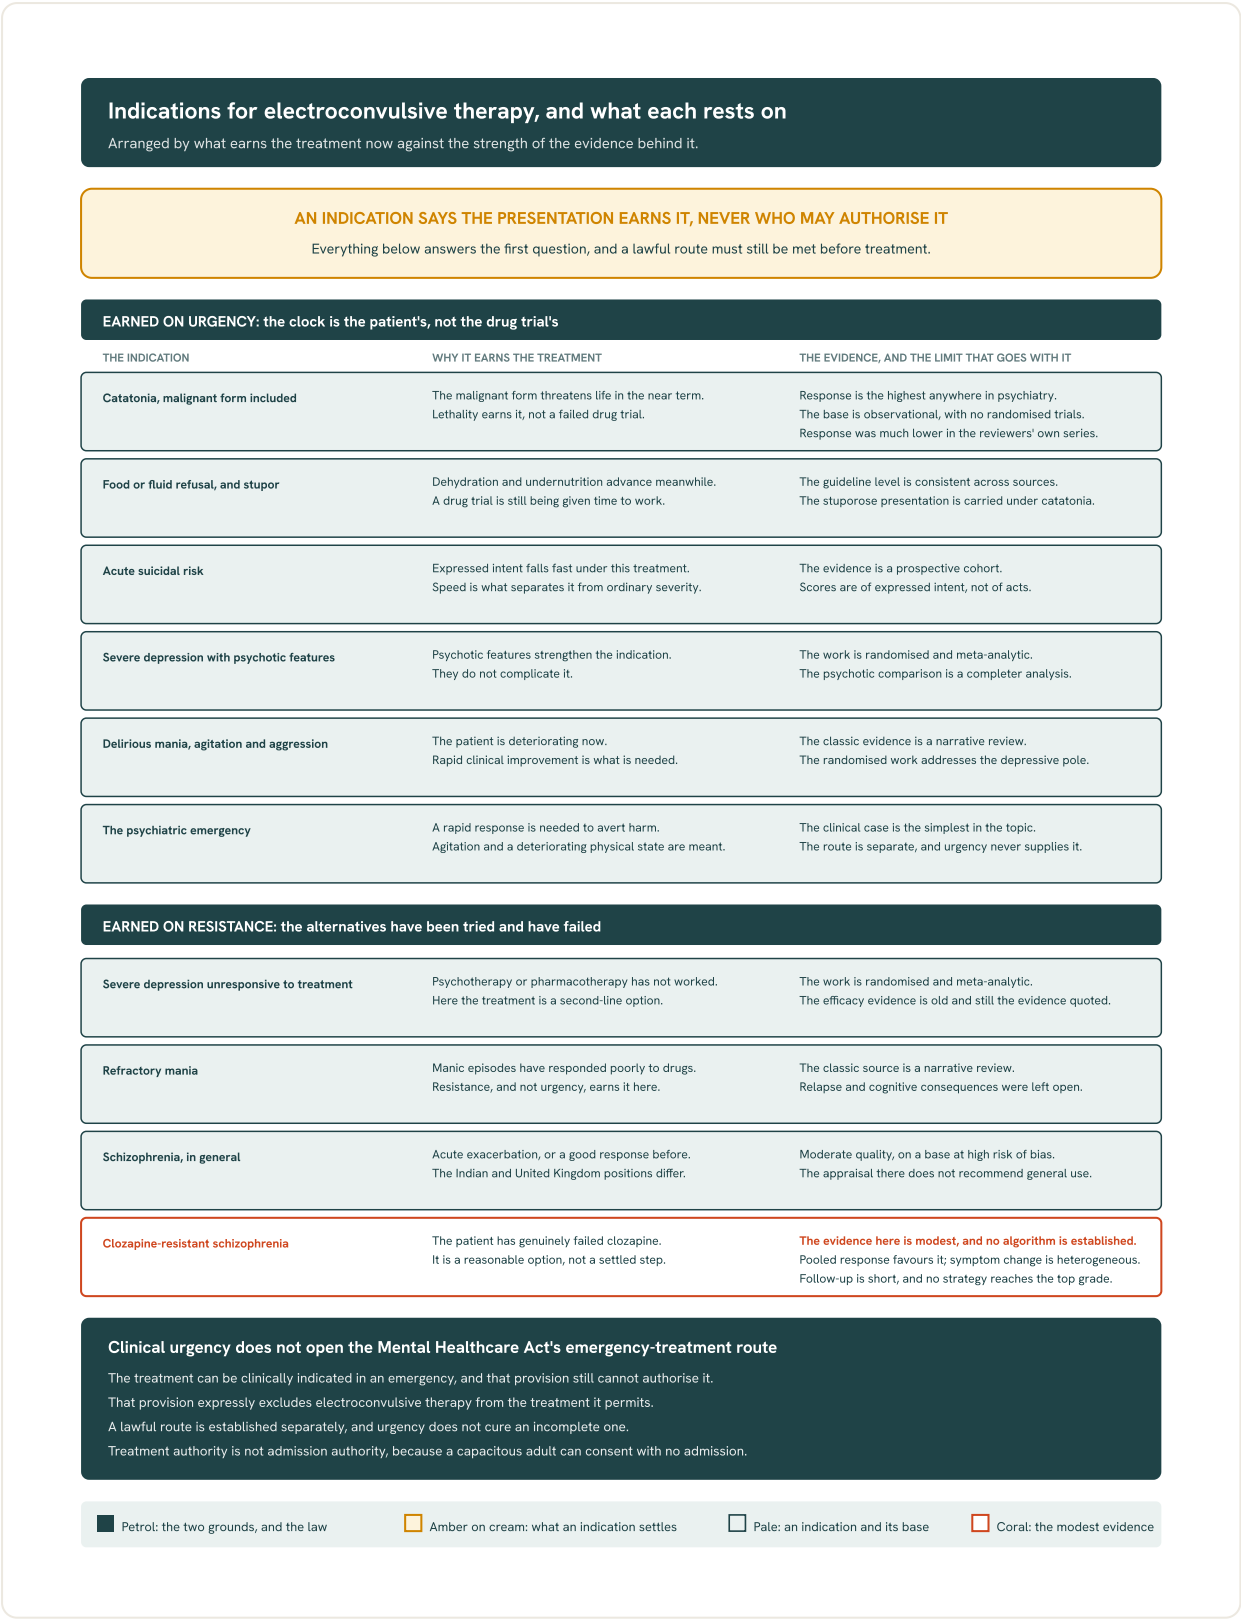

Fig 27.4. The indications for electroconvulsive therapy set out by what earns the treatment now against the strength of the evidence behind each: catatonia, food or fluid refusal, acute suicidal risk, psychotic depression, delirious mania and the psychiatric emergency on urgency; unresponsive depression, refractory mania, schizophrenia and the clozapine-resistant patient on resistance, that last one modest and with no established algorithm; and, along the foot, the statutory point that clinical urgency does not open the emergency-treatment route.

4.1 What an indication settles, and what it leaves open

An **indication** is a clinical judgment that a presentation is of the kind ECT treats and that benefit against risk favours giving it. It is not an authority to treat. Everything below answers the

first question; the second belongs to this chapter's account of consent, and the statutory provisions it turns on are named in words here and numbered only in the Mental health legislation and forensic psychiatry notes.

Weight the guideline before leaning on it. The current Indian Psychiatric Society guideline controls Indian practice questions, and records its own method: it was prepared by a consensus-based recommendation method, no formal systematic literature search was conducted, and it states in terms that it is a guidance document for practitioners rather than a directive or mandatory instruction. Where an effect size is at stake the number therefore comes from the trial, and the guideline carries the practice position.

RULE **An indication says the presentation earns ECT; it never says who may authorise it.** Each must still meet a lawful route before a treatment is given, and a strong answer to one question is no answer to the other.

4.2 Severe depression: food refusal, stupor and acute suicidal risk

Depression carries the strongest evidence, and within it one group of features moves ECT from a later option to a first one. A peer-reviewed review of the guideline position states it in a sentence: most guidelines recommend ECT as the first-line treatment for a severe depressive episode with psychotic features, catatonia, high suicide risk, or food or fluid refusal, and as a second-line treatment for a severe episode unresponsive to psychotherapeutic or pharmacological intervention. **Food refusal** earns its place because it puts a physiological clock on the decision: dehydration and undernutrition advance while a drug trial is still being given time to work. The Indian guideline's wording for it is poor oral intake, and its Table 1 depression rows read poor oral intake, high suicidal risk, a high level of distress requiring rapid symptom remission, psychotic features, melancholic features, peripartum depression, treatment resistance, and severe mixed affective features.

Depressive **stupor** needs care, because no source in this fragment's evidence list uses that term: both grounded statements carry it under catatonia, where a stuporose depressive presentation sits nosologically. It is written here as the catatonic pole of a severe depressive episode, immobility with failing intake being an indication on two grounds at once.

The efficacy evidence is old and still the evidence quoted, from the United Kingdom ECT Review Group's meta-analysis. Real ECT beat simulated ECT, 6 trials and 256 patients, standardised effect size minus 0.91 with a 95% confidence interval of minus 1.27 to minus 0.54. ECT beat pharmacotherapy, 18 trials and 1144 participants, standardised effect size minus 0.80 with a 95% confidence interval of minus 1.29 to minus 0.29. The negative sign is the direction of benefit, the effect being measured on depression scores.

Psychotic features strengthen the indication rather than complicate it, and that is measured. The collaborative remission study reported on 253 patients: remission among completers **87%** overall, **95%** in psychotic against **83%** in non-psychotic depression, with improvement more robust and appearing sooner in the psychotic patients. Those are completer rates, which the source says of itself.

Acute suicidal risk earns ECT on speed, which is what distinguishes it from ordinary severity. Expressed suicidal intent was scored before every session in 444 patients with unipolar depression: 131 patients, 29.5%, reported suicidal thoughts and acts at baseline, and the score fell to 0 after 1 week, or three treatments, in 38.2% of them, after 2 weeks, or six treatments, in 61.1%, and by the end of the course in 80.9%. The authors' conclusion is examinable: for a patient at risk, ECT should be considered earlier than at its conventional last-resort position.

TRAP **Quoting the NICE technology appraisal as current guidance for ECT in depression.** Its recommendations on depression were removed from that document and replaced by the depression guideline published in 2009, while its recommendations on catatonia, prolonged or severe manic episodes and schizophrenia did not change. It remains quotable for those and never for depression.

4.3 Catatonia: the strongest indication, on the weakest design

Catatonia earns ECT on two grounds worth keeping apart: response, better here than anywhere else in psychiatry, and mortality, since in the malignant form it is the near-term lethality of the presentation, not the failure of a drug trial, that earns the treatment. The guideline's catatonia rows carry that split, listing catatonia resistant to a benzodiazepine trial, a good response in past episodes, and malignant catatonia with a risk of imminent mortality.

A systematic review of ECT in catatonic patients reports **response rates ranging from 80% to 100%** across the retrospective observational studies, effective in all forms of catatonia including after benzodiazepines have failed, and above any other treatment in psychiatry. Inside the same review, a record review of 178 patients across 270 episodes used ECT alone in 55 patients, about 30%, resolving catatonic symptoms in 85%; where malignant catatonia was suspected, response was 89%, 9 of 11.

The counterweight comes from the same review. In the reviewers' own series ECT improved 59% of cases although pharmacotherapy had failed in 85% of the patients, attributed to a high prevalence of psychotic disorders, to ECT being reached only after two months of pharmacotherapy, to prior antipsychotic exposure, and to neurological comorbidity in one third. Both halves belong: the indication is the strongest on the list, and its design limit is the limit of its whole evidence base, these being observational series rather than randomised trials.

The boundary is exact in both directions. The entity, the lorazepam challenge, the differential against neuroleptic malignant syndrome and the structured rating scale are named here and taught in the Other psychotic disorders, delusional syndromes and catatonia notes. The technique stays on this chapter, split three ways: why the presentation earns ECT, which is this account; the stimulus dose, which is its dosing account; and the schedule, including the accelerated daily or initially twice-daily one used in life-threatening presentations, which is its account of the acute course. The assembled protocol for malignant catatonia has exactly one owner there, and no second copy is built here.

4.4 Mania, acute and refractory

The manic indication is not only about resistance. The Indian guideline's mania rows are a need for rapid clinical improvement, persisting or clinically significant agitation and aggression, treatment-resistant mania, severe mixed affective symptoms, and delirious mania. Some are urgency claims and some resistance claims, earning the treatment differently: agitation and delirious mania because the patient is deteriorating now, resistance because the alternatives have failed.

The classic evidence is a review of published experience over fifty years, which concluded that ECT is associated with remission or marked clinical improvement in 80% of manic patients and is effective for patients whose manic episodes have responded poorly to pharmacotherapy. Cite it for what it established, not as current practice: it is a narrative review rather than a meta-analysis, more than thirty years old, and its authors left relapse, cognitive consequences and the choice of placement for further study. Its observations on the seizure threshold in mania and on course length belong to this chapter's dosing and schedule accounts.

The modern randomised counterpart addresses the depressive pole, which is the trap here. A systematic review with exploratory meta-analysis of randomised trials in treatment-resistant bipolar disorder found ECT similarly effective for treatment-resistant bipolar depression as for treatment-resistant unipolar depression, odds ratio 0.919 with a 95% confidence interval of 0.44 to 1.917. It supports the refractory affective indication and says nothing about mania. The United Kingdom appraisal reaches mania from the other side, its surviving recommendation 1.1 permitting ECT only to achieve rapid and short-term improvement of severe symptoms after an adequate trial of other treatment options has proven ineffective, or where the condition is considered potentially life-threatening, in catatonia and in a prolonged or severe manic episode.

4.5 Schizophrenia, and the clozapine-resistant patient

Here two authoritative sources say different things, and the skill is to state both with their provenance rather than pick.

QUESTION	INDIAN PSYCHIATRIC SOCIETY GUIDELINE (2023)	NICE TECHNOLOGY APPRAISAL 59 (2003, UPDATED 2009)
SCHIZOPHRENIA IN GENERAL	Listed: acute psychosis requiring high-intensity management; acute exacerbations of positive psychotic or affective symptoms; good response in past exacerbations; postpartum psychosis	Recommendation 1.9: the current state of the evidence does not allow the general use of ECT in the management of schizophrenia to be recommended
RESISTANT AND CLOZAPINE-RESISTANT	Listed as treatment-resistant schizophrenia and as clozapine augmentation in clozapine-resistant schizophrenia	Not addressed by its terms; the statement is about general use

The randomised evidence for treatment-resistant schizophrenia is thinner than either position implies. The Cochrane review pooled 15 studies and 1285 participants and rated moderate-quality evidence that added ECT improves medium-term clinical response against standard care

alone, risk ratio 2.06 with a 95% confidence interval of 1.75 to 2.42, in 819 participants across 9 studies, with no clear advantage on other outcomes and 14 of 15 studies, 93.3%, at high risk of bias. Against clozapine added to standard care, the risk ratio for clinically important response was 1.23 with a 95% confidence interval of 0.95 to 1.58, from 162 participants in a single low-quality study, no clear difference either way.

For the clozapine-resistant patient the pooled result is favourable and the appraisals of it are not. The largest meta-analysis found adjunctive ECT superior on study-defined response at the post-ECT assessment, 53.6% against 25.4%, risk ratio 1.94 with a 95% confidence interval of 1.59 to 2.36 and a number needed to treat of 3, while remission at that assessment was 13.3% against 3.7%, a number needed to treat of 13 with a 95% confidence interval of 6 to 100. Response is common, remission is not, and the remission interval is too wide to carry precision. Heterogeneity was high: I-squared of 86% for symptomatic improvement at the post-ECT assessment and 95% at endpoint.

The best-known randomised trial is small and single-blind. In an intent-to-treat sample of 39 participants, 20 given ECT plus clozapine and 19 clozapine alone, 50% of the ECT plus clozapine patients met the response criterion and none of the clozapine group did; response in the crossover phase was 47%. Its own conclusion anchors what this chapter must say: further research is required to determine the persistence of the improvement and the potential need for maintenance treatments.

Three appraisals keep that at its true strength.

- A synthesis of six systematic reviews concluded that ECT probably augments response to clozapine, but that whether it leads to cognitive adverse effects cannot be determined because the certainty of the evidence is very low.
- A review of 46 studies of 25 augmentation strategies called ECT highly promising while adding that its conclusions are tempered by generally short follow-up periods and poor study quality.
- A meta-review of 21 meta-analyses found that no strategy met Grade A criteria and that augmentation with ECT for persistent positive symptoms met Grade B.

RULE **State the clozapine-resistant indication as modest, and say that no algorithm is established.** The effect sizes are real and the certainty behind them is not: heterogeneity is high, the trial base small and mostly single-blind, follow-up short, no strategy at the top grade. Offer it as a reasonable option in a patient who has genuinely failed clozapine, never as a step on a settled ladder.

4.6 The psychiatric emergency, and the authority it does not confer

The clinical half is the simplest statement in the topic. ECT is a first-line treatment when a rapid or definitive response is needed to avert harm to self or others, and acute suicidal risk, agitation, catatonia and a deteriorating physical status secondary to a psychiatric condition are among the situations meant. The list is examples rather than a closed set, and the guideline adds that every

indication is individualised against clinical need, the patient's preferences and the putative risk of adverse effects.

The statutory half is where a resident is most likely to be taught something unlawful, and the error is precise enough to name. ECT can be clinically indicated in an emergency, and the Mental Healthcare Act's provision on emergency treatment cannot authorise it, because that provision expressly excludes electroconvulsive therapy from the treatment it permits. Both statements are true and not in conflict. What follows is that a lawful route must be established separately, and that urgency does not cure an incomplete route. No emergency doctrine supplies the authority the Act withholds.

The second half is the one most often lost: TREATMENT authority is not ADMISSION authority. A capacitous adult can consent to ECT with no admission at all, so urgency never converts the question into whether the patient must first be admitted. The routes, and what each does and does not authorise, are enumerated in this chapter's account of consent for ECT in Indian practice. Every provision of the Act touching ECT and psychosurgery, including those on emergency treatment, the nominated representative and the statutory gate for a minor, belongs to the Mental health legislation and forensic psychiatry notes: named in words here, numbered only there.

TRAP **Writing emergencies into the indication list and stopping there.** A list that says ECT is indicated in an emergency, with nothing beside it, teaches a resident to reach for the Act's emergency-treatment provision and treat under it, which is not lawful. The paired error runs the other way: assuming that because that route is closed, an admission must be arranged first. It need not be, if the adult before you has capacity and consents.

MNEMONIC

NOT EATING, NOT MOVING, NOT SAFE, NOT WORKING

Not eating is food or fluid refusal and the clock it starts. **Not moving** is catatonia, the malignant form earning the treatment on mortality. **Not safe** is acute suicidal risk, where speed of relief is the point. **Not working** is treatment resistance across depression, mania and schizophrenia. A fifth line belongs with the four: none is a lawful route, and each still needs one.

4.7 Each indication at its true strength

INDICATION	THE EVIDENCE, AND THE LIMIT THAT GOES WITH IT
SEVERE DEPRESSION WITH PSYCHOTIC FEATURES	Randomised and meta-analytic; the psychotic comparison is a completer analysis
FOOD OR FLUID REFUSAL, AND THE STUPOROSE PRESENTATION	Guideline-level and consistent; carried nosologically under catatonia
ACUTE SUICIDAL RISK	Prospective cohort; scores are of expressed intent, not of acts
CATATONIA, MALIGNANT FORM INCLUDED	Very high response but entirely observational, and much lower in the reviewers' own series, whose size is not stated
ACUTE AND REFRACTORY MANIA	A narrative review; the randomised work addresses the depressive pole
SCHIZOPHRENIA, GENERAL	Two authoritative sources disagree; moderate quality on a base at high risk of bias
CLOZAPINE-RESISTANT SCHIZOPHRENIA	Modest, no algorithm: pooled response and remission favour it with no heterogeneity, the heterogeneity belongs to the continuous symptom-change outcome, and follow-up is short
THE PSYCHIATRIC EMERGENCY	Clinically clear; the statutory route is separate and never supplied by urgency

PITFALL

Answering with one undifferentiated list. These indications do not stand on evidence of one kind: catatonia on observational series, depression on randomised and meta-analytic work, mania on a narrative review, the clozapine-resistant patient on a small and heterogeneous trial base. An answer that grades them reads as clinical judgment; one that recites them cannot say which would survive a challenge.

ECT is indicated where the presentation is of the kind it treats and benefit against risk favours it: severe depression, most strongly with psychotic features, food refusal or acute suicidal risk; catatonia, on the strongest response evidence in psychiatry and the weakest design; acute and refractory mania; schizophrenia, where the Indian and United Kingdom positions differ and both are stated; the clozapine-resistant patient, modest with no established algorithm; and the psychiatric emergency, where the clinical case is strongest and the Act's emergency-treatment provision still cannot authorise treatment.

5 · Contraindications and high-risk conditions for ECT

A contraindication is a statement that a treatment must not be given at all, and the difficulty here is that the field does not agree on whether electroconvulsive therapy has one. Two positions are in print, each from a named source with a date, and a candidate who has met only

one will be wrong in one of two directions: barring a patient who could have been treated, or taking a patient with an intracranial mass and papilloedema to the suite. This account states both, gives the physiology behind the older one, and teaches each condition that raises risk beforehand with its modification.

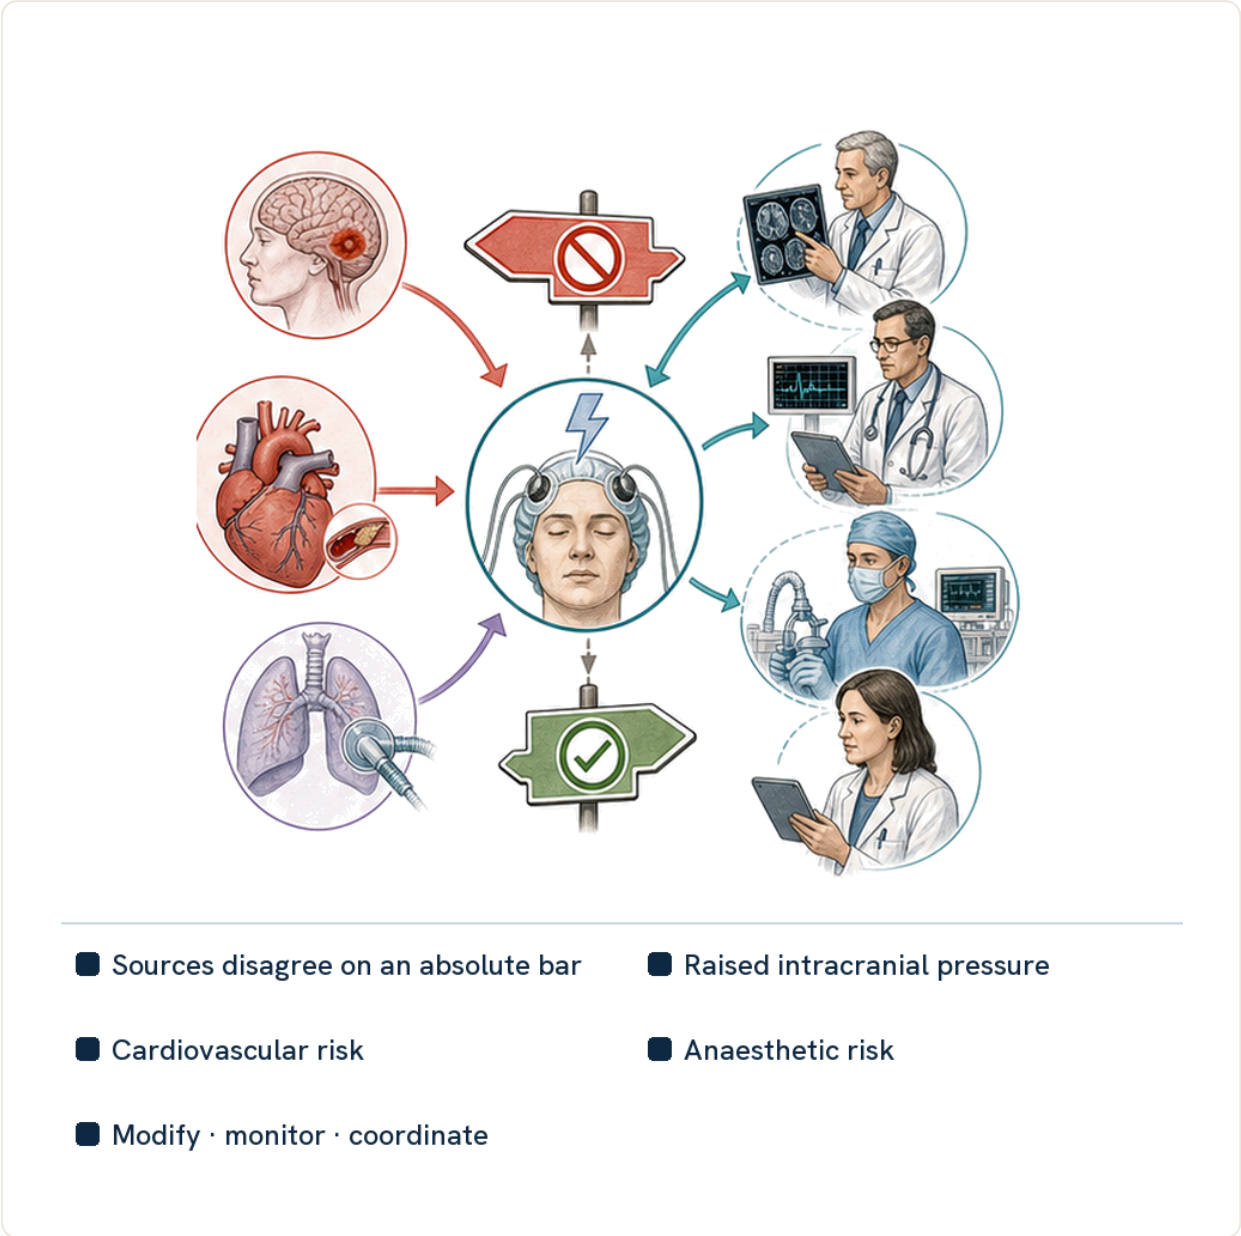

Fig 27.5 Published sources differ on whether ECT has an absolute contraindication. Raised intracranial pressure and major cardiovascular or anaesthetic risk demand individual assessment, risk modification, monitoring and coordinated specialist planning.

Owned here is the risk profile before treatment: the contested status of absolute contraindication, the intracranial question the dispute turns on, and the high-risk conditions. Named and not re-taught, each owned by another account in this chapter: the complications that actually occur, by the other complications and adverse effects of electroconvulsive therapy; the workup and anaesthetic conduct that manage these risks, by the pre-ECT workup and anaesthesia, its agents, muscle relaxant and airway; the clinical grounds, by the indications for ECT; and pregnancy, age and comorbidity as populations, by ECT in special populations. Risk beforehand against complication afterwards: two objects, not one.

1980	74 percent	one patient
THE YEAR POSITION TWO WAS CONCLUDED, AND STILL A COMMON EXAM KEY	COMPLICATIONS IN THE REPORTS OF ECT WITH AN INTRACRANIAL NEOPLASM BEFORE 1984	THE WHOLE DIRECT EVIDENCE ON ECT WITH RAISED INTRACRANIAL PRESSURE ALREADY PRESENT

5.1 Two positions, with their provenance and their dates

Both are written out, because the disagreement is real and this account does not settle it.

Position one is the modern task-force position: there are no absolute contraindications to electroconvulsive therapy, and every listed condition is a risk to be quantified and managed with the anaesthetist. It reaches this page through a peer-reviewed anaesthesia review of 2022, which attributes it to the American Psychiatric Association consensus statement of 2001. The two halves must not be split: in the very next breath the same passage names uncontrolled hypertension, coronary artery disease, congestive heart failure, aortic stenosis, implanted cardiac devices, atrial fibrillation, obstructive lung disease, asthma and increased intracranial pressure with or without mass lesions as conditions carrying a relatively high risk that may result in death during treatment. Position one is not a claim that nothing is dangerous; it is a claim about where the danger is adjudicated.

The position holds at the current end. A review of electroconvulsive therapy in intracranial pathology, published in 2025, concludes that no absolute contraindications have been established, frames the transient rise in intracranial pressure as the reason the question keeps being asked, and calls its own evidence base very sparse, mostly case series and short retrospective studies. It also states what modern practice is: a decision made case by case by a team involving both the psychiatric and the neurosurgical services.

Position two is that raised intracranial pressure with a space-occupying lesion is an absolute contraindication. It is standard in Indian teaching and common as an examination key, and it has a provenance: it is the conclusion of the last large review before the modern case literature, by Maltbie and colleagues in 1980, recorded as such by the 2020 review that set out to test it.

A limitation is shared, and neither side is graded above the other on it: neither the task-force text of 2001 nor the review of 1980 was opened at source. What is established is what a later peer-reviewed paper reports each to hold.

RULE **Write both positions with their dates, and never present "no absolute contraindication" as settled and uncontested.** The modern position is a claim about method, that risk is quantified and managed rather than made prohibitive in advance. A reader given it as a licence, without what the older position was protecting against, has been taught something unsafe.

5.2 The physiology that makes position two reasonable

Position two is not superstition, and its mechanism is examinable. Electroconvulsive therapy induces a rise in cerebral blood flow, in intracranial pressure, in intraocular pressure and in cerebral oxygen consumption. Where compliance is normal those rises are transient and settle. The whole of position two is what the same rises mean in a patient whose compliance has already been consumed by a mass.

The chain from the general rise to the specific danger runs in a fixed order, first proposed by Carter in 1977. Seizure activity raises blood pressure and cerebral blood flow; that increases the oedema around the tumour; the oedema raises intracranial pressure further; neurological signs follow. The 2020 review treats this as the likely cause of the more prominent adverse events in its own series, and records that a corticosteroid was given to 12.5 percent of its patients to reduce the risk of acute oedema, saying only that it is therefore possible such premedication lowers the risk. No agent dose belongs here: drug conduct is the workup and anaesthesia item's.

Two honesties travel with this mechanism. No magnitude is available: no grounded source states how large the rise in intracranial pressure is, and the review describing the rises says the mechanisms behind them are incompletely understood, so direction and transience are taught and size is not carried. And the word herniation appears in none of the sources this account rests on. The grounded chain ends at neurological signs; herniation is the endpoint the older teaching was written to prevent, and naming it as the feared outcome is legitimate while asserting it as a documented consequence is not. That gap is declared, not closed. The same sentence grounds the ocular limb, which is why raised intraocular pressure and retinal detachment sit in the set below.

5.3 The outcome data each position was reading

Position two was a reading of outcomes, not an opinion. In reports published up to 1984 on treatment in patients with intracranial neoplasms, complications were recorded in **74 percent** of 38 patients and death in **8 percent** of 29 patients. The denominators differ, so these are not two proportions of one sample. The source supplies the confound itself: some who died had aggressive tumours such as glioblastoma, so attribution to the treatment is not clean. The figures reach this page through a safety review of 2025 reporting an earlier review, which bounds them without doubting them.

The modern series behind position one is small. Across reports from 1984 to 2019 there are 40 patients. Adverse effects occurred in **15 percent** and all were reversible; none died from treatment; the authors judged it beneficial in 36 of the 40 patients, which is 90 percent. The decisive sentence sits in that paper: only one patient was reported to have had raised intracranial pressure before the procedure, and came through without adverse effect. That is the closest the literature comes to answering this item's question, and it is one patient.

TRAP **Reading the difference between the two eras as pure progress in technique.** The comparison is not like for like and the modern authors say so. The tumour was known beforehand in 72.5 percent of modern cases, allowing precautions, and neurological symptoms preceded treatment in 12.5 percent of them against 45.7 percent of the older group, which held more aggressive tumours. The modern series is safer partly because it is a different population.

5.4 Where Indian practice actually sits

The current Indian guideline, of 2023, gives its high-risk conditions in a table headed *clinical conditions requiring caution while administering ECT*, grouped into four systems, and its running text introduces the physical examination as the way to identify any **relative contraindications**.

Raised intracerebral pressure with an intracerebral space-occupying lesion heads the cerebral group. The Indian guideline therefore sits with position one, and that framing is itself the finding.

Its operative instruction is sharper than either slogan. For a symptomatic intracranial mass, and for recent ischaemic or haemorrhagic stroke, it says treatment may warrant postponement until the risks of complications are minimised: a relative bar with a condition attached. The same row states that cerebral implants and foreign bodies are not an absolute contraindication and that treatment may be given in consultation with neurologists. Its electrode-placement instructions belong to this chapter's account of ECT technique and electrode placement, its relaxant instruction to the workup and anaesthesia item.

IN INDIA

Two Indian facts point in opposite directions and both are true. Indian *teaching* writes raised intracranial pressure with a space-occupying lesion as an absolute contraindication; the current Indian *guideline* does not. Give the guideline position, and name the taught position with its date.

5.5 How the intracranial condition is actually found

The condition this item turns on is usually not looked for in advance. Routine neuroimaging before a course is not mandatory and its yield is very low: one retrospective study found a single abnormal scan preventing treatment out of 108 scans done as routine pre-treatment imaging, which is 0.93 percent. Selective imaging is suggested for patients at risk: a prior aneurysm, a heritable aneurysm disorder, headache, and age above 60 with hypertension or smoking. What triggers imaging afterwards is any new neurological symptom: significant lateralisation of the seizure, a transient postictal paralysis, aphasia or a secondary seizure.

What is mandatory is the bedside examination. The Indian guideline of 2023 makes fundoscopy a mandatory part of the pre-treatment physical examination. That is the practical link: **papilloedema** is what raised intracranial pressure looks like at the bedside, and the examination exists, in the guideline's words, to identify relative contraindications and prevent complications.

5.6 The high-risk conditions, and the modification that manages each

The set below is explicitly open: the safety review supplying the last row introduces its own list with the word *include*, marking it as not closed. Neither list is the answer to what the high-risk conditions are.

SYSTEM GROUP	CONDITIONS NAMED	MODIFICATION THAT MANAGES IT
CEREBRAL	Raised intracerebral pressure with an intracerebral space-occupying lesion; unstable cerebral aneurysm; recent intracerebral haemorrhage or stroke; and phaeochromocytoma, which sits in this row only because the source table's column layout puts it here, its hazard being a catecholamine-driven hypertensive surge rather than anything cerebral	Postponement of a symptomatic mass and of recent stroke until risks are minimised; shunt patency confirmed; blood pressure held with short-acting parenteral antihypertensives in aneurysm
OCULAR	Raised intraocular pressure; retinal detachment	The induced rise in intraocular pressure is the mechanism, transient in the ordinary case
CARDIAC	Recent myocardial infarction; poor cardiac output; unstable arrhythmias; high anaesthetic risk (ASA level 4 or 5); third degree burns	Wait 4 to 6 weeks after infarction; blood pressure controlled with short-acting agents; anticoagulation considered in valvular disease; restimulations limited in heart failure, with functional capacity assessed; pacemakers safe with cardiology consultation
NEUROMUSCULAR	Spinal injuries; bone fractures; recurrent dislocations	Managed through the relaxant and the technique, both owned by the workup and anaesthesia item
NAMED BY THE MODERN REVIEW	Recent myocardial infarction; intracranial aneurysm above a threshold size; proximal deep vein thrombosis; phaeochromocytoma; systemic infection	Avoided or given with high caution on a favourable risk-benefit ratio; deep vein thrombosis singled out for extreme precaution, fatalities being associated with it

Three entries need their detail, because each is where a memorised line goes wrong. The **infarction window** is the plainest conflict here after the intracranial one: the Indian guideline of 2023 says consider waiting 4 to 6 weeks; the safety review of 2025 writes it as an infarction within the last 4 weeks. The disagreement is stated, not resolved.

The **aneurysm** is not theoretical. Across 27 published cases, treatment was safe with secured and unsecured aneurysms up to 2.1 cm, with one fatal exception: a patient died of subarachnoid haemorrhage after rupture of an anterior cerebral artery aneurysm of 1.9 cm, 2 days after a tenth right unilateral treatment, the peri-ictal pressure having risen sharply despite a short-acting agent. The review states that treatment is not universally safe in aneurysm and that risk rises with size. Note the consequence for any threshold: the paper names aneurysms larger than 1 cm as high risk, yet the fatal one was larger and safe cases are reported above it. Size is a gradient, not a cut-off.

The **mass** is not one thing. A mild mass effect does not appear to preclude treatment provided there is no midline shift, and the largest tumour reported without adverse effect measured 8.1 by 7.6 by 4.1 cm. That is what makes position one operable at the bedside. It does not retire position two, and this account must not be read as doing so: position two's claim is that the PRESENCE of an intracranial mass is an absolute bar, and recasting that claim as really being about midline shift would resolve the chapter's flagship conflict in the permissive direction on evidence that is a series of case reports. No source here defines when a mass effect stops being mild, none quantifies a midline shift, and no such threshold is asserted, so the discriminator is not available as a bedside rule.

PITFALL

Printing any of these lists as the complete set. The task-force passage quoted earlier for position one adds conditions the Indian table does not carry as such, so severe pulmonary compromise, decompensated heart failure and severe valvular disease belong on any honest version. A vascular malformation liable to rupture with a pressure surge is often taught here too; no source grounded for this account names it, so it is flagged rather than printed as established.

5.7 Pregnancy: on the risk list, not the contraindication list

Pregnancy is not a contraindication to electroconvulsive therapy, and the distinction this item exists to draw appears here in its cleanest form. Two instructions travel with that: pregnancy testing in all women of reproductive age, and fetal exposure to anaesthetics minimised. The risk side is stated alongside, not instead: guidance holds that risks may be enhanced during pregnancy, in older people and in children and young people, and fatalities including fetal deaths have been reported after treatment in the presence of pregnancy among other conditions, with the caveat that attribution is not established in every case. How treatment is then modified belongs to this chapter's account of ECT in special populations, and the statutory position on minors to its account of consent for ECT and the legal aspects under the Mental Healthcare Act.

5.8 What stands in place of a contraindication list

Guidance from the appraisal tradition does not answer this item with a list at all. It requires a documented assessment of the risks and potential benefits to the individual, and names what that assessment must weigh:

- the risks associated with the anaesthetic;
- current comorbidities;
- anticipated adverse events, particularly cognitive impairment;
- the risks of not having the treatment.

It gives a procedure, not a set of barred conditions, which is itself evidence about where the guideline tradition sits.

The last element is the one a contraindication list silently omits, and it is why the modern position can be stated as risk quantification rather than prohibition: a patient in catatonic stupor who is not eating carries a risk from not being treated that no table of conditions records. The

cognitive limb belongs to this chapter's account of the cognitive side effects of ECT; owned here is the framework.

MNEMONIC

Two dates, four systems, one patient

Two dates: position two is 1980, position one is 2001 and later. **Four systems**: the Indian caution table runs cerebral, ocular, cardiac and neuromuscular, and the list is open. **One patient**: the single reported case treated with raised intracranial pressure already present is the whole of the direct evidence.

5.9 The anaesthetic considerations, and the consequence this item must point at

Every condition here is managed with the anaesthetist rather than adjudicated alone, which is what position one means in practice. The high anaesthetic-risk class in the Indian cardiac group is an anaesthetic judgement inside a psychiatric guideline, and managing the aneurysm patient's blood-pressure surge is an anaesthetic act. The evaluation and investigations, fasting and the medication review, pre-oxygenation and the airway, the induction agent and muscle relaxation in full all belong to this chapter's account of the pre-ECT workup and anaesthesia. No agent, no dose and no step of the sequence is restated here.

One consequence must be pointed at rather than left implied. A patient in whom a cerebrovascular event is managed rather than barred carries a neuromuscular-blockade consequence, and that consequence belongs in full to the workup and anaesthesia item, which states its window and grounds it.

RULE **Do not carry the word "recent" across from this item to the blockade question.** Recency here marks the cardiovascular and cerebral risk of the induced seizure, highest close to the event and falling with time. The neuromuscular-blockade risk after a cerebrovascular event does not run in that direction, and it is not discharged by the event ceasing to be recent. Nothing here says a patient is past the blockade risk because the stroke is old; that window is the workup and anaesthesia item's to state and ground.

Electroconvulsive therapy has two positions on contraindication and both are written with their dates: no absolute contraindication, from the task-force tradition of 2001 and the reviews following it, and the intracranial mass as an absolute bar, from the last large review before the modern literature in 1980, still standard teaching and a common key. The mechanism behind the older position is the induced rise in cerebral blood flow and intracranial pressure, and the chain from seizure to peritumoural oedema to neurological signs. The current Indian guideline files raised intracranial pressure under caution and instructs postponement rather than prohibition; every other high-risk condition is quantified and managed with the anaesthetist, each carrying its own modification.

Electroconvulsive therapy: technique and dose

6 · Pre-ECT workup and anaesthesia (agents, muscle relaxant, airway)

Modified ECT is a general anaesthetic given in order to induce a seizure, which puts most of the treatment's physical risk in the anaesthetic room rather than at the stimulus dial. The psychiatrist neither prescribes nor gives it, but selects the patient, orders the workup and reads a seizure the induction agent has shaped. What is examinable is what must be settled before a course, and when the usual relaxant must not be used.

Owned here: the evaluation and its investigations, fasting and the medication review, pre-oxygenation and the airway, the induction agents, neuromuscular blockade in full, the anticholinergic question, the tourniquet method, and recovery. Named but not re-derived: the seizure threshold and stimulus dose, which belong to this chapter's account of stimulus dosing; the conditions that raise risk beforehand, to the risk profile; the interactions, to concurrent medication.

2, 6, 8 HOURS OF FASTING FOR CLEAR LIQUIDS, LIGHT MEALS, AND FRIED OR FATTY FOOD	**7 to 10** DAYS AFTER A DENERVATING INJURY AT WHICH HYPERKALAEMIC RISK PEAKS	**Not mandatory** THE ROUTINE PRE-ECT BLOOD PANEL, PER THE CURRENT INDIAN GUIDELINE

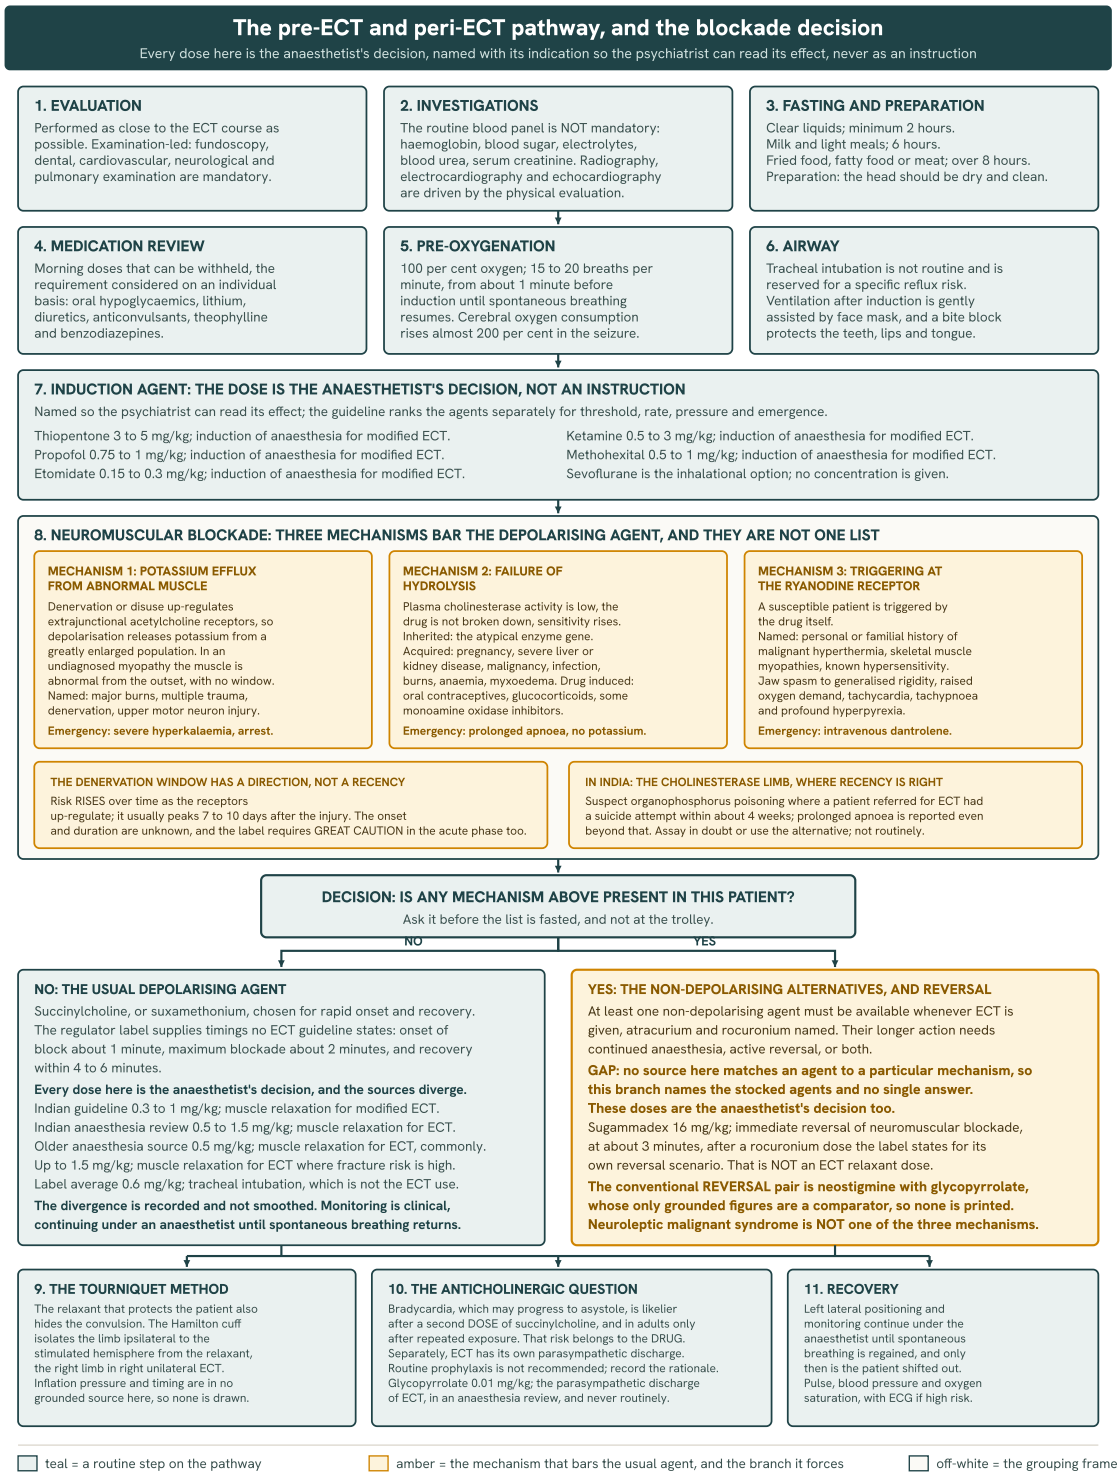

Fig 27.6. The pathway before and around a treatment, with neuromuscular blockade drawn as a decision rather than a default: on one branch the usual depolarising agent, on the other the non-depolarising agents that must be stocked, taken when any one of the three mechanisms named on the plate bars the depolarising agent. Three things are deliberately absent from that branch. No grounded source here matches a particular alternative agent to a particular barring mechanism, so it names the stocked class and declares the gap, not one drug. It carries no relaxant dose for any alternative agent, the one rocuronium figure being the reversal label's own antecedent and marked as not an ECT dose. And the neuroleptic malignant syndrome preference is not here, because it is not one of the three mechanisms and the item's text records that succinylcholine given for ECT in it is described as safe. Every dose shown is named with its indication as the anaesthetist's decision rather than as an instruction.

6.1 The evaluation before a course

The **pre-ECT evaluation** is a joint fitness-for-anaesthesia assessment whose first rule is timing: the guideline requires it be performed as close to the ECT course as possible, because a workup done weeks earlier certifies a patient who no longer exists.

The examination is asked as it stands. Fundoscopic examination is mandatory along with other systemic examinations, and so are dental evaluation for loose or missing teeth, cardiovascular examination for arrhythmias, assessment for neurological comorbidities and pulmonary clinical evaluation. Fundoscopy is the window on raised intracranial pressure, taken up by the risk-profile account; loose teeth matter because the masseter contracts whatever the relaxant does.

6.2 The investigations: what is required, and what is not

Candidates fail this by reciting a battery. The guideline states that for general anaesthesia haemoglobin, blood sugar, electrolytes, blood urea and serum creatinine would facilitate detection of common risk-enhancing comorbidities but are not mandatory, and radiography, electrocardiography, echocardiography and other tests are indicated on the physical evaluation.

RULE **Pre-ECT investigation is driven by the clinical evaluation, not by a fixed list.** The mandatory content sits in the examination, not the laboratory; the tests that earn a place are those a finding asked for, an electrocardiogram because an arrhythmia was heard, a potassium level because the relaxant question is live.

6.3 The morning of a treatment: fasting and the medication review

Fasting is graded by what was eaten, and the intervals are quoted, not recalled: ECT is given fasting, after **2 hours from clear liquids, 6 hours from milk and light meals, and over 8 hours from fried food, fatty food or meat**. The same guideline table adds one preparation step alongside the intervals, outside the passage quoted here: the head should be dry and clean for the procedure, which is a scalp and electrode-contact requirement and not a fasting one.

The review is drug by drug that morning. The morning dose of oral hypoglycaemics, lithium, diuretics, anticonvulsants, theophylline and benzodiazepines can be withheld, considered on an individual basis. The opposite list is forgotten: scheduled antihypertensives, thyroxine, antiemetics, antireflux drugs, antianginals, bronchodilators and anticholinergics should not be withheld and can be taken orally 2 hours before the procedure with small sips of water. Which drug moves the threshold belongs to concurrent medication.

6.4 In the suite: pre-oxygenation, the airway and what must be stocked

Pre-oxygenation answers a measured demand, because cerebral oxygen consumption increases almost 200% during the seizure, so the recommendation is ventilation with 100% oxygen at 15 to 20 breaths per minute, from approximately 1 minute before induction until spontaneous breathing resumes. Hyperventilation may prolong the seizure; its threshold effect belongs to stimulus dosing.

Intubation is not routinely required unless there are specific risk factors for reflux, ventilation after induction is gently assisted with a face mask, and a bite block protects the teeth, lips and

tongue. That source predates current consensus and is carried for want of a plainer one. The bite block is the step most often left out of an answer: the stimulus contracts the masseter by a route the relaxant misses. The room is stocked: at least one non-depolarising agent such as atracurium or rocuronium must be available alongside succinylcholine.

6.5 The induction agent: rankings that do not run in the same order

The induction agent decides how easily a seizure is obtained, how long it runs, how the circulation behaves and how fast the patient wakes, and the guideline gives these as separate rankings.

RANKING	ORDER AS THE GUIDELINE GIVES IT
SEIZURE THRESHOLD, PROCONVULSANT TO ANTICONVULSANT	ketamine, etomidate, methohexital, sevoflurane, thiopentone, propofol
PROPENSITY TO INCREASE HEART RATE	ketamine, methohexital, thiopentone, etomidate, propofol
PROPENSITY TO INCREASE MEAN ARTERIAL PRESSURE	ketamine, etomidate, methohexital, thiopentone, propofol
EMERGENCE TIME, LONGEST TO SHORTEST	ketamine, etomidate, thiopentone, methohexitone, propofol, sevoflurane

Read together they show the trade: ketamine sits at the proconvulsant end of the threshold ranking and the worst end of rate, pressure and emergence, and propofol the reverse on threshold, rate and pressure, with sevoflurane alone shorter than propofol on emergence. Each figure below is the anaesthetist's decision, named so the psychiatrist can read its effect on the seizure, never as an instruction.

- **Thiopentone.** 3 to 5 mg/kg for induction in modified ECT, owned by the anaesthetist and not taught here as a prescribing instruction: fast acting, reduces seizure duration less than propofol, increased arrhythmia risk.
- **Propofol.** 0.75 to 1 mg/kg for induction in modified ECT, owned by the anaesthetist: shortens seizure duration and raises the threshold, but better haemodynamic stability in cardiovascular risk, and quicker emergence, against injection pain.
- **Etomidate.** 0.15 to 0.3 mg/kg for induction in modified ECT, owned by the anaesthetist: prolongs seizure duration and may reduce the threshold, useful where it is high, against a hyperdynamic response, longer emergence and adrenocortical suppression.
- **Ketamine.** 0.5 to 3 mg/kg for induction in modified ECT, owned by the anaesthetist: seizure effect unclear with a modest enhancing effect, sedative and analgesic, against emergence phenomena, poorer haemodynamic stability and raised intracranial pressure.
- **Methohexital.** 0.5 to 1 mg/kg for induction in modified ECT, owned by the anaesthetist: the gold standard, whose problem in India is sparse availability.
- **Sevoflurane.** The inhalational option, comparable to thiopentone, useful where venous access is difficult, with better haemodynamic stability, enhancing muscle relaxation, and in

pregnancy reducing uterine contraction. Enhanced muscle relaxation is listed as a general advantage of the agent, not as a property of its use in pregnancy. The guideline gives no concentration, so none is supplied.

Propofol with ketamine, called ketofol, can balance seizure duration against haemodynamic effect; short-acting opiates or dexmedetomidine spare dose but need more evidence in ECT; and the differential effects of anaesthetic agents are dependent on their dose. Calling an agent proconvulsant is therefore a statement about a dose.

6.6 Neuromuscular blockade, part one: the depolarising agent

Succinylcholine, or suxamethonium, is the depolarising blocker for modified ECT, chosen for rapid onset and recovery. The label supplies timings no ECT guideline states: blockade develops in about 1 minute, maximum blockade may persist about 2 minutes, and recovery follows within 4 to 6 minutes. Read the middle figure as the label writes it: what persists for that interval is the MAXIMUM of the block and not the block itself, so nothing on this page promises breathing when it elapses. Its average of 0.6 mg/kg is for tracheal intubation, not ECT, an indication owned by anaesthetic practice and named only so it is never taken for ECT. Monitoring is clinical: it continues under an anaesthetist until spontaneous breathing is gained.

The ECT dose is not agreed, and the divergence is recorded, not smoothed. The Indian psychiatry guideline gives **0.3 to 1 mg/kg** for relaxation in modified ECT, owned by the anaesthetist. An anaesthesia review gives **0.5 to 1.5 mg/kg** for relaxation in ECT, also owned by the anaesthetist. An older one gives 0.5 mg/kg as the commonest relaxant dose in ECT, owned by the anaesthetist, and alone names who needs more: up to 1.5 mg/kg for relaxation in ECT in severe cachexia, osteoporosis or skeletal injury, owned by the anaesthetist. Fragile bones need more relaxation, not less.

6.7 Neuromuscular blockade, part two: the mechanisms that bar the depolarising agent

The situations that contraindicate a depolarising blocker do not share a mechanism, and the difference is not academic, because the emergency each produces is treated differently. The routes are potassium efflux from abnormal muscle, driven after denervation or disuse by up-regulated **extrajunctional acetylcholine receptors**; failed hydrolysis where **plasma cholinesterase**, or pseudocholinesterase, is deficient; and ryanodine-receptor triggering in **malignant hyperthermia**. One hyperkalaemia story across all three prepares the wrong emergency.

MECHANISM	WHAT GOES WRONG	CONDITIONS NAMED, WHICH IS NOT A CLOSED LIST	THE EMERGENCY
POTASSIUM EFFLUX FROM ABNORMAL MUSCLE	Receptors up-regulate after denervation or disuse, so depolarisation releases potassium from a greatly enlarged population; in an undiagnosed myopathy the muscle is abnormal from the outset	Major burns, multiple trauma, extensive denervation of skeletal muscle, upper motor neuron injury; the label adds chronic abdominal infection, subarachnoid haemorrhage, degeneration of the nervous systems	Severe hyperkalaemia which may result in cardiac arrest
FAILURE OF HYDROLYSIS	Plasma cholinesterase activity is diminished, the drug is not broken down, and sensitivity rises	Genetic abnormalities of plasma cholinesterase; pregnancy, severe liver or kidney disease, malignancy, infection, burns, anaemia, myxoedema; oral contraceptives, glucocorticoids, certain monoamine oxidase inhibitors, organophosphate insecticides	Prolonged block with apnoea. No potassium is involved, and no grounded source here states the management, so none is printed
TRIGGERING AT THE RYANODINE RECEPTOR	A susceptible patient is triggered by the drug	Personal or familial history of malignant hyperthermia, skeletal muscle myopathies, known hypersensitivity	Masseter spasm progressing to generalised rigidity, increased oxygen demand, tachycardia, tachypnoea and profound hyperpyrexia, treated with intravenous dantrolene sodium as an adjunct to supportive measures

The potassium mechanism reaches a patient by more than one route, and their timing differs. After denervation or disuse the receptors must change first, so a window opens and widens. In an undiagnosed myopathy there is none: the boxed warning records rare reports of acute rhabdomyolysis with hyperkalaemia, ventricular dysrhythmias, cardiac arrest and death after succinylcholine in apparently healthy paediatric patients later found to have undiagnosed skeletal muscle myopathy, most frequently Duchenne muscular dystrophy, which bears on the adolescent treated under the statutory gate for minors that the Mental health legislation and forensic psychiatry notes carry. Where potassium is already high no receptor change is needed: the label directs great caution in electrolyte abnormalities and digitalis toxicity, because succinylcholine may then cause cardiac arrest due to hyperkalaemia.

RULE **The hyperkalaemic danger of a denervating insult RISES over time as receptors up-regulate, so recency is not the marker of safety.** Note what the label does NOT say: it does not certify the early period as low risk. It requires GREAT CAUTION during the acute phase and contraindicates the agent after it, so both phases carry an instruction and neither is a clearance. The label states the direction plainly: the risk increases over time and usually peaks at 7 to 10 days after the injury, depends on its extent and location, and its precise onset and duration are not known. The contraindication matches, applying after the acute phase of injury. Since the duration is unknown, this account teaches direction and peak and prints no date of safety.

TRAP **Reading a hemiplegic patient's blockade risk off the recency of the stroke inverts the window and clears exactly the wrong patient.** The recency wording attached to a cerebrovascular or cardiac event in this chapter's account of the risk profile concerns the risk of the induced seizure, highest close to the event. Blockade risk runs the other way. Letting one set the other refuses the relaxant before the receptors have up-regulated, where the label still requires great caution and prints no interval of safety, and hands a depolarising agent to the established hemiplegic in whom danger has built for weeks.

MNEMONIC

POTASSIUM, PROLONGED, PYREXIA

One P for each mechanism, and none shares an emergency with another. **Potassium** is the denervation, disuse and abnormal-muscle route, ending in hyperkalaemic arrest. **Prolonged** is the cholinesterase route, where the emergency is prolonged apnoea and no source here states its management. **Pyrexia** is malignant hyperthermia, treated with dantrolene. The mechanisms are the whole set; the conditions inside each are not, so a patient absent from a list has not been cleared.

IN INDIA

The cholinesterase mechanism has an Indian limb, and is the one place recency is the right marker. Where a patient referred for ECT has a suspected or known suicide attempt within 4 weeks, organophosphorus poisoning should be suspected; prolonged apnoea is reported even after 4 weeks; the pseudocholinesterase level may be assessed in doubt or a non-depolarising agent used; routine determination is not recommended. In renal disease, non-depolarising agents can be preferred, and in haemodialysis patients potassium should be done within 24 hours before ECT. Note the strength difference. the guideline frames its list, adding severe widespread burns, hypercalcaemia and severe neuromuscular disease, as situations in which non-depolarising relaxants may be considered, while the label states several as contraindications.

6.8 Neuromuscular blockade, part three: the alternatives and their reversal

A contraindication is useful only with a replacement, and here the replacement is a class rather than a name. The **non-depolarising blockers** named for ECT are atracurium, mivacurium and rocuronium, whose shared cost is that their relatively prolonged action will need continued anaesthesia, active reversal after treatment, or both. What the guideline settles is stock and not selection: at least one non-depolarising agent such as atracurium or rocuronium must be available alongside succinylcholine.

TRAP **Answering "which agent replaces succinylcholine" with a single drug name.** The three barring mechanisms are not one list, and no source carried in this chapter matches a particular alternative to a particular mechanism, so no one agent can be the answer to all three. The honest answer names the class, says at least one member must be stocked, and leaves the choice within it to the anaesthetist on the mechanism in front of them. Naming one agent silently answers the cholinesterase-deficient patient too, which is the limb where a wrong choice reproduces the prolonged block the substitution exists to avoid.

One agent is reported as the usual practical choice, and it is named as that rather than as the answer to a mechanism. Mivacurium is the drug most often administered as an alternative to succinylcholine during ECT, which is a statement about ECT practice in general and not about which mechanism has barred the depolarising agent in the patient in front of you. Its figures follow for that reason alone. Seizure modification is inadequate at 0.08 mg/kg of mivacurium for relaxation in ECT, owned by the anaesthetist and quoted only for what follows. At least 0.15 mg/kg should be used for relaxation in ECT, owned by the anaesthetist, because a dose trimmed to shorten the block buys an unmodified convulsion under a patient who looks paralysed. A second source disagrees with that figure rather than supporting it, and the disagreement is the honest state: only a full intubating dose, 0.2 mg/kg, gave effective relaxation during ECT, and higher doses caused histamine release and hypotension. Read the two together as a range of opinion on what is adequate, never as one figure evidencing the other. Atracurium at 0.5 mg/kg needed more time to reach a satisfactory train-of-four ratio.

Reversal changed that. Rocuronium and vecuronium were generally given only as precurarising agents, but could theoretically be used with sugammadex. **Sugammadex** encapsulates the relaxant rather than inhibiting an enzyme: 16 mg/kg is recommended where blockade must be reversed soon, approximately 3 minutes after a single 1.2 mg/kg dose of rocuronium, owned by the anaesthetist, and that timing is what makes the alternative usable. Its one reported use in ECT is a single case, never a schedule: the train-of-four ratio recovered to 0.9 within 2 minutes and the first breath within 3 minutes. The conventional REVERSAL pair, which is not a relaxant, is neostigmine with glycopyrrolate, whose only grounded figures are a trial comparator and are not printed. Read the next sentence against that distinction, because the preference belongs to the relaxant and not to the reversal: after neuroleptic malignant syndrome it is rocuronium with sugammadex that is called the more promising method of muscle relaxation, although the same source states that evidence is lacking for a shared pathophysiology with malignant hyperthermia and that succinylcholine given for ECT in it is safe: caution, not a proven contraindication.

GOOD TO REMEMBER

Ask the relaxant question before the list is fasted, not at the trolley. Is there a denervating or disuse lesion, and how long ago was the insult, remembering that risk RISES toward the peak this page states in the rule above and that the acute phase carries its own caution, so recency is not safety in either direction? What may have lowered cholinesterase: organophosphate, liver or renal disease, pregnancy, a family history of prolonged apnoea? Has anyone in the family had malignant hyperthermia?

6.9 The anticholinergic question

Two separate routes slow the heart here and the sources attach them to different things. The first is the stimulus: an anaesthesia review names an initial parasympathetic discharge of ECT as what an anticholinergic is given to antagonise. The second belongs to the drug, not to the stimulus: the incidence of bradycardia, which may progress to asystole, is higher after a second dose of succinylcholine; in adults it is seen only after repeated exposure; and pretreatment with an anticholinergic such as atropine may reduce bradyarrhythmias. Read the second as a dose effect, because that is what the label describes: it says nothing about a second electrical stimulus. A restimulation may carry both, a further discharge and, where a second dose of relaxant is given with it, the label's raised bradycardia risk, and that is why the session that goes to restimulation is a cardiac event as well as an electrical one.

The guideline settles it against routine use. Routine prophylactic use of anticholinergics such as atropine or glycopyrrolate, and of beta blockers, calcium channel blockers, nitrates, hydralazine and ganglionic blockers for cardiovascular stability, is not recommended, and wherever used the rationale should be noted. An anaesthesia review is permissive: glycopyrrolate at 0.01 mg/kg is preferred to antagonise the initial parasympathetic discharge of ECT, intramuscularly at least 3 minutes before the procedure or intravenously just before induction, owned by the anaesthetist and named only so the psychiatrist recognises what is given. It benefits patients on beta blockers and those whose threshold is unset.

6.10 The tourniquet method, recovery and monitoring

The **Hamilton cuff method** exists because the relaxant that protects the patient from a convulsion also hides it. It monitors motor seizures by isolating the ipsilateral limb from muscle relaxants, the right limb in right unilateral ECT, and is preferred in modified ECT because it indicates generalisation. The inflation pressure and its timing are in no grounded source.

Recovery is physiological, not timed. Left lateral positioning and monitoring in the suite continue under an anaesthetist until spontaneous breathing is gained, and only then is the patient shifted to the recovery room. There, pulse rate, blood pressure and oxygen saturation are monitored, with the electrocardiogram in high-risk patients, the example being cardiac disease. Postictal confusion is measured, not waited out: orientation and gait are assessed for recovery to baseline or near baseline before shifting the patient out.

Recovery is a staffed competency, not a room. The guideline specifies a recovery nurse trained in post-anaesthesia care, able to monitor vital signs, pulse oximetry and electrocardiogram, give oxygen, fluids and suction, and support disorientation, delirium or agitation.

The evaluation is done as close to the course as possible and is examination-led: fundoscopy, dental, cardiovascular, neurological and pulmonary examination are mandatory, the blood panel is not, imaging and cardiac tests are indication driven. Fasting is graded at 2, 6 and 8 hours. The induction agent is chosen against separate rankings, ketamine proconvulsant but worst for rate, pressure and emergence. Succinylcholine is the usual relaxant, barred by separate mechanisms whose emergencies differ: potassium efflux from abnormal muscle, failed cholinesterase hydrolysis producing apnoea, and ryanodine triggering treated with dantrolene. Denervation risk RISES over time, with the onset and the duration expressly unknown and great caution required in the acute phase too, and peaks at 7 to 10 days, so recency is never the marker there. A non-depolarising agent must be stocked and never under-dosed.

7 · ECT technique and electrode placement (bilateral, right unilateral, bifrontal)

Two things are decided before any current flows in electroconvulsive therapy: where on the head the two electrodes sit, and what shape of electricity passes between them. The placement is fixed entirely by bony landmarks; the waveform and the electrical parameters fix what the stimulus contains; the impedance test says whether the circuit on the head is the one intended, and the monitoring says what the brain did with it.

Owned here in full and defined nowhere else: each electrode placement with its landmarks and geometry, the stimulus waveform, the electrical parameters that define a stimulus, impedance testing, and the monitoring of the induced seizure. Named and never re-derived, each with its own account elsewhere in this chapter: the comparison between the placements, a dose-dependent trade-off, in the notes on bilateral against right unilateral treatment; the threshold, titration and the adequate-seizure criteria, in the notes on stimulus dosing; the amnesias, in the notes on cognitive side effects; the anaesthetic conduct, in the notes on the pre-ECT workup.

three	four	100 to 3000
MEMBERS OF THE BILATERAL CLASS IN THE CURRENT INDIAN GUIDELINE	ELECTRICAL PARAMETERS THAT TOGETHER DEFINE A STIMULUS	OHMS: THE STATIC IMPEDANCE WINDOW ON ONE NAMED DEVICE

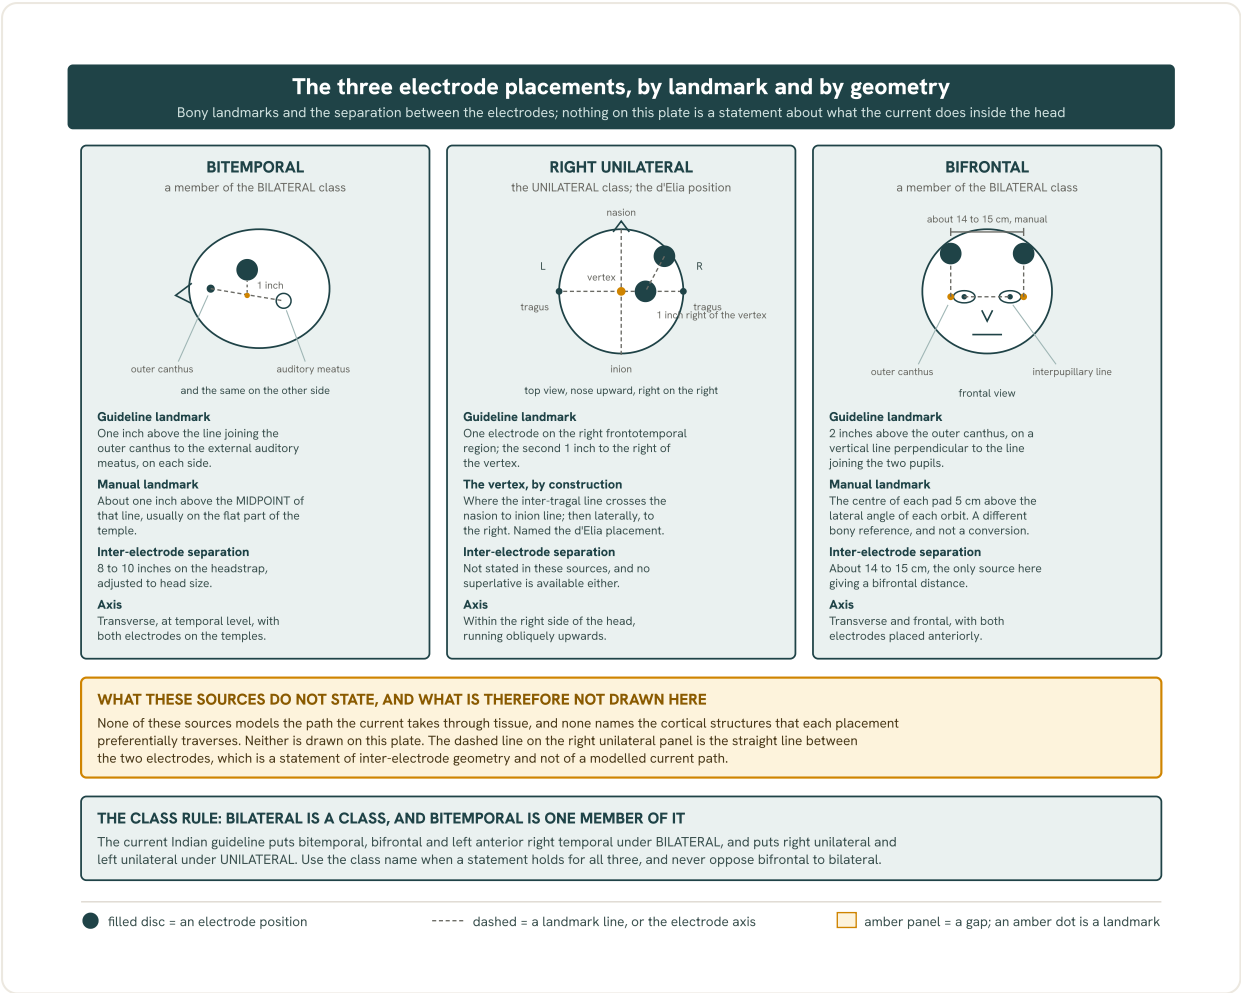

Fig 27.7. The three placements drawn by their bony landmarks and by the separation between their electrodes: bitemporal one inch above the line from outer canthus to external auditory meatus, and above the midpoint of that line in the device manual, with the electrodes eight to ten inches apart on the headstrap; right unilateral in the d'Elia position, one electrode right frontotemporal and the second one inch to the right of the vertex, the vertex itself constructed from the inter-tragal line crossing the nasion to inion line; and bifrontal two inches above the outer canthus in the guideline, five centimetres above the lateral angle of the orbit in the manual and about fourteen to fifteen centimetres apart, two measurements against two bony references rather than one figure converted, with bitemporal and bifrontal both members of the bilateral class, and no current path or traversed cortical structure drawn because no source here states one.

7.1 Bilateral is a class of placements, not one placement

The taxonomy must be right before any landmark is learnt, because every later comparison is phrased in it. The current Indian guideline classifies placements under two headings, Bilateral and Unilateral. Bilateral has three members: bitemporal, bifrontal and left anterior right temporal. Unilateral has two: right unilateral and left unilateral. **Bilateral** therefore names a class; **bitemporal** is one member of it, not a synonym for it.

The consequence is what gets examined. **Bifrontal** is a bilateral placement, not a third option outside the bilateral class. Written the other way it makes the placement comparison unreadable, since a sentence contrasting bilateral with bifrontal contrasts a class with one of its members. That comparison belongs to the notes on bilateral against right unilateral treatment; this fragment answers only the prior question, which is what each placement physically is.

RULE **Bilateral is the class; bitemporal, bifrontal and left anterior right temporal are its members.** Use the class name when a statement holds for all three and the member name when it does not, and never oppose bifrontal to bilateral. The guideline's numbered headings are the authority, not usage.

7.2 Bitemporal: the classical placement

The Indian guideline of 2023 calls bitemporal the classical method and defines it by one line on the face: an electrode in the frontotemporal region, one inch above the imaginary line joining the outer canthus and the external auditory meatus, and the same on the other side.

The guideline does not say which point on that line is meant. The manufacturer's manual does, and adds the separation: about one inch above the mid-point of that line, usually on the flat part of the temple, with the electrodes **8 to 10 inches** apart on the perforated headstrap, by head size. The guideline gives the height above the line, the manual the point on it and the distance; neither is complete alone.

7.3 Right unilateral in the d'Elia position

The right unilateral montage is two points far apart, the second defined by a construction rather than by a bone. One electrode sits on the right frontotemporal region and another 1 inch to the right of the vertex, the vertex being where two imaginary lines cross, one joining the two tragi and the other joining nasion to inion. The construction is examinable in itself: inter-tragal line, nasion to inion line, their crossing, then laterally to the right.

The manual states the eponym: for right unilateral placement the d'Elia placement is recommended. The same manual carries the conduct, which is not incidental: the skin over the right temple is cleaned and dried and the pad applied to bare skin, then the hair near the vertex is parted and the scalp moistened thoroughly with saline. Hair lies under one of these electrodes and not the other, which is why the saline step attaches to the vertex electrode and why that is the one that misbehaves on the impedance check.

7.4 Bifrontal, and two landmarks that must not be merged

Bifrontal puts both electrodes over the frontal regions, and two independent statements of where are carried here. The Indian guideline puts them 2 inches above the outer canthus, on an imaginary vertical line perpendicular to the line joining the two pupils. The device manual puts the centre of each pad 5 cm above the lateral angle of each orbit, about 14 to 15 cm apart, the only source here giving a bifrontal inter-electrode distance.

These are two measurements, not one measurement in two dresses. The units differ and the bony reference differs with them: the outer canthus is the soft-tissue corner of the eye, the lateral angle of the orbit a point on bone. They land close together on a real head and remain separate quotations from separate documents. Nothing here converts one into the other, because a converted figure is an arithmetic step by the author rather than a quotation, putting on the page a number that neither source states.

PITFALL

Converting the bifrontal landmark out of one source's units into the other's and reporting the result as though a guideline had said it. Both are printed against their own bony references, so the reader can quote whichever document a question asks about. The same discipline governs every parameter here: quote the source, name it, and neither average nor convert between sources.

7.5 What the landmarks fix, and what they do not

Geometry is what a landmark buys. Bitemporal puts both electrodes on the temples, so the axis between them runs transversely at temporal level; bifrontal puts both anteriorly, so the axis is transverse and frontal; right unilateral puts one at the right temple and the other just right of the vertex, so the axis lies within the right side of the head and runs obliquely upwards, and the wide separation is what makes this the long-distance montage over the non-dominant side.

What these sources do not state matters as much, because the temptation is to supply it from memory: none models the path the current takes through tissue, and none names the cortical structures each placement preferentially traverses.

AXIS	BITEMPORAL	RIGHT UNILATERAL	BIFRONTAL
CLASS	Bilateral	Unilateral	Bilateral
GUIDELINE LANDMARK	One inch above the line from outer canthus to external auditory meatus, each side	Right frontotemporal, plus 1 inch right of the vertex	2 inches above the outer canthus, on the perpendicular to the interpupillary line
MANUAL LANDMARK	About one inch above the mid-point of that line	Named as the d'Elia placement; vertex scalp moistened	Centre of each pad 5 cm above the lateral angle of the orbit
SEPARATION CARRIED HERE	8 to 10 inches	Not stated in these sources, and no superlative is available either: both separations that ARE stated, in the bitemporal and bifrontal columns of this row, exceed the span from a right temple electrode to a point one inch right of the vertex	About 14 to 15 cm

7.6 Waveform: sine wave, brief pulse, ultrabrief pulse

The **stimulus waveform** is the shape of the electricity in time. The original sine-wave stimulus had a long pulse width of 8.3 ms and was inefficient, using more energy than neurons require in order to discharge; the square-wave brief pulse of 0.5 to 1.5 ms that replaced it reduced cognitive side effects while keeping efficacy. The Indian guideline states the modern position as a recommendation, not as history: a brief or ultrabrief pulse is strongly recommended and should

be given with a constant current device, and sine-wave and constant voltage systems are not recommended in modern practice, on safety grounds.

The bands are where the sources disagree, so each is stated with its body. The Indian guideline of 2023 defines brief pulse as 0.5 to 2 ms and ultrabrief as 0.2 to 0.4 ms. The Australian and New Zealand college guideline of 2019 defines brief pulse as 0.5 to 2.0 ms and ultrabrief as 0.25 to 0.3 ms. The two GUIDELINE brief-pulse bands agree, as the two quoted sentences above show, and it is that agreement and no wider one that may be claimed: a third and narrower brief-pulse upper bound, from a meta-analysis, appears elsewhere in this chapter, so a candidate who memorises the narrowest answers wrong against both guidelines. The ultrabrief bands do not agree at all. An answer giving any one band as the definition without naming its body has adopted a source silently.

The guideline attaches a relation to pulse width, and it holds for pulse width only. Pulse width is likely to have a linear effect on cognitive adverse effects, broader widths being associated with worse ones; an ultrabrief pulse of 0.3 ms has a cognitive advantage over brief pulses with right unilateral placement in depressive disorders, though antidepressant efficacy may be compromised with it; and a lower brief-pulse range of 0.5 to 1 ms may be considered optimal for a rapid clinical effect. The college guideline bounds where that has been shown: for ultrabrief bilateral treatment the published evidence is very limited and efficacy is lower than with brief-pulse bilateral treatment. Both are statements about pulse width inside a placement, and neither licenses carrying this direction across to another parameter. No comparison between placements is made here.

7.7 The four parameters, and why charge alone is not the dose

A stimulus is a tuple, not a number. The arithmetic comes first: electrical charge = current intensity x pulse width x pulse frequency x train duration. The guideline then warns against the natural misreading of its own equation. Charge is generally treated as a linear measure and the chief parameter of dosing, but that approach is faulty: the four parameters in combination, along with electrode placement and the frequency and duration of sessions, are what should be considered in choosing a protocol. Two stimuli of equal charge built from different parameters are different stimuli.

Current intensity is the parameter that is not moved. Historically 500 to 1000 mA has been used, most devices default to 800 to 900 mA, and current correlates linearly with tolerability, cognitive effects and seizure quality, but is held constant during dose incrementation. Low-amplitude stimulation is named in the same paragraph as investigational, its clinical utility yet to be understood; that status is the teaching point and no current band for it is carried.

Pulse frequency is the counterintuitive one. It is the number of biphasic pulses per second, the inverse of the interpulse interval, ranging from 20 to 240 pulses per second, that is 10 to 120 Hz of bidirectional pulse pairs. Lower frequencies are more efficient: a seizure is elicited at a lesser charge with a lower frequency when all else is held constant. That sits awkwardly beside how

devices behave: many increment the dose by raising frequency, so the default increment works against efficiency in the patient whose threshold is already high.

Train duration is the parameter that is moved. It is the most commonly modified parameter for setting the dose; most devices offer 0.2 to 8 s and some up to 16 s; no limit has been examined or recommended for the highest duration; and charge is raised by lengthening the train until the device's limit is reached. What multiple of the measured threshold that charge should be belongs to the notes on stimulus dosing.

MNEMONIC

CURRENT, WIDTH, RATE, TRAIN

The four parameters in the order of the charge equation. **Current** is held constant. **Width** names the waveform brief or ultrabrief. **Rate** is more efficient when lower, the opposite of the intuition. **Train** is the one moved to change the dose.

7.8 One device's specification, read as a device's

Hardware bounds the tuple. One widely used constant-current device specifies a 0.9 A constant current limited to 450 V; 10 to 70 Hz in 10 Hz increments, extending to 140 Hz in the low pulse-width programs; a pulse width of 0.25 to 1.5 ms in 0.25 ms increments, with 0.3 ms available; a train duration of 0.08 to 8.00 s; and a standard maximum output across 220 ohms impedance of 504 mC, that is 99.8 joules.

TRAP **Quoting a device's maximum output, or any of its bounds, as a universal figure.** Every value above belongs to one named device at one revision of its manual; another device has other bounds. The guideline bands for pulse width are the general statement; a specification is not. Write the device's name beside its numbers, or do not write them.

7.9 Impedance: static, dynamic, and why the check is not housekeeping

Two impedances are measured and they are not the same measurement. Stimulation has to overcome the combined resistivity of scalp, skull and other tissues. Static impedances are measured before stimulation using high-frequency alternating pulses, dynamic impedances during passage of the stimulation current, and static impedance can partly be influenced by skin preparation. **Static impedance** is thus the pre-stimulus check the operator can act on, **dynamic impedance** a property of the treatment itself.

The static test has a window and an interpretation at each end. It checks the quality of the skin-to-electrode contact; on one named device the reading should be greater than 100 ohms and less than 3000 ohms before the stimulus is administered, and a reading below 100 ohms suggests a short circuit, probably in the stimulus cable. The ends fail differently: too low says the current has found a path that is not the patient, too high that it will struggle to find one.

The check earns its place because contact quality reaches the seizure. In a single-centre retrospective analysis of 78 patients across 1757 bifrontal sessions from 2012 to 2020, static and dynamic impedance were strongly correlated, and dynamic impedance was significantly related

to Maximum Sustained Power and to the Average Seizure Energy Index but to no other seizure quality criterion; aiming for low static impedance might reduce dynamic impedance, so good skin preparation is recommended. The design bounds the claim: retrospective, one centre, bifrontal treatment only.

GOOD TO REMEMBER

A high static reading calls for a sequence, not a shrug.

- Press each electrode firmly against the skin again, especially the vertex electrode in unilateral treatment.
- Moisten the hair and scalp under the vertex electrode with saline.
- Recheck the skin preparation steps.
- Only then replace the pads, the lead-wires and the stimulus cable, in that order.

7.10 Monitoring the induced seizure

Three records are taken of one event: cortical, muscular and cardiac. What the guideline requires at the station is specific. Vitals monitoring calls for a sphygmomanometer, a reflex hammer, oxygen saturation and ECG, alongside the apparatus with its bite block and the electroencephalogram and ECG monitors.

For the cortical record the montage is specified. The electroencephalogram is a direct measure of seizure activity and is recommended wherever available; bilateral recording from at least two channels, FP1 and FP2, referenced to the ipsilateral mastoid is preferred, and where only one channel is available a contralateral channel is preferred. The fallback is contralateral because a channel over the non-stimulated side is the one that can show generalisation.

The motor record is neither optional nor a substitute. Electroencephalogram recording can carry artefacts from muscle movement and from technical problems, so motor monitoring should always supplement it. The instrument for seeing a motor seizure in a relaxed patient is the isolated-limb method: the Hamilton cuff method is recommended for monitoring motor seizures by isolating the limb ipsilateral to the stimulated hemisphere, the right limb in right unilateral treatment, from the muscle relaxant. The side is the point of the method, not a detail of it: a convulsion in the limb ipsilateral to the stimulated hemisphere is evidence that the seizure crossed to the other hemisphere and generalised. The cuff as anaesthetic conduct belongs to the notes on the pre-ECT workup; only its use as an instrument for reading the seizure is taught here.

A modern device consolidates this onto one trace, with four recording channels: 1 and 2 for the electroencephalogram, 3 for the electromyogram and 4 for the ECG. From those it computes named indices, the postictal suppression index with a range of 0 to 100 per cent, the average seizure energy index, maximum sustained electroencephalogram power and coherence with the time to peak of each, the Duke University measures, power spectral analysis, and peak heart rate. The range of the suppression index is grounded; no threshold on it is, and none is invented. What counts as an adequate seizure belongs to the notes on stimulus dosing.

IN INDIA

The current Indian Psychiatric Society guideline, published in 2023, settles four choices on this page: a brief or ultrabrief pulse from a constant current device; the placement landmarks quoted above, bifrontal among them in inches; a two-channel electroencephalogram referenced to the ipsilateral mastoid; and motor monitoring always supplementing it. Where a device manual or a college guideline states a different figure, name the document beside it.

Bilateral is a class containing bitemporal, bifrontal and left anterior right temporal; unilateral contains right unilateral and left unilateral. Bitemporal sits one inch above the line from outer canthus to external auditory meatus, above its mid-point in the manual; right unilateral is the d'Elia position, right frontotemporal plus one inch right of the vertex; bifrontal is two inches above the outer canthus in the guideline and five centimetres above the lateral angle of the orbit in the manual, two statements and not a conversion. A stimulus is current intensity, pulse width, pulse frequency and train duration together, and the seizure is read on the electroencephalogram, on an isolated limb and on the ECG at once.

8 · Bilateral versus right unilateral ECT (efficacy versus cognitive trade-off)

The choice between a bilateral placement and right unilateral placement is the decision in a course of electroconvulsive therapy most often carried in memory as a fixed ranking, and a fixed ranking is the one thing it is not. Whether right unilateral treatment is as good as bilateral treatment has no answer until the dose is named, because the two have different dose-response relations. Written as a ranking the comparison is memorable and clinically false; written as a function of the multiple of seizure threshold it is correct and usable.

Owned here in full: the trade-off between efficacy and cognitive cost across the placements, the evidence base behind it, where bifrontal placement sits within it, and how the choice is made for a given patient. Named here and not re-derived, each with its own account in this chapter: what each placement is, with its landmarks, geometry and current path; what the seizure threshold is and how it is titrated; and the amnesias themselves, their course and their monitoring. This account states only how placement and dose move that cognitive cost, never what the cost consists of.

17% against 65%	792	6 times
RESPONSE NEAR THRESHOLD, RIGHT UNILATERAL AGAINST BILATERAL, IN THE TRIAL THAT SEPARATED DOSE FROM PLACEMENT	PATIENTS IN THE POOLED COMPARISON FINDING NO DIFFERENCE ONCE THE MULTIPLE IS HIGH	THRESHOLD, ABOVE WHICH RIGHT UNILATERAL PLACEMENT NO LONGER HOLDS A COGNITIVE ADVANTAGE OVER BITEMPORAL

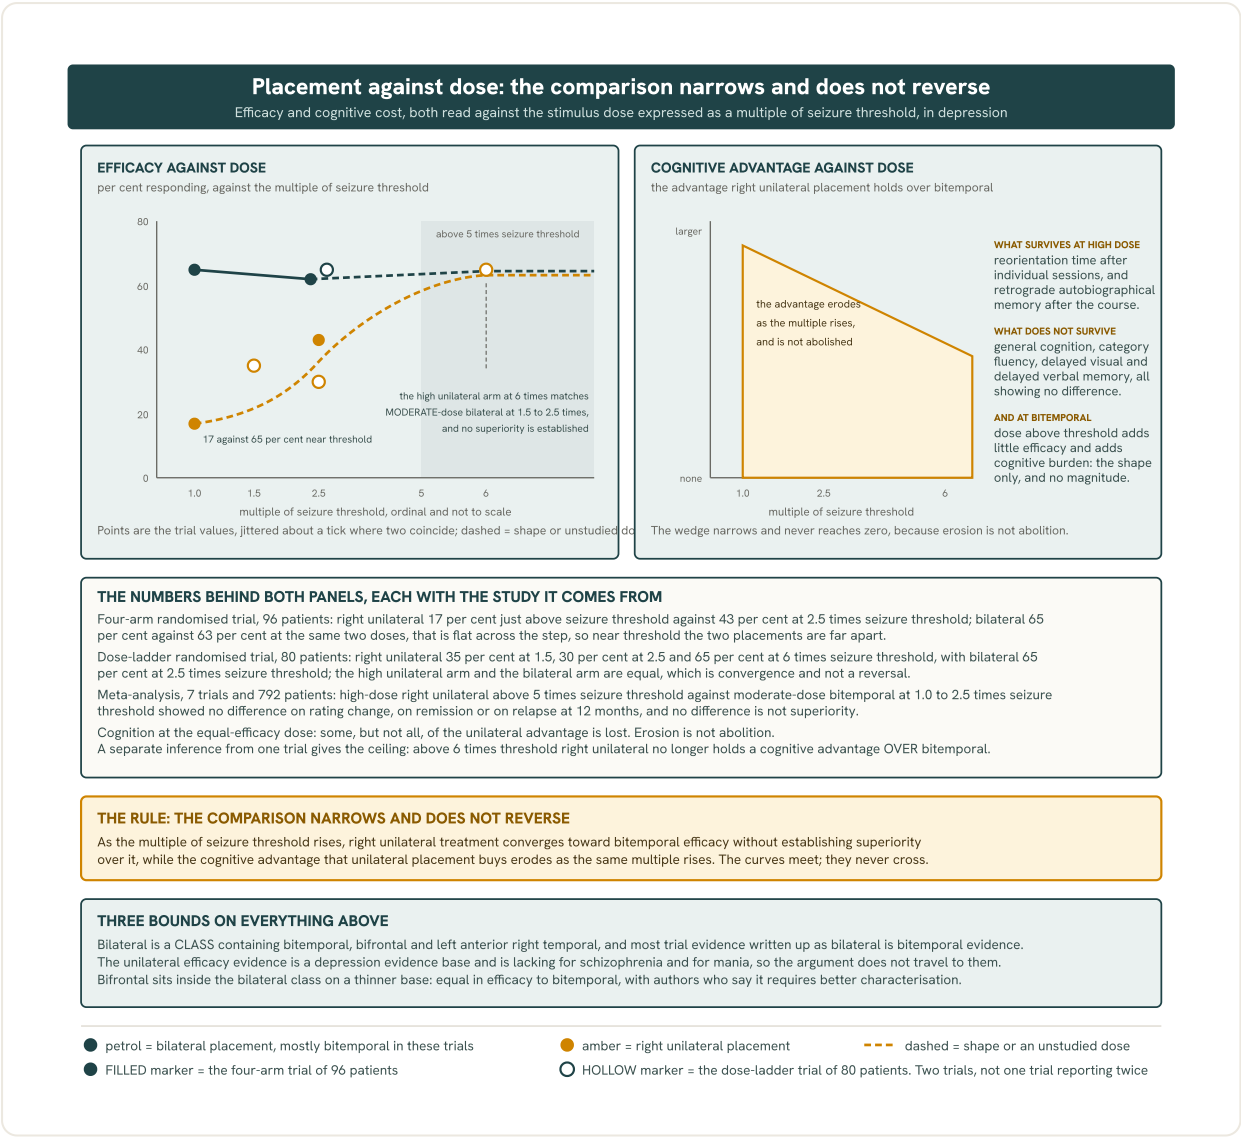

Fig 27.8. Efficacy and cognitive cost read as functions of the stimulus dose expressed as a multiple of seizure threshold, rather than as a fixed ranking of the placements. On the left, bilateral response is already near its maximum at a low multiple and stays flat, while right unilateral response is markedly inferior near threshold and rises to meet it at six times seizure threshold, so the two lines converge and never cross and no superiority of right unilateral over bitemporal placement is established. Read the meeting point precisely, because the geometry invites a stronger claim than the evidence carries: no bilateral arm in any trial here was dosed above two and a half times threshold, so the bilateral line is drawn solid only across the doses actually studied and dashed beyond them, and the match at six times is high-dose right unilateral against MODERATE-dose bilateral rather than two arms compared at the same dose. On the right, the cognitive advantage that unilateral placement buys narrows as the same multiple rises but is not abolished, surviving in reorientation time and in retrograde autobiographical memory and not in general cognition, category fluency or delayed visual and verbal memory. Both halves are stated together, and all of it is a depression evidence base.

8.1 Bilateral is a class of placements, not a placement

The terminology has to be settled before the comparison can be read, because two words are used across this literature as though they were interchangeable and they are not. **Bilateral** is a class of placements, and it has three members, not two: the current Indian guideline lists **bitemporal**, **bifrontal** and left anterior right temporal placement under the bilateral heading. Bitemporal is one member of it. Bifrontal is another member of the same class, so it is not a third option sitting outside a bilateral pair, and the word pair is itself the error, because the class is a set of three. Left anterior right temporal placement is the member most often dropped from an answer, and

dropping it is how a candidate ends up with a two-member class. What each placement is, where its electrodes sit and which way the current runs, is taught in this chapter's account of the placements themselves and is not restated here.

The distinction earns its place because of what it does to the numbers. Most of the trial evidence written up as bilateral is bitemporal evidence: the programmes used the standard bitemporal montage and their reports call it bilateral. A figure carried under the class word is a class-level figure and stays one. Every claim below names which of the two its evidence rests on; evidence about bilateral electroconvulsive therapy is never read here as evidence about bitemporal placement; and no class-level effect size is attached to bifrontal or to bitemporal individually. Where a source pooled the class and never reported the split, the within-class breakdown is not carried here and is recorded as a declared gap, because an inferred breakdown would be indistinguishable on the page from a measured one.

EVIDENCE	LABEL THE SOURCE USES	WHAT THE CLAIM RESTS ON
THE FOUR-ARM DOSE-BY-PLACEMENT TRIAL	Bilateral	Bitemporal, since that programme used the standard bitemporal montage: bitemporal evidence under the class word
THE TRIAL OF HIGH-DOSE RIGHT UNILATERAL AGAINST A ROBUST BILATERAL COURSE	Bilateral	The class; the comparator is not separated into its members, so no figure from it is narrowed here
THE 2017 META-ANALYSIS OF CONVERGENCE AND RESIDUAL COGNITIVE ADVANTAGE	Bitemporal	Bitemporal, named as such by its authors, which makes it the cleanest source here
THE 2003 META-ANALYSIS OF BILATERAL AGAINST UNILATERAL	Bilateral	The class, pooled across doses: class-level and dose-mixed on both axes
THE BIFRONTAL META-ANALYSIS	Bifrontal, bitemporal and right unilateral, separately	The three named separately, which is why it is used here for bifrontal

8.2 Near threshold the two placements are far apart

The bottom of the dose range is anchored by one double-blind randomised trial, and its design is what makes it decisive. 96 depressed patients were assigned to right unilateral or bilateral treatment at either a low dose, just above the seizure threshold, or a high dose at 2.5 times the threshold. What the multiple of threshold is, and how the threshold beneath it is measured, belongs to this chapter's account of stimulus dosing and is taken as read.

The results are two relations and not one, which is the teaching point. For right unilateral placement the **dose-response relation** was steep: **17 per cent responded at the low dose against 43 per cent at the high dose**. For bilateral placement it was flat across the same step: **65 per cent at the low dose and 63 per cent at the high dose**. Near threshold, right unilateral treatment is markedly inferior and bilateral efficacy is already near its maximum. A later meta-

analysis states the settlement plainly: the effectiveness of right unilateral ECT depends on the strength of the electrical dose above the seizure threshold, and it is relatively ineffective at the doses nearer threshold, 1.0 to 2.5 times the seizure threshold, used in bitemporal ECT.

The asymmetry is stated per placement, and per placement is the only way it is true: with right unilateral placement, stimuli much higher than the seizure threshold are necessary for effective treatment, while in bilateral ECT they add little to efficacy while increasing the cognitive burden of the treatment. Two cautions travel with that sentence. It is an introductory assertion in a paper about thresholds, not the finding of a trial that randomised dose and measured cognition at bitemporal placement, so its shape may be taught and no magnitude attached to it. And its direction holds for this parameter only; no general law about work and cost is inherited from it anywhere in this chapter.

RULE **As the multiple of threshold rises, right unilateral treatment converges toward bitemporal efficacy without establishing superiority over it, while the cognitive advantage that unilateral placement buys erodes as the same multiple rises.** Both halves are said together or neither is said usefully. The first alone sells a high unilateral dose as free, which it is not, since the cognitive advantage is what is spent to buy the efficacy. The second alone sells it as pointless, which it is not, since a clinically meaningful advantage survives at the top of the range. The comparison narrows and does not reverse.

8.3 At a high multiple the comparison narrows

The convergence was established by a second double-blind randomised trial with a wider dose ladder. 80 depressed patients were randomised to right unilateral treatment at 50, 150 or 500 per cent above the seizure threshold, or to bilateral treatment at 150 per cent above it. Convert those before reading on, because the rest of this chapter speaks in multiples and the commonest error here is to read the largest of them as five times threshold rather than six: 50, 150 and 500 per cent above threshold are 1.5, 2.5 and 6 times threshold, and the bilateral arm at 150 per cent above threshold is 2.5 times it. **High-dose right unilateral and bilateral treatment were equal in response rate at 65 per cent, and roughly twice as effective as the low-dose arm at 35 per cent or the moderate-dose arm at 30 per cent**. That is convergence and not a reversal: the two placements meet, and no superiority of right unilateral treatment over bilateral treatment is established anywhere in it.

The pooled position agrees, and it is also the source that names its comparator properly. Seven trials and 792 patients compared high-dose right unilateral treatment, above 5 times the seizure threshold, with moderate-dose bitemporal treatment at 1.0 to 2.5 times threshold, and found no difference on depression rating change, with a Hedges's g of -0.03 and a 95 per cent confidence interval of -0.17 to 0.11; on remission, with a risk ratio of 1.06 and an interval of 0.93 to 1.20; or on relapse at 12 months, with a risk ratio of 1.42 and an interval of 0.90 to 2.23.

Two readings of that are wrong in opposite directions. No difference is not superiority: every interval straddles the null, so the wording is **convergence without established superiority**, and calling high-dose unilateral treatment better than bitemporal treatment goes past the evidence.

Nor is no difference an argument for a low unilateral dose, since the result is conditional on the high multiple.

8.4 What the higher multiple costs, and what it does not

The cognitive advantage is not free of the dose either, and the same meta-analysis states the erosion and its limit in one sentence, which is the form to reproduce: some, but not all, of the cognitive advantage of right unilateral ECT is lost when it is given at a dose sufficient to achieve equal clinical efficacy with bitemporal ECT. Erosion is not abolition, and that is why the placement is still chosen at a high multiple rather than abandoned once the efficacy gap closes.

What survives is domain-specific, and it is grounded in two domains and no others. Right unilateral treatment kept an advantage on reorientation time after individual sessions, a mean difference of -8.28 minutes with a 95 per cent confidence interval of -12.86 to -3.70, and on retrograde autobiographical memory after the completed course, a Hedges's g of -0.46 with an interval of -0.87 to -0.04, while there were no differences for general cognition, category fluency, or delayed visual and verbal memory. A claim of a broad cognitive advantage at high dose is therefore not available; a claim of a real one in named domains is.

The trial evidence carries the counterweight most directly. In the week after the randomised phase, bilateral treatment produced greater impairment than any dosage of unilateral treatment on several measures of anterograde and retrograde memory, and at two months the retrograde deficits were greatest among the patients treated bilaterally. Greater than any dosage means the advantage was not abolished even at the top of the ladder, and the later assessment means it was not merely a same-week effect. What those impairments are and how they are tracked belongs to this chapter's account of the cognitive cost; only their movement with placement and dose is settled here.

The ladder has a ceiling on this axis, drawn from a single trial rather than a pooled estimate. The only included study that favoured bitemporal placement on autobiographical memory, and not significantly, had dosed right unilateral treatment at 8 times the seizure threshold, from which the authors infer that there is no cognitive advantage in going beyond 6 times threshold for right unilateral ECT. It is their inference from one trial, and it gives the practical top of the useful range.

TRAP **Answering which placement is better without being told the dose.** The question is under-specified and the examiner usually knows it. Near threshold the bilateral placements are clearly better; at a high multiple the efficacy difference is not demonstrable and part of the cognitive advantage has gone with it. Naming the multiple before answering is most of the examinable content.

8.5 Why an older pooled estimate says bilateral is better

A resident who has read the older literature meets an apparently contradictory finding, and it is not a contradiction. The 2003 systematic review and meta-analysis found bilateral treatment more effective than unilateral treatment across 22 trials and 1408 participants, with a standardised effect size of -0.32 and a 95 per cent confidence interval of -0.46 to -0.19, that is a

small to moderate advantage for bilateral placement. Its trials did not separate high-dose unilateral treatment from low-dose and moderate-dose unilateral treatment. This chapter's reading of that is that the review pooled across the very variable the comparison turns on, so a pooled estimate over a mixture of doses answers a different question from a comparison at a stated multiple; the reading is stated as a reading, because the review does not describe its own placement analysis in those terms. What the review does say about dose it says separately, and it points the same way: high dose ECT is more effective than low dose. The older figure is cited for what it established when it was published and never as current practice.

8.6 Where bifrontal placement sits, and how thin its evidence base is

Because bifrontal placement is a member of the bilateral class, the question is not whether it beats the class but where it sits inside it. A meta-analysis comparing bifrontal with bitemporal and with right unilateral treatment found efficacy equal between bifrontal and bitemporal, with a Hedges's g of 0.102 and a confidence interval of -0.110 to 0.313, and equal between bifrontal and right unilateral, with a standardised mean difference of -0.12 and an interval of -0.378 to 0.139; post-treatment decline on the Mini-Mental State Examination was less for bifrontal than bitemporal, with a g of 0.89 and an interval of 0.054 to 1.724, but not less than for right unilateral; and the authors conclude that bifrontal treatment is not more effective than the other two and, given the longer experience with them, requires better characterisation. That last clause answers how the evidence bases differ in size: the bifrontal one is younger and thinner, not contrary.

The current Indian guideline takes a stronger position, recorded beside the meta-analysis rather than merged with it. Clinical trials have shown that bifrontal is equally if not more effective than bitemporal placement, but with lesser cognitive effects, in patients with mania, depression as well as schizophrenia. Under the precedence this series declares, the guideline controls Indian practice questions; it does not dissolve a meta-analytic finding that bifrontal treatment is not more effective and needs better characterisation. The disagreement is named and deliberately not resolved.

GOOD TO REMEMBER

Do not let the class word do the arguing. If a source says bilateral, ask which member it used; if it says bitemporal, that is a claim about one member only; and if a figure was pooled over the class, it stays a class figure and may not be handed to bifrontal or to bitemporal alone.

8.7 How the choice is actually made for a patient

The dose-dependent comparison is the second question at the bedside and not the first, because it is an argument about one diagnosis. The evidence for the efficacy of unilateral ECT is available only for depression, and it is lacking for the other common indications, namely schizophrenia and mania. Every trial and meta-analysis above is a depression study, so carrying the convergence argument to a patient treated for schizophrenia or mania exceeds the evidence, and in Indian practice, where schizophrenia is a common indication, that limit does real work.

Where the indication permits the choice, the working rule is that **dose is matched to placement** rather than set once for the machine. A current college guideline states that bitemporal and unilateral treatment are both effective when dosed adequately, that cognitive side-effects are greater with bitemporal placement and with higher stimulus doses, and that doses up to 6 times threshold can maximise the efficacy of unilateral treatment while doses at 1.5 times threshold are usually sufficient for bilateral treatment. Read the unilateral figure as an upper bound and not as a range, because an upper bound is the only form this passage of the college guideline gives. The same guideline states that multiple a second time, in its dosing footnote, in a form that carries a FLOOR as well as a ceiling, and it is the floor that disagrees with the current Indian guideline. Both college forms and the Indian figure, with the disagreement between them, belong to this chapter's account of stimulus dosing and are printed there with their bodies and years. What must not happen here is what the open-ended form invites: quoting it alone reads as agreement and dissolves a disagreement that is real. The multiples themselves and how the threshold beneath them is titrated belong to this chapter's account of stimulus dosing, where those figures are taught with their sources and their disagreements.

Selection is not only cognitive. One grounded non-cognitive reason decides real cases: bifrontal treatment has less impact on cardiac rhythm during the stimulus than the other forms, so it is worth considering in a patient at risk of an arrhythmia induced by the treatment.

- **Indication first.** Depression admits the whole argument. Schizophrenia and mania do not, on the unilateral evidence base as it stands.
- **Then the cognitive stake.** The higher it is for this patient, the stronger the case for right unilateral placement dosed properly rather than dosed near threshold.
- **Then the medical constraint.** An arrhythmia risk is a positive reason to consider bifrontal placement, independent of any cognitive argument.

IN INDIA

Two facts shape this choice here more than the trial literature does. The unilateral evidence base is a depression evidence base, and schizophrenia is a common indication, so a bilateral placement is the default for many patients on grounds of evidence rather than habit. And the current Indian guideline, published in 2023, is more favourable to bifrontal placement than the meta-analytic literature is; quote both, with the body and the year attached to each.

MNEMONIC

CLASS, MULTIPLE, INDICATION

Before comparing placements, name the **class**: bilateral is a class of three, bitemporal, bifrontal and left anterior right temporal, so say which of them the evidence used. Before ranking them, name the **multiple** of seizure threshold, because the ranking is a function of it and has no fixed answer without it. Before carrying the ranking to the patient in front of you, name the **indication**, because the unilateral evidence base is a depression evidence base.

PITFALL

Teaching the comparison as bilateral works better, unilateral is kinder. It is compact, it is what most candidates say, and it is wrong twice over: true only near threshold on the efficacy half, and overstated on the cognitive half at the doses right unilateral treatment is actually given at. Give the dose-dependent form, with both halves stated together.

Bilateral is a class of three placements, bitemporal, bifrontal and left anterior right temporal, and most trial evidence written as bilateral is bitemporal evidence. Near threshold, right unilateral treatment is markedly inferior while bilateral efficacy is already near maximal. As the multiple of threshold rises, right unilateral treatment converges toward bitemporal efficacy without established superiority over it, while the cognitive advantage that unilateral placement buys erodes without being abolished, surviving in reorientation time and retrograde autobiographical memory. The comparison narrows and does not reverse. Bifrontal placement sits inside the bilateral class on a thinner evidence base, and the choice is made on the indication first, then the cognitive stake, then the medical constraints.

9 · Stimulus dosing, seizure threshold and adequate seizure criteria

Almost every decision in a course of electroconvulsive therapy is expressed in units of one measured quantity, the electrical dose at which this patient's brain will seize. The seizure threshold is neither a device setting nor a property of the diagnosis. It is measured in the individual patient, differs enormously between patients, moves within the same patient across a course, and the treatment dose is written as a multiple of it. A resident who can define it, set it, dose against it and judge the seizure that followed can run a course.

Owned here in full: the determinants of the threshold, how the stimulus is set, the dose as a multiple of threshold, the rise across a course, the restimulation rules and the criteria for an adequate seizure. Named here and not re-derived, each with its own account in this chapter: what each placement is and the parameters that define a stimulus; the efficacy against cognition comparison between placements; the amnesias and their monitoring; which drugs move the threshold; and why an induced seizure helps.

12-fold	1.5 to 6	47%
RANGE IN THRESHOLD BETWEEN PATIENTS IN THE TRIAL THAT QUANTIFIED IT	TIMES THRESHOLD: THE DOSE IS A MULTIPLE, SET BY PLACEMENT AND PULSE WIDTH	AVERAGE RISE IN THRESHOLD BY THE SIXTH TREATMENT WHEN IT WAS RE-TITRATED

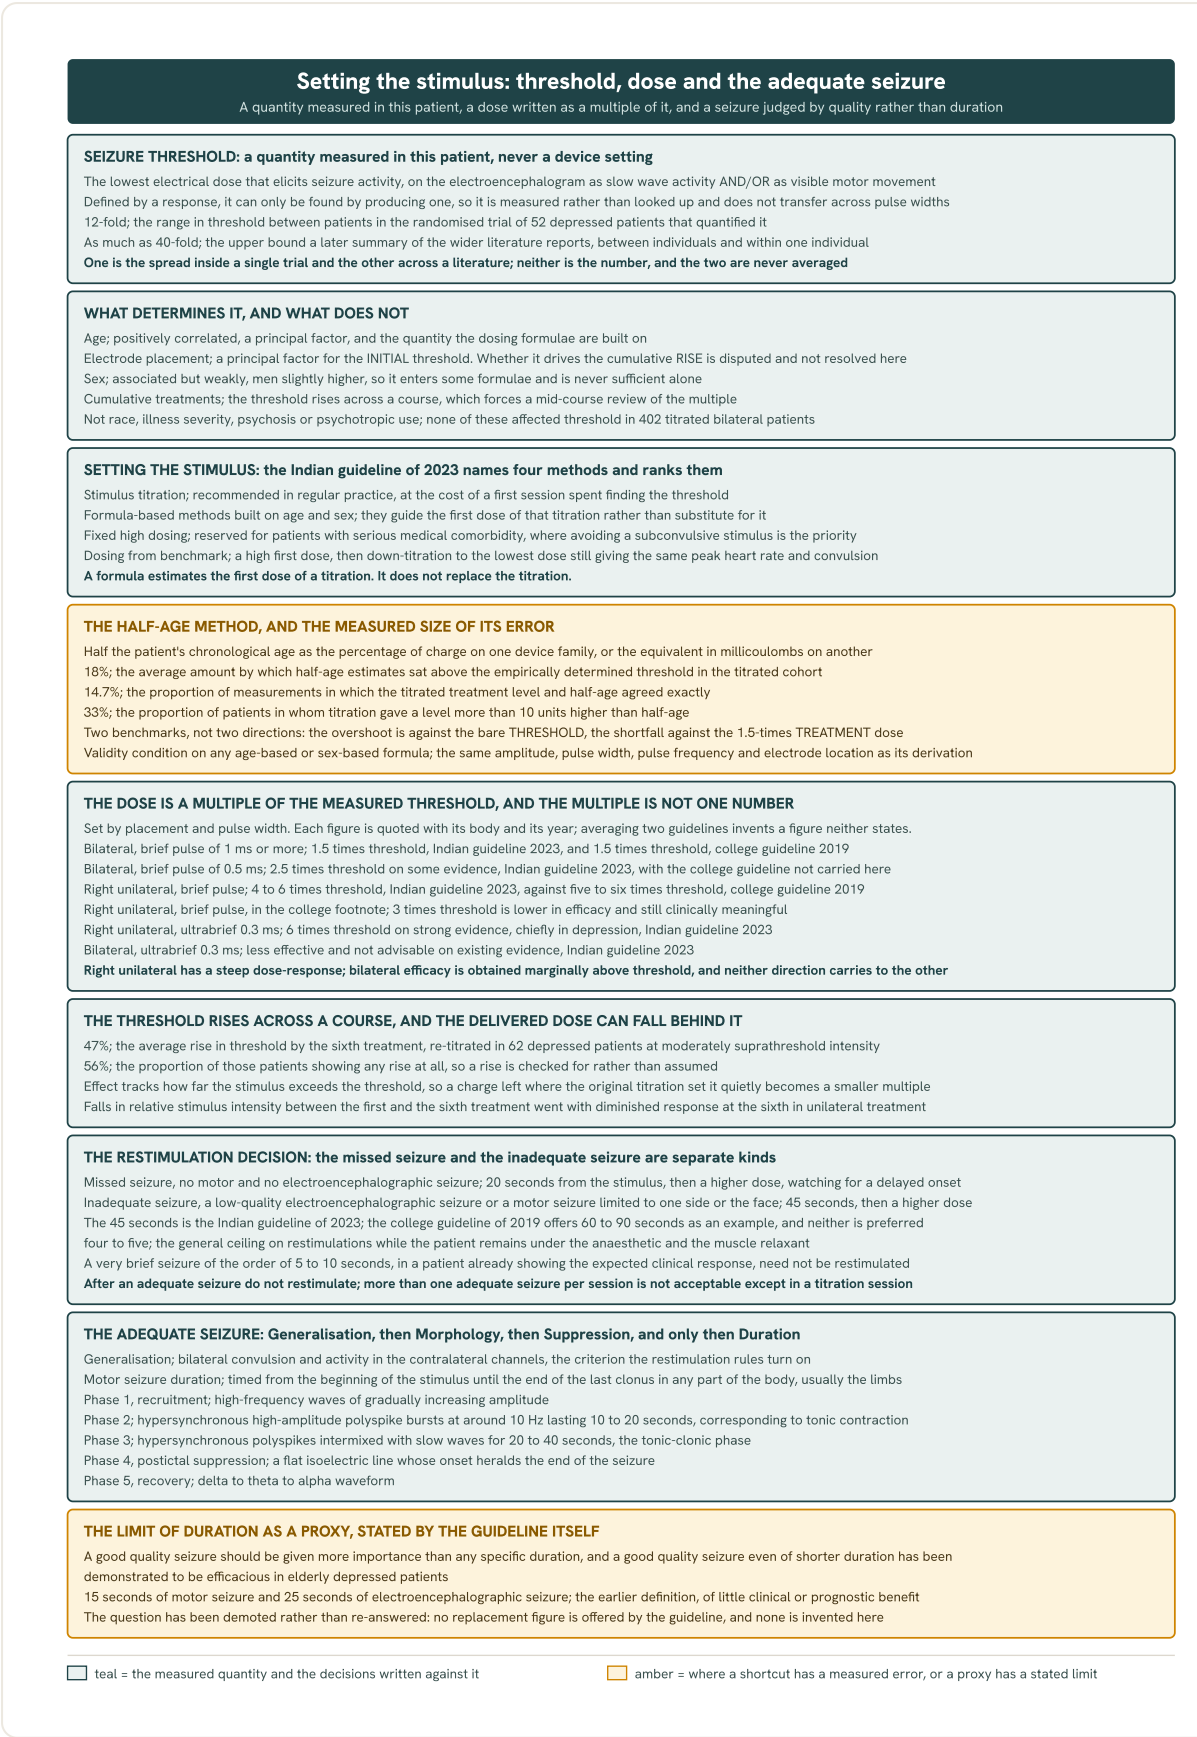

Fig 27.9. The seizure threshold is measured by titration, varies enormously between patients and rises across a course in only some of them; the dose is a multiple of it, sized by placement and pulse width and not by one rule; a formula estimates only the first dose and its two reported errors are measured against two different benchmarks rather than running in two directions; and adequacy is judged by generalisation, electroencephalographic morphology and postictal suppression, the classical duration criteria being retired with no replacement figure offered.

9.1 A measured quantity, not a machine setting

The **seizure threshold** is the lowest electrical dose which elicits seizure activity, as seen on the electroencephalogram, that is slow wave activity, and/or visible motor movement. The disjunction is load-bearing and is quoted as the guideline writes it: either sign will do, and reading it as a requirement for BOTH would make the ordinary case of an electroencephalographic seizure without visible movement under adequate relaxation look subthreshold, which is exactly the reading the missed-seizure rule below contradicts. The definition has consequences. Being defined by a response, it can only be found by producing one, so it is measured rather than looked up. Being defined against a particular stimulus, it is a property of the patient and the waveform together, so a threshold obtained at one pulse width does not transfer to another. And being a floor rather than a treatment, it produces a seizure without necessarily treating the illness, which is why the prescription is a multiple of it.

Stimulus titration turns the definition into a number: a low stimulus is given, and if no seizure follows the dose is stepped up within the same session until one does. That dose is this patient's threshold for this session.

9.2 What determines the threshold, and how wide the range is

The examinable fact is that the threshold does not behave like a constant. The randomised trial that quantified it titrated 52 depressed patients to just above threshold and found a **12-fold** range in the minimum intensity needed to produce a seizure, with sex, age, placement and cumulative treatments each associated with it. A later summary of the wider literature puts the reported variation, between individuals and within one individual across conditions, at **as wide as 40-fold**, which is an upper bound and not a point value. One is the spread inside a single trial, the other across a literature; neither is the number.

In 402 patients receiving bilateral treatment with dose titration, threshold correlated with age and was slightly higher in men, while race, severity of illness, psychosis and psychotropic use did not affect it.

DETERMINANT	WHAT THE EVIDENCE SAYS, AND HOW IT BEARS ON DOSING
AGE	Positively correlated; a principal factor, and what the formulae are built on
ELECTRODE PLACEMENT	A principal factor; bilateral carried a higher initial threshold and a greater cumulative rise, so a threshold measured under one placement does not carry to another
SEX	Associated but weakly; men slightly higher. Enters some formulae, never sufficient alone
CUMULATIVE TREATMENTS	Associated; threshold rises across the course, forcing mid-course review of the multiple
MEDICATION AND ELECTRICAL PARAMETERS	Each contributes; pulse width, frequency and stimulus duration matter, so a formula holds only in the parameter set it came from
RACE, SEVERITY, PSYCHOSIS, PSYCHOTROPIC USE	Did not affect threshold in the large titrated cohort; never a reason to start higher

9.3 Setting the stimulus: the methods and their ranking

The current Indian Psychiatric Society practice guideline, published in 2023, names four ways of arriving at a dose and ranks them. **Stimulus titration** is recommended in regular practice, at the cost of a first session spent finding it. **Formula-based methods**, built on age and sex, guide the first dose of that titration rather than substitute for it. **Fixed high dosing** is reserved for patients with serious medical comorbidity in whom avoiding a subconvulsive stimulus is the priority. **Dosing from benchmark**, a high first dose then down-titration to the lowest dose still producing the same peak heart rate and tonic-clonic convulsion, is the better alternative where fixed high dosing is used.

The titration runs at different speeds: larger increments in elderly patients, smaller in adolescents and younger adults.

RULE **A formula estimates the first dose of a titration; it does not replace the titration.** A formula approximates across a population a quantity that is measured in an individual, which is why the guideline says to use it for the first dose and then titrate.

9.4 The half-age formula, and the size of its error

The **half-age method** estimates the stimulating dose from the patient's chronological age, using half that age as the percentage of charge on one device family, or the equivalent in millicoulombs on another, as the starting point at the first session. The device clause is part of the formula: the same numeral means a different delivered charge on a different device. The standing criticism is that it is a gross estimate, unaccommodating to individual variation in threshold and less sensitive than dose titration.

That criticism has been measured. In the large titrated cohort, half-age estimates averaged **18%** above the empirically determined threshold; the titrated treatment level and half-age agreed

exactly in only 14.7% of measurements; and titration gave a level more than 10 units higher than half-age in 33% of patients. Those two figures are measured against two different quantities, and reading them as two directions of one error is the mistake this paragraph exists to prevent. The overshoot of **18%** is half-age measured against the bare THRESHOLD, and it is the authors' own summary figure, taken from a passage this claim row does not quote. The shortfall in 33% of patients is measured against the titrated TREATMENT dose of 1.5 times threshold, with more than 10 units the margin that counts as a shortfall. A figure a fifth above the threshold is by construction below a level set at half again as much, so the two are one direction read off two benchmarks. What follows for practice is only that the formula overshoots the threshold on average, which is its residual use, since fewer stimulations are then needed.

The Indian guideline attaches a validity condition to every age-based or sex-based formula. The stimulus must have the same amplitude, pulse width, pulse frequency and electrode location as the derivation it came from, all four together, and medications and anaesthetic agents move the threshold in any case.

TRAP **Quoting a formula as though its number carried across devices, waveforms and drug regimens.** A formula is valid only inside the parameter set it was derived in, and the commonest error is to treat half the age as a universal constant rather than a percentage of charge on a named device family at a named pulse width.

9.5 Dose as a multiple of threshold, and why the multiple differs

The therapeutic dose is prescribed as a multiple of the measured threshold, and that multiple is not the same number everywhere. It is set by placement and pulse width, because the dose-response relation differs between them. In right unilateral treatment that relation is steep: stimulation at threshold has relatively low efficacy, and markedly suprathreshold dosing is what achieves efficacy over a course. In bilateral placements efficacy is already obtained marginally above threshold, which is where the guidelines set it, so raising a bilateral dose further is not where bilateral efficacy comes from; what a higher dose does to cognition belongs to this chapter's account of the cognitive cost. Carrying one direction across the placements, either way round, is how this topic is taught wrongly.

PLACEMENT AND PULSE WIDTH	INDIAN PSYCHIATRIC SOCIETY GUIDELINE (2023)	AUSTRALIAN AND NEW ZEALAND COLLEGE GUIDELINE (2019)
BILATERAL, BRIEF PULSE OF 1 MS OR MORE	Marginally suprathreshold, 1.5 times threshold	Effective at that level or just above, 1.5 times threshold
BILATERAL, LOWER BRIEF PULSE OF 0.5 MS	Some evidence suggests 2.5 times threshold	Not carried here
RIGHT UNILATERAL, BRIEF PULSE	4 to 6 times threshold	five to six times threshold, with a footnote recording 3 times as lower but still clinically meaningful
RIGHT UNILATERAL, ULTRABRIEF 0.3 MS	Strong evidence for 6 times threshold, chiefly in depression	Not carried here
BILATERAL, ULTRABRIEF 0.3 MS	Less effective and not advisable on existing evidence	Not carried here

The right unilateral brief-pulse cell is where the sources disagree. The Indian guideline of 2023 gives 4 to 6 times the threshold; the college guideline of 2019 gives five to six times, its footnote recording 3 times threshold as lower in efficacy but still clinically meaningful. One structural difference travels with that disagreement and the table above cannot show it: the Indian figures are stated under pulse-width conditions, while the college's two multiples are given in sentences that attach no pulse-width condition at all, so filing them in a pulse-width row is this chapter's arrangement and not the college's. Each belongs in an answer with its body and year attached. Averaging them would invent a figure neither states, and the lower bound stops markedly suprathreshold dosing being read as the only thing that works. One caution travels with the Indian multiples: the increment ought to be made at fixed amplitude, pulse frequency and pulse width, but most devices cap train duration and raise pulse frequency instead, so the guideline says its figures should be read with that in mind.

9.6 The titration session and its narrow exception

The guideline is explicit that markedly suprathreshold stimulation is not necessary on the first day of titration even for unilateral treatment, and might be considered only in extremely rare life-saving conditions such as neuroleptic malignant syndrome or intractable seizures. The shape of the exception matters: a life-threatening presentation can justify abandoning stepwise measurement for a dose that will certainly work.

A consistency note is owed. The Other psychotic disorders, delusional syndromes and catatonia notes have already told the reader that malignant catatonia is treated with liberal stimulus dosing to induce well-generalised seizures. The guideline sentence is consistent with that in shape, carving out the life-threatening case, but it names neuroleptic malignant syndrome and intractable seizures and not malignant catatonia. The earlier statement is therefore supported by analogy rather than by naming.

9.7 The threshold rises, and the dose can fall behind it

The threshold is not fixed even within one patient. The study that measured this re-titrated at the first and the sixth treatments in 62 depressed patients treated at moderately suprathreshold intensity. The threshold rose by approximately **47%** on average, but only 56% of patients showed any rise at all. Each part matters: the average rise is large enough to count, and nearly half showed none, so a rise is checked for rather than assumed. There it went with increasing age and not with gender, electrode placement or initial threshold, which sits in tension with the earlier trial's finding that bilateral treatment carried the greater cumulative rise. The tension is recorded, not resolved.

The clinical consequence is what gets examined. Therapeutic effect tracks the degree to which the stimulus exceeds the threshold, so if the threshold climbs while the delivered charge stays where the original titration set it, the relative stimulus intensity quietly falls. In a separate cohort, falls in relative stimulus intensity between the first and the sixth treatments were associated with diminished response at the sixth in unilateral treatment, which is where the steep unilateral dose-response predicts the drift will bite.

> **GOOD TO REMEMBER**
>
> If a responding patient stalls mid-course, ask whether the seizure is still adequate and whether the charge is still the multiple it was meant to be. Frequency of treatment is a separate lever: it buys speed of response at a cognitive price, with equivalent efficacy at the end of the course, and belongs to this chapter's account of the acute course and its schedules.

9.8 Restimulation: the missed seizure and the inadequate seizure

Failure at the trolley must be separated by kind, because each kind has its own rule. A **missed seizure** is no seizure at all: if there is no motor and no electroencephalographic seizure even after **20** seconds from completion of the stimulus, restimulation may be attempted at an increased dose, and a delayed-onset seizure should be watched for.

An **inadequate seizure** is a seizure that happened but was not good enough: a low-quality electroencephalographic seizure, or a motor seizure that did not generalise, limited to one side of the body or to the face. The Indian guideline directs restimulation at a higher dose after **45** seconds, and bounds the attempt as follows.

- **How many.** Restimulation may be attempted while the patient remains under the anaesthetic and the muscle relaxant, generally four to five times.
- **The cost of more time.** A top-up dose of anaesthetic can be requested to extend the window, but top-up doses reduce the quality of the seizure obtained.
- **When not to chase.** If the seizure is very brief, of the order of 5 to 10 seconds, and the patient is showing the expected clinical response, restimulation need not be administered.

The delay before the second stimulus is the second disagreement, and each source is stated as it stands. The Indian guideline of 2023 gives 45 seconds. The college guideline of 2019 offers 60 to 90 seconds as an example rather than a rule, and gives the reason the delay is bounded above as

well as below: if it is too long a top-up dose becomes necessary, and the resulting seizure could be poor, negating the benefit while potentially worsening cognition. Neither figure is preferred here.

The sources agree at the other end: restimulation on the same day after an **adequate seizure**, which is multiple monitored electroconvulsive therapy, is not recommended by the Indian guideline, and the college guideline holds that delivering more than one adequate seizure per treatment session is not acceptable practice except in a session where threshold is being determined.

IN INDIA

Indian practice is governed by the Indian Psychiatric Society's current guideline, published in 2023: titration is recommended, the formula is only a starting point for it, quality outranks duration, and the classical numeric criteria are named as retired. Where a college guideline gives a different figure, as for the right unilateral multiple and the restimulation delay, name both with their bodies and years.

9.9 The adequate seizure, and the limits of duration

Adequacy is judged on the motor seizure, the electroencephalographic seizure and what follows, with duration the weakest signal rather than the definition. **Motor seizure duration** is timed by an explicit convention: the time from the beginning of the stimulus until the end of the last clonus in any part of the body, which usually ends in the limbs. A good-quality motor seizure moves through induction during or soon after stimulation, tonic contraction, bilateral convulsions, a gradual ending, a comatose stage, then return of consciousness.

The ictal electroencephalogram runs in numbered phases, and it is morphology rather than length that carries the information.

- Phase 1, recruitment: high-frequency waves of gradually increasing amplitude.
- Phase 2: hypersynchronous high-amplitude polyspike bursts at around 10 Hz lasting 10 to 20 seconds, corresponding to tonic contraction.
- Phase 3: hypersynchronous polyspikes intermixed with slow waves for 20 to 40 seconds, the tonic-clonic phase.
- Phase 4, **postictal suppression**: a flat isoelectric line, whose onset heralds the end of the seizure.
- Phase 5, recovery: delta to theta to alpha waveform.

Generalisation is read off the same trace: a good-quality seizure shows activity in the contralateral channels, which is the criterion the restimulation rules turn on.

MNEMONIC

Generalised, Morphology, Suppression, then Duration

Judge the seizure in that order: whether it **Generalised**, in the limbs and the contralateral channels; whether the **Morphology** moved through its phases; whether **Suppression** followed, the flat isoelectric phase whose onset marks the end; and only then how long it lasted, because **Duration** is the weakest signal.

The limit on duration is stated by the guideline itself. A good quality seizure should be given more importance than any specific duration, and a good quality seizure even of shorter duration has been demonstrated to be efficacious in elderly depressed patients. The classical numeric definition, still a common exam key, is named and retired in one breath: the earlier definition of 15 seconds of motor seizure and 25 seconds of electroencephalographic seizure is found to be of little clinical or prognostic benefit. No replacement figure is offered and none is invented here: the question has been demoted, not re-answered.

PITFALL

Reciting the retired numeric criteria as the current definition of an adequate seizure. They are worth knowing because they are still asked, but the guideline finds them of little clinical or prognostic benefit. Write them as the earlier definition, say that quality rather than a new number replaced them, and invent no replacement.

TRAP **Treating a generalised seizure as proof that the treatment was adequate, and any seizure as proof that the dose was right.** A generalised seizure is necessary for a therapeutic effect and not sufficient for one, which is why the dose is a multiple of threshold rather than whatever charge produced a convulsion. The paired error is to restimulate a patient who has already had an adequate seizure to chase a longer one.

The seizure threshold is the lowest electrical dose that produces a seizure in this patient at this session; it varies enormously between patients, rises across a course in only some of them, is best measured by titration with a formula used only to pick the first dose, and carries a treatment dose set as a multiple sized by placement and pulse width rather than by one rule. Adequacy is judged by generalisation, electroencephalographic morphology and postictal suppression, duration being the weakest signal.

10 · Modified versus unmodified (direct) ECT

Modified electroconvulsive therapy is the treatment given under anaesthesia with a muscle relaxant, and in India it is the only lawful form of it. The contrast with the unmodified or direct technique is therefore not a preference between two ways of doing the same thing. It is the difference between current practice and a practice the statute has closed, and a candidate who treats it as a matter of resources or of taste has misread the strongest legal statement in this chapter. What is examinable is the mechanical reason modification exists, what the unmodified

technique cost the patients who received it, and the fact that the bar on it is legal rather than advisory.

Owned here: the technique contrast, why the unmodified form was once used, what it cost in injury and in the patient's experience of being treated, what modification does and does not abolish, and the settled Indian legal position. Named but not re-derived: the anaesthetic agents, the muscle relaxant, the airway and the equipment of the room, which belong to this chapter's account of the pre-ECT workup and anaesthesia; the introduction of anaesthesia and muscle relaxation as historical events, to its account of the history and evolution of the treatment; the seizure threshold, the stimulus dose and every criterion of seizure adequacy, to its account of stimulus dosing; consent as it is actually taken, to its account of consent and the legal aspects; and the prohibiting provision itself, with its number, its wording and its classification, to the Mental health legislation and forensic psychiatry notes.

2 per 100,000	Unlawful	86 against 50
FRACTURE RISK PER ECT UNDER MODIFIED TECHNIQUE	THE STANDING OF UNMODIFIED ECT IN INDIA, NOT MERELY INADVISABLE	PER CENT CONSENTING TO A FUTURE COURSE, MODIFIED AGAINST UNMODIFIED

10.1 What modification actually modifies

Modification adds two things, an anaesthetic and a muscle relaxant, and of the two it is the relaxant whose target is the convulsion rather than the treatment. Both are required, and the statutory bar admits no reading on which relaxant alone would count as modified. The rationale runs in three steps. First, during the motor seizure the muscles of the trunk and limbs contract forcefully and repetitively, predisposing to injuries to muscles, joints, teeth and bones. Second, that motor seizure is irrelevant to the therapeutic action of the treatment. Third, it is therefore abolished by an intravenous muscle relaxant given after the anaesthesia in the ECT premedication. The middle step carries the whole argument: nothing therapeutic is surrendered when the convulsion is removed, so modification is not a concession to comfort or to appearances. It deletes the mechanism of injury and leaves the mechanism of benefit standing.

Two consequences are worth holding apart. The first is anatomical. What the relaxant abolishes is the **motor seizure**, the visible convulsion of trunk and limb; the cerebral seizure the stimulus induces is untouched by it, and a patient whose limbs are still is still having the seizure that treats them. That is why modification does not weaken the treatment, and why an isolated-limb tourniquet exists as a way of watching a convulsion that has been abolished everywhere else. The second is procedural. The relaxant follows the anaesthetic rather than preceding it, and the agents on that trolley, their doses, their contraindications and the airway conduct around them belong to this chapter's account of the pre-ECT workup and anaesthesia, which owns the tourniquet method too and which names the same relaxant this account's source names, succinylcholine.

10.2 What the unmodified technique was, from an Indian record of it

Unmodified, or direct, electroconvulsive therapy is the same stimulus given with neither anaesthesia nor a relaxant, so the generalised convulsion runs its course in the patient's body. It

appears in this chapter in two capacities only, as a historical practice and as an unlawful one, and it is described here rather than gestured at because a description written from the modern side alone softens into a list of theoretical hazards. The record used is a retrospective review of **637 patients treated between 1990 and 1995** at an Indian institute. Nothing in the ledger establishes that its author worked that service, and the receipt in fact shows the cohort reported from a different institution than the one where the patients were treated, so the record's authority rests on what it documents rather than on the author's proximity to it.

The technique is recorded plainly. All the patients were given ECT with an unmodified, bitemporal, sine wave device; there were two doctors, a junior and a senior resident, with multiple nursing and ward staff, but no anaesthetist; Boyle's apparatus was used for mandatory pre-ECT oxygenation and after care; and careful manual restraining of patients during the convulsion was done at all vulnerable joints by multiple ward staff and trainee nurses. The last of those is the sentence to remember. **Manual restraint** at the vulnerable joints was the physical substitute for a muscle relaxant, and it is the reason joint and bone injury is the characteristic harm of the technique. Bone rather than long bone: the injuries this record actually names are a cervical vertebral compression fracture, a dental extraction, a jaw dislocation and back muscle spasm, and not one of them is a long bone. Force applied across a joint against a muscle contracting maximally is not only a safeguard; it is a second path by which load reaches the same bone.

Why the technique was used at all is answered by the arrangement that record describes rather than by any argument advanced in its favour. The treatment came first and its modification came later, a chronology this chapter's account of the history and evolution of electroconvulsive therapy carries; until an anaesthetist could be put in the room, what remained available was the original technique. The series shows that economy exactly: a separate ECT station in each ward, a spacious room holding one ECT table, the ECT machine, Boyle's apparatus and an attached recovery space, staffed by residents, nurses and ward staff. Treatment could be given at ward level, in volume, without competing for anaesthetic manpower or theatre time. No row in this claim list states that rationale in so many words, so it is read off the arrangement and named as an inference rather than asserted as a finding.

10.3 What it cost: the injuries, case by case

The same series lists the injuries that ended a course, and they fall into four families that map exactly onto the tissues the rationale above named.

- **Bone.** Surgical emphysema developed in a 26-year-old woman in whom the radiograph taken after ECT revealed a compression fracture of the fourth cervical vertebra, managed conservatively with a cervical collar.
- **Tooth.** A traumatic dental extraction occurred at the first ECT session in a 45-year-old woman with an acute psychosis.
- **Joint.** Recurrent jaw dislocation occurred in a 28-year-old woman with recurrent mania, who had a past history of safe treatment with ECT.

- **Muscle.** Severe back muscle spasm, with no fracture on radiography, was the reason ECT was discontinued in two more young male patients.

The list teaches more than the injuries themselves. The patient with recurrent jaw dislocation had been treated safely in the past, which disposes of the intuition that a course completed without incident predicts the next one: this risk is per session and mechanical, not a settled property of the person. The dental extraction happened at the very first session, so no accumulation of treatments was needed to produce it. And the back-spasm cases carried no radiological fracture at all, which is the reminder that a normal film does not mean an uninjured patient.

10.4 The rate that series reported, and the caveat that never leaves it

The same paper reports its overall outcome, and the two halves of that report are quoted together or not at all. **637 patients, 6.94 per cent of total admissions, received ECT with meticulous standard of care except the provision of anaesthesia; satisfactory improvement was noted in 95.45 per cent of patients, with no noticeable or reported complication in 89.05 per cent, and premature termination of ECT for complications in 2.19 per cent**. Read on its own, that is the most misusable paragraph in this chapter.

Its author does not leave it on its own. Regarding complications, he writes, there must be under-reporting for not having any screening tool, only the noticeable side effects having got recorded in the files; even so, the serious complications were much less than those reported prior to the 1960s. The consequence is exact rather than rhetorical. **Under-reporting** of that kind makes a complication-free figure an upper bound on safety and not a measurement of it, because the numerator was assembled from whatever happened to be noticed by a busy ward. Musculoskeletal complications were recorded in ten patients, of whom five were severe enough to stop the course, and no film was taken in the rest, which limits the fracture count in the same direction. The series is admitted here for what it establishes about a historical practice. It is not evidence about current practice and it does not qualify the statutory bar by any degree.

TRAP **Quoting the complication-free figure from this series as though it showed the unmodified technique to be acceptably safe.** The author says in the next breath that complications were necessarily under-reported, so the figure bounds what was noticed rather than what occurred. And a perfectly measured figure would settle nothing here, because the technique is barred by statute: its measured harm rate is a fact about history, never an argument about what to do on Monday.

10.5 What it was like for the patient

Injury counts are not the whole cost, and the comparison that reaches the rest was made prospectively in 100 euthymic bipolar patients, 50 of them treated with modified and 50 with unmodified ECT. The majority of all patients, 78 per cent, were satisfied with treatment and 88 per cent with the outcome, without significant differences between the modified and unmodified groups; forgetfulness at 70 per cent and headaches at 57 per cent occurred in all groups, the only significant difference in forgetfulness being that it was reported by more manic patients treated with unmodified ECT. Stop before that final clause and the difference between the techniques

looks like a matter of decorum, which is why the clause is carried: the one adverse-effect difference the source reports runs against the unlawful technique.

The difference sits in what the patients feared and in what they would agree to again. Depressive and manic patients treated with unmodified ECT reported concerns of brain damage and of physical harm significantly more frequently, and **while 86 per cent of patients treated with modified ECT consented to a future treatment, this fell significantly, to 50 per cent, after unmodified ECT**. That is the shape of the finding and it should be kept: satisfaction did not separate the groups, willingness to go through it again did, and by a wide margin. The cohort is Turkish, from a country that mandated modified ECT in 2005, so it is carried for the direction of its finding rather than as an Indian figure.

10.6 What modification buys, and the one place it does not reach

Well-modified treatment produces markedly diminished skeletal muscle contraction and therefore minimal skeletal and dental risk, and the population figures are small enough to be worth quoting exactly. **The fracture risk with modified ECT is 2 events per 100,000 ECTs, and on recent data alone the risk may be as low as 0.36 events per 100,000 ECTs; the dental fracture risk with modified ECT is 0.02 per cent per ECT and 0.17 per cent per ECT course**. Those figures are what make the older injury reports legible. They describe the same treatment with the motor seizure taken out of it.

The residual risk is not spread evenly and part of it is in the operator's hands. Pre-existing bone and dental disease increase the risk; good seizure modification, proper use of bite blocks and effective jaw immobilisation during ECT reduce it. That the **bite block** and **jaw immobilisation** appear on a list of what protects a patient under modern technique is the tell: the jaw is the one place the relaxant does not reach, because the masseter is driven by direct stimulation of the muscle rather than through the neuromuscular route the relaxant blocks. **Seizure modification** is accordingly a quality with degrees rather than a box that has been ticked, and the equipment and airway conduct that deliver it belong to this chapter's account of the pre-ECT workup and anaesthesia.

> **GOOD TO REMEMBER**
>
> Quote the fracture figures as what they are, population rates under well-conducted modified technique. They do not transfer to a patient with known bone or dental disease, in whom the same review states the risk is higher, and the assessment that finds that disease before a course belongs to the pre-ECT workup rather than to this contrast.

10.7 The Indian position: unlawful, not inadvisable

In India the question of modified against unmodified treatment was settled by Parliament rather than by preference. The statute prohibits electroconvulsive therapy given without muscle relaxants and without anaesthesia. The provision that says so, its number, its text and its place in the scheme of prohibited and restricted procedures belong to the Mental health legislation and forensic psychiatry notes, and are named here rather than renumbered, because a chapter that

reprints a section number it did not itself ground is how a legal fiction enters a syllabus. What this account states is the consequence for technique, and it is blunt. Direct treatment is not a rougher version of the same thing that a hard-pressed unit falls back on; it is unlawful. The bar the legislation notes carry admits no exception, so no degree of urgency turns the direct technique into something a clinician is entitled to weigh.

IN INDIA

The working form of that rule in a district hospital is a timetabling rule and not a clinical one. Where no anaesthetist is available today, what changes is the day of the treatment and never the technique of it. The statutory conditions attached to consent for ECT, including who consents for whom, sit with this chapter's account of consent and the legal aspects and with the Mental health legislation and forensic psychiatry notes. What belongs here is the narrower point that the law fixes the technique itself, not merely the paperwork around it.

RULE **In India the modified technique is not the better of two ways to give electroconvulsive therapy; it is the only lawful one.** Everything the unmodified technique is taught for is historical: what it was, what it injured, and what it felt like to receive. Write it in the past tense, name the statutory bar in words and attribute it to the Mental health legislation and forensic psychiatry notes, and never write a sentence in which a clinician is choosing between the two.

AXIS	MODIFIED ECT	UNMODIFIED (DIRECT) ECT: HISTORICAL, AND UNLAWFUL IN INDIA
STANDING TODAY	The lawful form of the treatment	Prohibited by statute, per the Mental health legislation and forensic psychiatry notes
WHAT HOLDS THE BODY	An intravenous muscle relaxant, given after the anaesthesia	Manual restraint at all vulnerable joints by ward staff
MOTOR SEIZURE	Abolished; the cerebral seizure is untouched	Ran to completion in the trunk and limbs
SKELETAL AND DENTAL COST	2 skeletal fractures per 100,000 ECTs, with dental fracture a separate and much commoner cost at 0.02 per cent per ECT, which is an order of magnitude above the skeletal figure and is the one to compare against the opposite cell	Cervical compression fracture, dental extraction, jaw dislocation, back spasm
WOULD ACCEPT IT AGAIN	86 per cent	50 per cent

MNEMONIC

SLEEP, SLACK, SHIELD

Sleep is the anaesthetic and **slack** the muscle relaxant that abolishes the motor seizure; the statute requires them, and their absence is precisely what the word unmodified meant. **Shield** is the bite block with effective jaw immobilisation, which good practice adds because the masseter contraction is driven directly by the stimulus and not through the junction the relaxant blocks. The agents behind the first pair belong to the pre-ECT workup and anaesthesia account, never to this one.

Modification abolishes the motor seizure and nothing therapeutic: the relaxant follows the anaesthetic, the cerebral seizure is untouched, and the injuries of the unmodified technique were mechanical, running from cervical spine to tooth to jaw to back muscle. In India the modified form is not the safer choice but the only lawful one, and the provision that says so is named in words, never renumbered, from the Mental health legislation and forensic psychiatry notes.

Electroconvulsive therapy: effects, consent and course

11 · Cognitive side effects of ECT (anterograde and retrograde amnesia)

The cognitive cost of electroconvulsive therapy is the adverse effect that decides whether a patient consents, whether a course is finished and whether the treatment keeps its place in practice, and it is not one deficit but several running on different clocks. Merging them is the commonest error here: the evidence that one recovers comes from a corpus that could not measure another, so a candidate who has fused them will quote a real finding about the wrong phenomenon. This account holds them apart, gives the modifiers and the monitoring, and reports the persistence question as contested.

Owned here is the cognitive cost in full: the three phenomena, patient-reported memory loss, the modifiers, the monitoring, and the contested status of persistent retrograde deficit. Named and not re-taught, each owned by another account in this chapter: what each placement is and waveform, by technique and electrode placement; the efficacy-against-cognition trade, by the placement comparison; the threshold and stimulus dose, by stimulus dosing; frequency and the schedule, by the acute course; a confusional state past its window, by complications; concurrent drugs, by drug interactions.

5 to 45 minutes	29 percent to 55 percent	6 to 12 months
ORIENTATION GENERALLY RETURNS WITHIN THIS WINDOW AFTER AN ADEQUATE SEIZURE	PATIENTS REPORTING PERSISTENT MEMORY LOSS ON THE STRICT DEFINITION	FOLLOW-UP OVER WHICH AUTOBIOGRAPHICAL LOSS STAYED STABLE, NOT RECOVERING

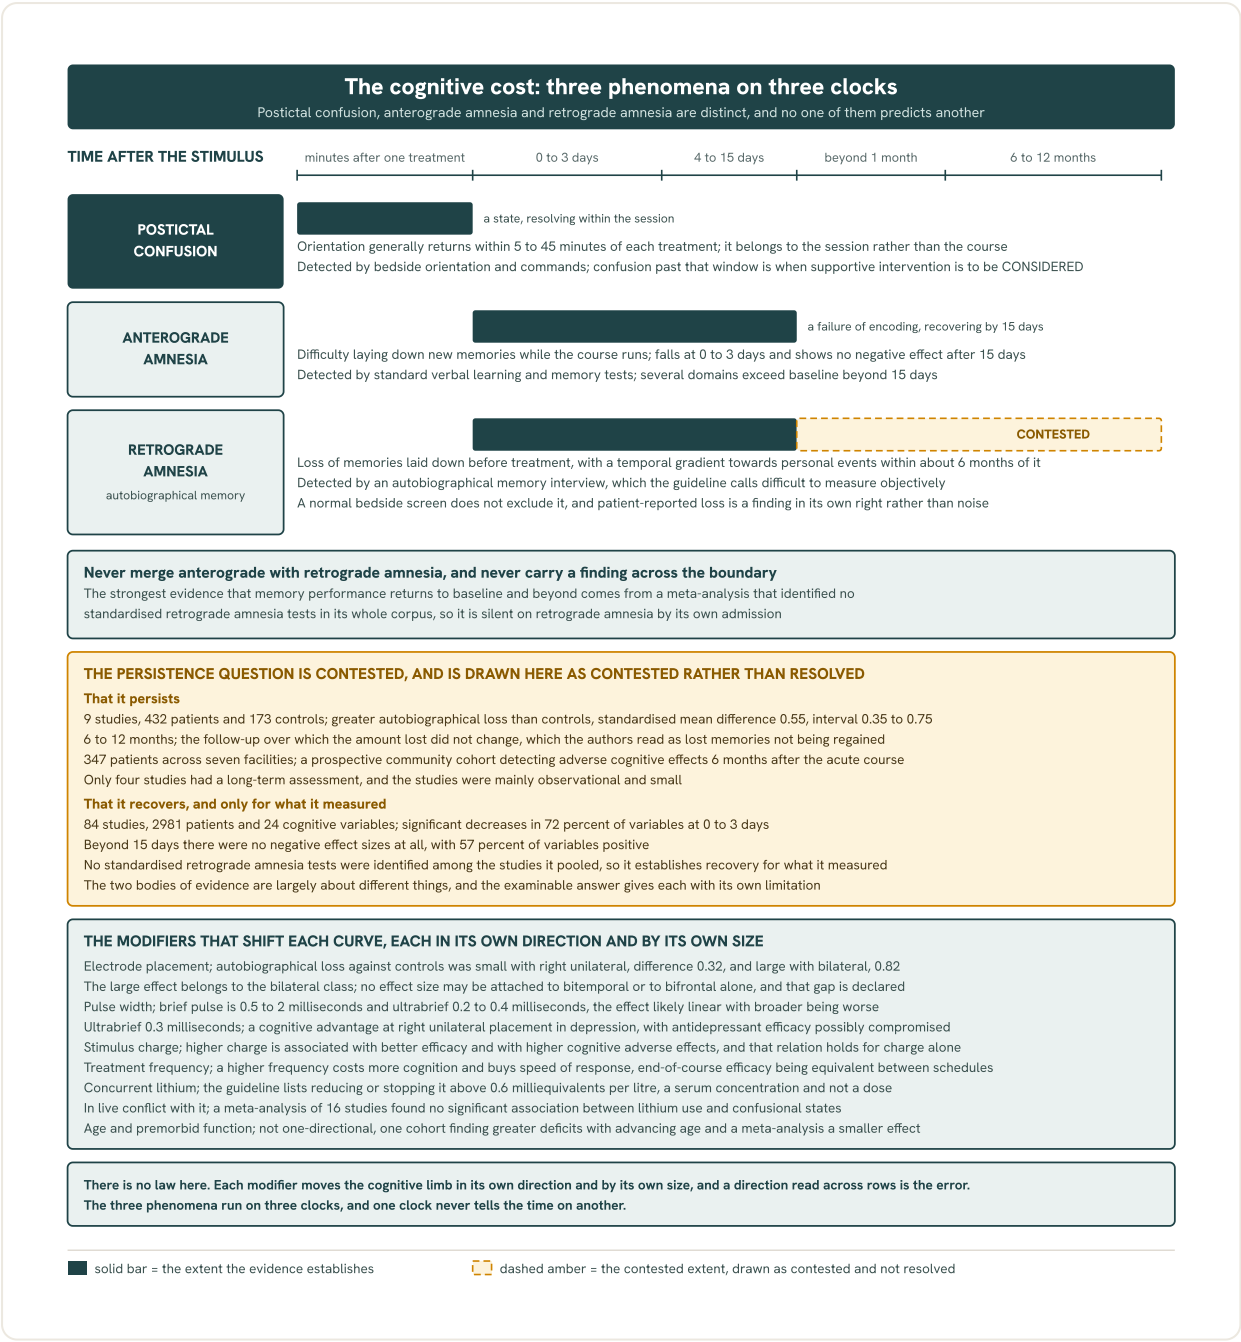

Fig 27.10. The cognitive cost is three phenomena on a common time axis and not one deficit: postictal confusion, a state resolving within minutes of each treatment; anterograde amnesia, a failure of encoding that falls in the first days after a course and recovers with several domains exceeding baseline; and retrograde amnesia, a loss of what was already encoded, with a gradient towards events near the treatment, hard to measure, and of contested persistence, the plate marking that persistence as contested rather than settling it, while each modifier shifts its own limb in its own direction and by its own size.

11.1 Three phenomena, not one deficit

They separate once asked what was lost and when it was laid down. **Postictal confusion** is the disorientation of the minutes after each induced seizure, expected after every treatment and belonging to the session rather than the course. **Anterograde amnesia** is difficulty laying down new memories while the course runs, so the treatment period itself becomes patchy. **Retrograde amnesia** is loss of memories laid down before treatment, and its most studied form is **autobiographical memory**, the record of the patient's own life events. A state, a failure of

encoding, and a loss of what was already encoded: no one predicts another, and a patient can pass a bedside screen and still describe a hole in the year before treatment.

RULE **Never merge anterograde with retrograde amnesia, and never carry a finding across the boundary.** The strongest evidence that memory performance returns to baseline and beyond comes from a meta-analysis that identified no standardised retrograde amnesia tests in its whole corpus. It is silent on retrograde amnesia by its own admission, and quoting its headline as reassurance about lost life memories is the most examinable misuse of evidence here.

AXIS	POSTICTAL CONFUSION	ANTEROGRADE AMNESIA	RETROGRADE AMNESIA
TIME COURSE	Orientation generally returns within 5 to 45 minutes of each treatment	Falls at 0 to 3 days, no negative effect after 15 days	Measurable from the end of the course, with a gradient towards recent events
HOW IT IS DETECTED	Bedside orientation and commands	Standard verbal learning and memory tests	An autobiographical memory interview; the guideline calls it difficult to measure using objective cognitive tests
PROGNOSIS	Resolves within the session	Recovers, several domains exceeding baseline	Contested, and reported as contested

11.2 Postictal confusion, and where it stops being normal

Confusion after an induced seizure is part of the procedure until it outlasts its window. The current Indian guideline states that patients generally regain orientation within 5 to 45 minutes after an adequate seizure, and that confusion with poor response to commands, with or without behavioural agitation, continuing past that period or very severe within it, is when supportive intervention is to be CONSIDERED, which is the guideline's own strength and not a requirement. The window is both reassurance and alarm; the intervention belongs to the account of complications.

Confusion is not one state either. The cleanest separation comes from a prospective cohort of 145 adults aged 55 or over treated for a major depressive episode; the population is part of the number, and these are not general adult figures. At least one subtype occurred in **55.9 percent**. Postictal agitation, at 29.5 percent, and **prolonged time to reorientation**, at 28.3 percent, were common; postictal delirium, at 5.9 percent, and **interictal delirium**, arising between treatments rather than after one, at 4.2 percent, were not. Recurrence separated them further, which changes the plan for the next treatment: 66.7 percent for interictal delirium and 50.0 percent for prolonged reorientation, against 12.5 percent for postictal delirium. The authors note that their instruments were not designed to measure subtypes during a course.

11.3 Anterograde amnesia: the deficit that recovers

This limb has the strongest evidence and the most reassuring answer, and it reassures only about itself. A meta-analysis of 24 cognitive variables across 84 studies and 2981 patients found

significant decreases in **72 percent** of variables at 0 to 3 days. From 4 to 15 days all but one confidence interval included zero or showed a positive effect, and beyond 15 days there were no negative effect sizes at all, with 57 percent of variables positive; processing speed, working memory, anterograde memory and some executive functions improved beyond baseline.

A domain map of 91 studies and 3762 individuals across 11 cognitive domains gives the same shape with the domains named: no significant change in global cognition on a bedside screen within 24 hours of the last treatment, small to medium decreases at 1 to 28 days in autobiographical memory, verbal fluency and verbal memory, and improvement on almost all domains beyond 1 month. The deficit is therefore domain-specific rather than global, and a bedside screen is the wrong instrument for finding it.

11.4 Retrograde amnesia: the distinct phenomenon

This is the limb patients care about and tests are worst at. The Indian guideline says both halves in one sentence: it is among the most distressing adverse effects, and difficult to measure using objective cognitive tests. A normal bedside screen therefore does not exclude it.

Its shape is not random. A systematic review across 15 studies established a **temporal gradient**: the memories predominantly affected are of personal events near the treatment, within about 6 months of it, rather than of the distant past. The same review names three technique features that reduce autobiographical loss, each taught elsewhere in this chapter: a brief pulse rather than a sine wave stimulus, unilateral rather than bilateral placement, and titration of the current against the patient's own seizure threshold.

The reviewers add a confound that travels with the whole literature: the direct effect of the depressive state on memory is not controlled for, a depressed patient recalling their own life poorly before any treatment. That is why the size of the effect is hard to pin down, and it is not a reason to discount a patient's account.

11.5 The persistence question, which stays contested

Whether retrograde deficit persists must not be answered crisply. Two bodies of evidence point in opposite directions, each honest about its limits, and both are set out rather than adjudicated.

That it persists. A meta-analysis of 9 studies, 432 patients and 173 controls found greater autobiographical loss in treated patients than controls, a moderate pooled standardised mean difference of 0.55, 95 percent confidence interval 0.35 to 0.75. The decisive finding is stability, not size: the amount lost did not change between the end of treatment and follow-up at 6 to 12 months, which the authors read as lost memories not being regained. Their limits travel with it: only four studies had a long-term assessment, so none was possible on long-term effects, and the studies were mainly observational and small. The second pillar is a prospective community cohort of 347 patients across seven facilities: it detected adverse cognitive effects 6 months after the acute course, with bilateral placement giving more severe and persisting retrograde amnesia than right unilateral.

That it recovers. The recovery meta-analysis is the strongest statement on the other side, and its bearing here is bounded by a sentence in its own results: no standardised retrograde amnesia tests were identified among the studies it pooled. It establishes recovery for what it measured, not for a variable nobody measured. The two bodies of evidence are largely about different things.

TRAP **Answering "does memory loss after electroconvulsive therapy persist?" with a single word.** "No" quotes a recovery result from a corpus with no retrograde instrument in it. "Yes" states as settled a finding resting on a handful of long-term assessments in observational studies. The examinable answer gives each side with its limitation and says the question is open.

11.6 Patient-reported memory loss, a finding and not noise

Patient-reported memory loss diverges from measured loss, and the divergence is itself what must be taught. In the review above, objective measures placed autobiographical loss under 6 months after treatment while subjective accounts placed it beyond 6 months. A descriptive systematic review of 35 studies of patients' own views found at least one third reporting persistent memory loss, rates on the strict definition running from 29 percent to 55 percent, and the rate did not depend on whether the study was clinician-led or patient-led. It concluded that the professional statement for patients then current, holding that over 80 percent were satisfied and that memory loss was not clinically important, was unfounded. That review is dated 2003 and its target is a statement of that period, not a current college position.

The Indian guideline gives the practice rule directly: subjective assessment of memory impairment is to be given due importance alongside objective assessment and to be part of routine cognitive assessment. Its explanation of why report exceeds measurement is a caution about instruments, not about patients: some cognitive domains are difficult to assess reliably and sensitively with standard tools, which can lead to higher subjective reporting. It names four contributors: that insensitivity; functional impact larger than measured severity; decline belonging to the illness and becoming visible once insight returns; and preoccupation with psychopathology.

RULE **Where patient report and objective testing diverge, the divergence is the finding, not a reason to discount the report.** The guideline offers its contributors as explanations of the gap and never as grounds for dismissal, and the first of them says the tests are insensitive. An answer that files persistent memory complaints under "subjective" and moves on has failed the item.

11.7 The modifiers that shift each curve

Each modifier moves the cognitive limb in its own direction and by its own size. The relation established for one parameter is the relation for that parameter, and reading a direction across rows is the error this chapter prevents.

MODIFIER	WHAT IS GROUNDED ABOUT ITS COGNITIVE EFFECT	REST OF IT TAUGHT BY
ELECTRODE PLACEMENT	Against controls, autobiographical loss was small with right unilateral, standardised mean difference 0.32, interval 0.06 to 0.57, and large with bilateral, **0.82, interval 0.49 to 1.15**. Bilateral is the source's own word and names a class. The Indian guideline separately holds bifrontal to have lesser cognitive effects than bitemporal in mania, depression and schizophrenia, and right unilateral lesser cognitive adversities	Technique; the placement comparison
PULSE WIDTH	Brief pulse is 0.5 to 2 milliseconds, **ultrabrief pulse** 0.2 to 0.4 milliseconds; the effect is likely linear, broader being worse. An ultrabrief pulse of 0.3 milliseconds has a cognitive advantage over brief pulses with right unilateral placement in depressive disorders, the guideline adding in the same breath that antidepressant efficacy may be compromised	Technique and waveform
STIMULUS CHARGE	Higher charge is associated with better efficacy and higher cognitive adverse effects, with the guideline's caution that charge is not a linear measure but a combination of several electrical parameters. The relation holds for charge alone	Stimulus dosing
TREATMENT FREQUENCY	A higher frequency costs more cognition. It buys speed of response and is not an efficacy lever, end-of-course efficacy being equivalent between the schedules	The acute course
CONCURRENT LITHIUM	The guideline lists reduction or stopping of drugs such as lithium, at serum levels above 0.6 milliequivalents per litre, among the steps for cognitive effects. A serum concentration, not an administered dose, and in live conflict with the meta-analysis below	Drug interactions

MODIFIER	WHAT IS GROUNDED ABOUT ITS COGNITIVE EFFECT	REST OF IT TAUGHT BY
AGE AND PREMORBID FUNCTION	Not one-directional. The community cohort found greater deficits with advancing age, lower premorbid intellectual function and female gender; the autobiographical meta-analysis found higher age associated with a smaller effect; the domain map found verbal fluency worse in younger adults	Special populations

The lithium row is a genuine conflict and is written as one. A meta-analysis of 16 studies found no significant association between lithium use and confusional states on its primary model, an odds ratio of 2.09 reaching significance at 2.38 only on a sensitivity model with a different estimator, and no significant differences in global cognition, autobiographical memory or verbal fluency. Its authors state that current evidence does not show a significant increase in cognitive side effects and that methodological limitations preclude definitive conclusions. Both are reported.

PITFALL

Narrowing the placement figure from bilateral to bitemporal. The large effect belongs to the bilateral class, and bifrontal is itself a bilateral placement, so the pooled corpus is not bitemporal only. No effect size may be attached to bitemporal or to bifrontal individually from this evidence, and the source reports no within-class breakdown; the gap is declared, not filled. The guideline's separate statement that bifrontal is gentler than bitemporal neither corrects nor is corrected by a meta-analysis that never separated them.

11.8 How cognition is monitored across a course

Monitoring starts before the first treatment. The Indian guideline requires a **baseline cognitive assessment**, so later change can be attributed, then sorts instruments by what they see. The Hindi Mental Status Examination and the Mini Mental Status Examination are named as simple tools not sensitive to the subtle change associated with treatment; the Montreal Cognitive Assessment battery and the Brief ECT Cognitive Screen as used internationally; the Battery for ECT-Related Cognitive Deficits as validated in the Indian population and recommended at initiation and across the course. Instruments are named only; no content, scoring or cut-off is reproduced.

The cadence is stated: progress in clinical symptoms and in cognitive and other adverse effects is monitored at least once a week while the course runs. A second, differently sourced standard is a United Kingdom technology appraisal of 2003 requiring cognitive function to be monitored on an ongoing basis and at a minimum at the end of each course. Two provenance facts travel with it: its recommendations on depression were replaced in 2009 by the national depression

guideline, while those on catatonia, prolonged or severe manic episodes and schizophrenia have not changed.

What is monitored matters as much as how often: the domain map states that a bedside global screen has extremely limited utility for tracking change, and recommends that assessment cover autobiographical memory, verbal fluency and verbal memory.

IN INDIA

The Indian position is more specific in two examinable ways. It names a battery validated in the Indian population and recommends it at initiation and through the course, rather than leaving instrument choice open. And it directs that patient-reported impairment be given due importance alongside objective testing, making the patient's account a required part of the record.

11.9 What is done when cognitive effects appear

The Indian guideline gives a seven-step menu for cognitive adverse effects during a course, used singly or in combination. Each step is a cognitive-management decision here; the parameter behind it is taught by the account named above.

1. Space the sessions out.
2. Switch to unilateral placement.
3. Switch to a briefer pulse width.
4. Reduce the stimulus dose.
5. Reduce or stop drugs known to affect cognition, such as lithium above 0.6 milliequivalents per litre.
6. Reduce the anaesthetic where it has been given high.
7. Terminate the course where the risks outweigh the benefits.

The guideline attaches a caution that makes this a judgement rather than a checklist: the decision is balanced against the possible reduction in effectiveness these steps carry. A patient made cognitively comfortable and left depressed has not been helped.

IN PRACTICE

Take a baseline before the first treatment, so a later complaint has something to be compared against. Ask about life memories specifically, not only orientation and word lists: the instrument that finds retrograde loss is a conversation about the patient's own past. And when a patient reports a hole the tests do not show, record it as a finding.

MNEMONIC

THREE CLOCKS

Minutes for postictal confusion, orientation generally back within 5 to 45 minutes. **Days to weeks** for anterograde amnesia, worst at 0 to 3 days and recovered beyond 15 days. **Months, and contested** for retrograde amnesia. One clock never tells the time on another.

The cognitive cost is three phenomena on three clocks: postictal confusion, resolving within minutes of each treatment and a complication only when it outlasts its window; anterograde amnesia, measurable in the days after a course and recovering to baseline and beyond; and retrograde amnesia, predominantly for events near the treatment, hard to measure, and of contested persistence, the two sides being a stable autobiographical loss at long-term follow-up and a recovery meta-analysis with no retrograde instrument. Patient-reported loss is a finding in its own right, assessed routinely and weighed alongside testing. The risk is shifted by placement, pulse width, charge, frequency, concurrent medication, age and baseline function, each in its own direction. Cognition is assessed at baseline and watched at least weekly with a sensitive instrument, and the seven-step menu is what is done when the cost appears.

12 · Other complications and adverse effects of ECT (cardiovascular, prolonged seizure)

The complications of electroconvulsive therapy are the events that occur during and after a treatment that was correctly indicated and correctly given. They are a different object from the conditions that make a patient risky before the first stimulus, and they are examined separately: one question asks what happens in the suite and the recovery room and what is done about it, the other asks whom you should hesitate to treat. This account answers the first.

Owned here: the cardiovascular sequence and its arrhythmia and ischaemia risk, the cardiac-event and mortality estimates, prolonged and tardive seizures, postictal agitation and delirium, headache, muscle soreness and nausea, dental and musculoskeletal injury, anaesthetic complications, and the emergence of mania on treatment. Named here and taught elsewhere in this chapter: the conditions that raise risk beforehand, by contraindications and high-risk conditions for ECT; the induction agents, relaxant and airway, by pre-ECT workup and anaesthesia; the threshold and the stimulus dose, by stimulus dosing, seizure threshold and adequate seizure criteria; the drugs that move the threshold, by drug interactions with ECT; and the whole cognitive limb, anterograde and retrograde amnesia, by cognitive side effects of ECT.

1 in 50	180 seconds	2.1 per 100,000
PATIENTS DEVELOPING A MAJOR ADVERSE CARDIAC EVENT OVER A COURSE	THE INDIAN DEFINITION OF A PROLONGED SEIZURE, WHICH IS NOT THE POINT AT WHICH TERMINATION IS ATTEMPTED	DEATHS ATTRIBUTED TO THE TREATMENT, PER TREATMENT GIVEN, IN THE POOLED INTERNATIONAL REVIEW

12.1 The cardiovascular sequence, in its fixed order

The cardiovascular effect is not one event but a sequence produced by autonomic nervous system activation, and the order is the examinable part. **Parasympathetic discharge** comes first: an initial **10 to 15 seconds** of vagal outflow in the tonic phase, with bradycardia and occasional asystole. The **sympathetic surge** follows in the clonic phase, a pronounced response of hypertension, tachycardia and other arrhythmias, peaking **1 minute** after the stimulus and generally resolving within **5 to 10 minutes**.

Bradycardia in the seconds after the stimulus is expected physiology, not a surprise, which is why antimuscarinic premedication is decided in advance, agent and dose belonging to the workup and anaesthesia account. The same activation raises cerebral metabolic rate, cerebral blood flow and intracranial pressure, and intraocular and intragastric pressure with them; what that means in a patient who already has a space-occupying lesion is the contraindications account's question.

PITFALL

Teaching the sympathetic surge as the whole cardiovascular story. A candidate who names only hypertension and tachycardia has dropped the phase that produces asystole, and with it the reason an antimuscarinic is considered at all. Give both phases, in order.

12.2 Why the same surge lands differently on different hearts

The sequence is the same in every patient and the consequence is not. Major depression may itself alter autonomic nervous system activity and increase the risk of arrhythmia and of sudden cardiac death, so the surge does not land on a neutral baseline. The treatment may also cause an acute rise in **QT dispersion**, which may predispose to arrhythmia in its own right. A third contribution is the workup and anaesthesia account's to teach: all the induction agents used prolong the QT interval. Three contributions, one patient, one moment.

12.3 How often a cardiac event actually happens

The quantified answer comes from a systematic review and meta-analysis of 82 studies covering 106,569 patients and 786,995 ECT treatments. Approximately **1 in 50 patients**, or 2 percent, develop a major adverse cardiac event, and the risk per treatment is approximately **1 event in 200 ECT treatments**. Those two round numbers are the review's own glosses on one pair of model estimates, and the estimates are 25.83 per 1,000 patients and 4.66 per 1,000 treatments on its Poisson model. Read them as the composite and not as a component of it: this is one finding written twice, once as a rate and once in round terms, and a page that prints both as though the precise pair were a sub-rate of the round pair states a part larger than its whole. The review's two estimators disagree substantially on the per-treatment figure, so a printed number owes the reader its model.

Both denominators travel together. The per-patient figure is proportionally higher because most patients receive a whole series, and because a course is usually stopped once a serious event has occurred.

GOOD TO REMEMBER

A rate quoted without its denominator is not a small imprecision, it is a different fact. Told it is two percent, a patient hears the risk of the whole course; told one in two hundred, they hear tomorrow morning. Say which you are answering.

12.4 Mortality: two estimates measuring two different things

There is no single mortality figure, and a resident who has memorised one has usually memorised it without its construct. The two pooled estimates carried here are not interchangeable.

AXIS	ALL-CAUSE DEATH AFTER TREATMENT	DEATH ATTRIBUTED TO TREATMENT
WHAT IS COUNTED	Any death within 30 days, whatever its cause; cardiac death was 29 percent of deaths	Deaths judged related to treatment, which is an act of attribution
CORPUS	41 studies, within the meta-analysis that produced the cardiac-event figures	15 studies, 32 countries, 766,180 ECT treatments, 16 ECT-related deaths
ESTIMATE	**0.42 per 1,000 patients** and **0.06 per 1,000 treatments**, Poisson model	**2.1 per 100,000 treatments**, 95 percent interval 1.2 to 3.4
WHAT TRAVELS WITH IT	Dropping the studies that reported only that no adverse events occurred raised it to 0.75 per 1,000 patients	In the 9 studies published after 2001, covering 414,747 treatments, there was 1 reported ECT-related death
ITS LIMIT	The authors state a death may follow treatment without being caused by it	A death not judged related never enters the numerator

The comparator the second review offers is what a frightened patient is asking about: it sets its figure beside a reported general-anaesthesia mortality of 3.4 per 100,000 for surgical procedures, and concludes that death caused by this treatment is extremely rare. One gap is declared rather than filled: the older textbook estimate expressed per patient rests on a task-force document this account could not open, and is not reproduced here.

TRAP **Quoting one figure as the mortality of electroconvulsive therapy.** The two differ by an order of magnitude and neither is wrong: one counts every death in a fixed window, the other only deaths judged caused by treatment, and the denominators differ too. State the construct and the denominator with the number, or do not state the number.

12.5 The prolonged seizure: two numbers doing two different jobs

This is the most commonly mistaught parameter in the chapter, and the error is always that the two figures are collapsed into one. The Indian guideline defines a **prolonged seizure** as a seizure longer than **180 seconds**. In the same sentence it states that termination can be attempted if a seizure extends beyond **120 seconds**, and that conditional wording is the guideline's own. One figure answers what counts as prolonged and is a definition; the other answers when you may act and is a permission.

RULE **The definitional threshold and the action threshold are separate numbers doing separate jobs, and the action threshold sits earlier.** A seizure is called prolonged past one figure; termination may be attempted past a shorter one. Collapse them, in either direction, and you have taught either a delay in acting or an intervention on a seizure that has not met the definition.

Before any drug, airway and respiration are monitored closely until the seizure has completely stopped. The guideline then names the classes that may terminate it: a benzodiazepine,

phenytoin, valproate, or a barbiturate, which is usually the anaesthetic agent already used for induction. That last detail is the practical one, because the drug is already drawn up. Its next steps are to stop theophylline or lithium temporarily or consider alternatives, and to consider shifting to an anticonvulsant anaesthetic agent; which drug moves the threshold in which direction belongs to the drug interactions account.

No dose is supplied by the guideline for any terminating agent, and none is supplied here: that gap is declared rather than filled from a remembered emergency protocol. Where prolonged seizures recur across a course the guideline suggests considering a reduction in stimulus dose, with its own caution attached: seizure duration is highest near the threshold dose, so raising the dose may in some situations shorten the seizure rather than lengthen it. The threshold itself belongs to the stimulus dosing account. **Status epilepticus** is named by the guideline in its emergency drug tray and among the differential diagnoses for recurrent postictal delirium, alongside the non-convulsive prolonged seizure, which is a seizure continuing without motor accompaniment and is therefore found by suspicion in a patient who does not reorient. No treatment-specific protocol and no frequency is given for either, and none is invented here.

IN INDIA

These thresholds are the Indian guideline's and are the ones to give in an Indian examination. They are a guideline convention rather than a physiological constant, and definitions differ between traditions. The other traditions' documents could not be opened here, so this account states the Indian figures with their attribution and claims nothing about what replaces them elsewhere.

12.6 Tardive seizure, and the seizure with nothing to see

A **tardive seizure** is a seizure happening within hours of an ECT session, after the patient has recovered from the treatment itself. Other causes of a seizure must be investigated rather than assumed away: a patient having a course can also have hypoglycaemia, an electrolyte disturbance or an intracranial event. The manifestations may be non-motor, which is the point residents miss, so a nurse watching for a convulsion will not see it. The seizures need to be aborted with anticonvulsant medicines, with no agent and no dose named by the source.

12.7 Postictal agitation and delirium

Postictal agitation is the acute agitated confusional state on emergence. A systematic review and meta-analysis of 21 articles and 66,047 patients, whose corpus was restricted to patients aged 18 or over and so is an all-adult figure rather than a late-life one, found a mean incidence of **13.9 percent** at the patient level and **12.4 percent** at the session level, rising to 18.0 percent and 16.5 percent once studies at high risk of bias in outcome measurement are removed, which are the figures its authors recommend using. Older reports range from about 8 percent to 65 percent, a spread produced by differing definitions, procedures and populations. Of the 7 prognostic factors meta-analysed none reached significance, so there is no validated predictor, and about 34 percent of those who have had it may have it again. One cross-reference belongs with these figures, because the chapter carries a higher one and a reader meeting both should not read a contradiction: this chapter's account of the cognitive side effects reports postictal agitation

at a substantially higher rate in a cohort restricted to later life, and the difference between the two is the population and not the phenomenon.

The Indian guideline's management sequence runs in this order, and the order is the answer.

1. Secure a safe environment, maintain airway, breathing and circulation, and protect the intravenous line.
2. Reduce environmental stimuli, with gentle, temporary physical restraint only where needed to prevent self-harm.
3. Give an intravenous benzodiazepine or an anaesthetic agent where agitation is persistent or severe. No agent is named and no dose given for this step.
4. Use a low-dose antipsychotic where the benzodiazepines have been ineffective.
5. In recurrent cases evaluate physical causes: electrolyte imbalance and infection are the two named.
6. Consider a non-convulsive prolonged seizure, status epilepticus or a tardive seizure as differentials.
7. For recurrence, a prophylactic higher dose of anaesthetic or benzodiazepine may be considered.

One prescribing number appears in that ladder and it is the only one this account carries. The guideline's worked example of the low-dose antipsychotic step is haloperidol given intramuscularly at **2 to 5 mg**, a prescribing decision owned by the treating team and not taught here, with a repeated dose when necessary, for postictal delirium with agitation where benzodiazepines have been ineffective. It is printed so a psychiatrist recognises what has been given and why, not as an instruction: that prescribing decision is the anaesthetist's, and the agents used earlier in the ladder are the workup and anaesthesia account's. Two flags travel with it. Its receipt is a professional body's guideline and not a drug regulator's product label, which was not read here. And the guideline states no starting dose, no ceiling and no minimum interval between repeats, so the tuple is incomplete, and an incompleteness left visible is safer than one closed from memory. Postictal confusion shades into the cognitive effects proper, and that limb, anterograde and retrograde amnesia, is the cognitive side effects account's.

12.8 Pain: headache, muscle soreness and nausea

These are the complications the patient actually reports, grouped by the guideline as pain appearing as headache, muscle soreness or joint pain. **Headache** is generally mild and treated with simple analgesia if severe, paracetamol, aspirin and the non-steroidal anti-inflammatory drugs being named without a dose attached to any of them. **Muscle soreness** has a pattern worth knowing: it is intense after the first session and would not be much with later sessions, so a patient warned in advance is not frightened by it. Intense fasciculation from the depolarising relaxant contributes, and a reduction of relaxant dose or a change of relaxant may be considered, which belongs to the workup and anaesthesia account. Nausea and vomiting generally travel with the headache and answer the same analgesia, with antiemetic options named where severe. No

incidence figure for any of the three is available here; that absence is declared rather than filled with a remembered percentage.

12.9 The injury that survives modification

Modification abolishes almost all of the musculoskeletal injury of the convulsion, and residents conclude from that it abolishes all of it. **Temporomandibular joint dislocation** follows uncoordinated contraction of the temporalis, pterygoid and masseter muscles, and happens with modified ECT because those muscles are stimulated directly by the current. Direct stimulation does not travel through the neuromuscular junction the relaxant is blocking, so the masticatory muscles are not protected by the blockade protecting everything else. Prevention is mechanical: firm holding of the jaws during the stimulus. A dislocation is examined for and relocated.

The recovery-room evaluation adds tongue bite and mucosal injury, and musculoskeletal injuries including fractures and dislocations; the pre-treatment examination makes dental evaluation for loose or missing teeth mandatory, which belongs to the workup and anaesthesia account. No rate for any of these injuries is given here, and injury under modified against unmodified technique is the modified versus unmodified ECT account's.

12.10 Anaesthetic complications, and what the recovery room watches

Anaesthetic complication is a category in its own right, and the Indian guideline treats it as one twice. It plans for it at the pre-anaesthetic evaluation, where investigations or interventions are arranged for conditions carrying a substantial risk of complications related to general anaesthesia. And it records it afterwards: the procedure record has a remarks row for any complication during or after treatment, and the footnote defining that row opens with prolonged seizures and apnoea as a single paired entry, then bradycardia or tachycardia, hypotension or hypertension, and post-ECT confusion or delirium, with a requirement to write how each was handled. **Apnoea** is the anaesthetic limb of that list and the recovery-room list adds aspiration. Why apnoea happens and in whom is the workup and anaesthesia account's.

No frequency exists for any anaesthesia-specific complication here, and none may be inferred from a guideline asking for the event to be documented: a documentation requirement is evidence that the event happens, not an incidence. In the recovery room, pulse, blood pressure and oxygen saturation continue to be monitored, electrocardiography in patients with a history of cardiac disease, feeding is avoided until full consciousness returns, and orientation and gait are assessed before the patient is shifted out.

MNEMONIC

AAA, then TEN

The recovery room watches for Agitation or delirium, Aspiration and Arrhythmia, then Tardive seizure, Enuresis or encopresis, and Neuroleptic syndrome. The three A's need action within minutes; the last three are what a tired team stops looking for once the patient is quiet.

12.11 Treatment-emergent mania

The emergence of mania during a course is a recognised adverse effect, and the whole of the current Indian guideline's direction on it is one clause: ECT may be continued or the frequency reduced based on clinical needs. There is no stopping rule, no threshold and no incidence figure, and what a reduction in frequency costs belongs to the course, frequency and number of ECT sessions account.

The published evidence behind any more confident answer is small. A systematic review searching from 1980 to August 2020 screened 1,662 articles and found 12 articles describing the treatment course of emergent hypomania or mania, in **17 patients** altogether. Nine of those patients had no known history of a manic or hypomanic episode and carried a unipolar diagnosis, which is the clinically useful fact in the record: the switch is not confined to patients already known to be bipolar. Four treatment courses were identified, and the authors state the available data are insufficient to support definitive conclusions. The incidence is therefore not established, no percentage is printed here, and antidepressant switch rates are not carried across to a different intervention in a different population.

> The complications that occur are a separate object from the conditions that raise risk beforehand: the cardiovascular sequence runs parasympathetic first and sympathetic second within a short window; roughly one patient in fifty has a major adverse cardiac event over a course and roughly one event occurs per two hundred treatments; mortality has two estimates measuring two constructs, neither quotable without its denominator; the prolonged seizure carries a definitional threshold and a separate, earlier action threshold, with terminating agents named by class and no dose; and postictal agitation, tardive seizure, pain, injury under modification, apnoea and aspiration, and emergent mania complete the list, each with a management step and, where no figure is grounded, a declared absence.

13 · Consent for ECT and legal aspects under MHCA

Consent for electroconvulsive therapy in India is not an act of signing but the establishment of a lawful route, and the commonest way a resident goes wrong is to treat it as a form. The Act defines what informed consent means, names who may give it in each situation a ward produces, closes one route absolutely, gates another behind a statutory body, and imposes a duty to follow the instruction a patient wrote before losing capacity.

Owned here is the practice: what the patient is told, how capacity is judged and recorded, who consents when the patient cannot, re-consent, withdrawal, and the emergency distinction. Provisions below are named in words and never renumbered; the numbering, the prohibited-against-restricted classification and the review Board's machinery are the Mental health legislation and forensic psychiatry notes'. Consent as doctrine is the Forensic ethics, consent and legal procedure notes'. The technique contrast is this chapter's account of modified against unmodified (direct) ECT; the clinical modifications its account of ECT in special populations.

seven days	an application	ten cases
THE INTERVAL AT WHICH THE PATIENT'S CAPACITY IS REVIEWED AGAIN, THE CONSENT ITSELF NOT BEING WHAT THE ACT PUTS ON REVIEW	THE ONLY LAWFUL EXIT FROM A DIRECTIVE THAT REFUSES THIS TREATMENT	THE WHOLE INDIAN OPERATIONAL RECORD OF THE BOARD GATE FOR MINORS

13.1 What the Act means by informed consent

The Act carries its own definition of **informed consent**, stricter than ward habit. It is consent given for a specific intervention, without force, undue influence, fraud, threat, mistake or misrepresentation, obtained after disclosing adequate information including the risks and benefits of that intervention and the alternatives to it, in a language and manner the person understands. Four requirements are asked at once, and the first decides this topic: consent is intervention-specific, so a general consent taken at admission is not consent to electroconvulsive therapy, and the alternatives limb is the one most often dropped.

13.2 The emergency, and the authority the Act withholds

Here a resident is most likely to be taught something unlawful. Electroconvulsive therapy can be clinically indicated in an emergency. The Act's provision on emergency treatment cannot authorise it, because that provision expressly excludes electroconvulsive therapy from the treatment it permits. Neither statement qualifies the other. What follows is that a lawful route must be established separately, and that urgency does not cure an incomplete route.

The second half is the one most often lost: treatment authority is not admission authority. A capacitous adult can consent to electroconvulsive therapy with no admission at all, so urgency never converts the question into whether the patient must first be admitted. That is a proposition about what the Act does not require rather than anything it states affirmatively: what could be grounded is only that the Indian guideline's pre-treatment evaluation form asks the clinician to record whether the patient is an outpatient or an inpatient, so outpatient treatment is contemplated in Indian practice. That absence is offered here as the absence it is.

RULE **Urgency changes the timetable, never the route.** A patient who is not eating, catatonic or acutely suicidal earns speed in arranging a lawful route: capacity assessed now, the directive looked for now, the application filed today. Urgency never earns a shorter route.

13.3 The lawful routes, and the limit that travels with each

The Act supplies a small set of routes, each with its own trigger and its own ceiling. A route taught without its limit is how this topic goes wrong.

ROUTE	WHERE THE AUTHORITY COMES FROM	THE LIMIT THAT TRAVELS WITH IT
THE CAPACITOUS ADULT	His own informed consent, capacity deemed present	Neither a proxy nor a past document displaces it; a decision others think unwise is not incapacity
THE ADULT LACKING CAPACITY	The supported-admission provision: directive first, then his own consent with the representative's support	Substituted consent only where nearly total support is needed, only temporarily, recorded, capacity reviewed every seven days
THE ADVANCE DIRECTIVE	His own written instruction, invoked when he ceases to have capacity	Runs in either direction and more often bars than authorises; a valid refusal binds the team, the only exit an application to the Board
THE NOMINATED REPRESENTATIVE	Appointed in writing, or by the Act's deemed order of precedence	He does not displace a capacitous adult's own consent; his duties bind him to the patient's wishes
THE MINOR	The legal guardian, the nominated representative by operation of law	Treatment needs the guardian's informed consent and prior permission of the concerned Board, with no clinician discretion

13.4 The first route: the adult who has capacity

The default route is the patient's own consent, and the Act starts from a presumption. Every person, including a person with mental illness, is deemed to have **capacity** to make decisions regarding his mental healthcare or treatment, the test being functional and disjunctive: to understand the relevant information, or to appreciate any reasonably foreseeable consequence of deciding or not deciding, or to communicate the decision by any means. Named in words here; the statutory definition is the Mental health legislation and forensic psychiatry notes'. And a decision perceived by others as inappropriate or wrong does not, by itself, mean that the person lacks capacity, which forecloses the commonest shortcut of all: reading a refusal as proof that the patient cannot decide.

The limit is stated twice. A patient admitted on his own request is not to be given treatment without his own informed consent, and the establishment may not require a nominated representative's consent or presence in order to admit him; separately, a capacitous decision overrides any advance directive he wrote earlier. Taking the relative's signature as well is a habit, not a requirement. That statement is drafted about the patient admitted on his own request; no provision stating the limit generally for a person not admitted could be grounded, and the gap is declared.

13.5 The second route: the adult who lacks capacity

Where capacity is absent the Act does not simply hand the decision to the family. It routes treatment through its **supported admission** provision, and the order of authority there is fixed:

an advance directive, if any, is taken into account first, and then the informed consent of the patient with the support of his nominated representative. Only where he needs nearly total support in deciding may the representative temporarily consent to the treatment plan on his behalf, and then the consent is recorded in the medical records and his capacity reviewed every seven days.

Substituted consent is therefore a rolling, revisable state: a course over several weeks crosses that review more than once. The provision is drafted for a person admitted under it, and no free-standing treatment-consent provision for an adult lacking capacity and not admitted could be grounded; that too is a declared gap.

13.6 The third route: the advance directive, which more often says no

A resident who meets the **advance directive** only as a way of saying yes will treat a refusal as an obstacle to work around. Every person who is not a minor may make a directive in writing specifying the way he wishes to be treated for a mental illness and the way he wishes not to be; it is invoked only when he ceases to have capacity and lapses when capacity returns; a capacitous decision overrides any directive he wrote earlier; and a directive made contrary to any law in force is void from the beginning. It therefore runs in either direction, and the refusing limb is the commoner one in practice: the instrument working, not a defect. The void limb disposes of a directive purporting to authorise treatment given without anaesthesia and muscle relaxation, prohibited outright: this chapter's account of modified against unmodified (direct) ECT.

Now the provision this topic most needs. It is the duty of every medical officer in charge of a mental health establishment, and of the psychiatrist in charge of a person's treatment, to give treatment in accordance with that person's valid advance directive, subject only to the Board-review provision. That is a duty, not a consideration to be weighed, and it reaches the treating psychiatrist directly. A valid directive refusing electroconvulsive therapy binds the treating team: there is no bedside-override limb in it, no urgency limb and no senior-clinician limb.

Where a mental health professional, a relative or a care-giver desires not to follow a directive, the Act tells him to apply to the concerned Board. The Board gives an OPPORTUNITY OF HEARING to all concerned parties, including the person whose directive is in question, and may uphold, modify, alter or cancel it against five considerations: voluntariness; whether he meant it to apply to circumstances such as these; whether he was sufficiently informed; whether he had capacity then; and whether its content is contrary to other laws OR CONSTITUTIONAL PROVISIONS. Both of those are worth reading exactly. An opportunity of hearing is the natural-justice formula and is not the same as a promise that everyone is heard, and the fifth consideration carries a constitutional limb that a shortened list drops. The intention limb is what an ECT case usually turns on. The route out of a refusal is that application, never a bedside decision to disapply the directive, and urgency creates no exception. No statutory time limit appears on the face of the provision, so how quickly a Board sits is not promised.

The Act does put emergency treatment beyond the reach of a directive; that cannot open a route to electroconvulsive therapy over a refusal, because the emergency-treatment provision itself

forbids its use. The exclusion is real and, as to this treatment, empty. And a practitioner is not liable for unforeseen consequences of following a valid directive, and is not liable for not following one if he was never given a copy: that turns on possession of the document, not on his view of its merits.

TRAP **Meeting the advance directive only as a route to yes.** Its commoner operation is to bar a treatment, and the refusing directive is a form the statute names first. A resident who has met only the authorising face reads a refusal as a clinical problem to solve, and solving it clinically is the unlawful act.

13.7 The fourth route: the nominated representative, and the ceiling on the role

The **nominated representative** may be appointed by the person himself in writing, and where nobody has been appointed the Act supplies a deemed order of precedence: the individual named in the advance directive, a relative, a care-giver, a person appointed by the Board, and finally a state welfare official. What the role obliges is not proxy preference: he must consider the person's current and past wishes, life history, values, cultural background and best interests, and give particular credence to the person's own views.

Authority without a limit teaches a resident to collect the wrong signature.

- A nominated representative does not displace a capacitous adult's own valid consent.
- He substitutes where capacity is absent; he cannot consent over a capacitous patient's refusal.
- Where he consents for a patient who lacks capacity but is audibly protesting, what the patient says must be weighed.

13.8 The fifth route: the minor, and the gate that leaves no discretion

A person aged below eighteen is not considered capable of giving consent for treatment, and consent for admission and for interventions is obtained from the nominated representative. For a minor the Act fixes who that is: the **legal guardian** is the nominated representative, unless the concerned Board orders otherwise on an application showing that he is not acting in the minor's best interests or is otherwise unfit, when it may appoint a suitable willing individual instead.

The gate has limbs that bind together: the informed consent of the legal guardian, and prior permission of the concerned Board. The current Indian recommendations state it and its consequence in one breath: where a psychiatrist recommends this treatment for a minor under specific clinical conditions, guardian consent and prior permission from a Mental Health Review Board are mandatory, and the Act gives the clinician no discretionary powers for using electroconvulsive therapy in minors. They record the worry the gate creates, that delay or disapproval could impede treatment of suicidal risk and catatonia, and answer it with process rather than an exception: the minors-specific instance of the teaching that urgency does not cure an incomplete route.

What the gate costs in practice has been reported once. One tertiary centre described the first six months of operating it: ten cases, a written summary submitted in each, the caregivers' informed consent sought first and permission after that, a response within a few days without inordinate

delay or objection, and permission denied in no case. That is a single-centre series from an institute with its own Board, and not a national expectation.

The Indian guideline adds what the statute does not: oral or verbal **assent** from the minor as the age permits, alongside written informed consent from the parents or nominated representative, and concurrence by two independent psychiatrists, or a psychiatrist and a physician. That concurrence is professional and not statutory, and presenting it as part of the gate misstates the law.

A minor cannot make an advance directive, but the legal guardian can make one for the minor, and since the instrument runs either way it can bar this treatment as readily as request it. If the minor attains the age of eighteen during the hospital stay he is to be classified as an independent patient, that is communicated to him, and treatment continues on that footing or as a patient requiring high support. Where the Board has displaced the guardian, guardian and representative differ, and whose consent the gate then requires is unanswered by the sources.

IN INDIA

A pair of Indian facts is routinely conflated. The statute supplies the gate for a minor: guardian consent and prior permission of the concerned Board. The guideline supplies more: the minor's own assent, and a second psychiatrist's concurrence. Name which is which.

13.9 The consent as it is taken, documented, re-taken and withdrawn

The Indian guideline states the conversation and its documentation. Written informed consent is taken before treatment begins, on the principles of shared decision-making. It covers the anticipated benefits and the possible short-term and long-term adverse effects in this individual, including the risks of the anaesthesia as well as of the treatment, plus the type of treatment, the modification procedure, the electrode placement and expected outcomes. Unless the patient disagrees, caregivers are made part of the process. Where the patient lacks the capacity to consent, that is documented; any advance directive is examined; and, in accordance with that directive, consent MAY be obtained from the nominated representative. The permissive form is the guideline's own: the representative route is conditional on what the directive says, not an automatic next step.

Read the order, because it is the Act's order too: the directive is examined first, and the representative's consent comes after it and in accordance with it, never instead of it.

Re-consent is given as triggers rather than as an interval: consent is taken again when the patient regains the capacity to consent, when a minor attains the age of eighteen, and before continuation or maintenance treatment is initiated, the clinical condition, the purpose and the character of the treatment having all changed by then. That indication itself is this chapter's account of continuation and maintenance ECT.

The guideline states the right in the patient's own terms: he may refuse consent now, and may withdraw consent during the course of treatment, and in either case the best available alternative

treatments will be provided without any prejudice. That second half is the part residents omit, and it makes the right real rather than nominal.

RULE **Record the route, not only the signature.** The note should say which route was used: capacity present and consent taken from the patient; or capacity absent, the directive looked for and recorded, and the representative's consent taken temporarily with the review date entered; or the guardian's consent with the Board's permission on file.

MNEMONIC

ADULT, ABSENT, ADVANCE, AGENT, AGE

Adult: the capacitous adult's own consent, an unwise choice not being incapacity. **Absent**: capacity absent, so the supported route, substituted consent temporary and recorded, with the patient's CAPACITY reviewed every seven days. **Advance**: the directive, which runs either way and binds when it refuses, the exit being an application to the Board. **Agent**: the nominated representative, who never displaces a capacitous adult. **Age**: the minor, needing guardian consent and prior permission of the concerned Board.

PITFALL

Writing the emergency into the answer as though it were a route. It is a clinical urgency, never a source of authority, and the Act's emergency-treatment provision excludes this treatment by name. The paired error runs the other way: assuming that because that route is closed the patient must be admitted first. He need not be.

Consent for this treatment is the establishment of a lawful route, measured against the Act's definition of informed consent: intervention-specific, voluntary, and informed as to risks, benefits and alternatives. The routes are the capacitous adult; the adult lacking capacity, under the supported provision with substituted consent temporary and recorded and the patient's capacity reviewed every seven days; the advance directive; the nominated representative; and the minor, through guardian consent with prior permission of the concerned Board. Each carries a limit: no proxy and no past document displaces a present capacitous decision, and a valid directive refusing this treatment binds the team, the only exit an application to the Board. The emergency provision is not a route to this treatment, a lawful route must be established separately, and urgency does not cure an incomplete one. Consent is written, taken again when capacity returns and before continuation treatment, and may be withdrawn at any point without prejudice.

14 · ECT in special populations (pregnancy, elderly, adolescents)

A special population does not change what electroconvulsive therapy is; it changes the plan built around it, meaning who else evaluates the patient, what is monitored, which ordinary choice is deliberately reversed, and what the conversation before treatment must contain. The four special populations are different problems: pregnancy an evidence problem before a

technique one, old age a selection problem in which the usual instinct runs backwards, the minor a legal problem, comorbidity a co-management one.

Owned here is the clinical modification each population requires, and nothing else. Named below and not re-taught: the anaesthetic conduct being modified, owned by the pre-ECT workup and anaesthesia; the consent practice being varied, owned by consent for ECT and the legal aspects; and likewise the cognitive cost, the conditions raising risk beforehand, concurrent drugs, the titration and the placement comparison. The statutory gate on ECT for a person under eighteen belongs to the Mental health legislation and forensic psychiatry notes; it is named here in words and never renumbered.

20 weeks THE GESTATION PAST WHICH THE SETTING CHANGES, NOT THE TECHNIQUE	**no randomised trials** IN THE LARGEST SYNTHESIS OF ECT IN PREGNANCY	**0.35** OLDER AGE AS A PREDICTOR OF RESPONSE, AS A STANDARDISED MEAN DIFFERENCE

14.1 Pregnancy: the modification, the monitoring and the threshold

The Indian guideline states its own scope before its list. These steps are most applicable in the second and third trimesters, and the risk evaluation is a joint activity of the psychiatrist, the anaesthetist and the obstetrician. That is structural, not courteous: each item follows from a physiological change an obstetrician reads better.

Hydration is maintained through the fast, with intravenous fluid if dehydration is noted. A **left lateral or pelvic tilt** maintains aorto-caval circulation, the supine gravid uterus otherwise cutting venous return just as a surge is induced. Pre-oxygenation is provided but hyperventilation avoided, the instruction most often got backwards: blowing off carbon dioxide favours the seizure in ordinary practice, while here placental oxygen delivery governs. An H2 blocker or antacid is considered against the raised aspiration risk. The anticholinergic line is a trade and not a prohibition: routine anticholinergic premedication is avoided even though the guideline concedes in the same sentence that it would reduce the risk of foetal arrhythmias. Memorise the first half and you have a rule; carry both and you have a decision. The agents and sequence are the workup and anaesthesia account's; no dose appears here.

Monitoring is doubled. Doppler or cardiotocography is used for the foetus before, during and after treatment, alongside maternal vitals. Then the threshold: after 20 weeks of gestation, treatment should preferably be given where obstetric support is available, with **tocolytics** and preferably a **tocodynamometer** to hand against induced labour or abortion. The guideline hedges with preferably twice, and the hedge is carried rather than tightened. Past that gestation what changes is the room, not the treatment.

14.2 The comparative claim, and the three things it does not say

The sentence a resident will meet is that ECT is safe and effective in pregnancy and is a preferred option, given its lesser risk of teratogenicity compared to many psychotropics. It supplies a comparator, a class and not a drug: many psychotropics. A domain: teratogenicity. A direction: lesser, for ECT.

It does not supply the gestational window in which the comparison holds, nor the illness severity at which it holds, nor any graded strength of evidence. It says nothing about outcomes other than teratogenicity, which matters because the register evidence below points the other way on preterm delivery and the newborn's condition at birth. Those absences cannot be filled from another source here, so they are not.

RULE **Never write that ECT is often the safer option in pregnancy without stating what it is safer than, in which period of the pregnancy, for which severity of illness, and at what strength of evidence.** The published sentence is bounded on one axis only, and the bare version silently promises a general safety finding no source here states.

14.3 What the pregnancy evidence base is, and what it cannot settle

The largest and most recent synthesis included 82 reports carrying information on more than 1,300 pregnancies and deliveries, and its composition is the point: 57 were case reports and 14 were case series, the remainder non-randomised or retrospective. There are no randomised trials, so a clinical position rests on the weakest available design.

What it reports is reassuring in shape: the most frequent adverse events were generally mild and transient. But the same synthesis records, across the reviewed reports, 1 placental abruption, 21 premature deliveries, 6 congenital malformations and 4 stillbirths. Then the authors state the limit themselves, in the sentence that must travel with every reassuring one: because information was limited, causal links between modified ECT and many of these adverse events were difficult to establish, and no inference could be drawn about differential effectiveness or safety between important patient subgroups or across variations in technique.

That cuts both ways and residents usually take one. The harms cannot be confidently attributed to the treatment; neither can the reassurance. A literature that cannot establish causation cannot establish its absence, so the reassuring picture and its limit are one object, never taught apart.

14.4 The register cohort, and why the comparator decides the answer

The largest observational study inside that review is a Swedish population-based register cohort of 793, propensity-score matched. On effectiveness it reassures: response rates matched those of non-pregnant women receiving ECT. On obstetric outcome, the control group decides the answer.

Premature delivery ran at 14.4 per cent against 9.0 per cent compared with psychiatrically hospitalised pregnant women not given ECT, an odds ratio of 2.33, confidence interval 1.15 to 4.73, which is significant. Against the second, additional pregnancy control group it ran at 10.9 per cent, odds ratio 2.16, confidence interval 0.75 to 6.22, which does not exclude no effect. A low 5 minute Apgar score behaves identically: 9.3 per cent against 2.1 per cent, odds ratio 3.68, confidence interval 1.58 to 8.55 against the first, and 2.2 per cent, odds ratio 2.53, confidence interval 0.59 to 10.90 against the second. The same table carries the finding that cuts the other way, and it travels with the rest: none of the reported preterm births occurred in close time proximity to treatment, which weakens the causal link. These figures are attributed to the review's own table at the review's year, the primary study not having been opened here.

The reviews then disagree for methodological, not empirical, reasons. An overview identified 9 articles, of which 5 met inclusion criteria, covering 32 to 339 patients, foetal deaths ranging from 2 to 12. 1 of the 5 recommended ECT only as a last resort while the others called it relatively safe, the split attributed to differing inclusion criteria and differing attribution of adverse events, and that is read at abstract level here. Reviewers of overlapping literature reached opposite recommendations because they counted differently: the question is unsettled at the level of method, not of data.

TRAP **Quoting a risk figure without its comparator.** Every significant obstetric signal here loses significance when the control group changes, and every one keeps its point estimate. Carry the preterm figure without its comparator and you report a hazard the study does not establish; carry only the non-significant comparison and you report a safety it does not establish.

14.5 What the uncertainty puts into the consent conversation

The perinatal review draws an explicit consequence from its own uncertainty, and it is a consent instruction rather than a treatment one. Modified ECT is an important option for severe perinatal depression, and informed consent practice should reflect the knowledge gaps identified in the review as well as the well-known side effects, and should be set against the substantial adverse consequences of untreated or undertreated maternal depression. That supplies the honest comparator for the risk discussion and makes the gaps a required disclosure: not a reason to withhold, not a reason to soften the account, but content the woman is entitled to. How consent is taken, meaning capacity, the nominated representative, re-consent and withdrawal, is the consent for ECT and legal aspects account's.

14.6 The elderly: not merely tolerable candidates but preferentially good ones

Start with the effect size, because the order matters. A meta-analysis screened 2193 articles and included 34. Older age predicted remission at a standardised mean difference of 0.26 and response at 0.35, at P less than 0.001. Psychotic features predicted remission at an odds ratio of 1.47 and response at 1.69; severity predicted response at 0.19 but not remission. The authors conclude that ECT is particularly effective in patients with depression with psychotic features and in elderly people with depression, and the Indian guideline agrees from practice: response rates in elderly depression exceed those in mixed-age populations.

Carry that first, and as an effect size rather than an impression, because everything below is a burden to be managed and a resident who meets the burdens first reads this section as reasons to withhold. Age is a positive predictor; the burdens are separate facts about the same patient, not the price of the benefit.

High seizure threshold, missed seizures, medical comorbidity and postictal delirium are all commoner in old age. The cognitive concern is located rather than generalised, which is the guideline's most careful sentence here: cognitive adverse effects are of greater concern primarily when ECT is indicated for dementia-related behavioural disturbance. That is a statement about one indication, not a blanket caution about age. The amnesias and how cognition is tracked are the cognitive side effects account's.

The modifications follow, each owned elsewhere. Propofol may be avoided and anticonvulsants minimised, the agents being the workup and anaesthesia account's. Non-convulsive shocks are minimised, for which a higher initial dose and faster increments may be considered; the titration is the stimulus dosing account's, and increments means the electrical dose, never the number of treatments in a week. Right unilateral or bifrontal placement is preferred to bitemporal, a preference inside a comparison the bilateral versus right unilateral account owns, and age does not reverse it. A lower range of brief or ultrabrief pulse may be considered. One number sits alongside: concomitant lithium above 0.6 is avoided for the risk of **postictal delirium**. The unit is a separate point and gets its own sentence rather than an interruption inside that clause. The guideline prints it here as 'mq/l', which is a typographical error for milliequivalents per litre; the error is reproduced rather than silently repaired, because substituting the unit one believes was meant is how a wrong number enters a chapter, and the same guideline spells the same unit 'meq/l' at the second place the same figure appears, which this chapter's account of drug interactions with electroconvulsive therapy carries.

14.7 Adolescents and minors: the gate first, then the four headings

For a person under eighteen the statutory question is answered before any clinical one. That gate, its prohibition and the narrow exception that opens it, are taught in full by this chapter's own account of consent for electroconvulsive therapy and the legal aspects, which is where to go for them; the Mental health legislation and forensic psychiatry notes own only the numbering and the wider classification of the provisions. The gate is named here rather than restated, and is never renumbered. Nothing below creates an exception to it: the criteria decide whether ECT is the right treatment, never whether it may lawfully be given.

The clinical frame sets out four headings, all of which must be satisfied.

- Heading A is specific clinical features: high risk to self from active suicidal ideas or behaviours, high risk to others from severe repetitive aggression, catatonic features, or long illness with inadequate response.
- Heading B is the adequacy of pharmacological or psychotherapeutic intervention.
- Heading C is that alternatives, including other medications, other routes and other brain stimulation methods, were considered and not found suitable.
- Heading D is that medical contraindications for modified ECT have been ruled out by pre-anaesthetic check-ups, where the word modified is doing real work, modified being the only lawful form in India.

Heading B is the one to learn, because the urgent case is answered there. It is satisfied when recommended treatments have been used in adequate dose and duration with inadequate change; or when recommended treatments have been initiated but would take time to be effective, during which time the clinical features might pose a significant risk to the patient; or when the child is not tolerating the up-titration required to reach recommended doses. The middle limb answers the objection that a child cannot wait for a drug to work: the waiting itself can be the risk, stated as a clinical criterion inside the gate, not a shortcut around it.

TRAP **Reading urgency as a legal exception.** Heading B answers the urgent case clinically and leaves the statutory position untouched; a fast clinical justification is not an authority to treat. The reverse error is as common: treating the gate as a reason to conclude that ECT is unavailable to a young person in a dangerous state.

One thing genuinely reverses here, on a single physiological fact. **Prolonged seizures** are commoner in this age group, so proconvulsant or seizure-neutral induction agents such as etomidate and ketamine are best avoided. Elsewhere those agents are reached for precisely to protect a poor seizure; here that virtue is the hazard. Their comparative effects belong to the workup and anaesthesia account, and no dose is stated. The same guideline records that the literature is limited, that no differential efficacy or safety has been shown, and that a second psychiatrist's opinion is useful.

IN INDIA

The published Indian experience is uncontrolled tertiary-centre case series, which is what it must be called before its rates are read. The first reported 25 patients below the age of 18 over 12 years, with catatonia the commonest indication at 68 per cent, and after a mean of 10 treatments the response rate was 76 per cent. A later series from the same group covered 51 individuals up to 19 years of age over 7 years, a mean of 8 treatments producing significant improvement in 86 per cent. At a third centre, twenty-two children treated over a ten-year period, the youngest aged 10, had prolonged seizure as the commonest side effect at close to 35 per cent.

The international series agree on the shape and the mechanism. Fifty-one adolescents of mean age around 16, in a United States series covering 1991 to 2013, had bitemporal treatment over a mean of 9 sessions with clinically significant improvement in 77 per cent, and it records that prolonged seizure duration is common in young people and declines with age across adolescence. That age gradient is why the anaesthetic choice changes. A Swedish national register covering 118 young people under 19, from 2012 to 2016 used right unilateral placement over a mean of 7 sessions, and fifty-seven per cent responded adequately, adverse effects in 25 per cent being minor. The placements differ between the series and that difference is not a recommendation.

14.8 Physical comorbidity: co-management, organ by organ

Here the population is an organ, and the modification takes one form: optimise it before, protect it during, share the decision with its specialist. The conditions raising risk beforehand, and the interval after a recent infarction, are the contraindications account's.

SYSTEM	WHAT IS MODIFIED	WHY
CARDIAC	Blood pressure optimally controlled, with short-acting antihypertensives during treatment if needed; anticoagulation considered in valvular disease; multiple restimulations avoided in congestive heart failure, with functional capacity assessed by 2D echocardiogram and treadmill test; short-acting parenteral antihypertensives in aneurysm; conduction defects and pacemakers generally safe, given only in consultation with cardiologists	A brief surge is met with agents of equally brief effect
CEREBRAL	Postponement after recent ischaemic or haemorrhagic stroke and with a symptomatic intracranial mass until the risk of complications is minimised; patency of a ventriculo-peritoneal shunt confirmed; after craniotomy, electrodes placed away from the site to avoid a very high charge density; depolarising muscle relaxants avoided in multiple sclerosis; cerebral implants and foreign bodies not an absolute contraindication, treatment given in consultation with neurologists	An opened skull conducts differently, and a defect concentrates charge
RENAL	Adequate muscle relaxation, with non-depolarising agents preferred; in haemodialysis patients, serum potassium measured within 24 h before treatment	A depolarising relaxant releases potassium a failing kidney cannot excrete
RESPIRATORY	Hypoventilation avoided, since it leads to respiratory acidosis, hyperkalaemia and further acid-base imbalance; theophylline discontinued 24 h before treatment, for the risk of prolonged seizures and status epilepticus	Ventilation is supplied, not spontaneous, so its adequacy is a decision

PITFALL

Reading the two relaxant lines as one rule. One avoids a depolarising agent in multiple sclerosis, the other prefers a non-depolarising agent in renal disease: two members of an open group reached by different routes, not one instruction generalised.

MNEMONIC

Room, rate, reversal, ruling, review

Room: past the stated gestation, pregnancy changes where treatment happens, not how. **Rate**: in the elderly the response rate leads. **Reversal**: in minors the agents chosen elsewhere to protect a seizure are avoided. **Ruling**: the gate is statutory and comes first. **Review**: comorbidity is co-managed with the organ's specialist.

The examinable core is a habit, not a list: say what the plan changes, name who else is in the decision, and state the evidence at the strength it has. The comparative claim in pregnancy never travels without the three things it does not say; the elderly get their effect size first and their burdens second; the minor gets the gate named, then the four headings.

15 · Course, frequency and number of ECT sessions

An acute course of electroconvulsive therapy is a schedule rather than a single decision, and the schedule settles how fast the patient recovers, what that costs in memory and when treatment stops. How often treatments are given is the parameter most often remembered as an efficacy lever, and it is not an efficacy lever. A much faster schedule exists for presentations that kill within days, bought with mortality rather than impatience.

Owned here in full: the acute course and every schedule on it, treatment frequency and the twice-weekly against thrice-weekly comparison, the accelerated schedule for life-threatening presentations, the number of treatments by indication, judging response, the mid-course decision and stopping, with the malignant catatonia protocol assembled end to end. Named and not re-derived, each with its own account here: why catatonia and its malignant form earn the treatment; the seizure threshold, its titration and the adequate-seizure criteria; and the cognitive cost. Continuation and maintenance treatment begin where this ends. The catatonia entity, the lorazepam challenge, the malignant catatonia against neuroleptic malignant syndrome differential and the rating scale are the Other psychotic disorders, delusional syndromes and catatonia notes'.

2 to 3 per week	8 to 12	3 to 5 days
THE INDIAN ACUTE-COURSE FREQUENCY, A RANGE AND NOT ONE SCHEDULE	TREATMENTS BEFORE AN INDIAN COURSE MAY BE CALLED A FAILURE	OF DAILY OR TWICE-DAILY BILATERAL TREATMENT OPENING A MALIGNANT CATATONIA COURSE

15.1 The acute course, and what treatment frequency means

The acute course is the block of treatments that brings the present episode to remission, described by three things: how often treatments are given, how many, and what stops them. **Treatment frequency** is the first, and it is a construct rather than a schedule, because the guidelines state it as a range. The Indian guideline gives the acute course as **2 to 3 sessions per week**, and its consent supplements state what the patient is told, ECT on alternate days or twice a week for about 2 to 3 weeks.

A policy guideline adds the spacing rule, that ECT is usually given two or three times per week in an acute course, spaced as evenly as possible across the week. Two schedules dominate within it, the **twice-weekly schedule** and the **thrice-weekly schedule**, and what separates them is not how well the course works.

15.2 What the faster schedule buys, and what it does not

Two double-blind randomised trials carry the comparison, each holding anaesthetics constant with a weekly simulated treatment in the slower arm. The first found that both schedules significantly improved depression scores, with no difference in outcome either 1 week or 1 month after the series ended, while response to ECT three times a week was significantly faster and cognitive effects more prominent. The replication found no significant difference in antidepressant outcome, with significantly more rapid response on the thrice-weekly schedule, associated with more severe memory impairment.

Their joint synthesis adds what decides the teaching: the antidepressant effect of the two schedules at the end of the course was equal, while the thrice-weekly schedule induced more severe memory impairment even when the number of treatments in the series did not differ significantly. The cost belongs to the spacing, not to receiving more treatments, so it cannot be argued away by pointing at the total. The reviewers give the rule with its premise: when rapid improvement is clinically warranted, thrice-weekly ECT may be preferred, given that both schedules are equally efficacious.

RULE **Treatment frequency buys SPEED of response, and it is not an efficacy lever: both schedules reach equivalent efficacy at the end of the course, and the faster one reaches response sooner at a higher cognitive price.** Written the other way round it teaches a resident to impose extra cognitive injury for a gain that does not exist. **Speed of response** is a real good where the illness is racing; where it is not, the price is paid for nothing.

15.3 How thin the evidence beneath that rule is

The only meta-analysis confirms the efficacy half and prices the slower schedule in days: twice-weekly ECT produced a similar change in depression score, with a statistically significant longer duration of treatment of roughly 4.8 to 6.5 days. It fixes the lower bound too, since thrice-weekly ECT was significantly more efficacious than once-weekly ECT, and reports no cognitive endpoint, corroborating the efficacy and duration halves only.

Outside depression the trade is half established. The one comparison in schizophrenia, a retrospective series of 43 patients, found more rapid response on the thrice-weekly schedule, equal effectiveness, and no significant difference in cognitive impairment at the end of the study: the speed finding reproduces, the cognitive one does not. Nothing newer exists, since a review of trials to March 2019 found no original research study examining the issue of frequency of ECT sessions among its 30 studies. The rule rests on trials from the 1990s and on consensus, and saying so is part of teaching it.

15.4 Which schedule each tradition actually recommends

The shorthand is a two-camp story, the United Kingdom twice weekly and North America thrice weekly, and the sources do not support it. What is grounded is practice: in the United States and Israel thrice-weekly ECT is a common practice, while in the United Kingdom twice-weekly sessions are commonplace. Practice is not recommendation, and the American position is itself a range: the task force recommends twice or thrice weekly sessions, cautioning that more frequent sessions could result in higher cognitive deficits and that frequency should be reduced if cognitive effects are of serious concern. The United Kingdom limb ties higher frequency to lethality, not impatience: the college handbook recommends twice weekly for bilateral and for unilateral ECT, with thrice-weekly bilateral reserved for life-threatening illness and only while the threat is high.

One exception inverts that and stops the twice-weekly preference reading as a blanket law: given the slower speed of response already seen in ultrabrief ECT, that form should routinely be given three times per week. Where no source settles a jurisdiction's recommendation the gap is declared: none states thrice weekly as a North American recommendation.

15.5 The accelerated schedule, and what buys it

Twice against thrice weekly is not the whole of frequency, and what it omits matters when the clock is short. In malignant catatonia the course opens on an **accelerated schedule**: in view of the life-threatening potential of malignant catatonia, bilateral treatments daily or twice daily for 3 to 5 days are often required to achieve a rapid result, followed by ECT at conventional frequencies until complete resolution. Why the presentation earns treatment is this chapter's account of the indications, and the entity and its differential are those catatonia notes'. The schedule is assembled here and nowhere else.

The same guideline grades it, with trigger, endpoint and step-down: if there is partial or no response to lorazepam within 48 to 72 hours, institute bilateral ECT once or twice daily for up to 5 days until malignant catatonia abates, followed by ECT three times per week until sustained improvement, usually 5 to 20 treatments in total. Its grade is D, expert consensus and not trial evidence, part of the teaching. A second jurisdiction corroborates it, introducing ECT with closer spacing, that is successive days, for rare severe and life-threatening states such as malignant catatonia, then resuming at 2 or 3 per week, but not twice-daily treatment, which rests on the consensus guideline alone.

The comparable emergency is not handled identically: in neuroleptic malignant syndrome, if clinical features persist, consider bilateral ECT three times weekly or, in severe cases, once or twice daily until the syndrome abates, then three times per week until sustained improvement, to a total of 5 to 20 treatments, graded C. Accelerated dosing opens the malignant catatonia course and is held in reserve here.

What buys the extra cognitive cost is mortality, and the evidence is survival data. Across five series, 51 of 54 patients treated with ECT survived, whereas only 6 of 14 given antipsychotics and supportive care recovered, and timing decided the rest: **16 of 19 patients receiving ECT**

within 5 days of onset survived, while none of 14 starting beyond that 5-day point recovered. These are historical series inside a current guideline, cited for what they established, not as a practice parameter. The trade is the chapter's usual one, priced differently: where the competing risk is death within days, speed outweighs the cognitive cost, and that cost is this chapter's account of the cognitive effects.

STEP	MALIGNANT CATATONIA	NEUROLEPTIC MALIGNANT SYNDROME
TRIGGER TO TREAT	Partial or no response to lorazepam within 48 to 72 hours	Clinical features persist
PLACEMENT AND STIMULUS	Bilateral, the stimulus dosed liberally to secure a well-generalised seizure; threshold, titration and adequacy are this chapter's dosing account	Bilateral, under the same account
OPENING FREQUENCY	Daily or twice daily, for 3 to 5 days	Three times weekly by default, once or twice daily in severe cases
ENDPOINT OF THAT PHASE	Until malignant catatonia abates	Until the syndrome abates
STEP-DOWN	**Step-down** to three times per week until sustained improvement	Three times per week until sustained improvement
TOTAL AND GRADE	Usually 5 to 20 treatments, grade D	A total of 5 to 20 treatments, grade C

TRAP **Giving malignant catatonia the ordinary twice-weekly or thrice-weekly course.** The decision to treat is right and the schedule too slow, which in a presentation whose survival turns on how early treatment starts is a wrong answer with a right diagnosis attached.

15.6 How many treatments, and by which indication

No source fixes a course length in advance: the number of ECTs should not be predetermined but should be based on the needs of individual patients. Around it sit the examinable figures. The task force gives **6 to 12 sessions for depression**, higher where the protocol changed and in schizophrenia, and practice sits inside it, the mean number of ECT sessions being between 6 and 10 in most studies, which its reviewers say cannot be read without knowing why courses stopped.

In catatonia practice was wider than any recommendation: most studies reporting frequency described ECT three times weekly, ranging between daily and twice weekly, with sessions from 3 to 35 and a mean of 9, and no data on the superiority of these protocols. For non-malignant acute catatonia the guideline sets a floor, that where ECT is administered in acute catatonia it should be given at least two times weekly, tying the count to response, risks and side effects. Direction is grounded where a number is not: in general the response to ECT is seen after more sessions in schizophrenia than in depression and mania.

15.7 Judging response, the mid-course decision, and stopping

Two rhythms of assessment run through a course. The Indian guideline requires a structured, indication-specific symptom rating tool weekly wherever feasible, and a clinical assessment after every ECT, preferably within 24 hours and certainly before the next session, with symptoms and cognitive and other adverse effects monitored at least once a week. A policy guideline sets another cadence, clinical assessments at least twice per week, with structured rating scales before commencing and at the end: the difference is jurisdictional.

The **mid-course review** carries two thresholds, not to be merged. Technique changes first: **switching unilateral to bilateral, or ultrabrief to brief pulse, may be considered after a risk-benefit analysis if improvement is not noted after four to eight sessions**. Failure is declared much later, since a minimum of 8 to 12 ECT sessions should be provided in acute courses before considering failure of response, with continuation beyond 12 sessions decided after a risk-benefit analysis. The United Kingdom handbook is stricter and conflicts with that floor: bilateral ECT for depression may be stopped if there is no improvement at all during the first six treatments, and continued to 12 sessions where there is some. Both are printed and the conflict named, not resolved.

Clinically, ECT may be terminated at any time if complete clinical improvement or remission is achieved, and the course is generally stopped as soon as remission is achieved, or if initial improvement remains unchanged for two additional sessions. Current United Kingdom depression guidance has two limbs: stop ECT for a person with depression immediately if the side effects outweigh the potential benefits, or when stable remission has been achieved. The endpoint is **stable remission** and not response, the wording of the superseded appraisal: assess clinical status after each session and stop when a response has been achieved, or sooner on adverse effects, monitoring cognitive function at a minimum at the end of each course, which stays quotable for catatonia, a prolonged or severe manic episode and schizophrenia only.

- **After every treatment.** A clinical assessment, before the next one.
- **Once a week.** A structured rating tool where feasible, plus adverse effects.
- **At the mid-course review.** If nothing has moved, change technique before changing the verdict.
- **At remission.** Stop; current depression guidance ends on remission, not response.
- **Before calling it a failure.** Count what was given; the Indian floor is high.

> **GOOD TO REMEMBER**
>
> Cognitive concern is a reason to slow a course down, not only to change the placement: both the task force and the policy guideline say to reduce the frequency where cognitive effects are a serious concern. Slowing costs time to remission and not the eventual result.

IN INDIA

Three numbers come from the current guideline, the last two from a single passage: two to three sessions per week, the minimum of eight to twelve sessions before failure is considered, and the four to eight session point at which technique changes instead. The last two are routinely confused, the earlier changing placement or pulse width, the later changing the verdict. Schizophrenia is common here and responds after more sessions, so a long course may be ordinary for it.

MNEMONIC

SOONER NOT STRONGER, DYING BUYS DAILY, COUNT BEFORE YOU CALL IT FAILED

Sooner not stronger is the frequency question: the faster schedule reaches response earlier and costs more memory, and both finish in the same place. **Dying buys daily** is the accelerated regimen: lethality, not impatience, pays for the added cognitive cost, and the schedule steps down once the emergency abates. **Count before you call it failed**: change technique at the earlier threshold, and count what was given before declaring failure.

PITFALL

Writing a faster schedule into an answer as though it made the course more effective, which it never does. The consequence is clinical: the resident who believes it imposes avoidable memory impairment on a patient who would have reached the same end point anyway.

The acute course runs at two to three treatments a week, and treatment frequency buys speed of response rather than efficacy: both schedules reach equivalent efficacy at the end of the course while the faster reaches response sooner and costs more cognitively, established in depression, not schizophrenia. Malignant catatonia and comparable life-threatening presentations open instead on an accelerated schedule of daily or twice-daily bilateral treatment for a few days, triggered by failure of the lorazepam trial, run until the syndrome abates and stepped down to three times a week, because mortality pays for the cognitive cost. No course length is fixed in advance; response is assessed after every treatment and rated weekly; technique changes at the earlier non-response threshold and failure only at the later; the course stops at stable remission.

16 · Continuation and maintenance ECT

An acute course of electroconvulsive therapy buys a remission and does not keep it, and what is put in place in the weeks after the last treatment decides whether the remission survives. A patient left with nothing active after remission is at very high risk of relapse, heaviest in the first weeks. Continuation and maintenance treatment answers that fact: medication continued, or treatment on a lengthening interval, or both. It is examined as a sequence of intervals, written here.

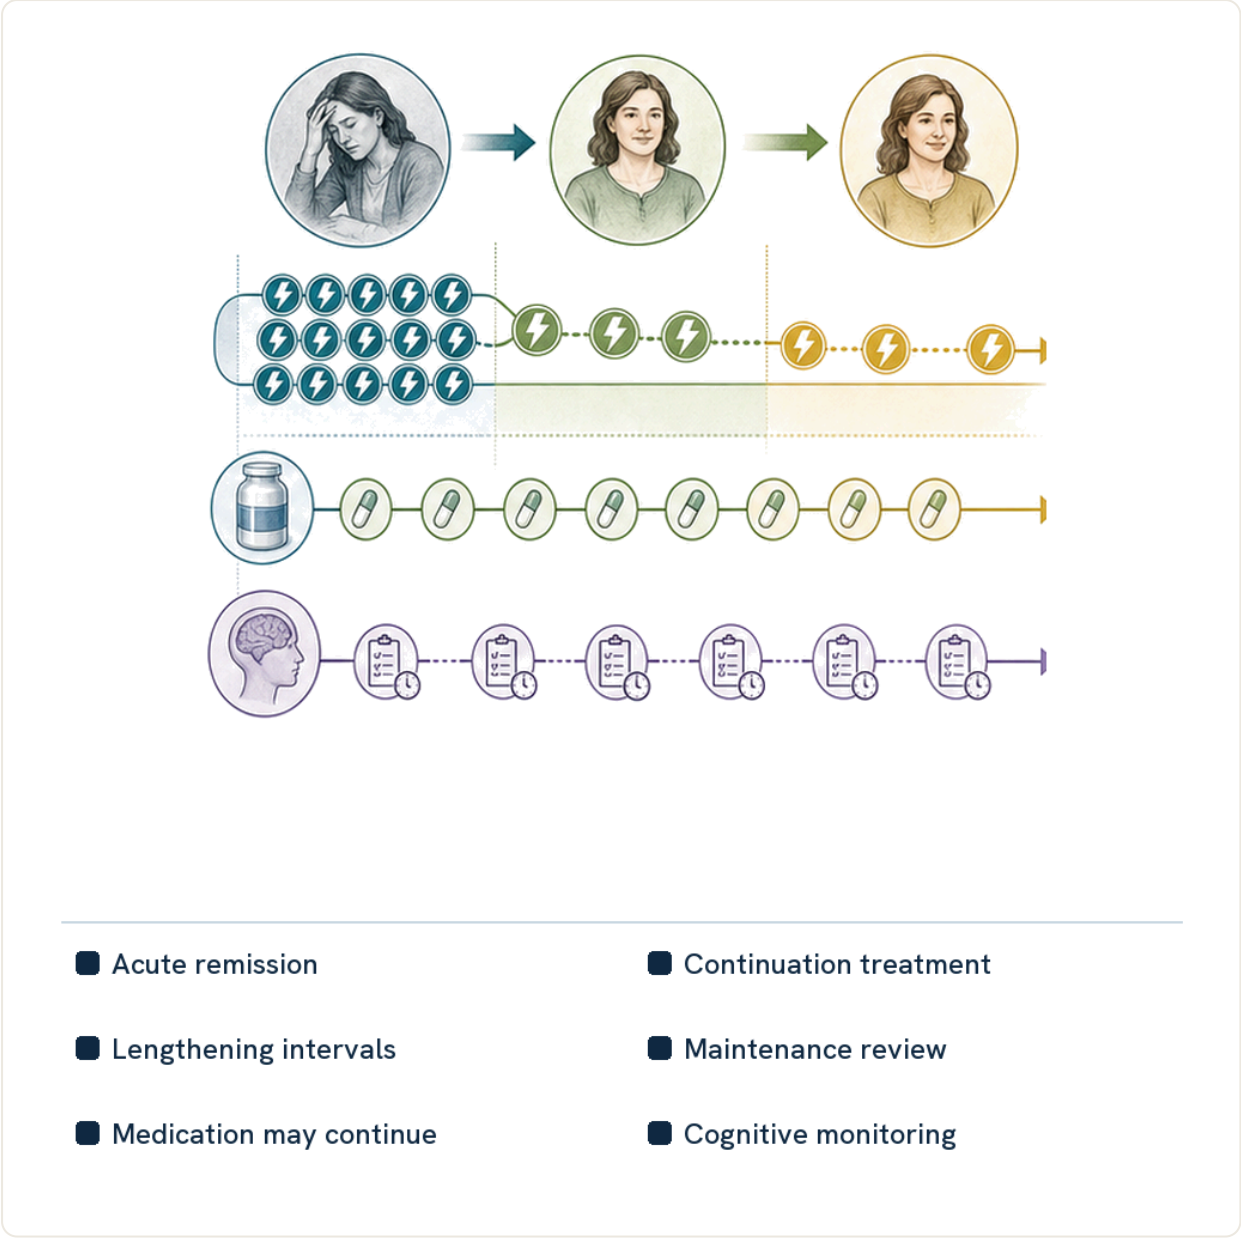

Fig 27.11 An acute ECT course produces remission but does not secure it. Active continuation treatment begins immediately, treatment intervals may lengthen into maintenance, medication may continue, and ongoing need and cognition are reviewed.

Owned here in full: the relapse problem after a successful course, the continuation pharmacotherapy that must follow it, and continuation and maintenance electroconvulsive therapy itself, meaning its indications, its tapering schedule of intervals, its maintenance interval, its duration and review, its cognitive monitoring, its evidence and the unsettled question of its stimulus dose. Named and not re-derived, each owned elsewhere in this chapter: the acute course and its frequency, which end where this section begins; the seizure threshold and its titration; the amnesias; and the drugs that move the threshold. The choice of continuation drug belongs to the Mood disorders: pharmacotherapy notes.

84%	1 to 12 weeks	3 to 6 months
RELAPSE AFTER A SUCCESSFUL COURSE WHEN NOTHING ACTIVE FOLLOWS IT	THE MAINTENANCE INTERVAL BAND, ONCE THE CONTINUATION PHASE IS OVER	HOW OFTEN COGNITION IS REASSESSED ON A MAINTENANCE COURSE

16.1 The problem this section exists to answer

The trial that defines the problem randomised remitters to placebo, nortriptyline, or nortriptyline with lithium. Over 24 weeks the relapse rate was **84%** on placebo, 60% on nortriptyline alone and 39% on the combination. Two readings follow. Without active treatment virtually every remitter relapses within 6 months of stopping, so no acute course ends without a continuation plan. And the danger is front-loaded: on the combination, all but one relapse occurred within 5 weeks of the end of the course, while on placebo or nortriptyline alone relapse accrued throughout. The weeks straight after the last treatment are the ones that need cover, which is what every schedule below is for.

16.2 Continuation pharmacotherapy, and whether ECT does better

Continuation pharmacotherapy is the default and is not optional. The current United Kingdom depression guideline of 2022 states that if depression has responded to a course, the clinician should start or continue antidepressant medication or a psychological intervention to prevent relapse and to provide ongoing care, and consider lithium augmentation of the antidepressant. Which antidepressant, at what dose, and how the lithium augmentation is set up are the Mood disorders: pharmacotherapy notes'.

Whether continued treatment beats continued drugs was tested head to head: 201 patients who had remitted with bilateral treatment, randomised to continuation electroconvulsive therapy or to continuation lithium with nortriptyline for 6 months. Relapse was 37.1% in the continuation electroconvulsive therapy arm and 31.6% in the drug arm, with no significant difference in overall survival curves or in time to relapse. Both beat a historical placebo control, and both had limited efficacy, with more than half of patients either relapsing or dropping out.

TRAP **Writing continuation electroconvulsive therapy as the stronger option because it is more intensive.** The head-to-head trial found no difference in relapse or in time to relapse against continuation drugs. It is an alternative for the patient in whom drugs have failed, are not tolerated or are refused, not an upgrade for everyone who responded.

16.3 Continuation and maintenance: two phases, one line between them

The two words are not interchangeable, and the boundary between them is a duration. **Continuation electroconvulsive therapy** follows the **index course** and consolidates the improvement obtained; **maintenance electroconvulsive therapy** begins beyond that line and prevents a new episode. The Indian guideline draws the line at 6 months and names the conditions in which either is used: major depressive disorder, bipolar disorder and schizophrenia. Who earns an acute course at all is this chapter's account of the indications. A second guideline draws the same line and adds the operative instruction: if patients remain well during the continuation phase, the interval between treatments should be progressively extended.

AXIS	CONTINUATION PHASE	MAINTENANCE PHASE
WHEN IT RUNS	From the end of the index course, up to 6 months of remission	Beyond 6 months from the treated episode
PURPOSE	Consolidating what the index course obtained	Prophylaxis against a further episode or recurrence
INTERVAL	Weekly to monthly, extended progressively while the patient stays well	**One session every 1 to 12 weeks**, and occasionally less frequently
SETTING	Both are generally administered as outpatient treatments	
CONSENT	Obtained again before either begins, because the clinical condition, the purpose and the character of the treatment have all changed	

The consent row is not a formality: what has changed since the first conversation is the condition, the purpose, now relapse prevention rather than rescue, and the treatment's own character, meaning its frequency and its endpoint. The statutory machinery is this chapter's account of consent and the law.

16.4 The taper: the schedule of intervals, in order

This is the schedule the reader was promised, and it begins where the acute course ends; this chapter's account of the acute course and its frequency stops there. The Indian guideline states the sequence plainly: an effective acute course is gradually tapered down from twice a week to weekly, then fortnightly, then monthly, tailored to the patient's clinical needs. Two instructions travel with it: the course should not be prefixed, and it should be planned dynamically and scheduled on periodic clinical review. Once the continuation phase is over, **maintenance is usually given at a frequency ranging from one session every 1 to 12 weeks**, with pharmacological and psychological alternatives weighed in the risk to benefit analysis while it is planned. Three named schedules fill it in, differing in how much is fixed in advance.

SCHEDULE	THE INTERVALS, IN ORDER	WHAT IT IS FOR
STEP-DOWN ECT	One treatment 1 week after the index course is completed, a second 2 weeks after the first, then a continuation protocol if required	Bridging the end of the index course; relapse rates can be lower than with abrupt cessation
FIXED SLOW TRANSITION	Weekly for 4 weeks, then every 2 weeks for 2 months, then monthly thereafter	The trial-derived fixed taper, and the most concrete sequence available
SYMPTOM-TITRATED SCHEDULE	4 continuation treatments over 1 month, then further treatment only as needed under a symptom-titrated algorithm, alongside continued medication	The flexible alternative; it gave better mood outcomes than medication alone at 24 weeks with no significant difference in global cognitive screening

One indication carries a tighter band. In bipolar disorder, more frequent sessions may be required than for other indications, with inter-treatment intervals as short as one to three weeks. The same guideline settles a question that arises there: mood switches occur at a rate similar to that seen with antidepressant medication, concurrent lithium may reduce the risk, and in general a switch is not an indication to stop treatment.

MNEMONIC

TWICE, WEEKLY, FORTNIGHTLY, MONTHLY

The taper in the order it is asked for: from the acute schedule of **twice** a week, down to **weekly**, then **fortnightly**, then **monthly**, and out into the maintenance band. Each step down is earned at a review rather than reached on a calendar, which is why the course is never prefixed.

16.5 The principle that governs every interval

A resident who memorises the intervals and not the principle will schedule the wrong patient wrongly. The guideline states that the optimal timing and frequency of continuation and maintenance treatment is yet to be determined and probably varies between individuals, and gives the aim that orders the section: to extend the inter-treatment interval and minimise the cumulative number of treatments, in order to reduce the risk of cognitive side-effects. What is managed is cumulative exposure; the **inter-treatment interval** is how. The opposite failure is named too: adhering rigidly to a pre-defined transition schedule is problematic, and pursuing a fixed goal of an inter-treatment interval of one month, especially too quickly, may result in relapse, particularly in patients with rapid-cycling bipolar disorder, or depressive illness with a history of early relapse after treatment.

RULE **The maintenance course is scheduled to the patient, not to a target interval.** Lengthening the interval keeps cumulative treatments low, which is what limits cognitive risk; but a fixed transition pursued too fast precipitates relapse in the patients who needed treatment most. One practice avoids both errors: set the next interval at a review of this patient, not in advance.

16.6 Maintenance ECT is not given alone

Medication continues through the maintenance course rather than being replaced by it. The guideline directs that maintenance treatment should be given in conjunction with an antidepressant, unless there is a specific contraindication such as poor tolerability in an individual patient, and that lithium as a relapse-prevention strategy after a course has a strong evidence base and can be used together with maintenance treatment. The interval does one more job here: lithium is safer during maintenance than across an acute course precisely because treatments are much further apart, fortnightly to monthly rather than two to three times a week. Why lithium is a concern across an acute course, and how the threshold-moving drugs are handled around each treatment, are this chapter's account of concurrent medication and drug interactions.

16.7 The stimulus dose at maintenance: an open question, not a schedule

What the threshold is, and how titration measures it, is this chapter's account of stimulus dosing and the seizure threshold. The question that follows belongs here: when sessions are weeks apart, is the dose set at the original titration still the right dose? It is a real question because the threshold moves. It rises across a course of frequently repeated treatments and returns to baseline 6 months after treatment stops, leaving the continuation and maintenance window, longer than a few days and shorter than 6 months, unexamined. Three pieces of evidence bear on it, and none is a rule.

- **The series that framed it.** A retrospective study of 19 patients whose treatments were separated by at least 14 days found significant changes in seizure duration when treatments were separated by more than 60 days, read by its authors as **a fall in threshold or a loss of anticonvulsant action after 2 months, and as an indication to re-titrate after that time**. Its limits are part of the answer: the measured quantity was seizure duration, not the threshold, and the design was retrospective and small.
- **Lowering the dose on purpose.** A unit whose device was capped at 614 mC, 60% of the maximum possible output, asked whether the lower dose gave its maintenance patients better seizure quality, which is the direction that makes the positive finding an argument for re-titration rather than against it. In 15 patients, lowering the energy delivered increased seizure quality overall, which the authors read as an argument for re-titration during maintenance.
- **What is actually done.** In usual clinical practice a constant stimulus dose is delivered through the maintenance course, and the threshold is not re-titrated even when the interval between two successive sessions is longer. The same report describes a stable long-term maintenance patient whose threshold had fallen, which is why the practice is worth questioning.

Evidence on the effect of continuation and maintenance regimens on the threshold is scant, and there are no clear guidelines on the duration after which it has to be recalculated; the authors suggest periodic re-titration, which would prevent unwarranted high stimulus dosing and thereby reduce the risk of cognitive adverse effects.

TRAP **Quoting a re-titration interval as though a guideline had set one.** The figures come from a small retrospective series and a single-unit report, and the sources state that no clear guideline exists. Answer with the shape of the question: the dose is usually carried forward unchanged, the threshold may have moved by the time it is used, and periodic re-titration is reasonable practice rather than a schedule.

16.8 Cognitive monitoring across a maintenance course

The obligation is stated as an interval, and examined in that form. Patients receiving continuation or maintenance treatment must have regular cognitive assessment with a standardised instrument, every 3 to 6 months, or more frequently if significant or worsening deficits are identified, or if the patient is on lithium. The **standardised cognitive assessment** is the instrument; the interval lever is the intervention. What the deficits are, how anterograde and

retrograde amnesia differ in mechanism, course and prognosis, and how far a retrograde deficit persists, are this chapter's account of the cognitive side effects.

The monitoring is required because the evidence does not settle the question. Screening scores remain unchanged or increase during continuation or maintenance treatment. But neuropsychological testing of 11 patients treated for depression for an average of 3 years, with almost 2 months between treatments, identified deficits in learning and frontal function compared with controls, while studies of treatment given across a lifetime have shown no evidence of cumulative cognitive deficit. A screening instrument and a neuropsychological battery do not ask the same question, which is the likeliest reason they disagree, and why the obligation is to measure this patient.

GOOD TO REMEMBER

Three things are checked at every maintenance review: whether the illness is still quiet at the current interval, whether cognition has been formally assessed within the required window, and whether the patient is on lithium, which tightens that window. If the interval has been stretched and symptoms have broken through, shorten it and review again before concluding the treatment has failed.

16.9 How long it runs, and what ends it

No source located sets a fixed duration for maintenance treatment, and inventing one is how this question is usually answered wrongly. What is set instead is review: the need for maintenance treatment must be regularly reviewed and documented, and plans to continue or to cease should be made in consultation with the patient and their family. In that guideline's jurisdiction statutory consent also expires and must be renewed, turning the review into a fixed stop. The Indian position arrives there by another route: consent is taken again before continuation or maintenance begins, and the course is planned dynamically at periodic review rather than prefixed.

IN INDIA

Quote the Indian Psychiatric Society guideline of 2023: continuation and maintenance divided at the six-month line; the taper from twice a week to weekly, to fortnightly, to monthly; maintenance at one session every one to twelve weeks; no prefixed course, planned dynamically at periodic review; and fresh consent before continuation or maintenance begins, because the condition, the purpose and the character of the treatment have all changed.

PITFALL

Carrying a foreign statutory consent expiry into the Indian frame. One guideline's review point is a consent validity period set by that state's own mental health legislation, not an Indian rule. The Indian requirement is fresh consent before continuation or maintenance begins, with no stated expiry.

Relapse is the rule when nothing active follows a successful course, so continuation pharmacotherapy is started or continued in every case, and continuation electroconvulsive therapy is an alternative to it rather than an upgrade. The taper runs from twice a week to weekly, to fortnightly, to monthly, then into a maintenance band of one session every one to twelve weeks, tighter in bipolar illness; it is never prefixed, the aim is to lengthen the interval and minimise cumulative treatments, and the course is held to standardised cognitive assessment every three to six months and to a documented review deciding each time whether it continues.

17 · Drug interactions and concurrent medications with ECT

Concurrent medication is the part of an electroconvulsive therapy course that is settled before any current is set, because almost every patient arrives already taking drugs that change the seizure, change the anaesthetic, or change what the treatment does to them. A drug interaction here is never one fact. It carries a direction on the seizure, a consequence for the patient, and a management step, and the three come apart: a drug can shorten every seizure without harming anyone, and another can be dangerous while leaving the seizure untouched.

Owned here is the interaction: which drug moves the seizure in which direction, what follows, and how each class is managed. Named and not re-derived, each owned elsewhere in this chapter: the threshold itself and how a stimulus is set against it, by the account of stimulus dosing and the seizure threshold; the induction agents, the relaxant and the airway, by the account of the pre-ECT workup and anaesthesia; postictal confusion and amnesia, by the account of the cognitive side effects; and the continuation drug and maintenance schedule, by the account of continuation and maintenance ECT. No titration method and no induction dose appears here.

24 hours	600 mg a day	0.6
THE INDIAN PRE-TREATMENT DISCONTINUATION INTERVAL FOR THEOPHYLLINE	THE CLOZAPINE BAND AT WHICH THE THRESHOLD IS KNOWN TO FALL	THE ELDERLY SERUM LITHIUM LEVEL, IN MILLIEQUIVALENTS PER LITRE, ABOVE WHICH CONCOMITANT LITHIUM IS AVOIDED; THE GUIDELINE'S OWN SPELLING OF THAT UNIT IS DISCUSSED BELOW

17.1 Four classes, four different consequences

The controlling Indian statement asks for the psychotropic drugs that can interfere with anaesthesia and treatment to be evaluated beforehand, and it maps four classes to four distinct consequences:

- anticonvulsants increase the seizure threshold;
- antipsychotics such as chlorpromazine and clozapine are **pro-convulsant**, which is to say they lower it;
- lithium increases the risk of postictal delirium;
- tricyclic antidepressants increase the risk of cardiac adverse events during treatment and anaesthesia.

Read that for its structure, not as a list of drugs. Only the first two entries are threshold statements. The lithium entry is about the brain after the seizure and the tricyclic entry about the heart during the anaesthetic; neither says anything about how easily a seizure is produced.

RULE **State the direction on the seizure and the consequence for the patient as two separate claims, then the management step.** A drug that raises the threshold threatens the treatment: the seizure may be short or absent and the course may fail. A drug that lowers it threatens the patient: the seizure may not stop. A drug that does neither may still be the most dangerous thing on the chart.

17.2 The morning list, one instrument in two halves

The Indian guideline gives the bedside decision as two lists read together. On the **withhold half**, the morning dose of oral hypoglycaemics, lithium, diuretics, anticonvulsants, theophylline and benzodiazepines can be withheld, with the requirement considered on an individual basis. On the continue half, scheduled antihypertensives, thyroxine, antiemetics, antireflux drugs, antianginals, bronchodilators and anticholinergics should not be withheld and can be taken orally 2 hours before the procedure with small sips of water.

The withhold half is not a threshold list: the oral hypoglycaemic is held because the patient is fasting and the diuretic because of volume and electrolytes, neither having anything to do with the seizure. The continue half holds blood pressure, thyroid state, gastric acid, coronary perfusion and airway calibre, whose omission destabilises a patient about to be anaesthetised. Withholding one of those that morning is as much an error as continuing an interacting drug.

17.3 The drugs that raise the threshold

Benzodiazepines increase the seizure threshold, decrease seizure duration, decrease the potential efficacy of treatment and possibly increase cognitive side effects. The third of those matters most: it threatens whether the course works, not merely seizure length. Where the drug has been taken routinely the impact on adequacy may be smaller; it also adds sedation at induction.

Stop the benzodiazepine before the course where possible; a long-acting one may need some days. Where abrupt cessation risks a withdrawal seizure, taper and cease early in the course; that is safe because treatment is itself anticonvulsant. Non-benzodiazepine hypnotics act the same way close to a treatment. Where the drug cannot be stopped, two workarounds are named: a higher stimulus, whose setting belongs to the account of stimulus dosing and the seizure threshold, or reversal. Flumazenil 0.4 to 1.0 mg intravenously immediately before treatment is that reversal, a prescribing decision owned by the anaesthetist and not taught here, for the patient on high doses or unable to tolerate discontinuation; the figure is the anaesthetist's prescribing decision, printed so the psychiatrist knows what is being reversed, not as an instruction issued here.

Anticonvulsant mood stabilisers behave as their name promises: threshold up, seizure expression and duration down, efficacy possibly reduced. Where the anticonvulsant is only augmenting an antidepressant it should be withdrawn before the course begins. In bipolar disorder that is balanced against the risk of a manic swing. If it is continued, the dose can be reduced to the lower

end of the therapeutic range, and it is common practice to withhold the evening dose before each treatment and delay the morning dose until after recovery. The patient taking it for **epilepsy** is handled with the neurologist and carries an instruction that must never be dropped: the dose may fall further as the course proceeds, because treatment is itself potently anticonvulsant, and it must be restored to pre-treatment levels when the course ends.

TRAP **Teaching anticonvulsant reduction as settled practice.** The same guideline that advises withdrawal records the evidence against it: full-dose anticonvulsant through a course of bitemporal treatment gave faster recovery in bipolar disorder without deterioration in seizure quality (Rakesh and colleagues, 2017), and continuing sodium valproate did not affect seizure duration or recovery from mania (Haghighi and colleagues, 2013). The direction of the class effect is not in doubt; the instruction to reduce or withhold is contested for mania and should be written as contested.

17.4 Lithium, the interaction most often examined

No source carried here states that lithium moves the threshold in either direction, which is not the same as a finding that it leaves the threshold alone, and the silence is why it is misfiled so often. Its mechanism sits at the brain: treatment increases the permeability of the blood brain barrier and lets more lithium in at an unchanged serum concentration. With a narrow therapeutic index that is enough to produce toxicity in a patient whose blood level reads as therapeutic, and reports of severe confusion concentrate at the higher end.

The full interaction carries four consequences: delirium, prolonged seizures, toxic lithium levels and **prolonged neuromuscular blockade**. The last is not a psychiatric event; the relaxant and the management of a prolonged block belong to the account of the pre-ECT workup and anaesthesia, and it is named here so it is discussed with the anaesthetist beforehand rather than discovered on the list. The same source states, against a common teaching, that the combination is not an absolute contraindication and may be considered in certain EMERGENCIES where the benefits clearly outweigh the risks. The emergency restriction is the source's own and is the difference between a narrow carve-out and general permission.

Indian practice attaches a figure to the elderly patient: concomitant high-dose lithium **above 0.6** is avoided because of the higher risk of postictal delirium, and the same figure returns in the management of cognitive adverse effects, as the level above which lithium should be reduced or stopped. Both are population-qualified; neither is a general prohibition. The unit takes one sentence of its own, because the guideline is not consistent about it: it spells the unit 'mq/l' in the elderly bullet and 'meq/l' in the cognitive bullet, both mean milliequivalents per litre, the first is a typographical error, and both renderings are reproduced here rather than replaced by the unit this chapter believes was meant, since silently correcting a source is how a wrong number enters a chapter.

Suspend lithium before the course if clinically safe. If it is maintained, omit the evening dose before each treatment and delay the morning dose until after recovery, or run a lower regular dose at the lower end of the range. In bipolar disorder the risk of a manic swing on withdrawal makes this a weighing rather than a default. Case reports in ELDERLY patients indicate that

holding lithium for only 24 hours may still leave a level sufficient to contribute to delirium, and the population is part of the finding rather than a detail, so an omitted dose is not by itself a guarantee.

17.5 The drugs that lower it, and a divergence about theophylline

On the other side of the ledger, theophylline and bupropion can increase seizure duration and should be ceased before the course commences where possible. Theophylline is the more dangerous because of where it is met: a patient treated for asthma or chronic obstructive pulmonary disease, where the drug is doing necessary work and cannot simply be deleted.

Two grounded sources handle it differently and this account states the divergence rather than choosing. The Indian guideline gives a flat interval: theophylline is to be discontinued 24 hours before treatment because of the risk of prolonged seizures and status epilepticus. The second source gives no interval at all, says only that it should be ceased where possible, and names bupropion in the same breath. Carry the Indian interval into an Indian examination, and notice that the other source stops the drug without a clock and adds one the Indian sentence does not.

The interaction literature sharpens this. There are reports of status epilepticus after treatment, with high theophylline levels during treatment associated with status epilepticus, making this level-dependent rather than a presence-or-absence signal. Its management ladder ends somewhere more useful than stopping: taper the theophylline and continue bronchodilators and inhaled glucocorticoids, or reduce to the lowest therapeutic level and monitor closely, treating an exacerbation in the standard way before proceeding. That is substitution rather than withdrawal, and it is the asthmatic patient's answer. One thing must not be merged into it: the Indian guideline names theophylline again after a prolonged seizure has happened, as something to stop temporarily, and that is reactive, not a second version of the prophylactic interval.

17.6 Antipsychotics continued through a course

Antipsychotics are commonly continued and are generally well tolerated. Two hazards are named. Clozapine has many reports of safe use and also a risk of prolonged seizures and confusion, because it lowers the threshold; patients on it may also be at risk of tachycardia and of aspiration from hypersalivation. Typical antipsychotics can produce electrocardiographic abnormalities, QTc prolongation in particular.

The clozapine effect is dose-dependent and the band is stated: the threshold falls **usually at doses above 600 mg a day**, and a dose reduction before treatment may be considered on that basis. That figure is a prescribing decision belonging to the treating team, printed only to locate where the threshold effect becomes real; the indication for combining clozapine with treatment belongs to the account of the indications for ECT.

17.7 Antidepressants continued through a course

Antidepressants have generally been administered safely during treatment, with risks and benefits discussed with the patient; the class differences are what an examination wants. Tricyclic antidepressants carry reports of adverse cardiac effects, specifically QRS prolongation, atrioventricular block and hypotension, together with confusion and excessive sedation.

Venlafaxine carries reports of prolonged asystole and hypotension, with a dose signal: a possible increased risk of asystole **at doses above 300 mg a day**, again a prescribing matter for the treating team rather than an instruction here. The counterweight travels with it: a controlled study found nortriptyline and venlafaxine not associated with an increase in cardiac events compared with placebo (Sackeim and colleagues, 2009). Selective serotonin reuptake inhibitors are generally considered safe.

Monoamine oxidase inhibitors carry a rule rather than a caution. Their use with treatment has been associated with blood pressure changes, hyper-reflexia and seizures, and the patient taking one is at increased risk of hypertensive crisis if given a sympathomimetic agent or pethidine, so those agents are avoided during the course. Bupropion belongs with the threshold-lowering drugs above, and status epilepticus has been reported with its concomitant use.

One fact points forward. The majority of patients with a major depressive episode who respond are likely to relapse within six months without continuation pharmacotherapy, and it is standard practice to commence an antidepressant, usually from a different class, during or just before the end of the course. Which drug, on what schedule, and the maintenance course itself belong to the account of continuation and maintenance ECT.

17.8 The anaesthetic interactions

Several interactions above reach into the anaesthetic room: sedation at induction from the benzodiazepine, prolonged action of neuromuscular blocking agents from lithium, cardiac events from the tricyclics and venlafaxine, and two agents barred by the monoamine oxidase inhibitor rule.

The one a resident meets is in an elderly patient on a dementia drug. Acetylcholinesterase inhibitors may potentiate the bradycardia produced by the electrical stimulus and by suxamethonium, and they potentiate its muscle relaxant effect, particularly rivastigmine, which also inhibits butyrylcholinesterase, the enzyme that metabolises suxamethonium. The relaxant and the management of a prolonged block are the pre-ECT workup and anaesthesia account's in full; what belongs here is naming the drug that causes it, so its continued use is discussed with the anaesthetist rather than assumed. There are numerous case reports of the safe use of donepezil and rivastigmine during a course, and a systematic review indicated rivastigmine may even protect against treatment-induced cognitive impairment (Henstra and colleagues, 2017): an interaction to plan around, not a reason to stop the drug.

17.9 The ledger in one table

DRUG OR CLASS	DIRECTION ON THE SEIZURE	CONSEQUENCE	MANAGEMENT ACROSS A COURSE
BENZODIAZEPINES AND Z-DRUGS	Threshold up, seizure shorter	Course efficacy threatened; possibly more cognitive burden; sedation at induction	Stop early, long-acting ones days ahead; taper if withdrawal seizures threaten; else higher stimulus or flumazenil
ANTICONVULSANT MOOD STABILISERS	Threshold up, expression and duration down	Efficacy possibly reduced	Withdraw if only augmenting; balance against manic relapse; else low in range, doses withheld around treatment; restore at the end in epilepsy
LITHIUM	Not stated by the grounded sources	Postictal delirium, prolonged seizures, toxicity, prolonged neuromuscular blockade	Suspend if safe; else omit the evening dose, delay the morning dose, or run low in range
THEOPHYLLINE	Seizure longer; a threshold direction is not stated by the grounded sources	Prolonged seizure and status epilepticus, level-dependent	Indian interval beforehand, or taper with inhaled therapy substituted; sources diverge
BUPROPION	Seizure longer; a threshold direction is not stated by the grounded sources	Status epilepticus reported	Cease beforehand where possible; no interval carried
ANTIPSYCHOTICS (CLOZAPINE, CHLORPROMAZINE)	Threshold down (chlorpromazine and clozapine)	Prolonged seizures and confusion; tachycardia and aspiration risk with clozapine; QTc prolongation with typical agents	Usually continued; dose reduction considered in the high clozapine band
TRICYCLICS AND VENLAFAXINE	Neither direction	Cardiac events and confusion; asystole reports with venlafaxine, unconfirmed in a controlled study	Continued after weighing risk and benefit
MONOAMINE OXIDASE INHIBITORS	Neither direction	Blood pressure changes, hyper-reflexia, seizures; hypertensive crisis with sympathomimetics or pethidine	Continued, those agents barred
ACETYLCHOLINESTERASE INHIBITORS	Neither direction	Bradycardia potentiated; block prolonged, most with rivastigmine	Continued after discussion with the anaesthetist

MNEMONIC

UP, DOWN, AND NOT THE THRESHOLD AT ALL

Up: benzodiazepines and anticonvulsants, which threaten the course. **Down**: clozapine and chlorpromazine, theophylline and bupropion, which threaten the seizure ending. **Not the threshold at all**: lithium, the tricyclics and venlafaxine, the monoamine oxidase inhibitors and the acetylcholinesterase inhibitors, whose dangers are delirium, the heart, a crisis and a block. That third group is the one candidates lose.

A drug interaction across a course is three statements: a direction on the seizure, a consequence for the patient, and a management step. Benzodiazepines and anticonvulsant mood stabilisers raise the threshold and threaten the efficacy of the course, and are stopped, tapered or timed around each treatment. Clozapine, chlorpromazine, theophylline and bupropion lower it and threaten a seizure that does not stop. Lithium moves it in neither direction and is still the most examined interaction, because treatment lets more of it into the brain at an unchanged serum level, bringing delirium, toxicity and a prolonged block. Antipsychotics and antidepressants are usually continued, each class carrying a hazard rather than a prohibition. The threshold itself and the conduct of the anaesthetic are other accounts' in full.

Other neurostimulation therapies

18 · Repetitive transcranial magnetic stimulation (rTMS): mechanism, indications, parameters

Repetitive transcranial magnetic stimulation puts an electrical current into cortex without touching the skin, and it is dosed so that the current never becomes a seizure. That second half separates it from everything the electroconvulsive therapy half of this chapter has taught. The examinable weight sits in the parameters, because rTMS is prescribed as a set of values that travel together rather than as a dose, and each is referenced to a measurement taken from the patient's own cortex, the motor threshold, which a candidate must define, obtain and keep separate from the threshold this chapter has already taught.

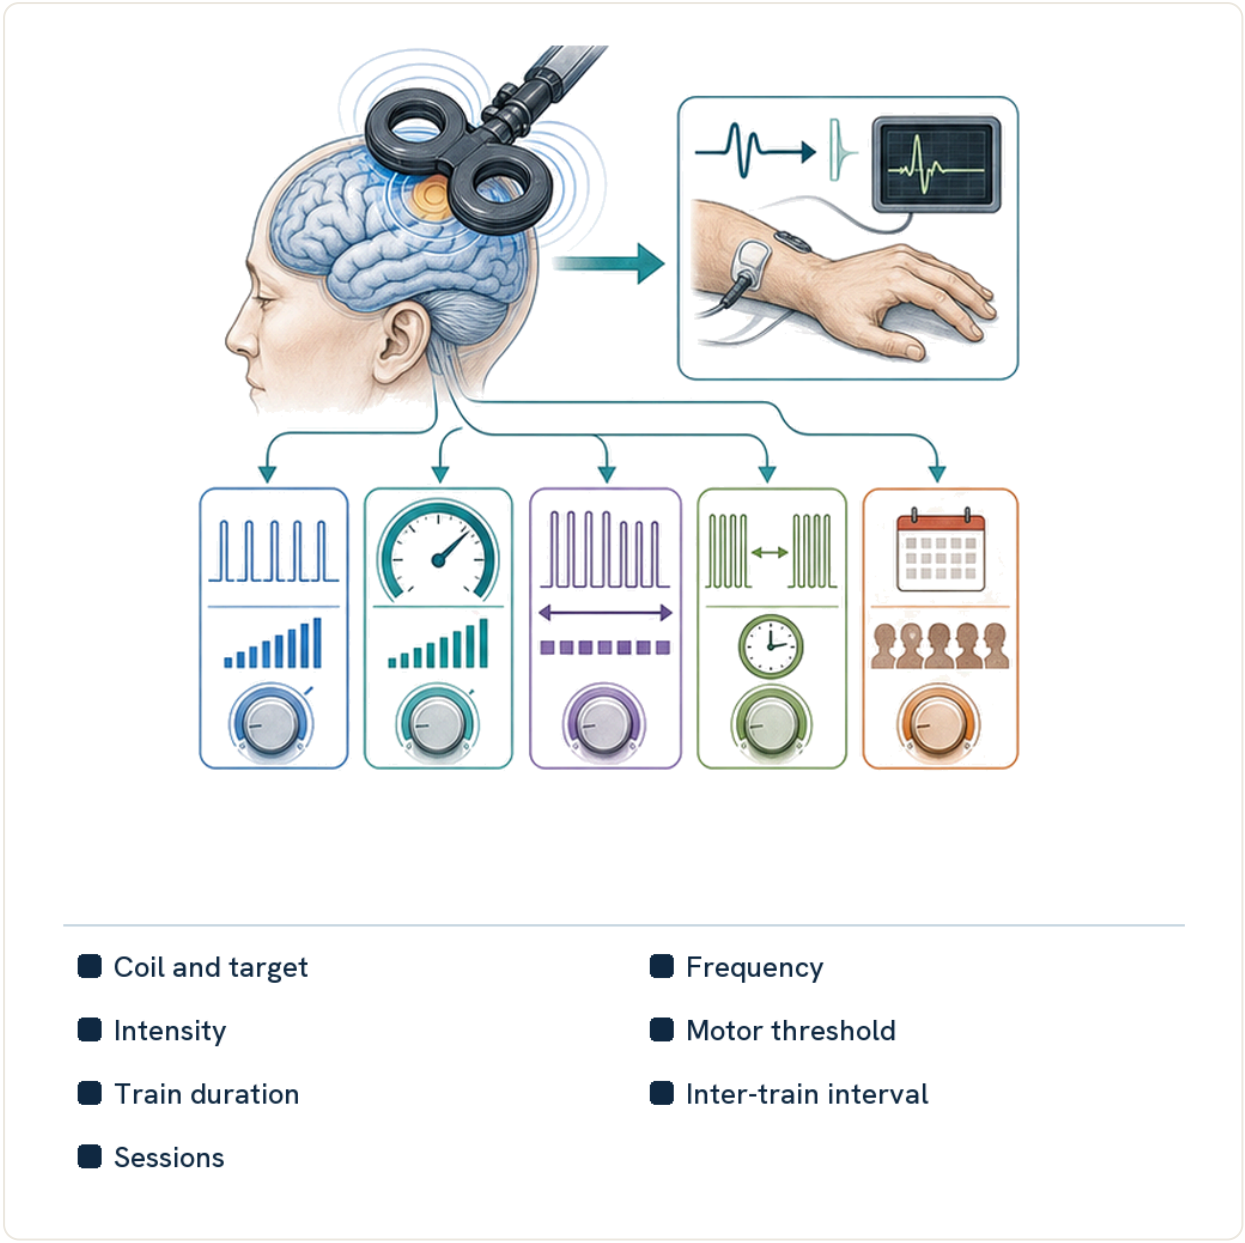

Fig 27.12 Repetitive transcranial magnetic stimulation is prescribed as a linked set of coil, target, frequency, intensity, train, interval and session parameters. Intensity is referenced to the individual's motor threshold, which is distinct from an ECT seizure threshold.

This account owns rTMS and nothing else, from the induction mechanism to the safety limits. It does not grade rTMS against the other devices of this band; that comparison, across invasiveness, target, reversibility, evidence and Indian availability, belongs to this chapter's cross-cutting synthesis and its band grid, and each of the other five items teaches its own device. The seizure threshold and the stimulus dose belong to this chapter's account of stimulus dosing, the seizure threshold and adequate seizure criteria, and why an induced seizure helps to its account of the mechanism of action and neurobiological theories of electroconvulsive therapy; both are named for contrast, neither re-derived.

18.1 Electromagnetic induction, and why the magnetic field is not the stimulus

Electromagnetic induction is the principle the technique rests on, and the chain runs in a fixed order. A high-voltage, high-current discharge system drives a transducing coil, and the discharge produces a strong, time-varying magnetic field at right angles to the coil, peaking at 1 to 2.5 Tesla and lasting under about 1 millisecond. With the coil tangential to the head, that field penetrates scalp and skull with minimal attenuation, and in the conductive tissue beneath it induces a secondary eddy current whose electrical field is perpendicular to the magnetic field and opposite in direction to the current in the coil.

The name of the technique misleads, and its defining source says so. The magnetic field does not stimulate cortical neurons; it serves only to induce an electrical current in neural tissue, and it is that induced electrical current that depolarises cortical axons and triggers action potentials at suprathreshold intensities. At the neuronal level the excitation is the same as with conventional electrical stimulation, and induction buys freedom from direct electrical contact with the skin. Because the brain is not homogeneous, tissue conductivity distorts the induced currents, so exact distributions can be modelled but never read off the coil position.

18.2 Sub-convulsive by design: how rTMS differs from ECT

Conventional therapeutic rTMS is **sub-convulsive** by design, not by accident. The current international safety consensus states the contrast in the form this chapter needs: in conventional rTMS the goal is to select parameters that minimise seizure risk, whereas the modality that uses the same induction to treat by producing a seizure selects parameters efficient at inducing one, and that modality is taught in this chapter's account of magnetic seizure therapy and the emerging neuromodulation techniques. In rTMS a seizure is an adverse event, not the therapeutic mechanism.

Two consequences of that absence must be held apart, because collapsing them is the error this chapter's axis rule forbids. The first is **cognitive**: at therapeutic intensity rTMS does not produce the amnestic syndrome that follows a course of electroconvulsive therapy, and the reason is structural: that syndrome follows the induced generalised seizure, and rTMS induces none. The second is **safety**: an unintended seizure can still occur, at a rate quantified below, and the published safety limits exist to bound it. These are different currencies, and the absence of the first neither abolishes nor excuses the second.

18.3 The motor threshold, and how it is determined

The **motor threshold** is what every rTMS intensity is referenced to, and it is measured in this patient rather than looked up. The international practical guide defines it by a relative-frequency criterion, the Rossini criterion: the lowest stimulus intensity, given as a percentage of maximum stimulator output, required to induce a motor evoked potential in **5 out of 10** trials. It is obtained with single-pulse stimulation at the optimal site over the hand area of the primary motor cortex. Two thresholds are defined and are not interchangeable: the **resting motor threshold**, read with the muscle relaxed, and the **active motor threshold**, read during tonic contraction, each with its own amplitude criterion. Those criteria, the contraction level and the step sizes of the standardised search are not carried here. The Indian guideline states the same

construct as an operator uses it, and adds the caveat that matters in a busy clinic: a threshold read by eye rather than by electromyography comes out significantly higher, and an inflated threshold inflates every intensity derived from it.

AXIS	INTERNATIONAL PRACTICAL GUIDE	INDIAN THERAPEUTIC GUIDELINE
CRITERION	Motor evoked potential in 5 of 10 trials	Response in at least 50 percent of stimuli, usually 5 of 10
MUSCLE	A hand muscle at the optimal motor site	Abductor pollicis brevis or first dorsal interosseous, contralateral
DELIVERY	Single pulse, figure-of-eight coil	Single pulse, graded small to high, every 5 seconds

RULE **The rTMS motor threshold and the ECT seizure threshold are different constructs, and neither may be carried across to the other.** The motor threshold is a corticospinal excitability measurement, read from a hand muscle with single pulses over motor cortex, expressed as a percentage of the stimulator's maximum output, and used to set a deliberately sub-convulsive intensity. The seizure threshold is the stimulus dose at which an adequate generalised seizure is produced, and all of it, including dose expressed as a multiple of threshold, belongs to this chapter's account of stimulus dosing, the seizure threshold and adequate seizure criteria. They share a word and nothing else: different physiology, different instrument, opposite purpose.

GOOD TO REMEMBER

Treat the motor threshold as perishable. It would ideally be measured before every session; in practice the value set before the first may carry through that week. Re-determine it if sessions fall more than a week apart, if medication doses change, after heavy alcohol or substance intake, or if the patient reports headache or scalp pain.

18.4 The stimulation parameters, and frequency

The **stimulation parameters** are target, intensity as a percentage of motor threshold, frequency, train duration with its intertrain interval, and total pulses per session and per course. The two protocols cleared for depression share a target and an intensity and agree on nothing else.

PARAMETER	FIGURE-OF-EIGHT COIL PROTOCOL	H1 COIL DEEP TMS PROTOCOL
DEVICES NAMED	Neuronetics NeuroStar, Magstim Rapid2, MagVenture MagVita	Brainsway Deep TMS
TARGET AND INDICATION	Left dorsolateral prefrontal cortex, major depressive disorder in adults	
INTENSITY	120 percent of motor threshold	120 percent of motor threshold
FREQUENCY	10 Hz	18 Hz
TRAIN DURATION	4 seconds	2 seconds
INTERTRAIN INTERVAL	26 seconds	20 seconds
PULSES (PER SESSION)	**3,000**	1,980

Protocols are conventionally divided at 1 Hz, with **high-frequency rTMS** above that figure and **low-frequency rTMS** at or below it. The direction of effect is the teaching point, not any single value: low frequencies reduce cortical excitability and faster frequencies increase it. Both cleared protocols are high-frequency and left-sided. The practice band of intensities around the labelled figure, and the specific low-frequency value, are not carried here. Train structure carries its own safety-relevant direction: shorter trains with longer intertrain intervals are less likely to induce a seizure, so a protocol is never described by its frequency alone.

MNEMONIC

Target, Intensity, Frequency, Train, Total

The five values that define an rTMS prescription: **Target**, by a stated localisation method; **Intensity**, as a percentage of motor threshold; **Frequency**; **Train** duration with its intertrain interval; and **Total** pulses and sessions.

TRAP **Quoting a pulse count from one protocol beside a frequency from the other, or presenting either tuple as the general settings of rTMS.** A candidate who writes one set of standard rTMS parameters has described a protocol no regulator cleared and no trial ran. Name the coil geometry, the device family and the indication whenever a value is quoted.

18.5 Coils, devices, and finding the target

Coil choice is a focality decision. The **figure-of-eight coil** is the most commonly used and the most focal; H coils serve deep TMS; double-cone and round coils are larger and less focal. The safety consequence is that the larger, less focal designs are more efficient at producing a seizure than the focal figure-of-eight, which is why the seizure-inducing modality of this band uses them and conventional rTMS does not. Whether the choice changes outcome is thinner than it looks: efficacy and acceptability across NeuroStar, MagPro and Magstim in depressive disorders did not differ significantly, on response ($p = 0.12$), discontinuation ($p = 0.84$) or remission ($p = 0.07$). H1 against figure-of-eight coils showed a larger reduction in depression severity in the H1 studies

and a trend to higher remission the other way, differences the authors deem not clinically relevant on a low volume of studies with no placebo control.

Targeting the dorsolateral prefrontal cortex uses four methods:

- The **centimetre rule**, placing the coil a fixed scalp distance anterior to the motor cortex, classically 5 cm, with slightly longer distances also used.
- The International 10-20 electroencephalography system, in which F3 is the left dorsolateral prefrontal site.
- Stereotactic frames.
- Neuroimage-guided frameless neuronavigation.

The consensus preference is explicit: the method most practical in time and accuracy is head measurement to identify F3 using 10-20 coordinates. What moved practice off the centimetre rule was error: in a trial informed by magnetic resonance imaging the coil had to be moved forward to the longest quoted distance in a substantial minority, the proportion not carried here. The Indian guideline agrees, calling neuroimaging more accurate and the 10-20 system a cost-effective alternative.

18.6 Theta-burst stimulation

Theta-burst stimulation patterns the pulses instead of spacing them evenly, and the values a candidate is examined on belong to two different protocols. The original neurophysiological parameters, described in 2005 and used by most subsequent work, are 3-pulse bursts at 50 Hz, the bursts repeated at 5 Hz, the theta rhythm the technique is named for, at 80 percent of the active motor threshold, typically over motor cortex. The therapeutic protocol differs: the pivotal depression trial targeted the left dorsolateral prefrontal cortex and referenced its intensity to the resting motor threshold, the safety update recording it as an exception to the usual intensity range, which is not carried here. The Indian guideline names three sub-forms: intermittent, continuous and intermediate theta-burst stimulation.

TRAP **Reading a theta-burst intensity across from the active motor threshold to the resting one, or quoting the original neurophysiological intensity as the depression dose.** The two reference intensity to different thresholds, so an intensity here is meaningless unless its threshold is stated in the same breath. On safety, the honest position is that a seizure has been recorded with the original parameters, and that theta-burst within the usual intensity range can be regarded as safe.

18.7 The acute course, the indication and the evidence

A course of rTMS is measured in weeks of daily attendance, and the whole course is the treatment. The consensus position is that a standard acute course lasting **20 to 30 treatment sessions over 6 weeks** will very likely be needed to achieve results consistent with the published regulatory trials. Two things follow. The full course, not a fraction of it, reproduces the trial result, so a patient stopped early has not had the treatment that was studied; and extension trials indicate that non-responders to a standard 20 to 30 session course may still respond if daily

sessions continue. The weekly cadence, session length and time to early symptom change are not carried here. The indication both grounded protocols carry is major depressive disorder in adults, under a United States clearance rather than an Indian one; the Indian guideline covers therapeutic rTMS across a wider set of neuropsychiatric disorders whose individual indications and evidence are not enumerated here.

18.8 Adverse effects and the unintended seizure

The adverse event that governs how rTMS is regulated is the **unintended seizure**, a different object from the therapeutic seizure of electroconvulsive therapy in every respect that matters: not sought, not dosed, not monitored for adequacy, not the mechanism of any benefit. Until recently it had never been quantified; a large survey now gives standardised risks. Pooled across protocols the risk is **7 seizures per 100,000 sessions**, over more than 300,000 sessions reported for 2012 to 2016, rising to 33 per 100,000 in subjects at elevated risk from medication, brain lesions or epilepsy. Within high-frequency rTMS the split is starker: 67 per 100,000 in those with risk factors against 1 per 100,000 without, while single, paired and low-frequency stimulation together ran at 8 per 100,000. The same document elsewhere puts the risk at under about 0.03 percent, and records that a TMS-induced seizure has never caused permanent damage in current practice and occurs only during stimulation.

One risk factor was new and is directly operational: lack of previous exposure. Over 62 percent of seizures occurred on the first exposure and 75 percent within the first three, and the Indian guideline carries those figures into Indian practice with the instruction to exercise high precaution during the initial sessions. The limitations belong beside the numbers: self-reported survey data, described by their own authors as no more than approximate and possibly biased in reporting, with numbers in low-risk individuals too small for valid comparison.

18.9 The safety limits, and what the most recent update actually published

Here a chapter can print something that does not exist. The original quantitative safety tables of intensity against frequency and train duration are Wassermann's, augmented and improved in later consensus papers. The most recent international update did not replace them: it decided expressly not to provide a formal update of the safety tables and proposed operational guidelines instead, with one hard ceiling. The parameters used to induce a seizure in the seizure-induction modality of this band, taught in this chapter's account of magnetic seizure therapy and the emerging neuromodulation techniques, must not be exceeded. The usual lowest such combination is **100 percent** of maximal stimulator output at 25 Hz in a single train lasting up to 10 seconds, and every combination of intensity, frequency and duration in conventional rTMS must remain well below it. The guidelines tell an investigator who exceeds the earlier limits what to do rather than what number to stop at:

- Balance risk against benefit explicitly, as the responsible investigator.
- Use neurophysiological monitoring, taking motor twitches as a warning of rising cortical excitation.
- Reconsider the protocol if a seizure occurs.

- Alert the scientific community rather than treating the event as local.

One limitation travels with the older tables: they were derived in healthy young subjects, with figure-of-eight coils only, over the primary motor cortex, and were never a universal map of safe parameters for every coil, target and patient.

PITFALL

Printing a quantitative rTMS safety table and attributing it to the most recent international safety update. That update declined to publish new tables, issuing operational guidelines and a single ceiling instead, so a table carrying its name is an artefact the reader cannot find in the source. Attribute the tables to the earlier work, and say plainly that the current position is operational rather than tabular.

18.10 rTMS in India: the suite and the regulatory position

The Indian guideline sets the equipment baseline for an rTMS suite: main unit, coil, cooling unit and control cable, power supply, electromyography machine, coil holder and computer, with provision for emergency seizure management including stored anticonvulsants and immediately available trained physicians. The sample specification is a stimulator of at least 50 Hz capacity with a burst mode, so theta-burst can be delivered. Note what that seizure provision is: an emergency provision, for an event the prescription is designed to avoid.

IN INDIA

The Indian device position is a checked absence and should be stated as one. The national risk-based classification list enumerates 131 devices in the Neurological category, and no entry corresponds to a repetitive transcranial magnetic stimulation system. Searching it for transcranial returns exactly one entry, a transcranial electrical stimulation system at serial 127, Class B, whose device is taught in this chapter's account of transcranial direct current stimulation. Electroconvulsive therapy systems, deep brain stimulators and vagus nerve stimulators are all listed, each taught in its own item; transcranial magnetic stimulation is not. This concerns device classification only. It establishes nothing about Indian product licensing of any named rTMS device, or any indication-specific authorisation, neither of which may be inferred from a foreign clearance.

rTMS induces a current in cortex by electromagnetic induction and is dosed to stay sub-convulsive, so it does not produce the amnestic syndrome of an ECT course, while an unintended seizure remains a rare, separately bounded safety risk; its intensity is a percentage of the motor threshold, a corticospinal measurement that is not the ECT seizure threshold; and its parameters are quoted only as a whole tuple belonging to a named protocol, coil and indication.

19 · Transcranial direct current stimulation (tDCS)

Transcranial direct current stimulation passes a weak, constant current between scalp electrodes and changes how likely cortical neurons are to fire, without ever making them fire.

That is the whole of its mechanism and its separation from the electroconvulsive therapy half of this chapter: no seizure is induced, none is wanted, and nothing is dosed to produce one. The difficulty is that a treatment this simple to deliver has an evidence base that is not simple at all, so a candidate who quotes the milliamps but not the trial result has learned the easy half.

This account owns tDCS and nothing else: the subthreshold mechanism with its qualification, the montage, the milliamps, the session and the course, the evidence and where it is weak, tolerability, and the home-use and regulatory questions. It does not grade tDCS against the other devices of this band; that comparison, across invasiveness, whether a seizure is induced, target, reversibility, evidence and Indian availability, belongs to this chapter's cross-cutting synthesis and its band grid, and every band item teaches its own device. Electromagnetic induction and the motor threshold belong to this chapter's account of repetitive transcranial magnetic stimulation, and the induced therapeutic seizure to this chapter's account of magnetic seizure therapy and the emerging neuromodulation techniques; each is named for contrast, neither re-derived.

2 mA	null	Class B
THE CURRENT OF THE ONE DEPRESSION PROTOCOL CARRIED HERE, NOT A UNIVERSAL SETTING	WHAT THAT TRIAL FOUND FOR ACTIVE STIMULATION AGAINST SHAM ON ITS ANTIDEPRESSANT OUTCOME	THE INDIAN DEVICE CLASSIFICATION, WHICH AUTHORISES NO PSYCHIATRIC INDICATION

19.1 What tDCS is, and the envelope that defines its family

Transcranial direct current stimulation belongs to a family the current safety and application guidelines call **low intensity transcranial electrical stimulation**, defined by a parameter envelope rather than by a mechanism. The envelope is a total intensity of 4 mA or less, for alternating waveforms measured peak to peak, a total stimulation duration of up to 60 minutes per session, electrode sizes of 1 to 100 square centimetres, and frequencies of 0 to 10,000 Hz. Direct current sits at the bottom of that frequency range, which is why it shares an envelope and a safety literature with the alternating and random-noise members.

The envelope carries arithmetic rules that are easy to breach without noticing. With more than one channel, the total intensity is the sum across all electrodes of the same polarity; with more than one session in a day, the total duration is the sum of the sessions. A montage or a schedule can therefore leave the envelope while every reading on the device looks compliant.

RULE **The envelope is a convention, not a safety limit, and its own source says so in terms.** The guideline that defines the family states that its parameter limits rest on convention and do not represent formal safety limits. Printing them as the safe maximum inverts the claim: they mark where the accumulated evidence stops applying, not where injury begins. Quote the envelope with that caveat attached, or do not quote it.

19.2 The subthreshold mechanism, and why polarity is not destiny

Low intensity stimulation modulates brain activity primarily through **subthreshold neuronal polarisation**. The induced electric field shifts membrane potentials without directly causing action potentials, making neurons more or less likely to fire in response to ongoing synaptic input, and through that shift it can influence synaptic efficacy, alter neuronal excitability and shape network-level oscillatory dynamics. Everything the technique does, it does to a cell already

receiving input: there is no step at which the device fires a neuron. That is the structural contrast with electroconvulsive therapy, prescribed precisely to induce a generalised seizure, and with the induction technique of this chapter's account of repetitive transcranial magnetic stimulation, not re-derived here.

The rule every candidate carries, that the anode excites and the cathode inhibits, is a simplification and has to be named as one. The guideline gives the mechanism and its qualification in one passage: tDCS is explained by a sustained polarity-specific change in membrane potential, and the mechanisms of low intensity stimulation vary with the current properties and with electrode placement. tDCS also always has at least one anode and at least one cathode, so every montage is active at each end and inert at neither. Direction and magnitude are therefore modified by montage, current density, duration and the state of the tissue, and the intensity at which the polarity relation stops holding is not carried here.

RULE **Polarity is not destiny: write the anodal and cathodal directions as a first approximation that names its own conditions.** The relation is real, and it is why a montage is described by which pole sits where. But the source states it beside the statement that mechanisms vary with current properties and electrode placement, so a sentence giving the direction without the modifiers has promoted a conditional finding into a law the source does not assert.

19.3 The montage, and the electrode that is not a return

The **montage** is the geometry: which electrode goes where, of what size, and with what current between them. Montage primarily shapes how current flows through the brain, while electrode design primarily affects tolerability, so a change made for comfort is not neutral to physiology. Since the family's electrodes span 1 to 100 square centimetres, and **current density** is current divided by the area it crosses, electrode size is part of the dose and not a detail of the kit: the same milliamps at a smaller electrode is a denser current at the skin and beneath it.

The fully specified montage carried here comes from a named trial, not a textbook default: the anode over F3 and the cathode over F4, a bifrontal arrangement over the prefrontal cortices. Read it as one protocol's geometry, tied to its indication and device, and notice what the **return electrode** is doing. It is not disposing of current at a neutral site; it sits over cortex and it stimulates. That is why the montage rather than the anode gets named, and why moving the second electrode changes the treatment.

19.4 Current, session duration and the course

tDCS is prescribed as a tuple, and the milliamps mean nothing on their own. In the DepressionDC trial, active stimulation was a constant **2 mA** direct current lasting 30 minutes, given as 24 sessions within 6 weeks, in adults with major depressive disorder not responding to a selective serotonin reuptake inhibitor, the stimulation added to that antidepressant rather than replacing it. The trial was triple-blind, randomised and sham-controlled across eight psychiatric centres in Germany, the device a named mobile direct-current stimulator, and the **sham** a ramp-up and ramp-down sequence reproducing the skin sensation without the treatment current.

AXIS	THE DEPRESSIONDC PROTOCOL	THE LOW INTENSITY FAMILY ENVELOPE
CURRENT	Constant 2 mA direct current	Total intensity 4 mA or less
SESSION DURATION	30 minutes	Up to 60 minutes per session
ELECTRODES	Anode F3, cathode F4	Sizes 1 to 100 square centimetres
COURSE	24 sessions within 6 weeks	Not addressed: the envelope bounds a session, never a course
WHAT IT IS	One trial's protocol, one indication, one device	A stated convention, expressly not a formal safety limit

TRAP **Printing one trial's current and session length as the settings for tDCS.** The values in the left column travel together: one protocol, one indication, one device, one montage. Quoted alone they describe a setting rather than the treatment that was tested; quoted beside the right column they invite the reader to treat a convention as a prescribing range. Name the trial, montage, indication and device whenever a milliamp figure is written down.

MNEMONIC

Montage, Milliamps, Minutes, Sessions

The four values that make a tDCS prescription, none meaning anything without the other three and the indication they were tested in: **Montage**, both electrodes named by site; **Milliamps**, with the electrode size that turns current into current density; **Minutes** per session; and **Sessions**, over a stated number of weeks.

19.5 The evidence, and where it is weak

The honest summary is that the evidence for tDCS is heterogeneous, and the trial this account carries in full is a negative one. DepressionDC was a triple-blind, randomised, sham-controlled multicentre trial of tDCS added to a selective serotonin reuptake inhibitor in major depressive disorder, reported in 2023, and its investigators state their own result plainly in a later peer-reviewed report of the same trial: the main trial did not show beneficial antidepressant effects of active tDCS over sham. That is the sentence to carry into an answer: it is the investigators' own and it is not hedged.

The rest of that record matters more than a summary verdict. The same secondary analysis found no group difference in neurocognitive change and no predictive value of baseline cognition, so in this trial the technique bought neither antidepressant benefit nor cognitive cost. That is the actual relation for this parameter in this trial, stated as such, with no general direction imported from elsewhere in this chapter. The blinding problem is structural rather than incidental: electrode designs that produce less sensation blind better, so sham reliability is not comparable across studies using different electrode designs, which means a pooled figure assembled across them pools degrees of blinding as well as montages.

What this account will not do is convert one trial into a verdict on the technique. No pooled estimate and no second trial are carried in the allowed claims, so the wider literature is called heterogeneous rather than summarised with a figure this fragment cannot ground. The primary report is paywalled and was not read at origin, so the quotation above is attributed to the investigators' open-access analysis.

PITFALL

Treating tolerability as evidence of efficacy. tDCS is cheap, portable, painless for most patients and easy to sham, and each is a reason it has been trialled widely rather than a reason it works. An answer that lists the practical advantages and then asserts antidepressant efficacy has skipped the step being tested. Name the negative trial and let the advantages explain the research interest rather than the conclusion.

19.6 Tolerability, and what actually causes a skin lesion

What patients report is local and mild:

- tingling, itching and warmth beneath the electrodes;
- sometimes described as burning or pressure;
- transient, subsiding shortly after stimulation;
- most prominent in the early sessions and habituating with repetition.

Because the sensation is what a patient notices, it is also the main threat to blinding, which is why a sham reproduces the ramp instead of leaving the device off.

The useful claim about skin injury is that it is a technique and equipment problem rather than a current problem. The guideline states that skin lesions are not an expected adverse event when best practices are followed and appropriate equipment is used, and that essentially every case report of a skin lesion during tDCS was correlated with poor technique or poor technology. Framed that way the claim tells a resident what to do, which a bare incidence figure would not.

GOOD TO REMEMBER

The practice points are specific. Prepare the skin by cleaning and drying it, and do not abrade it. Use electrodes verified for the stimulation being delivered, not electroencephalography recording electrodes and not transcutaneous nerve stimulation pads from another trolley. Read impedance as quality control and read it honestly: a low impedance is neither necessary nor sufficient for tolerated stimulation, so it confirms the setup rather than certifying the session.

19.7 Home-based tDCS, and the adjective that carries the safety data

Home use is the first question a patient asks about a portable device, and the answer turns on one adjective. A large-scale tolerability dataset, which the source describes in those terms and not as the largest, is an analysis of **6,779 sessions** of **remotely supervised at-home tDCS** delivered in clinical trial contexts. It reported no serious side effects and a session abort rate of 0.04 percent, the commonest side effect being mild tingling, itching and warmth distributed equally across active and sham. The guideline holds that remotely supervised home-based stimulation is safe

within the standards it sets, under medical prescription or in research settings, and that it buys accessibility and scale rather than any change in effect.

TRAP **Reading the home-use safety data across to an unsupervised consumer device.** Every session in that dataset was remotely supervised and delivered inside a clinical trial, with the equipment, montage, dose and reporting a trial imposes. Direct-to-consumer devices are discussed separately in the same guideline and this dataset is not extended to them. A patient asking whether a headset bought online is safe is not asking a question this evidence answers, and the reply names the supervision condition, not the session count.

19.8 The Indian position: a classification is not an authorisation

India's regulator has classified the device, which is a smaller statement than it appears, so the halves are held apart. The national classification of non-notified medical devices carries an entry for a transcranial electrical stimulation system, continuous current and pulsed current, intended for one or more psychiatric or neurological therapy types, and the intended-use text of that entry names transcranial direct current stimulation and transcranial alternating current stimulation expressly. The tail of the same entry names anxiety, depression, insomnia and addiction among those intended uses and assigns the device a risk class of B.

What that entry establishes is device classification and nothing more. Indication-specific authorisation is recorded separately, and it is recorded as absent: the current international guideline surveyed national regulatory positions and reports that no country in Asia has officially approved transcranial electrical stimulation devices as medical devices, except Singapore and South Korea. In that passage India appears only for its classification system, running from Class A at the lowest risk to Class D at the highest under the Medical Devices Rules of 2017. The absence is stated from a source rather than inferred, and approvals granted elsewhere are never read across to India.

IN INDIA

Write the Indian position as two lines, and never let the first stand in for the second. First: a transcranial electrical stimulation system exists as a classified device category, at a stated risk class, with intended-use text naming direct current stimulation and psychiatric conditions. Second: no indication-specific authorisation for such a device is established in India, and Indian product licensing of any named device is not established by this record either. A classification tells a manufacturer which regulatory pathway a device sits in; it does not tell a psychiatrist that an indication has been authorised.

RULE **A device classification is not an authorisation of an indication, and the two come from different sources.** Classification answers how a device is regulated; authorisation answers whether it may be marketed for a stated clinical use. Print only the classification and the reader supplies the missing half, and the half a reader supplies is always the permissive one.

tDCS shifts membrane potentials below the threshold for firing, so it changes the probability of a response to ongoing input and induces no seizure; its polarity rule is a first approximation conditioned by montage, current density, duration and tissue state, with both electrodes active; its dose is a tuple of montage, milliamps, minutes and sessions belonging to a named trial; its evidence is heterogeneous and the trial carried here is negative; and in India it is a classified device, which is not an authorised indication.

20 · Deep brain stimulation (DBS) in psychiatry

Deep brain stimulation is a permanently implanted electrode left switched on inside the brain, and in psychiatry it is the rung reached only after everything else has failed. The examinable weight sits in three places. The targets have names, and earlier chapters have already promised the reader those names. The sham-controlled depression trials built to settle the depression question did not meet their primary endpoints, which is a fact to be stated rather than managed. And the Indian legal position turns on a question the statute itself leaves open.

This account owns the psychiatric use of deep brain stimulation in full: the implanted system, the circuit rationale, the targets by name, the indications in refractory obsessive-compulsive disorder and refractory depression with the evidence as it reads, the parameters and programming, the adverse effects, and patient selection with the ethical and regulatory frame. It does not grade this device against the others of its band; that comparison belongs to this chapter's cross-cutting synthesis and its band grid. The obsessive-compulsive treatment algorithm that delivers a patient to this rung, and the cortico-striato-thalamo-cortical circuit as obsessive-compulsive neurobiology, are the Anxiety, OCD and trauma-related disorders notes'. The mood, impulse-control and cognitive sequelae of deep brain stimulation given for Parkinson disease are the Neuropsychiatry of systemic and neurological disease notes'. Ablative surgery and its irreversibility belong to this chapter's account of ablative psychosurgery, and the implanted but non-cranial vagus nerve system to its own item. Each is named here; none is re-taught.

VC/VS	8 of 9	130 to 180 Hz
AMONG THE MOST FREQUENTLY INVESTIGATED TARGETS IN OBSESSIVE-COMPULSIVE DISORDER, NAMED JOINTLY WITH THE NUCLEUS ACCUMBENS	GUIDELINES PLACING DBS AFTER ALL ELSE HAS FAILED	STIMULATION FREQUENCY ACROSS THE PSYCHIATRIC LITERATURE

20.1 The implanted system, and why it is no longer called a lesion

Deep brain stimulation is a chain of hardware a candidate should be able to draw. Intracerebral electrodes are placed by stereotactic technique, connected subcutaneously by extension leads, and driven by an **implantable pulse generator** sited in the subclavicular region or the abdomen. Nothing is removed and nothing destroyed: the generator is programmed from outside the skin, its settings revised at any visit, and the intervention ends when the device is switched off.

That is the fact that keeps this item apart from ablation. Stimulation was initially conceptualised as a reversible lesion and is now better described as a **circuit therapy**, and the mechanism as now stated is not inhibition of a target but replacement of a pattern: electrical pulses trigger action

potentials in axons both orthodromically and antidromically, generating new patterns of synaptic activity that overwrite the pathological ones. The history follows the same logic: stimulation entered psychiatry in 1999, when a Belgian group led by Nuttin reported stimulation of the anterior limb of the internal capsule in a patient with refractory obsessive-compulsive disorder, following the 1987 report of thalamic stimulation for parkinsonian tremor.

RULE **Deep brain stimulation and ablative psychosurgery are different kinds of intervention, and the difference is not one of degree.** The published framing of the choice is exactly this trade: the irreversibility and relative simplicity of lesioning against the reversibility, adjustability, and costs associated with stimulation. Ablation destroys tissue, cannot be undone, and carries no device to fail. Stimulation leaves the anatomy intact and can be titrated or stopped, and buys that with a foreign body, a battery, a programming clinic and a failure mode the lesion lacks. Write neither as the more advanced version of the other; the ablative procedures are this chapter's own account of ablative psychosurgery.

20.2 The circuit rationale, and the targets by name

The targets are what earlier chapters have already promised, so they are delivered here in full and split by indication, because the obsessive-compulsive target set and the depression target set are not the same set. For obsessive-compulsive disorder, the ventral capsule and ventral striatum and the nucleus accumbens have emerged as the most frequently investigated loci, with the anterior limb of the internal capsule, the bed nucleus of the stria terminalis and the subthalamic nucleus also receiving substantial attention; less conventional targets include the inferior thalamic peduncle, the caudate nucleus and various thalamic nuclei. For depression, the best studied targets have been the ventral capsule and ventral striatum, the subgenual or subcallosal cingulate cortex (Cg25), and the medial forebrain bundle.

Each target was chosen from a circuit argument, and those arguments explain why one target serves obsessive-compulsive disorder and another depression. The ventral capsule and ventral striatum, including the nucleus accumbens, is a key node of the reward circuit, with afferents from the ventral tegmental area and efferents to multiple limbic structures, and stimulation there was hypothesised to relieve anhedonia. The subcallosal cingulate was proposed as a mood-regulating hub on the basis of functional-imaging hyperactivity in depression. The superolateral medial forebrain bundle connects the ventral tegmental area with ventromedial prefrontal and orbitofrontal cortex, and its fibres course through the anterior limb of the internal capsule. That last detail is why one trajectory recurs under several target names: these are neighbouring parts of one white-matter corridor, not scattered points.

The field has also moved, and the direction is examinable: the preferred stimulation site within the anterior limb of the internal capsule has shifted posteriorly with tractography, and the emphasis has moved from grey-matter nuclei to white-matter convergence zones. A resident who learns a target as a nucleus has learned the older version of the idea.

MNEMONIC

VANS

Ventral capsule and ventral striatum, **A**nterior limb of the internal capsule, **N**ucleus accumbens, **S**ubcallosal cingulate: the psychiatric electrode targets an examiner expects by name. The first three cluster in one ventral corridor; ventral capsule and ventral striatum carries both the obsessive-compulsive work AND one of the two depression trials, and the subcallosal cingulate is the other. Do not let the corridor grouping become an indication grouping: the target sets overlap, which is the point the fragment makes below.

20.3 Refractory obsessive-compulsive disorder: where the guidelines actually put it

The honest answer to whether psychiatric DBS is recommended is a shape, not a yes. A systematic review of the guidelines for obsessive-compulsive disorder found that 9 guidelines were identified, 8 recommended that DBS is used after all other treatment options have failed, and one did not recommend DBS beyond a research setting. The gaps in that literature matter as much as the placement: only one guideline performed a cost-effectiveness analysis, and the other 8 did not provide details on safe or effective DBS protocols. A guideline that endorses a procedure without specifying how to deliver it endorses a direction, not a technique. The neurosurgical consensus is blunter: in its 2021 consensus guidelines the World Society for Stereotactic and Functional Neurosurgery considers DBS an emerging but not yet established treatment, because the current evidence does not meet its standards.

The outcome figures are correspondingly wide, and the width is the teaching point rather than any midpoint a candidate might quote. Response rates for DBS in obsessive-compulsive disorder across studies range from 10 to 61 percent, largely because of differences in electrode placement, electrode type and stimulation. A response rate quoted without its target and its settings therefore tells the reader nothing.

PITFALL

Reading the United States authorisation as evidence of the kind a premarket approval carries, or as an Indian permission. The obsessive-compulsive authorisation is a **Humanitarian Device Exemption, number H050003, decided in 2009**, and a humanitarian exemption is not a premarket approval: it is a small-population route demanding a lower evidentiary showing. Its scope is narrow: bilateral stimulation of the anterior limb of the internal capsule, as an adjunct to medications and as an alternative to anterior capsulotomy, for chronic, severe, treatment-resistant obsessive compulsive disorder in adult patients who have failed at least three selective serotonin reuptake inhibitors. Collapsing that into approved for OCD overstates both the evidentiary standard and the jurisdiction.

20.4 Refractory depression: two pivotal sham-controlled trials, and two different endpoints

Both pivotal sham-controlled trials of deep brain stimulation for depression failed to separate active stimulation from sham on their primary endpoints, and both were stopped for futility. That must be stated plainly: the open-label literature around each is encouraging, and a chapter reporting only the encouraging half is reporting a different field.

The subcallosal cingulate trial, BROADEN, followed encouraging open-label work with reported response rates of 36 to 66 percent. Its endpoint was defined in its own report as frequency of response, defined as a 40 percent or greater reduction in depression severity from baseline, averaged over the fourth to sixth months of the double-blind phase, with a futility analysis performed when approximately half the proposed sample had received implantation and completed the double-blind phase. The result: both groups showed improvement, but there was no statistically significant difference in response during the double-blind, sham-controlled phase, with 12 patients (20 percent) responding in the stimulation group against five patients (17 percent) in the control group. The trial was halted because of a low probability of success on that interim futility analysis.

The ventral capsule and ventral striatum trial, RECLAIM, ran a different design and used a different threshold. Patients were randomised to active versus sham stimulation in a blinded fashion for 16 weeks, followed by an open-label continuation phase, and the primary outcome measure was response, defined as a 50 percent or greater improvement on the Montgomery and Asberg Depression Rating Scale from baseline. The result was again negative: no significant difference in response rates between the active arm (3 of 15 subjects, 20 percent) and the control arm (2 of 14 subjects, 14.3 percent), and no significant difference in the rating-scale change as a continuous measure on completion of the 16-week controlled phase, and the trial was terminated for futility.

RULE **The two trials did not share a primary endpoint, and printing one threshold for both invents a fact.** BROADEN's response threshold was a 40 percent or greater reduction in depression severity, averaged over the fourth to sixth months. RECLAIM's was a 50 percent or greater improvement on the Montgomery and Asberg Depression Rating Scale, assessed at the end of a fixed blinded window. Different thresholds, different scales, different timepoints, different targets. Quote each trial with its own definition, or quote neither.

AXIS	BROADEN	RECLAIM
TARGET	Subcallosal cingulate	Ventral capsule and ventral striatum
RESPONSE DEFINED AS	40 percent or greater reduction in depression severity from baseline	50 percent or greater improvement on the Montgomery and Asberg scale
BLINDED WINDOW	Averaged over the fourth to sixth months of the double-blind phase	16 weeks
RESULT ON THAT ENDPOINT	No significant difference; 12 (20 percent) against five (17 percent)	No significant difference; 3 of 15 (20 percent) against 2 of 14 (14.3 percent)
STOPPED	Halted on interim futility analysis	Terminated for futility

The criticism raised against both is of design rather than of the device, and a candidate should be able to state it without using it to explain the results away. Short blinded phases and limited parameter adjustment likely contributed to the negative findings. Later work is offered against the negative result and should be given as what it is, later and less controlled. Open-label follow-up suggested response rates rising over 1 to 3 years, and tractography work reported response rates above 80 percent when stimulation targeted the convergence zone of forceps minor, cingulum bundle and uncinate fasciculus. And on the same ventral target, another double-blind trial that allowed a one-year optimisation phase before a crossover comparison reported significant differences favouring active stimulation, with response rates of 50 to 60 percent. Two trials on one target reaching opposite conclusions is a live disagreement, not a resolved question, and the difference is largely how long the operator was allowed to programme before the comparison was made.

20.5 Stimulation parameters and programming

Programming does not begin in the operating theatre. Across the psychiatric literature stimulation was mostly bilateral, starting 6 to 8 weeks after surgery, the interval letting the acute surgical effect settle before any setting is judged. The reported settings are **4 to 6 V** of amplitude, 60 to 120 microseconds of pulse width and 130 to 180 Hz of frequency.

What those figures are must travel with them: ranges derived from a systematic review of heterogeneous studies across several targets and electrode types, not a validated protocol and not a manufacturer specification. The same review names variance in target and electrode type as a principal source of the wide response range. Read the trial criticism above against this section and it stops being a statistical complaint: a fixed short blinded window with restricted adjustment means the comparison was made before the operator had finished finding the setting, which is a different objection from an underpowered sample.

20.6 Adverse effects, and the implant effect

The adverse effects divide by source, the division a consent conversation follows. Device-related complications reported across the psychiatric literature included lead damage or malposition, and postoperative infections, some of which necessitated **explantation** or generator replacement. That last clause is the one to hold: a psychiatric implant can end with the hardware coming out. On the surgical side, seizures occurred at a rate consistent with other intracranial procedures, and isolated incidents of intracranial haemorrhage were described. The stimulation-related effects specific to each target and each setting are not carried in this record and are declared as a gap rather than filled from memory.

One phenomenon here explains something about the trials. The reviewers name an **implant effect**, a temporary improvement following electrode placement, possibly linked to microlesioning, and offer it alongside cognitive placebo effects and natural fluctuation as reasons the active and sham arms did not separate. A sham arm in this field is not an untreated arm: it is a patient who has had a craniotomy and an electrode placed, and whose device is off. The mood, impulse-control and cognitive sequelae of stimulation given in a movement-disorder indication

belong to the Neuropsychiatry of systemic and neurological disease notes; they are named here and not taught.

20.7 Patient selection

Selection is where the honest evidence position becomes a clinical rule, and the candidate definitions are strict in both indications.

- Obsessive-compulsive disorder: severe or extreme illness of more than five years' duration, having exhausted first-line and second-line treatments including cognitive behavioural therapy, several selective serotonin reuptake inhibitors, clomipramine and antipsychotic augmentation at adequate doses and durations.
- Depression: severe depression on standardised scales, illness duration beyond two years, marked functional impact, and documented resistance to multiple pharmacological regimens and to electroconvulsive therapy, or a patient for whom electroconvulsive therapy is not appropriate, not acceptable or declined.

Two things follow. Resistance must be documented rather than asserted, so the trials of treatment, their doses and durations are in the record before the question is raised. And electroconvulsive therapy sits upstream of stimulation in the depression pathway, so a referral made without it, or without a stated reason it cannot be used, skips a rung.

20.8 India, the law, and a question the Act does not answer

IN INDIA

The Indian device position is a classification and only a classification. The national risk-based list carries the deep brain electrical stimulation system, designed to apply electrical stimuli to specific areas of the deep brain for the treatment of movement disorders, psychiatric disorders or chronic, severe, intractable pain, in the highest risk class, Class D. Two things follow and neither may be softened. The classification names psychiatric disorders in its own intended-use text, so the category exists in Indian regulatory language. But it establishes nothing about product licensing of any named system in India, and nothing about any indication-specific psychiatric authorisation; neither may be inferred from the classification, and neither from the foreign humanitarian exemption above.

The legal question is unsettled, and this account states it as unsettled rather than answering it. The Mental Healthcare Act restricts psychosurgery, and that restriction, with its dual requirement of informed consent and Board approval, is the Mental health legislation and forensic psychiatry notes' provision; it is named in words here and never renumbered. The question is whether an implanted stimulation system for refractory obsessive-compulsive disorder falls within psychosurgery for the purposes of that restriction, because if it does, the dual requirement attaches. Read against the statute's own text the answer does not arrive: the Act restricts psychosurgery but nowhere defines it, its definitions clause contains no entry for psychosurgery, and the word appears in the Act only in the restricting provision itself. The Act's own definition therefore does not settle the question, and it is recorded here as a declared gap. A

regulation defining the term could settle it; none was located. The practical consequence is caution rather than paralysis: a unit contemplating an implant proceeds as though the stricter reading may apply, and takes the question to its Board and to legal advice. The consent conversation itself, as taken in Indian practice, is this chapter's account of consent for electroconvulsive therapy.

TRAP **Answering the psychosurgery question from memory, in either direction.** Writing that psychiatric deep brain stimulation is psychosurgery under the Act, or that it plainly is not, both assert something the statute does not say. The defensible answer names the restriction in words, says the Act does not define the restricted procedure, and leaves the question open. A second trap sits beside it: quoting the Act's section numbers here. Those belong to the legislation notes, and a chapter that reprints a number it did not itself ground is how a legal fiction enters a syllabus.

Deep brain stimulation is an implanted, adjustable, reversible circuit intervention, not a lesion, and its psychiatric targets are the ventral capsule and ventral striatum, the anterior limb of the internal capsule, the nucleus accumbens and the subcallosal cingulate; most guidelines place it after everything else has failed; both pivotal sham-controlled depression trials, on different targets and with different response thresholds, failed to separate active from sham and were stopped for futility, so the case now rests on later, less controlled work; and whether the Act's psychosurgery restriction reaches an implanted system is a question the statute leaves open.

21 · Vagus nerve stimulation (VNS)

Vagus nerve stimulation treats depression from outside the skull, by driving a peripheral nerve in the neck and letting that nerve carry the signal inward. It is the implanted device of this band whose electrode never enters the brain. Its centre of gravity is not the surgery but the latency: a response, where there is one, emerges over months, and the trial designed to detect it in weeks did not.

This account owns vagus nerve stimulation in full: the implanted left cervical system, the afferent route, the parameters and duty cycle, the regulatory position in both jurisdictions, the evidence with its limits, and the adverse effects. It does not teach the implanted intracranial device, whose surgical placement, psychiatric targets and trial evidence belong to this chapter's account of deep brain stimulation in psychiatry, named here and not restated. Nor does it grade the band's devices against one another: that comparison, across invasiveness, seizure induction, target, reversibility, evidence and Indian availability, belongs to the cross-cutting synthesis and its band grid.

p=0.238	12 months	58.2%
THE ACUTE SHAM-CONTROLLED PRIMARY ENDPOINT, NOT SIGNIFICANT	THE WINDOW OVER WHICH THE EFFECT SUPPORTING APPROVAL WAS MEASURED	VOICE ALTERATION IN THE EARLY MONTHS OF STIMULATION

21.1 The implanted system, and why it is not a cranial implant

The **VNS Therapy System** divides into what is inside the patient and what is not.

- An implanted **pulse generator**, carrying the battery and the programming, sits in a subcutaneous chest pocket.
- A **helical lead** runs from it into the neck and is wound on the cervical vagus nerve, passed between the sites with a tunneler.
- Outside the body are an external **programming wand** and its software, through which every parameter is set without a second operation, and a patient magnet.

The electrode therefore sits on a peripheral nerve, and implantation is a neck and chest procedure carrying the risks of a neck dissection and of a stimulated nerve, not those of an intracranial electrode. Implanted does not mean here what it means for the intracranial device taught elsewhere in this chapter.

21.2 The afferent route, and how far the record goes

Stimulation is delivered to the **left cervical vagus**, and the therapeutic traffic runs centrally rather than out to the viscera. The vagus there is predominantly afferent, so the fibres the electrode recruits carry impulses into the brainstem. The route taught runs from the **nucleus tractus solitarius**, the brainstem terminus of vagal afferents, to the **locus coeruleus** and the raphe nuclei, and on from those monoaminergic nuclei to limbic structures: a peripheral electrode producing a diffuse, slowly accumulating central effect rather than a focal one.

Where the grounding stops must be said. The generator and lead architecture is read from the regulator's own summary of safety and effectiveness data, while the left-sided placement and the brainstem-to-limbic pathway are standard teaching, stated as teaching, not captured verbatim from a primary source by this chapter's grounding, and recorded as a declared gap.

21.3 The stimulation parameters and the duty cycle

Every figure below belongs to one protocol, one indication, one target and one device, and none is a universal setting for vagus nerve stimulation. These are the settings actually reached at 12 months in the pivotal depression cohort, D-02, as printed in the labelling approved for the depression indication on the VNS Therapy System delivered to the left cervical vagus. They are not manufacturer defaults, not a starting prescription, and not transferable to the seizure indication.

PARAMETER	MEDIAN AT 12 MONTHS	RANGE IN THE COHORT
OUTPUT CURRENT (NO UNIT IN THE RECORD)	1.0	0 to 2.25
FREQUENCY	20 Hz	2 to 30 Hz
PULSE WIDTH	500 microseconds	130 to 750 microseconds
ON TIME	30 seconds	7 to 60 seconds
OFF TIME	5 minutes	0.3 to 180 minutes

One row carries no unit in the record it was read from: the labelling table as extracted gives the output current as a bare figure and does not say what it is measured in. No unit is printed here

and none may be supplied from memory, because a plausible unit beside a real number makes the number look grounded when the unit is not.

The **duty cycle** is what the ON and OFF times mean together: the device does not stimulate continuously but delivers current for the programmed ON time, stops for the programmed OFF time, and repeats indefinitely. The duty cycle is therefore not a fixed property of the device but an arithmetic consequence of those two times as programmed, changing the moment either is changed. No duty-cycle percentage is printed here, because computing one is arithmetic rather than a reading from the labelling.

MNEMONIC

SLOW

Subcutaneous generator in the chest. **L**eft cervical vagus carries the lead. **O**n and off, because stimulation is cyclical and never continuous. **W**ait, because the response is measured in months.

21.4 The regulatory position, in its separate parts

The regulatory claims a candidate must keep apart are device **classification**, product **licensing**, **indication-specific authorisation**, and **foreign clearance or approval**. Holding one says nothing about holding another. In the United States the Food and Drug Administration, through its Center for Devices and Radiological Health, approved the VNS Therapy System for depression under premarket approval P970003, supplement S050, decision date 15 July 2005. The authorised indication is precise: adjunctive long-term treatment of chronic or recurrent depression, in patients 18 years of age or older, experiencing a major depressive episode, who have not had an adequate response to four or more adequate antidepressant treatments. Read the wording: adjunctive means added to treatment, and long-term sits in the indication because the evidence is long-term.

IN INDIA

What is established is classification and nothing more. The national risk-based list names the antiseizure and psychiatric-therapy vagus nerve electrical stimulation system in the Neurological category at serial 9, Class D, with its programming system separately at serial 131 in Class C. There the Indian record stops. No Indian product licence for any named device, and no Indian indication-specific authorisation in treatment-resistant depression, was established by this chapter's grounding; both are declared gaps and neither may be inferred. The United States approval above is foreign status: it is not evidence of an Indian one and must never be written so a reader could take it for one. A provenance caution attaches to the list itself, hosted as final while its covering notice circulates the annexed classification for comment.

21.5 The acute randomised trial, which did not separate from sham

The pivotal acute study, **D-02**, is why this modality can be taught honestly at all. Patients with treatment-resistant depression were implanted, then randomised to active stimulation or to sham, the device present in both arms and left off in the sham arm, and the acute phase ran 3

months. The primary endpoint was the proportion of responders, a fall of 50 percent or more in the Hamilton score from baseline to exit.

In the evaluable population 15.3 percent of the active group responded, 17 of 111, against 10.0 percent on sham, 11 of 110. The difference was not statistically significant, p=0.238. Among the secondary measures only the self-rated inventory of depressive symptomatology separated on percent responders, 17.4 against 7.5 percent, p=0.032; the clinical global impression, the observer-rated depression and mania scales and the SF-36 did not.

21.6 The long latency, and what the approval rests on

The device was not approved on that comparison. After the acute analysis was completed, an alternate statistical plan for demonstrating effectiveness was adopted, comparing the 12 month results of the D-02 continuation phase against a separate observational study, D-04. That is the approval basis: a non-randomised comparison of an open-label extension against a different cohort.

The long-term primary analysis was a repeated-measures linear regression on raw Hamilton scores over the first 12 months of stimulation. The slope was minus 0.47 points per month in the completer population, n=177, p less than 0.001, with minus 0.45 in the evaluable population, n=205, and minus 0.40 in the intention-to-treat population, n=231. At 12 months Hamilton response was 29.8 percent and remission 17.1 percent, and sustained response was reached by 27 percent of completers, 47 of 177. Against the observational comparator the average Hamilton change at 12 months was minus 8.2 with the device against minus 4.9 with standard care, p=0.006, with response in 30 against 13 percent, p=0.003.

RULE **The long latency is not a caveat on the evidence; it is the shape of the evidence, and it decides how the device is judged and when.** An effect appearing as a slope over months cannot be detected by a trial reading its endpoint at 3 months, which is why the randomised comparison came out flat and why the authorised indication says long-term. A patient is therefore not a non-responder here at the point at which the same patient would be judged a non-responder to a drug. What is traded is TIME and not cognition; it is this device's own trade, and no direction carries over to any other device in the band.

TRAP **Quoting the long-term response and remission rates as though they came from the randomised sham comparison.** They did not. That comparison failed its primary endpoint; the long-term figures come from an open-label continuation set against a separate observational cohort. An answer giving the second without the first is not partial, it is wrong.

RECOVER is the modern test of the same question, described as the largest neuromodulation study in psychiatry to date: participants randomised to active against sham stimulation for a year, then a prolonged open-label phase. Preliminary reports indicate the primary endpoint was not met, while clinically meaningful improvements were observed in depressive severity, functioning and quality of life. This chapter's grounding read that in a peer-reviewed review and not in the primary report, and the review's own reading, that the device may act as a long-term

progressively acting adjunct whose effect symptom scales do not fully capture, is attributed rather than adopted.

21.7 Adverse effects, and the pattern that matters

The adverse effects divide by cause into what the operation does and what the stimulation does, and the second group carries a pattern worth memorising: the effects involving the voice persist across the first year while most of the rest settle. The frequencies are from the approved labelling for the depression indication.

STIMULATION-RELATED EVENT	0 TO 3 MONTHS (N=232)	9 TO 12 MONTHS (N=209)
VOICE ALTERATION	135 (58.2 percent)	113 (54.1 percent)
INCREASED COUGH	55 (23.7 percent)	13 (6.2 percent)
NECK PAIN	38 (16.4 percent)	27 (12.9 percent)
DYSPNOEA	33 (14.2 percent)	34 (16.3 percent)
DYSPHAGIA	31 (13.4 percent)	9 (4.3 percent)
PARAESTHESIA	26 (11.2 percent)	9 (4.3 percent)
LARYNGISMUS	23 (9.9 percent)	10 (4.8 percent)

The persistent entries are mostly of the voice, the airway and the neck, which is what an electrode wound on a nerve in the neck predicts, and the table above shows why the generalisation cannot be tightened further: dyspnoea persists and rises and is respiratory rather than laryngeal, neck pain persists and is somatic, and laryngismus is laryngeal yet largely settles. and voice alteration is the effect a patient notices and is asked about at every review. Cough, dysphagia and paraesthesia largely settle; dyspnoea does not. Surgery-related events in the acute phase were incision pain in 36 percent, device-site pain in 23 percent, device-site reaction in 14 percent and headache in 8 percent.

The serious events, as the labelling reports them: 30 serious adverse events in 27 subjects in the acute phase, including one death by suicide under active stimulation, with single reports of asystole and of bradycardia in the treatment group; and in the long-term phase worsening depression as 62 events in 31 subjects, 7 suicide attempts in 6 subjects, and one sudden unexplained death. None of that withholds the device where it is indicated; all of it must be described to the patient before implantation.

Vagus nerve stimulation is an implanted but non-cranial system: a generator in the chest, a lead on the left cervical vagus, an afferent signal reaching limbic structures through the brainstem. It stimulates intermittently, so the duty cycle follows from the programmed ON and OFF times. It holds a United States approval for adjunctive long-term treatment after four or more failed adequate antidepressant treatments and, in India, a device classification and nothing further. Its acute randomised comparison against sham did not meet its primary endpoint, the approval resting on a slope across the first year against an observational cohort. Its characteristic adverse effect, voice alteration, is common and does not settle.

22 · Magnetic seizure therapy and emerging neuromodulation

Magnetic seizure therapy uses the induction coil of transcranial magnetic stimulation at parameters chosen to produce a seizure deliberately, under anaesthesia, as an alternative to electroconvulsive therapy. It is the only modality in this group with randomised human comparisons against electroconvulsive therapy, and it is examinable for a reason that is not the hardware: it is this chapter's cleanest example of a claim that must be split in two, one half settled and one open, and a candidate who fuses them writes a sentence the sources do not carry.

This account owns magnetic seizure therapy and the other emerging approaches: low-intensity focused ultrasound, transcranial alternating and random-noise stimulation, and closed-loop or adaptive stimulation. Why an induced seizure helps is taught in this chapter's account of the mechanism of action and neurobiological theories of electroconvulsive therapy, and the cognitive cost of a course, with anterograde and retrograde amnesia held apart, in its account of the cognitive side effects of electroconvulsive therapy; both are named for comparison and neither is re-derived. The ablative form of focused ultrasound belongs with this chapter's account of psychosurgery, and the grid grading the whole band belongs to the cross-cutting synthesis. None of what follows is established psychiatric practice.

100 percent	5.3 percent	animal
OF MAXIMAL STIMULATOR OUTPUT, THE USUAL INTENSITY	REMISSION DIFFERENCE FAVOURING ECT IN THE CONFIRMATORY TRIAL, NON-INFERIORITY MET	THE LEVEL AT WHICH A DIFFERING SEIZURE PHYSIOLOGY IS DEMONSTRATED

22.1 The technique, and how it is dosed

Magnetic seizure therapy is defined by the international safety guideline as the use of transcranial magnetic stimulation to induce seizures deliberately, under anaesthesia, for the treatment of depression or other serious neuropsychiatric conditions. What it demands is electroconvulsive therapy infrastructure, not a transcranial magnetic stimulation clinic: general anaesthesia in a procedure room with a crash cart and an anaesthesia station, a multidisciplinary team, and the standard pre-electroconvulsive-therapy workup. The dose sits at the machine's ceiling rather than a fraction of it. Magnetic seizure therapy is usually given at **100 percent** of maximal stimulator output, at a frequency of 25 to 100 Hz, in a single train lasting up to 10 seconds.

The coil belongs in the prescription. Coils differ in their efficiency at seizure induction, and the larger, less focal designs, the twin coil and the double cone, are more efficient than the focal figure-of-eight; much of the published work has used round or double-cone coils over the vertex, a placement reported to have a lower seizure threshold than midline prefrontal placement. The property that gives the technique its rationale therefore works against the event it must produce, and the operator settles that by coil choice and placement rather than by dose. Threshold is titrated by successively increasing stimuli within a single anaesthesia session, as a seizure threshold is titrated for electroconvulsive therapy; the interval between stimuli is not carried here. Monitoring is two-channel frontomastoid electroencephalography with the motor expression of the seizure, isolated by a leg tourniquet placed before the relaxant. The section ends where the guideline ends: the optimal dose above the seizure threshold for a given coil is not known, and neither is the dosing that would maximise benefit while minimising side effects.

22.2 The rationale, and the two claims that are held apart

The stated rationale is control over where the stimulation acts: increased control over the site of stimulation permits sparing of brain regions related to the adverse effects of electroconvulsive therapy. Two claims sit behind that sentence, they are not equally strong, and separating them is the examinable content here.

What is unambiguous. Studies using realistic head modelling show that, even at maximal stimulator output intensity, the electric field induced in the brain by magnetic seizure therapy is much lower and much more focal than the field induced by electroconvulsive therapy. That follows from the coil geometry, and the site at which the seizure is initiated is correspondingly more restricted. Both statements are about the stimulus, and the modelling is established. Note what is NOT said: no row in this chapter's claim list, and no source quote in it, describes the field or the site as more SUPERFICIAL, so depth is an ungrounded attribute here and is not carried.

What is an evidence question. Whether the seizure that then follows propagates less widely than an electroconvulsive therapy seizure, and how much of the measured cognitive difference such reduced propagation would explain. Here the record is thinner and its level is part of the claim. Animal studies substantiate that seizures induced with magnetic seizure therapy are less robust and differ in their physiological expression from electroconvulsive therapy seizures; in a sensitive non-human primate model, magnetic seizure therapy was significantly safer than electroconvulsive therapy and did not differ from an anaesthesia-alone sham, neither modality showing neuropathological evidence of tissue damage. That is animal evidence, reported as animal evidence. A human demonstration of reduced propagation was not located for this chapter, and the share of the human cognitive difference attributable to propagation is unquantified. The guideline's own bridge from focality to tolerability is a belief, that the field difference is thought to underlie the superior side-effect profile, and prose that hardens it into a finding has changed the evidence while quoting it.

RULE **A focal field is not a confined ictus, and the two claims travel at different evidence strengths.** Say it in one form and keep the two objects straight: the induced electric field is much lower and much more focal than in electroconvulsive therapy, and the site of seizure initiation is correspondingly more restricted. That is settled modelling. Say separately, at the strength the sources carry, that such seizures are less robust and physiologically different in animals, that the human propagation question is open, and that propagation's contribution to the cognitive difference is unquantified. The error in one direction conflates the focal stimulus with the spread of what follows it, which the sources do not show; the error in the other is to deny any difference in propagation, which the animal data contradict.

22.3 The human evidence: two randomised comparisons

Two randomised comparisons against right unilateral ultrabrief electroconvulsive therapy exist, and a candidate should name both: citing the larger alone overstates how settled the position is. Both treated to remission, dropout, or a maximum of 21 treatments, and both paired remission on the 24-item Hamilton scale with worsening of autobiographical memory as co-primary outcomes, worsening defined in the confirmatory trial as a 25 percent reduction in Autobiographical Memory Test score. The confirmatory trial, CREST-MST, used a non-inferiority margin of 15 percent absolute difference in remission and delivered magnetic seizure therapy with a twin coil in a midline frontal position.

AXIS	CONFIRMATORY TRIAL IN MAJOR DEPRESSIVE DISORDER	PILOT TRIAL IN BIPOLAR DEPRESSION
DESIGN	Multisite randomised double-blind parallel-group non-inferiority trial, three academic centres in Canada and the United States	Double-blind randomised parallel-group pilot
NUMBERS	292 enrolled, 239 randomised	55 randomised, 45 given an adequate trial
REMISSION, MAGNETIC SEIZURE THERAPY AGAINST ELECTROCONVULSIVE THERAPY	22.5 percent against 27.8 percent, a difference of 5.3 percent favouring electroconvulsive therapy, non-inferiority established at p = 0.048	5 of 25 (20 percent) against 6 of 20 (30 percent)
MEMORY WORSENING, SAME ORDER	2.7 percent against 17.3 percent, p = 0.0003	2 of 28 (7.1 percent) against 6 of 27 (22.2 percent)
AUTHORS' OWN LIMIT	Enrolment concluded before the intended sample size was reached	Findings to be considered preliminary, given the small pilot sample

The tolerability figures point the same way as the memory outcome: withdrawal for non-serious adverse events ran at 12 participants on electroconvulsive therapy against 3 on magnetic seizure therapy. Its authors read that as supporting magnetic seizure therapy as a first-line convulsive therapy in major depressive disorder, particularly for a patient who refuses right unilateral ultrabrief electroconvulsive therapy. That is an author interpretation of a trial whose enrolment stopped short, in a technique whose optimal dose is acknowledged to be unknown.

TRAP **Reading the memory advantage in these trials as proof that the seizure stayed local.** The trials measured autobiographical memory, not seizure spread. They establish an outcome difference on a named instrument; what produced it, whether the weaker induced field, a difference in how the seizure expresses itself, or something else in the procedure, an outcome trial does not settle. Report the outcome as an outcome and the mechanism as a hypothesis.

22.4 Focused ultrasound, in its neuromodulatory form

Transcranial focused ultrasound delivers acoustic energy through the intact skull to a focus placed at depth, and one name here covers two different interventions. Low-intensity focused ultrasound for neuromodulation is reversible and generally operates at intensities below 100 W per square centimetre. High-intensity focused ultrasound typically employs acoustic intensities greater than 200 W per square centimetre and is an ablation tool; the psychiatric procedure built on it is taught in this chapter's account of psychosurgery. Collapsing the two converts a reversible research technique into a lesion.

One physical trade-off is worth carrying: lower frequencies cross the skull better while higher frequencies give better focal precision, so penetration and precision are bought against each other. The frequency and acoustic pressure bands, and the pulse duration, pulse repetition frequency, duty cycle and train duration, are not carried here. The evidence level is best given in the reviewers' own terms: mechanisms incompletely understood, long-term effects, optimal parameters and safety assessment requiring systematic elucidation, and auditory confounding an unresolved controversy.

22.5 Alternating and random-noise stimulation

The low-intensity transcranial electrical stimulation family is one envelope with several waveforms, defined by the same guideline that defines transcranial direct current stimulation. The current can be of constant intensity and polarity, which is transcranial direct current stimulation and has its own account in this chapter. It can instead be of variable intensity or polarity:

- alternating between polarities at a steady sinusoidal frequency, which is **transcranial alternating current stimulation**;
- alternating at a randomly changing frequency, which is **transcranial random-noise stimulation**;
- varying within a single polarity, as in oscillatory transcranial direct current stimulation.

The examinable point is the shared envelope: these are variants of one low-intensity technique bounded by a maximum current, a maximum session duration, an electrode-area band and a frequency band, rather than separate technologies with limits of their own; the bounds are not carried here. One reading convention travels with them: direct current intensity is reported baseline-to-peak, and for alternating and random-noise stimulation the convention used has to be specified, because the same waveform yields different figures under different conventions. What this record establishes is definitions and a safety envelope, not clinical efficacy for any psychiatric indication, and a tidy definition is not evidence of one.

22.6 Closed-loop and adaptive stimulation

Closed-loop stimulation, also called adaptive stimulation, adjusts its output from a signal recorded in the patient instead of delivering parameters fixed at programming. One regulatory authorisation for the principle exists, and its scope has to be quoted exactly. In 2025 the United States Food and Drug Administration approved, through a premarket approval supplement, an optional programming feature called adaptive deep brain stimulation, for bilateral stimulation of the internal globus pallidus or the subthalamic nucleus, as adjunctive therapy in levodopa-responsive Parkinson disease of at least 4 years duration that is not adequately controlled with medication.

Read the scope rather than the headline. That is a foreign regulatory status, for a neurological indication, at motor targets, on a platform whose psychiatric use is taught in this chapter's own account of deep brain stimulation. It authorises nothing in psychiatry and establishes nothing about the Indian regulatory position for any device. What it does establish is that closed-loop control has crossed from research into an approved product feature in at least one jurisdiction, which is why it appears in a psychiatry chapter at all.

MNEMONIC

MUAC

The four emerging approaches, ordered by how much human evidence each carries. **M**agnetic seizure therapy, with two randomised comparisons against right unilateral ultrabrief electroconvulsive therapy. **U**ltrasound, low intensity and focused, with mechanisms still being worked out. **A**lternating and random-noise currents, defined inside the low-intensity electrical stimulation envelope and no further. **C**losed-loop and adaptive stimulation, approved abroad for a motor indication. None of the four is established psychiatric practice.

Magnetic seizure therapy induces a therapeutic seizure with an induced electric field much lower and much more focal than that of electroconvulsive therapy and with a correspondingly more restricted site of initiation, which is settled modelling; whether the resulting seizure spreads less is supported in animals, open in humans, and unquantified as an explanation of the cognitive difference two randomised trials have measured; and low-intensity focused ultrasound, alternating and random-noise stimulation and closed-loop stimulation are each carried at their own evidence level, none of them established psychiatric practice.

23 · Psychosurgery (history, current indications, ethics)

Ablative psychosurgery treats psychiatric illness by destroying a small, deliberately chosen volume of brain tissue, and the tissue does not come back. That one fact governs the rest: the narrow indications, the weight of the consent, and the statutory machinery around it. The topic is examinable from both ends, the documented ethical failure in its history and the technique of a modern stereotactic theatre.

This account owns ablative neurosurgery for psychiatric illness in full: the descent from frontal leucotomy through its abuses to modern stereotactic and image-guided lesioning, the procedures with their targets and how each lesion is placed, the narrow indications, the evidence and the designs it rests on, the irreversibility, and the ethics. It does not draw the band comparison on invasiveness, seizure induction, target, reversibility, evidence and Indian availability; that grid belongs to the cross-cutting synthesis. Deep brain stimulation belongs to this chapter's own account of it, and the history of electroconvulsive therapy to the item owning it. The statutory restriction on psychosurgery belongs to the Mental health legislation and forensic psychiatry notes, named here in words and never renumbered.

four	60,000	50 to 60 percent
ABLATIVE PROCEDURES IN CURRENT USE, EACH WITH ITS OWN TARGET	PROCEDURES AT THE HEIGHT OF THE LEUCOTOMY ERA	RESPONSE IN REFRACTORY ILLNESS, ON LARGELY UNCONTROLLED DESIGNS

23.1 Two groups, not one family

Ablative psychosurgery is not the invasive end of a stimulation scale. Psychosurgical intervention divides into two groups: **lesioning** destroys tissue, stimulation delivers current to tissue that remains intact. Both groups share one principle, to intervene as little as necessary to restore a dysfunctional circuit, and the choice turns on indication, centre experience and patient preference, weighing the irreversibility and relative simplicity of lesioning against the reversibility, adjustability and cost of stimulation.

One qualification travels with the contrast so it is not overdrawn: deep brain stimulation was initially conceptualised as a reversible lesion, and the effects of lesioning are increasingly attributed to circuit reorganisation rather than to tissue destruction alone, so the families may converge in mechanism where they do not converge in reversibility.

RULE **Ablation and stimulation are two families, and the boundary between them is irreversibility, not degree of invasiveness.** Every stimulation modality of this band shares one property no ablative procedure has: switching the device off ends the intervention. Ablation destroys tissue, so it outlives every later decision, including the patient's own change of mind. It therefore appears in the band's grid for contrast, never as the most invasive rung of a stimulation ladder.

23.2 Frontal leucotomy: what was actually done

The named precursors are Gottlieb Burckhardt's cortical resections in psychotic patients and Fulton and Penfield's work on frontal-lobe physiology. In 1936, Egas Moniz, working with the neurosurgeon Almeida Lima, published his first series of 20 patients who underwent prefrontal leucotomy for severe depression, anxiety and aggression. The technique is the detail candidates omit: the lesions were made by free-hand injection of absolute alcohol into the frontal lobes, with **substantial symptom improvement reported in 14 of 20 patients**. Moniz later replaced the alcohol with a hand-held leucotome, making more restricted lesions.

Anatomically, the operation lesioned prefrontal white matter through small frontal burr holes, partially disconnecting the frontal cortex from its thalamic and limbic connections. The

outcomes were not uniform, and that is the point: anxiety and agitation decreased in some patients, while in others apathy, abulia, personality change or cognitive deterioration emerged. A free-hand disconnection produced benefit and injury from the same act.

23.3 The abuses, and the reform they forced

Abuse here means what was done, not disapproval of an era. Walter Freeman and James Watts popularised the procedure in the United States, redefining its access points and lesion strategies, and by 1942, the year their monograph was published, they had performed 200 lobotomies. Freeman then promoted more expedient versions, including the transorbital lobotomy, and advocated wide adoption with lax indications, with interventions performed outside the operating room and sometimes without a neurosurgeon. Volume reached up to 60,000 procedures, against the overcrowding of psychiatric institutions.

Three features make this an abuse rather than a therapeutic error: indications so loose the operation was offered where no case existed, delivery outside the operating theatre, and delivery sometimes without a surgeon. This high-volume, low-supervision phase is what fuelled the ethical and regulatory backlash that continues to stigmatise these procedures. Reform came from within the discipline: cortical undercutting and topectomies were introduced as more selective approaches, and Spiegel and Wycis then introduced the stereotactic frame in humans, lesioning the mediodorsal thalamic nucleus using X-ray ventriculography. Everything modern descends from that instrument: a lesion positioned by calculation and bounded by design.

TRAP **Telling the Freeman story as though it were the whole of psychosurgery, and stopping there.** The leucotomy era is why the field is regulated, and a candidate who cannot narrate it has not answered. But an answer ending in the mid twentieth century treats a living, narrowly indicated, image-guided operation as a curiosity, and says nothing about targets, technique, evidence or present-day consent.

23.4 The current procedures, their targets and their technique

Each has a named target, and the technique of the first two is what the anxiety and obsessive-compulsive disorder material promises the reader here.

PROCEDURE	TARGET	HOW THE LESION IS PLACED	ORIGIN AND MODERN FORM
ANTERIOR CAPSULOTOMY	The anterior limb of the internal capsule	Thermocoagulation, later radioactive yttrium-90 seeds; Leksell independently used parallel bipolar radiofrequency electrodes	Jean Talairach, 1949, for anxiety neuroses and obsessive compulsive disorders
ANTERIOR CINGULOTOMY	The anterior cingulate, lesioned bilaterally	Stereotactic frame, magnetic resonance guidance and intravenous sedation, through a single burr hole per side	Triple-lesion form standardised since 1996
SUBCAUDATE TRACTOTOMY	The posterior orbitofrontal cortex, bilaterally, using the pituitary sella as a landmark	Rod-shaped yttrium seeds creating radiation-necrotic lesions, later replaced by radiofrequency coagulation	Geoffrey Knight, 1965, adapting Scoville's orbitofrontal undercutting
LIMBIC LEUCOTOMY	The cingulate and orbitofrontal targets together	Cingulotomy combined with subcaudate tractotomy	Kelly and colleagues, 1973; now usually reached as a staged procedure

Anterior cingulotomy is best given as an operative sequence, because the sequence is what changed. The historical procedure made a single lesion of about 2 cm by 1 cm per side, under magnetic resonance guidance and intravenous sedation, using a stereotactic frame. Patients who had not responded at 9 to 12 months underwent anterior extension of the lesion, and since 1996 all three lesions per side are made simultaneously, as the triple-lesion or six-pack cingulotomy, through a single burr hole with a 10 mm exposed-tip electrode redirected along the contour of the cingulate gyrus. The staging follows from that: in the mid-1990s at Massachusetts General Hospital, patients who failed the initial six-pack cingulotomy were offered a subcaudate tractotomy, and cingulotomy followed by subcaudate tractotomy is a staged limbic leucotomy.

Anterior capsulotomy aims at white matter rather than cortex, and its history is one of energy sources rather than targets: thermocoagulation first, then radioactive yttrium-90 seeds, with Leksell independently using parallel bipolar radiofrequency electrodes. **Subcaudate tractotomy** and **limbic leucotomy** complete the set, the last being a deliberate combination on the reasoning that if each independently helps, combining them might do better.

MNEMONIC

CATS

Capsulotomy, anterior: anterior limb of the internal capsule. **A**nterior cingulotomy: anterior cingulate. **T**ractotomy, subcaudate: posterior orbitofrontal cortex. **S**taged limbic leucotomy: cingulotomy plus subcaudate tractotomy in one patient.

23.5 How the lesion is actually made

A target is not a technique. Three energy modalities are in use, each with its own working figures.

MODALITY	HOW THE ENERGY REACHES THE TARGET	WHAT IT DOES TO TISSUE
RADIOFREQUENCY THERMAL ABLATION	A stereotactically inserted electrode whose tip delivers a high-frequency alternating current at about 500 kHz	Ionic agitation and microscopic friction raise tissue temperature to around 70 to 85 degrees Celsius for several seconds, causing coagulative necrosis in a sharply delimited volume that depends on electrode geometry, temperature, duration and local microanatomy
STEREOTACTIC RADIOSURGERY, AS IN THE GAMMA KNIFE	Hundreds of collimated gamma-ray beams focused on an isocentre only a few millimetres across, with no intraparenchymal electrode	**High doses of about 140 to 180 Gy at the target, typically the anterior limb of the internal capsule in radiosurgical capsulotomy**
MAGNETIC RESONANCE GUIDED FOCUSED ULTRASOUND	Ultrasound delivered through the skull and focused on a deep target, using acoustic rather than ionising energy	At the focal point, absorption translates into heating to 55 to 60 degrees Celsius, producing thermal necrosis

PITFALL

Carrying a temperature or a dose across from one energy modality to another. The figures belong to the physics of each method: a coagulation temperature is not an ultrasound temperature, and neither is a radiosurgical dose. Quote a figure only with the modality it was measured in.

23.6 The indications, and what the evidence rests on

Ablation is offered for a very short list of conditions, and only after ordinary treatment has genuinely failed. The two current indications are:

- Genuinely refractory obsessive-compulsive disorder. The algorithm leading to surgical referral belongs to the anxiety, obsessive-compulsive and trauma-related disorder material.
- Refractory depression, on the same requirement of exhausted, adequately delivered treatment.

The headline finding is easy to misquote. Ablative approaches are not inferior in efficacy to stimulation techniques, with response rates around 50 to 60 percent, but the evidence base is largely composed of uncontrolled studies and direct comparative trials remain lacking. The caveat is half the finding: ablation has not been shown less effective than stimulation, it has been shown on weaker designs.

Procedure by procedure, the picture is consistent. Radiofrequency and radiosurgical capsulotomy show similar efficacy in several open-label series in refractory obsessive-compulsive disorder, Gamma Knife capsulotomy is now the more commonly used, and one double-blind controlled trial shows significant differences between active and sham; most studies remain single-centre

and non-randomised, and adverse effects including apathy, fatigue and cognitive change are described as not negligible. For cingulotomy, large cohorts show significant improvement, but effect sizes are more modest under modern outcome criteria: in one cohort of 64 patients with refractory obsessive-compulsive disorder, partial response was seen in 47 percent at 11 months, rising to 69 percent at 64 months, with 30 of the 64 undergoing a further procedure. Subcaudate tractotomy may confer a higher response rate than a repeat cingulotomy in cingulotomy non-responders, on a series of 31 patients. Limbic leucotomy shows the staging effect most sharply: it was effective in only 20 percent as the initial procedure but in 50 percent when staged after one or more failed cingulotomies, while the original series of 66 patients reported improvement in 89 percent with obsessive-compulsive disorder and 78 percent with major depression.

Response is a scale threshold, not a clinical judgement: response in obsessive-compulsive disorder is a 35 percent or greater improvement on the Yale-Brown Obsessive Compulsive Scale and remission a score under 8, with the source's own warning that the scale is not strictly linear, so dichotomous responder classification should be interpreted cautiously. The harms are real if uncommon: apathy, seizures, urinary incontinence and memory problems are reported in a minority.

TRAP **Quoting the response rate without the design that produced it.** Set beside a controlled stimulation trial, such a figure invites a comparison of numbers not measured in comparable ways. Carry both halves, and note that the source's own "not inferior" is a failure to show a difference on uncontrolled designs rather than a demonstration of equivalence: efficacy is not SHOWN inferior, and the studies are largely uncontrolled, single-centre and non-randomised, with direct comparative trials lacking.

23.7 The ethics, and the restriction that governs the operation

Ethics here constrains a living procedure; it is not a coda to the Freeman story. Contemporary psychosurgery is only ethically acceptable if it strictly respects the four principles of bioethics, autonomy, beneficence, non-maleficence and justice, in a population that is highly vulnerable and whose capacity to consent may be impaired and should be assessed with specific tools. The evidence problem then becomes an ethical one: limited worldwide experience and the scarcity of class I to II evidence for most procedures complicate the provision of fair, clear and balanced information to patients and families.

The consent failure to guard against has a name. **Therapeutic misconception** is the risk that a patient interprets participation in a clinical trial as individualised care, which becomes likelier when a neurosurgical option is perceived as a last therapeutic intervention. The corrective sits in the consent: it must clearly convey the experimental nature of some of these interventions, the uncertainty of outcomes, and a realistic balance of potential benefits and risks.

Historical controversies and abuses in prisoners and minors led the National Commission for the Protection of Human Subjects, in 1977, to recommend significant restrictions on psychosurgery. That is United States regulatory history and nothing more. In current practice, ethical tension persists at four levels:

- Social: pressure to control aggression or addictions.
- Medical: research enthusiasm.
- Industrial: device-related economic interests.
- Personal: concerns about identity and integrity.

Justice is easily left abstract; the literature makes it concrete through cost: deep brain stimulation is among the most expensive medical therapies and requires rigorous cost-effectiveness and equity analysis when proposed for treatment-resistant psychiatric disorders, named here for that principle only.

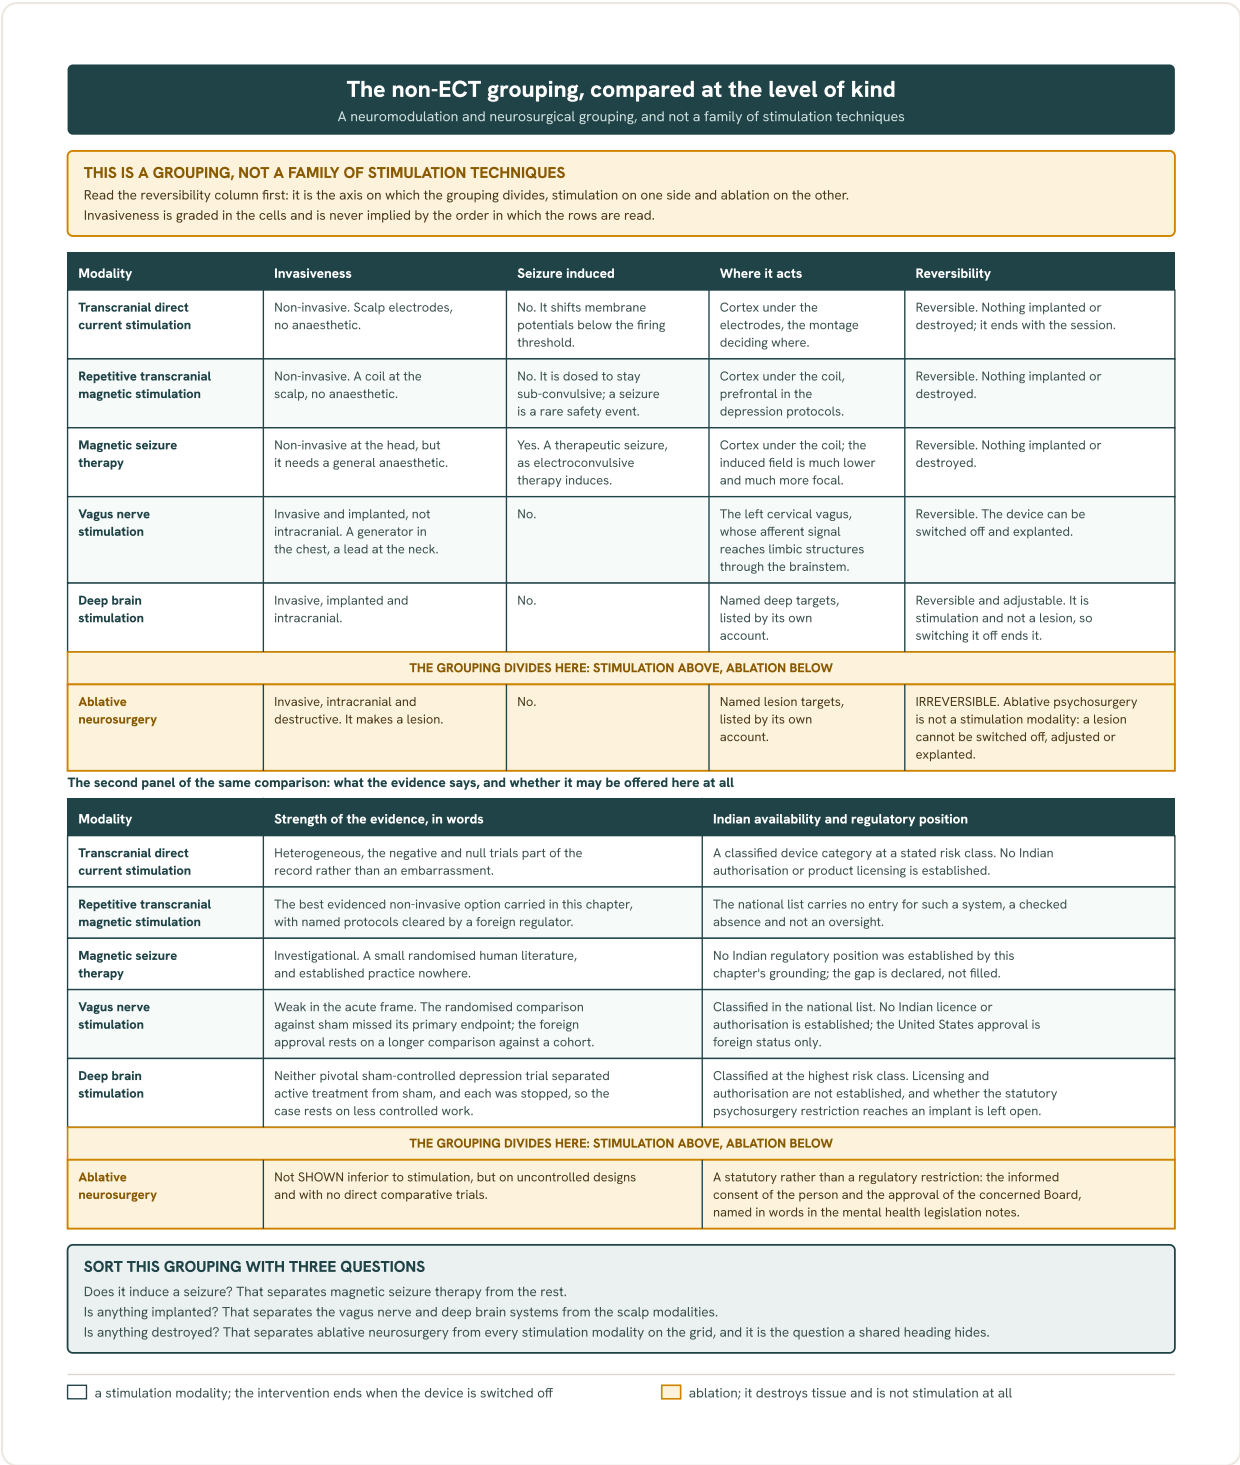
GOOD TO REMEMBER

The ethical pressure does not point in one direction. The same literature describes psychosurgery as occupying a narrow corridor between underuse and misuse, with current referral rates strikingly low relative to the burden of treatment-resistant illness. A trainee who has absorbed only the abuses reads every referral as a warning; one who has absorbed only the modern imaging underweights what a permanent lesion costs when refractoriness was assumed.

IN INDIA

The Indian constraint is statutory, not merely professional, and it is double: psychosurgery may not be performed on a person unless that person's informed consent has been obtained and the concerned Board has also approved it. That provision belongs to the Mental health legislation and forensic psychiatry notes' account of psychosurgery under the mental health legislation, is named here in words and never renumbered; go there for the wording and the route to the Board. Whether an implanted deep brain stimulation system falls inside that statutory definition belongs to this chapter's deep brain stimulation account and is a declared gap. The United States restriction above is not an Indian instrument and must never be written as though it were.

Ablative psychosurgery destroys tissue and is therefore not a member of the stimulation family, however invasive that family becomes; the procedures in use are anterior capsulotomy at the anterior limb of the internal capsule, anterior cingulotomy at the anterior cingulate in its triple-lesion form, subcaudate tractotomy at the posterior orbitofrontal cortex, and limbic leucotomy as the staged combination of the last two, made by radiofrequency, radiosurgery or focused ultrasound with parameters specific to each; the indications are genuinely refractory obsessive-compulsive disorder and depression; efficacy is not SHOWN inferior to stimulation and rests on largely uncontrolled designs with no direct comparative trials; and consent must survive impaired capacity and the therapeutic misconception, with India adding a statutory requirement of informed consent and Board approval that this chapter names and does not restate.



Cross-cutting synthesis

24 · Cross-cutting synthesis

Every other account in this chapter teaches one topic; this one is about how they hold together. An induced seizure is delivered at a measured dose, through a chosen placement, with a chosen shape of stimulus, on a chosen schedule, under an anaesthetic somebody else is giving, to a patient whose agreement has to be lawful. Move any one and something else moves with it: the topics **interlock**. The joint they turn on is the **stimulation dose**: what is delivered, how much, where, and what it costs. One boundary belongs here because it runs across the seam rather than inside any one item: the MOTOR THRESHOLD that bounds repetitive transcranial magnetic stimulation is a different construct from the seizure threshold that bounds this treatment, measured differently and meaning something different, and neither is carried across to the other. Each is taught in full by the item that owns it.

Owned here and nowhere else: the synthesis itself, how the parts move against one another, and the non-ECT comparison at the level of kind. Named in a clause and never re-derived, each with its own account: the mechanism theories, the seizure threshold, the placements and waveform, the placement-by-dose comparison, the cognitive cost, the anaesthetic conduct, the acute course, continuation and maintenance, the interacting drugs, and consent. No dose, multiple, percentage, current or session count is printed here.

Dose	Differs	Kind
THE SEAM THAT ALMOST EVERY OTHER DECISION HERE IS EXPRESSED AGAINST	THE DIRECTION AND THE SIZE OF THE TRADE, BY PARAMETER AND BY PLACEMENT	THE LEVEL THE NON-ECT MODALITIES ARE COMPARED AT, NEVER A SIBLING'S SETTINGS

The non-ECT grouping, compared at the level of kind

A neuromodulation and neurosurgical grouping, and not a family of stimulation techniques

THIS IS A GROUPING, NOT A FAMILY OF STIMULATION TECHNIQUES

Read the reversibility column first: it is the axis on which the grouping divides, stimulation on one side and ablation on the other. Invasiveness is graded in the cells and is never implied by the order in which the rows are read.

Modality	Invasiveness	Seizure induced	Where it acts	Reversibility
Transcranial direct current stimulation	Non-invasive. Scalp electrodes, no anaesthetic.	No. It shifts membrane potentials below the firing threshold.	Cortex under the electrodes, the montage deciding where.	Reversible. Nothing implanted or destroyed; it ends with the session.
Repetitive transcranial magnetic stimulation	Non-invasive. A coil at the scalp, no anaesthetic.	No. It is dosed to stay sub-convulsive; a seizure is a rare safety event.	Cortex under the coil, prefrontal in the depression protocols.	Reversible. Nothing implanted or destroyed.
Magnetic seizure therapy	Non-invasive at the head, but it needs a general anaesthetic.	Yes. A therapeutic seizure, as electroconvulsive therapy induces.	Cortex under the coil; the induced field is much lower and much more focal.	Reversible. Nothing implanted or destroyed.
Vagus nerve stimulation	Invasive and implanted, not intracranial. A generator in the chest, a lead at the neck.	No.	The left cervical vagus, whose afferent signal reaches limbic structures through the brainstem.	Reversible. The device can be switched off and explanted.
Deep brain stimulation	Invasive, implanted and intracranial.	No.	Named deep targets, listed by its own account.	Reversible and adjustable. It is stimulation and not a lesion, so switching it off ends it.
THE GROUPING DIVIDES HERE: STIMULATION ABOVE, ABLATION BELOW				
Ablative neurosurgery	Invasive, intracranial and destructive. It makes a lesion.	No.	Named lesion targets, listed by its own account.	IRREVERSIBLE. Ablative psychosurgery is not a stimulation modality: a lesion cannot be switched off, adjusted or explanted.

The second panel of the same comparison: what the evidence says, and whether it may be offered here at all

Modality	Strength of the evidence, in words	Indian availability and regulatory position
Transcranial direct current stimulation	Heterogeneous, the negative and null trials part of the record rather than an embarrassment.	A classified device category at a stated risk class. No Indian authorisation or product licensing is established.
Repetitive transcranial magnetic stimulation	The best evidenced non-invasive option carried in this chapter, with named protocols cleared by a foreign regulator.	The national list carries no entry for such a system, a checked absence and not an oversight.
Magnetic seizure therapy	Investigational. A small randomised human literature, and established practice nowhere.	No Indian regulatory position was established by this chapter's grounding; the gap is declared, not filled.
Vagus nerve stimulation	Weak in the acute frame. The randomised comparison against sham missed its primary endpoint; the foreign approval rests on a longer comparison against a cohort.	Classified in the national list. No Indian licence or authorisation is established; the United States approval is foreign status only.
Deep brain stimulation	Neither pivotal sham-controlled depression trial separated active treatment from sham, and each was stopped, so the case rests on less controlled work.	Classified at the highest risk class. Licensing and authorisation are not established, and whether the statutory psychosurgery restriction reaches an implant is left open.
THE GROUPING DIVIDES HERE: STIMULATION ABOVE, ABLATION BELOW		
Ablative neurosurgery	Not SHOWN inferior to stimulation, but on uncontrolled designs and with no direct comparative trials.	A statutory rather than a regulatory restriction: the informed consent of the person and the approval of the concerned Board, named in words in the mental health legislation notes.

SORT THIS GROUPING WITH THREE QUESTIONS

Does it induce a seizure? That separates magnetic seizure therapy from the rest.
Is anything implanted? That separates the vagus nerve and deep brain systems from the scalp modalities.
Is anything destroyed? That separates ablative neurosurgery from every stimulation modality on the grid, and it is the question a shared heading hides.

a stimulation modality; the intervention ends when the device is switched off

ablation; it destroys tissue and is not stimulation at all

Fig 27.13. The non-ECT interventions are read as one grouping and not as one family: transcranial direct current stimulation, repetitive transcranial magnetic stimulation, magnetic seizure therapy, vagus nerve stimulation and deep brain stimulation are stimulation modalities whose intervention ends when the device is switched off, while ablative neurosurgery destroys tissue and is irreversible, which is why the reversibility column rather than the order of the rows is what the grid is read on, and the one Indian instrument speaking directly to a modality is statutory, the psychosurgery restriction requiring the informed consent of the person and the approval of the concerned Board.

24.1 One measured quantity, and almost everything expressed against it

No account of how this treatment works is established, and the field says so in its own words, but every candidate account is an account of what an induced seizure does, so the seizure is the therapeutic event and the dose produces it. That dose is not a device setting. It is a multiple of a quantity measured in this patient, the lowest dose at which this brain will seize, which varies enormously and moves across a course. This is why the chapter reads as parameters rather than

protocols: fix the placement and the multiple still has to be chosen; fix the multiple and the placement changes what it buys.

Follow the chain forward and the chapter appears in order. The threshold sets the dose. The dose and placement together settle efficacy and cognitive cost, which is why the comparison between placements has no answer until the multiple is named. The cognitive cost is not one deficit but several on different clocks. The schedule spends the dose over time. Continuation and maintenance settle what happens to the gain once the course stops. Drugs continued across it move the threshold underneath everything. And the law settles, before any of this, whether the treatment may be given.

24.2 The trades differ, and the difference is the finding

Many of the choices along that seam trade among speed of response, efficacy and cognitive cost. Where they do, the direction and size of that trade differ by parameter and by placement, and the chapter asserts no law covering all of them, because several are not that kind of trade at all.

RULE **Read the trade off the parameter in front of you, and never inherit a direction from the parameter beside it.** Every general version of that rule attempted here was contradicted by the parameter next along. State what your parameter trades, at the placement you are standing at. Where a parameter does not behave like its neighbour, that is the finding.

CHOICES THAT DO TRADE AMONG THE THREE	WHAT MOVING IT ACTUALLY DOES	TAUGHT IN FULL BY
STIMULUS DOSE ABOVE THRESHOLD, AT RIGHT UNILATERAL PLACEMENT	The dose-response is steep here, so raising the multiple buys efficacy; the placement's cognitive advantage erodes as that multiple rises, without being abolished.	Stimulus dosing, and the placement comparison.
STIMULUS DOSE ABOVE THRESHOLD, AT BITEMPORAL PLACEMENT	Efficacy is already near maximal at a low multiple, so a higher dose here largely buys cognitive cost alone. The same knob, turned the same way, makes a different purchase.	The placement comparison.
THE PLACEMENT ITSELF	Not a fixed ranking, and never usable as one. Right unilateral treatment is markedly inferior near threshold and converges toward bitemporal efficacy at a high multiple without established superiority over it; the comparison narrows and does not reverse.	The placement comparison.
PULSE WIDTH	A narrower pulse is associated with a cognitive advantage at right unilateral placement in depressive illness, with antidepressant efficacy possibly compromised. The relation is bounded to pulse width inside a placement.	Technique and electrode placement.
TREATMENT FREQUENCY	A faster schedule buys speed of response at a higher cognitive price; end-of-course efficacy is equivalent between the schedules. Frequency is not an efficacy lever, and writing it as one imposes cognitive injury for a gain that does not exist.	The acute course and its schedules.

The second table stops the first from hardening into a law. These choices sit on the same seam and are not purchases among speed, efficacy and cognitive cost at all.

CHOICES THAT ARE NOT THAT KIND OF TRADE	WHAT MOVING IT ACTUALLY DOES	TAUGHT IN FULL BY
THE INDUCTION AGENT AND THE CONDUCT OF THE ANAESTHETIC	A different currency altogether. The agent shapes the seizure the psychiatrist then has to read, and is chosen against separate rankings for its effect on the threshold, the cardiovascular response and emergence, at no cognitive price.	The pre-ECT workup and anaesthesia.
THE AIRWAY, THE MONITORING AND THE TOURNIQUET	Not trades among speed, efficacy and cognitive cost in any form. The airway and monitoring buy safety and information; the tourniquet buys a limb on which the motor seizure can still be seen.	The pre-ECT workup and anaesthesia.
DRUGS CONTINUED ACROSS THE COURSE	A hazard rather than a purchase. They move the threshold underneath everything above, in either direction, each with a management step, and the direction belongs to the drug.	Drug interactions and concurrent medications.

24.3 Buying the right thing at the least price

A map with no single direction still yields a task. Decide first what this patient needs, efficacy or speed, because those are different purchases not made with the same parameter. Then buy it at the least cognitive price the illness and the law allow: the placement and multiple chosen together, the pulse width with them, the schedule for what it genuinely delivers. Where speed itself is the requirement, the schedule that answers it is the accelerated one, assembled only in this chapter's account of the course, frequency and number of sessions.

The cognitive price is not a fixed toll: the same efficacy can often be bought at different prices depending on how the parameters are combined.

> **PITFALL**
>
> The real-world error is not getting a parameter wrong. It is getting one right and then carrying its direction to the next: a clinician who has learned that a higher multiple earns a response at right unilateral placement raises it at bitemporal placement too, where efficacy was already near maximal, buying cognitive cost with nothing on the other side.

24.4 The handoffs a real course crosses

A single patient can walk a resident through most of this chapter. The difficulty is rarely inside a topic but at the joints, where the question changes shape and the governing account with it.

- **An indication becomes a consent question.** The presentation earns the treatment clinically, and the next question is not the dose but the authority: who may agree, and whether the route

is complete. Urgency strengthens the clinical case and completes no route.

- **A threshold titration becomes a placement decision.** The threshold is only part of an answer, because the multiple worth using depends on where the electrodes sit. They are chosen together, or the dose is chosen wrongly with great precision.
- **A cognitive complaint becomes a dosing change.** A patient reporting memory loss is a finding, not a nuisance, and the response is a change in the parameters that move it: placement, multiple, pulse width, schedule, drugs.
- **An acute response becomes a maintenance question.** A course that worked does not end the decision: relapse is the rule when nothing active follows.
- **A failed medication ladder becomes a modality question.** When the drugs have not worked, the question stops being which drug and becomes which intervention.

24.5 The law bounds the seam rather than sitting on it

The last element in the chain behaves unlike the others, and treating it as one more parameter is the commonest structural error. Consent, capacity and the statutory provisions do not tune the treatment; they settle whether it may be given at all, and on whose authority. Clinical urgency does not convert a missing authority into a present one: a lawful route has to be established separately, the emergency-treatment provision of the Act cannot supply it, and that is a point about treatment authority and not about admission, because a capacitous adult can consent to this treatment with no admission at all. The routes, an advance directive refusing treatment, the nominated representative and the minor's gate belong to this chapter's account of consent.

Statutory bars sit at the edges of the chapter, not inside its parameters. Unmodified, or direct, electroconvulsive therapy is unlawful in India rather than merely inadvisable, as this chapter's modified-against-unmodified contrast states with the history behind it. And ablative psychosurgery may not be performed without the person's informed consent and the approval of the concerned Board. Each provision belongs to the Mental health legislation and forensic psychiatry notes, named here in words and renumbered nowhere.

24.6 The non-ECT grouping, compared at the level of kind

The second part of the chapter meets the other interventions that act on the brain directly. They are read in the bank's own sequence, which ranks nothing: the grading of **invasiveness** is taught here, never implied by which item comes first. Each modality's own settings belong to its own account, and the accompanying plate carries this comparison as one grid.

Before the grid can be read honestly, the grouping needs its right name. This is a **neuromodulation and neurosurgical grouping**, not a family of stimulation techniques. The stimulation members share a property mattering more than their differences: switching the device off ends the intervention. Ablative neurosurgery does not share it. It destroys tissue, it is not stimulation at all, and it sits on the grid for contrast rather than as the invasive end of one gradient. That is why **reversibility** is the column to read first. It is the axis on which the grouping divides, stimulation on one side and ablation on the other, and the ablative psychosurgery account owns that irreversibility in full.

MODALITY	INVASIVENESS	SEIZURE INDUCED	WHERE IT ACTS	REVERSIBILITY
TRANSCRANIAL DIRECT CURRENT STIMULATION	Non-invasive. Scalp electrodes, no anaesthetic.	No. It shifts membrane potentials below the firing threshold.	Cortex under the electrodes, the montage deciding where.	Reversible. Nothing implanted or destroyed; it ends with the session.
REPETITIVE TRANSCRANIAL MAGNETIC STIMULATION	Non-invasive. A coil at the scalp, no anaesthetic.	No. It is dosed to stay sub-convulsive; a seizure is a rare safety event.	Cortex under the coil, prefrontal in the depression protocols.	Reversible. Nothing implanted or destroyed.
MAGNETIC SEIZURE THERAPY	Non-invasive at the head, but needs a general anaesthetic.	Yes. A therapeutic seizure, as electroconvulsive therapy induces.	Cortex under the coil; the induced field is much lower and much more focal.	Reversible. Nothing implanted or destroyed.
VAGUS NERVE STIMULATION	Invasive and implanted, not intracranial. A generator in the chest, a lead at the neck.	No.	The left cervical vagus, whose afferent signal reaches limbic structures through the brainstem.	Reversible. The device can be switched off and explanted.
DEEP BRAIN STIMULATION	Invasive, implanted and intracranial.	No.	Named deep targets, listed by its own account.	Reversible and adjustable. It is stimulation and not a lesion, so switching it off ends it.
ABLATIVE NEUROSURGERY	Invasive, intracranial and destructive. It makes a lesion.	No.	Named lesion targets, listed by its own account.	Irreversible. Ablative psychosurgery is not a stimulation modality: a lesion cannot be switched off, adjusted or explanted, and this cell is why the grouping is not one family.

The remaining axes are the second panel of the same comparison: what a modality is settles what it could do, while its evidence and regulatory position settle whether it may be offered at all.

MODALITY	STRENGTH OF THE EVIDENCE, IN WORDS	INDIAN AVAILABILITY AND REGULATORY POSITION
TRANSCRANIAL DIRECT CURRENT STIMULATION	Heterogeneous, the negative and null trials part of the record rather than an embarrassment.	A classified device category at a stated risk class. No Indian authorisation or product licensing is established.
REPETITIVE TRANSCRANIAL MAGNETIC STIMULATION	The best evidenced non-invasive option carried in this chapter, with named protocols cleared by a foreign regulator.	The national list carries no entry for such a system, a checked absence and not an oversight.
MAGNETIC SEIZURE THERAPY	Investigational. A small randomised human literature, and established practice nowhere.	No Indian regulatory position was established by this chapter's grounding; the gap is declared, not filled.
VAGUS NERVE STIMULATION	Weak in the acute frame. The randomised comparison against sham missed its primary endpoint; the foreign approval rests on a longer comparison against an observational cohort.	Classified in the national list. No Indian licence or authorisation is established; the United States approval is foreign status only.
DEEP BRAIN STIMULATION	Neither pivotal sham-controlled depression trial separated active treatment from sham, and each was stopped, so the case rests on less controlled work.	Classified at the highest risk class. Licensing and authorisation are not established, and whether the statutory psychosurgery restriction reaches an implanted system is left open.
ABLATIVE NEUROSURGERY	Not SHOWN inferior to stimulation, but on uncontrolled designs and with no direct comparative trials.	A statutory rather than a regulatory restriction: informed consent of the person and approval of the concerned Board, named in the Mental health legislation and forensic psychiatry notes.

GOOD TO REMEMBER

Sort this grouping with three questions. Does it induce a seizure? That separates magnetic seizure therapy from the rest. Is anything implanted? That separates the vagus nerve and deep brain systems from the scalp modalities. Is anything destroyed? That separates ablative neurosurgery from every stimulation modality on the grid, and it is the question a shared heading hides.

IN INDIA

Read the Indian column as four claims and never as one. A device classification says which regulatory pathway a device sits in; a product licence says a named device may be sold here; an indication-specific authorisation says it may be sold for a stated psychiatric use; a foreign clearance speaks to another jurisdiction, not this one. On this grid the classification claim is usually the only one available: Indian licensing and authorisation are not established for any modality, written as not established rather than left for a reader to infer. The one Indian instrument speaking directly to a modality is statutory, the psychosurgery restriction named above.

MNEMONIC

ONE KNOB AT A TIME

Before stating any trade, name the knob exactly: the dose, and at which placement; the pulse width, and at which placement; the schedule; the anaesthetic. Then read that knob's trade and stop. Do not carry the direction to the next, which has its own. And some controls here, the airway, the monitoring and the tourniquet, are not on this trade at all.

The stimulation dose is the seam: mechanism proposes it, the threshold measures it, placement conditions what it buys, the cognitive cost prices it, and the law bounds who may receive it. Many of the choices along that seam trade among speed of response, efficacy and cognitive cost, and where they do the direction and size of the trade differ by parameter and by placement; several, the airway, the monitoring and the tourniquet among them, are not that kind of trade in any form. The non-ECT grouping is not one family: its stimulation members end when the device is switched off, while ablation destroys tissue and cannot be undone.

TRAP **Answering a synthesis question with a single general rule.** The question invites it, because an examiner asking what the trade-off is sounds like one wanting a single sentence, and one sentence sounds like mastery. It cannot be right here: the relation at right unilateral placement is not the one at bitemporal placement, and the schedule's is different again. Name the parameter, give its relation with its condition, then say the others run differently.

Apply and consolidate

25 · Applying the chapter

A vignette in this territory almost never asks whether electroconvulsive therapy works; it asks whether this patient may lawfully be given it, with what, and at what price. Those are separate findings reached by separate reasoning, and the candidate who learned the chapter as a list of facts answers the question nobody asked. Name the kind of question before reaching for what you know.

These vignettes assert nothing of their own. Every threshold, multiple, interval, effect size and statutory provision they deploy is taught, and cited to its source, by the account that owns it, and is named here rather than restated. Cover each answer, decide what you would do, then read on.

Earned	Authorised	Priced
WHETHER THE PRESENTATION INDICATES THE TREATMENT	WHETHER A LAWFUL ROUTE EXISTS TO GIVE IT	WHAT THE CHOSEN PARAMETER ACTUALLY BUYS

25.1 How to work a vignette in this chapter

Sort the case before you answer it.

- An **indication question** asks whether this presentation earns the treatment.
- An **authority question** asks on what lawful basis it may be given, answered from the Act and never from severity.
- A **parameter question** asks what a change to placement, dose, pulse width, schedule or anaesthetic conduct buys and costs.
- A **modality question** asks whether a different device is the better answer, a family whose terms are not the terms of electroconvulsive therapy.

Each parameter has its own relation to efficacy and its own to cognition, so a relation established for one is never inherited by another, and some decisions here are not trades of that kind at all.

RULE **An indication and a lawful route are separate findings, and neither supplies the other.** Deciding that a presentation earns this treatment settles the clinical question completely and the legal question not at all. Answer both, in that order, wherever treatment is proposed, and say which of the two your reasoning has discharged.

25.2 Vignette: the emergency the emergency provision cannot authorise

Presentation. A woman in her thirties is in the third week of a severe depressive episode. She has taken almost nothing by mouth for days, is at times mute and immobile, refuses oral medication, and is dry, tachycardic and deteriorating. The consultant says she needs electroconvulsive therapy tonight. The resident proposes to treat under the Act's emergency-treatment provision and asks the family to sign an admission form.

Decision point. On what authority may this be given tonight, and does the urgency change the answer.

Reasoning to show. Split the case at once. The clinical half is uncontentious: food and fluid refusal, immobility and a deteriorating physical state secondary to a psychiatric condition are what the indications account carries as first-line where a rapid response is needed to avert harm. That finding is complete, and it authorises nothing. The legal half is where the resident errs: this treatment can be clinically indicated in an emergency, and the Act's emergency-treatment provision cannot authorise it, because that provision expressly excludes it. A lawful route must be established separately, and urgency does not cure an incomplete one.

The limb candidates lose: treatment authority is not admission authority. A capacitous adult can consent with no admission at all, so the emergency route closing never converts the question into whether she must first be admitted, and a family signature on an admission form is nobody's consent to this treatment. Assess her **capacity**, now and for this decision, the Act presuming every person to have it. If she retains it, the route is her own informed consent, intervention-specific and covering risks, benefits and alternatives; if not, the supported-admission route runs in its fixed order, the directive first, then her own consent with her representative's support, then temporary substituted consent.

Answer. Say the indication is clear and that it is not the authority. Do not treat under the emergency provision, which excludes this treatment by name. Assess capacity tonight, because that is what urgency buys: speed in establishing a route, never a shorter one. With capacity, take her own informed consent; without it, look for a directive first, then work the supported route. Record which route was used, not only that a form was signed, and rehydrate her now.

PITFALL

Writing the emergency in as though it were a source of authority. It is a clinical urgency and nothing more, and the Act's emergency-treatment provision excludes this treatment by name. The paired error costs the same marks: assuming that because that route is closed, an admission must be arranged first. It need not be, if the adult has capacity and consents.

25.3 Vignette: the directive that says no

Presentation. A man in his forties with recurrent severe depression had electroconvulsive therapy in an earlier episode. While well, he made a written **advance directive** refusing it in future. He is now in severe relapse, has lost capacity, is refusing food and is at high risk. His wife, his nominated representative, wants it given. The senior registrar says the directive cannot have been meant to cover a picture like this, and that the team should proceed.

Decision point. Does the directive bind the team, and if it does, what is the route out of it.

Reasoning to show. Name the instrument first, because a resident who has met it only as a way of saying yes reads refusal as obstruction. It runs in either direction, is invoked only when the maker ceases to have capacity, lapses when capacity returns, and is overridden by a later capacitous decision. A refusal is the instrument working, not a defect in it. The duty to treat in accordance with a valid directive falls on the medical officer in charge of the establishment and on the psychiatrist in charge of treatment, subject only to Board review. What that duty lacks is the examinable part: no bedside-override limb, no urgency limb, no senior-clinician limb.

The route out is an application. Where a professional, a relative or a care-giver desires not to follow a directive, the Act directs an application to the concerned Board, which hears all parties and may uphold, modify, alter or cancel it against the considerations the provision lists: voluntariness, whether he intended it to apply to circumstances such as these, whether he was sufficiently informed, whether he had capacity, and whether its content is contrary to other law.

That intention limb is what the registrar is arguing, and it is argued to the Board, never settled at the bedside.

Answer. The directive binds the team. Do not give the treatment. File the application to the concerned Board today, framed on the intention limb the registrar has already argued, and state the clinical urgency in it, urgency being a reason for the Board to move rather than to be bypassed. Meanwhile treat the relapse by every lawful means that remains. If capacity returns the directive lapses. Record the decision not to override it and the date of the application.

TRAP **Treating a refusing directive as a clinical problem to be solved.** A resident who has met only the authorising face of the instrument reads a refusal as an obstacle to good care, then solves it the way clinical obstacles are solved, at the bedside and under time pressure. That is the unlawful act. The only lawful exit is the application, and urgency creates no exception to it.

25.4 Vignette: the hemiplegic arm and the wrong clock

Presentation. A man in his sixties has a dense right hemiplegia following a stroke some months ago, and has since developed a severe depressive episode with poor oral intake. Electroconvulsive therapy is planned. The registrar reasons that the stroke is no longer recent, that the risk has settled, and tells the anaesthetist that the usual depolarising relaxant may be used.

Decision point. Is the recency of the stroke the right marker for the blockade decision, and what emergency is being risked.

Reasoning to show. Two risks run here on opposite clocks, which is why one word carried from one to the other is dangerous. The word recent, as it attaches to a cerebrovascular or cardiac event in the risk-profile account, concerns the cardiovascular and cerebral risk of the induced seizure: highest close to the event and falling with time, which is why that account recommends postponement. The registrar has read that direction correctly and applied it to a question it does not govern. The blockade question has its own mechanism: after denervation or disuse, extrajunctional acetylcholine receptors up-regulate, so a depolarising agent depolarises a greatly enlarged receptor population and releases potassium from it.

The receptors must change first, so the danger RISES as the up-regulation proceeds, peaking at the interval the workup and anaesthesia account states, and the label's own contraindication applies after the acute phase. The onset and duration of that risk period are expressly unknown, so no date of safety is printed here. Reading recency across therefore inverts the window: it refuses the relaxant before the receptors have up-regulated, where the label still requires great caution and prints no interval of safety, and hands it to the established hemiplegic in whom danger has built for weeks. It clears exactly the wrong patient, and the emergency it clears him into is severe hyperkalaemia which may result in cardiac arrest.

Answer. The stroke being old is a reason for concern about the relaxant, not reassurance about it, and saying so explicitly is the mark. Nor is this a decision for the anaesthetic room: the relaxant question belongs to the pre-treatment assessment, before the patient is fasted and listed. Ask what denervating or disuse lesion exists and how long ago the insult was, remembering that the

risk rises toward the stated peak rather than falling away from the insult, and ask about the emergencies that do not share this mechanism, lowered plasma cholinesterase ending in prolonged apnoea and the ryanodine route in malignant hyperthermia. The choice and dose of relaxant remain the anaesthetist's decision.

25.5 Vignette: which placement, and at what multiple

Presentation. A schoolteacher in her fifties with a severe first depressive episode has consented to electroconvulsive therapy and is frightened, specifically and articulately, of losing her memory. She was started on right unilateral placement at a dose just above her measured seizure threshold, on the stated ground that this is the gentle option. After several treatments she is no better, and the team is discussing a switch to a bilateral placement.

Decision point. Was the near-threshold unilateral course the gentle choice, and what does the switch change.

Reasoning to show. Refuse the question as posed: whether right unilateral placement is as good as a bilateral one has no answer until the dose is named, because the placements have different dose-response relations. Near the threshold, right unilateral treatment is markedly inferior while bilateral efficacy is already near its maximum, so the near-threshold unilateral course is not a gentle version of the treatment but an under-treated one. As the multiple rises, right unilateral treatment converges toward bitemporal efficacy without establishing superiority over it, and the cognitive advantage it buys erodes as that same multiple rises; state both halves or neither, since erosion is not abolition and a real advantage survives at the top of the range, domain-specific rather than broad.

Then the relation the chapter exists to protect. Stimulus dose above the threshold buys efficacy in right unilateral placement, where the dose-response is steep; in bitemporal placement, where efficacy is already near-maximal at a low multiple, a higher dose largely buys cognitive cost alone. That is one relation for one parameter and its mirror for another, and it is not a direction to be carried anywhere else. The threshold is measured in this patient rather than looked up and rises across a course, so the multiple she receives today is not the one she received in the first week unless somebody has checked.

Answer. Name the multiple before answering anything. The failure so far is a dosing failure rather than a placement failure, so the first correction is to dose the unilateral placement adequately against a re-measured threshold rather than abandon the placement carrying the advantage she asked for. Tell her what that advantage is and is not: it survives in named domains rather than across the board, and the same rising dose that buys the efficacy partly spends it. If an adequate course still fails, a switch is legitimate on efficacy grounds, with the cognitive cost stated.

25.6 Vignette: the memory complaint, and the family who want it faster

Presentation. A man in his forties is midway through an acute course for a severe depressive episode and is improving, slowly. His wife says he cannot recall the week of his admission at all and has patchy gaps for the months before it, including a family wedding. He scores normally on

the bedside screen the unit uses. The family, impatient with the pace, ask that treatments be given more often so that the treatment works better.

Decision point. What to do about the memory complaint, and whether to raise the frequency to improve the outcome.

Reasoning to show. Take the frequency request first, because it rests on a false premise. Treatment frequency buys speed of response; it is not an efficacy lever. The acute-course account established that the thrice-weekly and twice-weekly schedules reach equivalent antidepressant outcome at the end of the course, that the faster schedule reaches response sooner, and that it costs more in memory impairment even where the total number of treatments does not differ. The cost belongs to the spacing, not the number of treatments. The family are asking, without knowing it, to pay a cognitive price for a gain that does not exist; the malignant presentations measured in days earn speed, and this man does not.

Then the memory complaint, separating report from measurement. The cognitive cost is not one deficit but separate phenomena on separate clocks. Postictal confusion belongs to the minutes after each treatment. **Anterograde amnesia** is the difficulty laying down new memories while the course runs, which is why the week of admission is patchy, and it is the limb that recovers after the course. **Retrograde amnesia** is the loss of what was already laid down, with a gradient toward events near the treatment, which is what the missing wedding is; the Indian guideline calls it among the most distressing adverse effects and difficult to measure using objective tests. The normal bedside screen therefore excludes nothing.

Where his wife's account and the ward's testing diverge, the divergence is the finding. The Indian guideline directs that subjective memory impairment be given due importance alongside objective assessment, the reason report exceeds measurement being a caution about the instruments, not the patient. Its menu is what can be done: space the sessions, switch to unilateral placement, switch to a briefer pulse width, reduce the stimulus dose, reduce or stop drugs affecting cognition, reduce a high anaesthetic dose, and terminate the course where risks outweigh benefits, each step balanced against the effectiveness it may cost.

Answer. Decline the frequency increase on the right ground: not that it is unsafe, but that it does not buy what is being asked for, the end-of-course outcome being equivalent and only the speed and the cognitive price differing. On the memory, ask about life memories rather than orientation and word lists, because the instrument that finds retrograde loss is a conversation about his own past; record the wife's account as a finding; and space the sessions if anything, the opposite of what was requested. The encoding gap recovers; the loss around the wedding is contested.

RULE **Name the parameter before you name its price, because each has its own relation and none lends its direction to another.** The stimulus dose, the placement, the pulse width, the schedule and the anaesthetic conduct each stand in a different relation to efficacy and to cognition. A candidate who has learned one direction as the law of the chapter will apply it to the parameter it does not fit.

25.7 Vignette: the patient for whom the answer may not be electroconvulsive therapy

Presentation. A software engineer in his thirties has a moderate depressive episode that has not responded to successive adequate antidepressant trials. He is working, eating, sleeping badly, and denies suicidal intent. He is frightened of the memory loss he has read about, and asks instead about the magnetic treatment he has seen advertised; his family have read about a home device and about an implanted stimulator a relative received.

Decision point. Is a non-electroconvulsive device the right answer, and on what axes is that choice made.

Reasoning to show. Establish first that the question is genuinely open, because this case is mishandled by letting a device stand in for an urgently indicated treatment. He carries none of the features that move electroconvulsive therapy to a first-line position: no food or fluid refusal, no catatonia, no psychotic features, no acute suicidal risk. His treatment resistance is a second-line indication, so there is time to choose, and his fear is a reason to explain the cognitive cost rather than to steer him elsewhere. Then refuse the shape of his question: these devices are not a ladder with a single gradient. They differ on whether a seizure is induced at all, on invasiveness, on target, on reversibility, on the evidence for the indication, and on the Indian regulatory position, and those axes do not move together.

Then take each device on its own account. Repetitive transcranial magnetic stimulation induces no seizure, is referenced to a motor threshold measured in this patient, and needs weeks of daily attendance, a real question for a man with a job; its Indian position is a checked absence establishing nothing about licensing. Transcranial direct current stimulation induces no seizure, is authorised for no psychiatric indication in the Indian classification, and did not separate from sham in the depression trial carried here, which answers the home-device question. Deep brain stimulation is a permanently implanted electrode reached only after everything else has failed, and its sham-controlled depression trials missed their primary endpoints. Vagus nerve stimulation drives a peripheral nerve in the neck, its acute sham-controlled endpoint was not significant, and its approval rested on an effect measured over a long window. Carry nothing across: those relations belong inside electroconvulsive therapy.

Answer. The honest reply is a conversation rather than a device. Tell him his presentation does not make electroconvulsive therapy urgent, so there is room to choose; correct what he fears in the separated terms the cognitive account supplies; and if he then refuses it, record that as the valid refusal of a capacitous adult rather than an obstacle. Choose among the devices on the axes that differ, naming for each the evidence for this indication and what the Indian record establishes.

IN INDIA

Three Indian facts decide these cases. The Act supplies the routes and closes the emergency route to this treatment by name. The Indian guideline gives patient-reported memory impairment due importance alongside objective testing. And the Indian device-classification record governs the non-electroconvulsive family, a foreign clearance never being readable across.

25.8 The cases on one grid, and the thread through them

Set side by side, the cases are one discipline in different clothes, and the right-hand column is a single family of mistakes.

VIGNETTE	THE QUESTION IT REALLY ASKS	WHERE THE ANSWER COMES FROM	THE CLASSIC WRONG ANSWER
THE EMERGENCY AT NIGHT	Indication, then authority, as separate findings	The indications account, then the Act's routes	Treating under the emergency provision, or assuming admission comes first
THE DIRECTIVE THAT SAYS NO	Whether a valid refusal binds the team	The duty to follow a valid directive, and Board review	Deciding the maker's intention at the bedside instead of applying to the Board
THE HEMIPLEGIC ARM	Which clock the blockade risk runs on	The workup and anaesthesia account, which owns the window	Reading recency across from the seizure risk, clearing the wrong patient
THE FRIGHTENED TEACHER	What the dose does at this placement	The placement comparison and the stimulus-dosing account	Calling a near-threshold unilateral course the gentle option
THE IMPATIENT FAMILY	What a faster schedule actually buys	The acute-course account and the cognitive account	Raising the frequency to improve the end-of-course outcome
THE ENGINEER AND THE DEVICES	Whether another modality fits, and on what axes	Each device's own account, and the cross-cutting grid	Ranking the family on one gradient, or carrying the electroconvulsive relations across

The thread, stated once. Every case turns on refusing to let one finding answer for another: a clinical indication does not answer an authority question, a risk on one clock does not answer a risk on another, a relation established for one parameter does not answer for a second, and nothing established inside electroconvulsive therapy answers for devices whose terms differ.

MNEMONIC

ROUTE, RELAXANT, RELATION, REMAINDER

Rebuild the closer from these when a vignette empties your head. **Route**: an indication says the treatment is earned, never that it may be given, and urgency does not cure an incomplete route. **Relaxant**: the safety question runs on its own clock, recency is the wrong marker, and it is asked before the patient is fasted. **Relation**: name the parameter before you name its price, because none inherits a direction from another. **Remainder**: everything outside electroconvulsive therapy is a different family on different terms, compared on the chapter's grid rather than ranked.

Every vignette here separates findings that residents merge: the indication from the lawful route, one risk's clock from another's, and each parameter's own relation from a general direction that does not exist.

26 · Consolidation

The last useful thing to do with this chapter is not to read it again but to produce it from memory, with no answer in sight. Everything below is a question, and nothing is answered. That is the design: **active recall**, forcing an answer out of memory before checking it, fixes material for an examination, while an answer printed beside its question converts the exercise back into rereading. Answer each prompt in full, then turn back to the topic that owns it.

This section owns the device alone: the prompt list, a map of the errors that decide marks, and one frame for an unseen question. No multiple, threshold, rate, interval, dose or session count is printed, because an answer beside its question destroys the exercise. Where a prompt reaches a doctrine this chapter does not teach, it names the owner: the statutory provisions to the Mental health legislation and forensic psychiatry notes, the catatonia entity to the Other psychotic disorders, delusional syndromes and catatonia notes, and the algorithms and resistance ladder to the Mood disorders and Schizophrenia notes.

Retrieve	Route	Parameter
THE DEVICE THIS SECTION RUNS ON, NEVER REREAD	WHAT AN INDICATION NEVER SUPPLIES	NAMED BEFORE ANY TRADE IS STATED

26.1 How to use this list

Work the four groups in order; they follow the chapter's sequence: decide whether to treat, how to deliver it, live with what it does, then step outside the induced seizure. Answer aloud or on paper before opening anything.

RULE **Retrieve first, check second.** An answer-free list loses its value the moment you read an answer before producing one. **Retrieval practice** strengthens a memory trace in a way recognising a stated answer does not, and the two feel identical from the inside, which is why the candidate who revises by rereading empties out on a blank page.

26.2 Two habits that answer most of the list

Two moves produce most of the answers below. The first splits the clinical question from the legal one: whether this presentation earns the treatment is settled clinically, whether it may be given by establishing a **lawful route**, and a strong answer to the first is no answer to the second. The second names the parameter before any trade.

RULE **Name the parameter, then state its own relation.** Many choices in this chapter trade among speed of response, efficacy and cognitive cost, and where they do, the direction and the size of that trade differ by parameter and by placement. Some are not trades among those three at all: the airway, the monitoring and the tourniquet buy safety and information at no cognitive price. The chapter therefore asserts no law covering all of them. Stimulus dose above threshold behaves one way in right unilateral treatment and another in bitemporal; treatment frequency is a different trade again. State the relation for the parameter in front of you and inherit no direction from any other.

26.3 Group one: foundations and indications

Where the treatment came from, how it works, which presentations earn it, and what raises its risk.

1. Narrate the arc from a false premise to a modern procedure: whose hypothesis began it, what produced the first therapeutic convulsions, what ended the chemical era, and who achieved the first electrical induction.
2. State the field's own position on how the treatment works, then give the successive accounts in order, each with the observation it rests on and the residue it leaves.
3. List the presentations that earn the treatment and grade each by its evidence. Say where the Indian and United Kingdom positions on schizophrenia diverge, and what an indication never settles.
4. Give both positions on contraindication with the tradition attached to each, what stands in place of a contraindication list today, and why pregnancy belongs on the risk list.

26.4 Group two: technique and dose

Here the answers are parameters, and a parameter is correct only with its document.

1. Say what drives investigation before a course. Then take the depolarising relaxant: name the mechanisms that bar it, and which way the hyperkalaemic danger moves with time after a denervating insult.
2. Name the members of the bilateral and unilateral classes with each placement's landmark. Then name the stimulus parameters in the order of the charge equation, and why a charge figure alone specifies no dose.
3. Answer the placement comparison properly: what the evidence shows near threshold, what happens to the efficacy difference and separately to the cognitive advantage as the multiple rises, and the qualifier that stops convergence being read as overtaking.
4. Define the seizure threshold as a measured quantity rather than a machine setting, and why the therapeutic multiple is not one number across placements. Then judge a seizure: the criteria in order of weight.
5. State what modification modifies and what it leaves untouched, and name the injuries the unmodified technique produced. Then give the Indian position in the correct register: a statutory bar and not clinical advice, the modified form being the only lawful one, the

provision belonging to the Mental health legislation and forensic psychiatry notes and named there in words.

26.5 Group three: effects, consent and course

The longest group, and the one deciding most marks: where the treatment meets the patient, the law and the calendar at once.

1. Separate the three cognitive phenomena and give the clock each runs on. Say which recovers, which stays contested, and why a recovery finding from a corpus with no instrument for the second is not reassurance.
2. Give the cardiovascular sequence in its fixed order, and what a candidate naming only the second phase has dropped. Then explain why the two mortality estimates differ without either being wrong.
3. Name the lawful routes to giving this treatment in India, with the limit that travels with each, and say what urgency changes and what it never changes. Then state why the Act's emergency-treatment provision cannot authorise this treatment even where the presentation plainly earns it, why **treatment authority** is not **admission authority**, and what gate applies to a minor.
4. For pregnancy, state the comparative safety claim exactly as its source bounds it and what it does not say. For the elderly, what leads. For the adolescent, what comes first.
5. Say what the acute schedule is, what a faster schedule buys, what it costs and where both schedules end up. Then separate the point at which technique is changed from the point at which failure may be declared.
6. State what happens when nothing active follows a successful course, and what is therefore started in every case. Give the taper in the order it is asked for.
7. Give the three statements any drug interaction across a course requires, then sort the common agents into those that raise the threshold, those that lower it and those that do neither.

> **GOOD TO REMEMBER**
> Do not run this list once, the night before. Retrieval strengthens memory most when spaced, so sweep the four groups now, mark the prompts you missed, and return to those after some days.

26.6 Group four: the other neurostimulation therapies

Every modality here is defined by contrast with the induced seizure, so each prompt asks what the device does before what the evidence says.

1. Explain how current reaches cortex without touching the skin, and why the treatment is dosed to stay below a seizure. Then say why parameters quoted without their protocol and indication describe nothing ever trialled.
2. State what a weak constant current does to cortical neurons and what it never does. Give the polarity rule as a first approximation, then why a device classification is not an authorisation.

3. Name the psychiatric targets, and what separates this intervention from an ablative one. Then state what the two pivotal sham-controlled depression trials found.
4. Describe the implanted system and say why it is not a cranial implant, then why an effect appearing as a slope over months cannot be detected by a trial reading its endpoint early.
5. For magnetic seizure therapy, separate what the modelling settles about the induced field and the site of initiation from what remains open in humans about spread.
6. State the single property separating ablation from every stimulation modality, and why the two therefore do not form one family however the syllabus groups them. Name the current procedures with their targets, and give the double Indian statutory constraint in words.

26.7 The five answers this chapter punishes

More marks are lost on this chapter to five wrong answers than to genuine ignorance, because each is a compact, confident sentence that sounds like clinical sense. If anything you produced matches the middle column, reopen that topic first.

AXIS	THE ANSWER THAT LOSES THE MARK	THE ANSWER THAT EARNS IT	WHERE TO REOPEN
UNMODIFIED, THAT IS DIRECT, TREATMENT	Filing a statutory bar under clinical advice, as though the question were which technique is safer	In India it is unlawful, not merely inadvisable, and the modified form is the only lawful one; what remains teachable about the older technique is historical	modified against unmodified treatment, and the Mental health legislation and forensic psychiatry notes
THE EMERGENCY	Reaching for the Act's emergency-treatment provision because the presentation is desperate	The presentation can genuinely earn the treatment while that provision cannot authorise it, because it excludes this treatment by name; a lawful route is established even so, and urgency changes the timetable, never the route	indications, and consent
AUTHORITY	Assuming that because the emergency route is closed, the patient must be admitted first	Treatment authority is not admission authority: a capacitous adult can consent to this treatment with no admission at all	consent and the legal aspects
EFFICACY AND COGNITIVE COST	Carrying one parameter's relation across to another as though the chapter held a single law of stimulation	There is no such law; many choices trade among speed, efficacy and cognitive cost, the direction and size differing by parameter and by placement, and several are not trades among those three at all	the cross-cutting synthesis, and the item owning each parameter
TREATMENT FREQUENCY	Writing the faster schedule as the stronger one	What the faster schedule buys is speed of response; end-of-course efficacy is equivalent between the schedules, and the faster one reaches response sooner at a higher cognitive price	course, frequency and number of sessions

PITFALL

A sixth error runs underneath all five: quoting a figure away from the document stating it. A device's specification is that device's and not the field's; a guideline's threshold is that guideline's; a formula holds only inside the parameter set it was derived in; and a rate quoted without its comparator reports a hazard the study never established.

IN INDIA

Many answers here are Indian, and several differ from the Western default. The technique is settled by statute rather than preference; the minor's gate is statutory and comes first; the emergency route is closed by name; the national guideline, not a foreign one, governs the parameter answers where the two diverge; and for every device in the final group the Indian record is a risk classification and nothing more.

26.8 The master frame to run on any question

The whole chapter collapses into one procedure, its own spine gathered into five moves, so an unfamiliar question becomes a sequence of decisions rather than a scramble for the nearest rule.

MNEMONIC

SPINE

Settle the indication: does this presentation earn the treatment, and on what evidence? That is answered clinically, and first. **P**rove the route: an indication is never an authority, so establish a lawful route, remembering that urgency changes the timetable and not the route, and that treatment authority is not admission authority. **I**dentify the parameter: before stating any trade, say which is in front of you, because placement, stimulus dose, treatment frequency, pulse width and anaesthetic conduct each carry their own relation. **N**ame the source beside the figure: the device, guideline, trial or formula that produced it. **E**very provision in words: the Act's provisions touching this treatment are named, never renumbered, and belong to the Mental health legislation and forensic psychiatry notes.

TRAP **Answering a question that has not been fully asked.** Which placement is better, does memory loss persist, which schedule is stronger: each is under-specified, and the examiner knows it. The first has no answer until the multiple of threshold is named, the second none until you say which memory and by which instrument, the third none until you say what is bought.

Settle whether the presentation earns it, prove a lawful route before anything is given, name the parameter before you state its trade and inherit no direction from another, keep every figure beside the document that produced it, and name the Act's provisions in words: the rest is detail hanging off those five.

Previously asked

There is no indexed past-question bank for this chapter, so nothing in the table below is a catalogued past question and no board or year is claimed for any of them. Attributing a paper the index does not hold would be a fabrication, so in place of a board of origin each row is marked Representative, and the questions are written in the register an examiner uses. Electroconvulsive therapy is examined heavily and in every form the paper allows, as a long answer on indications, technique and dose, as a short note on a single population or a single

complication, and in the viva on the seizure the candidate has just been asked to describe, while the other neurostimulation therapies are examined mostly as short notes and as the second half of a compare-and-contrast. The list therefore maps the examined spine of this chapter rather than one board's recent record. Read it as a high-yield revision map, not as a set of questions on record.

QUESTION	MARKS	ASKED
Enumerate the indications for electroconvulsive therapy and discuss the strength of the evidence behind each, including its place in the psychiatric emergency.	10	Representative
Describe the pre-electroconvulsive-therapy workup and the anaesthetic conduct of a modified treatment, including the muscle relaxant and the situations in which the usual agent must not be used.	10	Representative
Electrode placement in electroconvulsive therapy. Compare bilateral with right unilateral placement on efficacy and on cognitive cost, stating the dose at which each comparison holds.	10	Representative
Define the seizure threshold, describe how it is measured, and explain how the treatment dose is set against it and judged adequate.	10	Representative
Modified against unmodified, that is direct, electroconvulsive therapy, and the Indian legal position on the direct technique. Short note.	*5*	Representative
Cognitive adverse effects of electroconvulsive therapy. Distinguish anterograde from retrograde amnesia, give the course of each, and discuss whether the retrograde deficit persists.	10	Representative
Complications of electroconvulsive therapy other than the cognitive ones, and their management in the suite and in the recovery room.	10	Representative
Consent for electroconvulsive therapy under the Mental Healthcare Act: the lawful routes, the advance directive, and the position of a minor.	10	Representative

QUESTION	MARKS	ASKED
Electroconvulsive therapy in pregnancy. Short note.	*5*	Representative
Electroconvulsive therapy in the elderly patient. Short note.	*5*	Representative
Discuss the frequency and number of electroconvulsive therapy sessions in an acute course, how response is judged, and what ends the course.	10	Representative
Continuation and maintenance electroconvulsive therapy. Short note.	*5*	Representative
Drug interactions and concurrent medication during a course of electroconvulsive therapy. Short note.	*5*	Representative
Mechanism of action of electroconvulsive therapy. State the principal neurobiological hypotheses, the observations each rests on, and what each fails to explain.	10	Representative
Repetitive transcranial magnetic stimulation: principle, the motor threshold, stimulation parameters, indication and adverse effects.	10	Representative
Transcranial direct current stimulation. Short note.	*5*	Representative
Vagus nerve stimulation in treatment-resistant depression. Short note.	*5*	Representative
Deep brain stimulation in psychiatry: the targets by indication, the evidence from the sham-controlled trials, and the Indian regulatory and legal position.	10	Representative
Psychosurgery: history, the current procedures and their indications, and the ethical and statutory constraints on the operation today.	10	Representative
Magnetic seizure therapy. Short note.	*5*	Representative

The shape of these questions is worth reading before their content. A ten-mark question that opens with enumerate, describe or compare wants a structured map rather than a definition, and the marks are won on the discriminations this chapter turns on: the difference between an indication and a lawful route, the difference between a definition and a permission, the difference between speed of response and efficacy, and the difference between a device classification and an indication-specific authorisation. A short note carries fewer marks and the same demand for the exact figure with the document that states it, because a device specification is that device's, a guideline threshold is that guideline's, a formula holds only inside the parameter set it was derived in, and a trial's parameters travel as a tuple with their protocol and their indication. Two habits earn marks across the whole list. Say which parameter is in front of you before stating any trade, since placement, stimulus dose, treatment frequency, pulse width and anaesthetic conduct each carry their own relation and none inherits another's. And name the Act's provisions in words, because a candidate who reprints a section number he has not read is doing the one thing this chapter is examined to prevent.

The quick review

One table, read down the left column and cover the right. Every line is taught in full somewhere above and nothing here is new: each is that topic's single must-hold line, so a line you cannot recover is a topic to reread rather than a fact to memorise here. Four things are load-bearing across the chapter. Every figure travels with the document that produced it: a specification, a threshold, a formula and a trial's parameters hold only inside the protocol they came from. There is no chapter-wide law about efficacy and cognitive cost: the direction and the size of any such trade differ by parameter and by placement, and several choices are not trades among those three at all, airway management and monitoring being done because they are correct. An indication is never an authority, so a lawful route is established separately and urgency changes the timetable, never the route. The Mental Healthcare Act's provisions are named in words throughout and never renumbered here. Where the Indian guideline and a foreign college guideline differ, both are printed with their body and their year.

ASK	HOLD
ELECTROCONVULSIVE THERAPY: FOUNDATIONS AND INDICATIONS	
MEDUNA, AND THE CHEMICAL ERA	An inverse relationship between seizures and schizophrenia, from a lack of glial cells in schizophrenia against an overgrowth in epilepsy: the founding premise, and it did not survive. Camphor in oil, then cardiazol; the era ended not on efficacy but on the unpredictable interval between injection and seizure.

ASK	HOLD
CERLETTI AND BINI, AND THE DECLINE	First electrical induction in a psychotic patient, Rome, April 1938, reported August 1939 at Copenhagen; the Central Institute of Psychiatry, Ranchi, followed, cardiazol in 1938 and electroconvulsive therapy in 1943. The mid-century fall was part earned, by regressive treatment to a deliberate acute brain syndrome, and part not, running well past those abuses.
THE MECHANISM: REGISTER AND HYPOTHESIS	Nobody has established how it works and no single mechanism should be assumed, so naming the anticonvulsant hypothesis as the mechanism contradicts the literature; low-dose right unilateral seizures lacked antidepressant efficacy, so seizure induction may be necessary but insufficient. That hypothesis is a postictal prefrontal inhibitory surge which terminates the seizure and enhances GABAergic function, and it does not cover efficacy outside depression.
THE TWO BIOMARKER ACCOUNTS	Neuroendocrine: a transient adrenocorticotrophic hormone, cortisol and prolactin rise, back to baseline in hours, so evidence of delivery rather than mechanism. Neurotrophic: hippocampal volume rises with session number, but greater enlargement went with worse outcome and volumes returned by six months, so not a biomarker of response.
DEPRESSION: INDICATION, EFFECT SIZES, SPEED	First line for a severe episode with psychotic features, catatonia, high suicide risk, or food or fluid refusal; second line where it has not responded to psychotherapy or medication. Effect sizes minus 0.91 against simulated treatment and minus 0.80 against pharmacotherapy, the negative sign being the direction of benefit. Suicidality fell to zero in 38.2 per cent after three treatments and 80.9 per cent by the end, so consider it earlier than its last-resort position.
CATATONIA, MANIA, SCHIZOPHRENIA: TRUE STRENGTH	Catatonia: response 80 to 100 per cent, including after benzodiazepines have failed, but on retrospective observational studies, the strongest indication on the weakest design. Mania: remission or marked improvement in 80 per cent. Schizophrenia: moderate-quality Cochrane evidence added to standard care, risk ratio 2.06; clozapine-resistant response 53.6 against 25.4 per cent, remission 13.3 against 3.7, so response is common and remission is not.
THE EMERGENCY, AND THE AUTHORITY WITHHELD	The treatment can be clinically indicated in an emergency, and the Act's emergency-treatment provision cannot authorise it, because that provision expressly excludes electroconvulsive therapy from the treatment it permits. Both are true: a lawful route is established separately, and no emergency doctrine supplies the authority the Act withholds.

ASK	HOLD
CONTRAINDICATION: TWO POSITIONS WITH THEIR DATES	Position one, the modern task-force position: no absolute contraindications, reaching the page through an anaesthesia review of 2022 citing the consensus statement of 2001. Position two, standard in Indian teaching: raised intracranial pressure with a space-occupying lesion, Maltbie 1980, on Carter's chain of rising cerebral blood flow, oedema and pressure. Both printed, neither graded above the other; routine neuroimaging is not mandatory, bedside fundoscopy is.
ELECTROCONVULSIVE THERAPY: TECHNIQUE AND DOSE	
THE EVALUATION, THE FAST AND THE MORNING LIST	As close to the course as possible, because a workup done weeks earlier certifies a patient who no longer exists; examination-led, the blood panel not mandatory and imaging indication driven. Fasting 2 hours from clear liquids, 6 from milk and light meals, over 8 from fried or fatty food. Cerebral oxygen consumption rises almost 200 per cent, so 100 per cent oxygen from 1 minute before induction until breathing resumes. Antihypertensives, thyroxine, antianginals and bronchodilators are not withheld.
SUCCINYLCHOLINE, WHAT BARS IT, AND RESTIMULATION	Blockade in about 1 minute, MAXIMUM blockade about 2, recovery in 4 to 6; the dose is the anaesthetist's. The under-dosing warning belongs to MIVACURIUM, where trimming to shorten its longer block is the temptation, and a dose trimmed there buys an unmodified convulsion under a patient who looks paralysed. Three mechanisms bar it: potassium efflux from abnormal muscle, deficient plasma cholinesterase, malignant hyperthermia. Prophylactic anticholinergics are not routine, and bradycardia is commoner after a second dose of relaxant, so a restimulation is a cardiac event.
BILATERAL IS A CLASS, AND THE LANDMARKS	Bilateral has three members, bitemporal, bifrontal and left anterior right temporal; bitemporal is one member, not a synonym for the class. Bitemporal: one inch above the outer canthus to external auditory meatus line. Right unilateral, d'Elia: right frontotemporal and 1 inch right of the vertex. Bifrontal: 2 inches above the outer canthus.
WAVEFORM, THE DISPUTED BAND, AND COGNITION	A brief or ultrabrief pulse with a constant current device is strongly recommended. The two GUIDELINE brief-pulse bands agree at 0.5 to 2 ms, and that agreement is bounded to them, a meta-analytic band of 0.5 to 1.5 ms also appearing in the chapter; ultrabrief does not agree at all, 0.2 to 0.4 ms in the Indian guideline of 2023 against 0.25 to 0.3 in the college guideline of 2019. Broader widths carry worse cognitive effects, and 0.3 ms has a cognitive advantage with right unilateral placement though efficacy may be compromised.

ASK	HOLD
THE FOUR PARAMETERS, AND WHY CHARGE IS NOT THE DOSE	Charge is current intensity multiplied by pulse width, frequency and train duration, but charge as the chief measure of dosing is faulty: equal charge from different parameters is a different stimulus. Intensity is held constant during incrementation, train duration is what moves, and lower frequencies are the more efficient.
IMPEDANCE, AND MONITORING THE SEIZURE	Static impedance is read before stimulation, dynamic during it; on one named device static should be above 100 and below 3000 ohms, too low meaning the current found a path that is not the patient, too high that it will struggle to find one. Monitoring is three records of one event, cortical, muscular and cardiac, with the Hamilton cuff isolating a limb from the relaxant.
THE SEIZURE THRESHOLD, AND THE RANGE	The lowest electrical dose eliciting seizure activity, electroencephalographic and motor. Found only by producing a response, not transferable across pulse widths, and a floor rather than a treatment, which is why the prescription is a multiple of it. A 12-fold range across 52 titrated patients, 40-fold across the wider literature: neither is the number.
FOUR DOSING METHODS, AND THE FORMULA'S ERROR	Stimulus titration in regular practice; formula-based methods guide its first dose rather than substitute for it; fixed high dosing for serious medical comorbidity. Half-age formula: half the chronological age as the percentage of charge on one device family, the device clause being part of the formula. Estimates averaged 18 per cent above the empirical THRESHOLD, which is the authors' own summary figure and sits outside the quoted passage, and matched the titrated TREATMENT level in only 14.7 per cent. Two benchmarks, not two directions of one error.
THE MULTIPLE DIFFERS BY PLACEMENT, AND THE THRESHOLD RISES	Right unilateral dose-response is steep, needing markedly suprathreshold dosing, while bilateral efficacy arrives marginally above threshold. The right unilateral brief-pulse cell is disputed, 4 to 6 times threshold in the Indian guideline of 2023 against five to six in the college guideline of 2019, and averaging invents a figure neither states. The threshold rises across a course, about 47 per cent on average but in only 56 per cent of patients.
RESTIMULATION BY KIND, AND THE ADEQUATE SEIZURE	A missed seizure is no seizure at all: nothing motor or electroencephalographic 20 seconds after the stimulus, restimulate at an increased dose. An inadequate seizure happened but was not good enough, and the delay is disputed, 45 seconds in the Indian guideline of 2023 against 60 to 90 in the college guideline of 2019. Quality matters more than duration: the earlier 15 and 25 second definition is of little prognostic benefit, so the question is demoted, not re-answered.

ASK	HOLD
BILATERAL AGAINST RIGHT UNILATERAL, BY MULTIPLE	As a ranking the comparison is memorable and clinically false; as a function of the multiple of threshold it is correct. Right unilateral 17 per cent at a low dose against 43 at 2.5 times threshold, while bilateral was 65 against 63; at a high multiple both reached 65 per cent. They converge toward one another, with no superiority of right unilateral established anywhere.
WHAT THE HIGHER MULTIPLE COSTS, AND ITS LIMIT	Some, but not all, of the cognitive advantage is lost when right unilateral is dosed to equal bitemporal efficacy: erosion, not abolition. Two domains survive, reorientation time and retrograde autobiographical memory. The unilateral efficacy evidence exists only for depression, so carrying the argument to schizophrenia or mania exceeds it.
UNMODIFIED, THAT IS DIRECT, TREATMENT: THE INDIAN POSITION	The statute prohibits electroconvulsive therapy given without muscle relaxants and without anaesthesia, so the modified form is the only lawful form and the direct technique is unlawful, not merely inadvisable. No degree of urgency turns it into something a clinician is entitled to weigh. The provision is named in words and never renumbered. Filing that statutory bar under clinical advice, as though the question were which technique is safer, is one of the five answers this chapter punishes.
WHAT MODIFICATION MODIFIES, AND ITS ONE GAP	Three steps: the motor seizure injures muscles, joints, teeth and bones; it is irrelevant to the therapeutic action; so a relaxant given after the anaesthesia abolishes it. The middle step carries the argument, and the cerebral seizure is untouched. The masseter is stimulated directly rather than through the junction the relaxant blocks, which is why bite blocks and jaw immobilisation still matter.
ELECTROCONVULSIVE THERAPY: EFFECTS, CONSENT AND COURSE	
THREE PHENOMENA ON THREE CLOCKS	Minutes for postictal confusion, orientation back within 5 to 45 minutes; days to weeks for anterograde amnesia; months, and contested, for retrograde. One clock never tells the time on another. The anterograde deficit is significant at 0 to 3 days, recovered by 15, and domain-specific rather than global.
RETROGRADE AMNESIA, AND WHAT STAYS CONTESTED	Hard to measure objectively, so a normal bedside screen does not exclude it; a temporal gradient, personal events within about 6 months rather than the distant past. Brief pulse, unilateral placement and titration each reduce autobiographical loss. Persistence stays contested: standardised mean difference 0.55 against controls, unchanged at 6 to 12 months, while the recovery meta-analysis pooled no standardised retrograde tests. At least one third of patients report persistent loss, so subjective assessment counts alongside objective.

ASK	HOLD
THE CARDIOVASCULAR SEQUENCE, AND THE PROLONGED SEIZURE	Parasympathetic first, 10 to 15 seconds of vagal outflow in the tonic phase with bradycardia and occasional asystole, then the sympathetic surge in the clonic phase, peaking at 1 minute. About 2 per cent of patients have a major adverse cardiac event, roughly 1 per 200 treatments. Prolonged means beyond 180 seconds while termination can be attempted beyond 120: a definition and a permission, and collapsing them loses the mark.
POSTICTAL AGITATION, THE TARDIVE SEIZURE AND THE JAW	Agitation: 13.9 per cent at patient level, 18.0 once studies at high risk of bias are removed, which is the authors' recommended figure, with no validated predictor among 7 factors. A tardive seizure comes within hours, after recovery, and may be non-motor. Temporomandibular dislocation happens under modification because those muscles are stimulated directly.
WHAT THE ACT MEANS BY INFORMED CONSENT	Consent for a specific intervention, without force, undue influence, fraud, threat, mistake or misrepresentation, after adequate information including risks, benefits and alternatives, in a language and manner the person understands. It is intervention-specific, so a general admission consent is not consent to this, and the alternatives limb is the one most often dropped.
TREATMENT AUTHORITY IS NOT ADMISSION AUTHORITY	The second half of the emergency error, and the more often lost. Assuming that because the emergency-treatment provision is closed the patient must first be admitted inverts the position: a capacitous adult can consent to this treatment with no admission at all. Urgency changes the timetable, never the route.
THE LAWFUL ROUTES, AND THE ADVANCE DIRECTIVE	His own consent first, on a presumption of capacity that a decision others think wrong does not rebut. Where capacity is absent: the advance directive first, then his own consent supported by his nominated representative, and only where he needs nearly total support may that representative temporarily consent. A valid directive is a duty on the treating psychiatrist, with no bedside-override, urgency or senior-clinician limb, so the route out of a refusal is an application to the Board.
THE MINOR'S GATE, AND RE-CONSENT	Below eighteen there is no capacity to consent, the legal guardian being the nominated representative unless the Board orders otherwise. Two limbs bind, the guardian's informed consent and prior permission of the concerned Board, with no clinical discretion; assent and two independent psychiatrists are professional additions, not statutory. Re-consent runs on triggers, not intervals: capacity returning, a minor attaining eighteen, and before continuation or maintenance. Refusal and withdrawal carry the best available alternative treatments without prejudice.

ASK	HOLD
PREGNANCY AND THE ELDERLY	Pregnancy: most applicable in the second and third trimesters, with left lateral tilt, routine anticholinergic premedication avoided and cardiotocography around each session. Causation is unsettled, and in the Swedish cohort the comparator decides the answer, premature delivery significant against one control group and not the other. The elderly run the other way: older age predicted remission and response, so preferentially good candidates rather than merely tolerable ones.
TREATMENT FREQUENCY BUYS SPEED, NOT EFFICACY	The acute course runs 2 to 3 sessions per week, spaced evenly. Two double-blind trials and their joint synthesis settle it: end-of-course antidepressant effect was equal, while the thrice-weekly schedule induced more severe memory impairment. The cost belongs to the spacing, not to receiving more treatments. Where rapid improvement is warranted the faster schedule may be preferred, both being equally efficacious, the slower one priced at roughly 4.8 to 6.5 days longer. Writing the faster schedule as the stronger one is one of the five answers this chapter punishes.
THE ACCELERATED SCHEDULE, AND WHAT BUYS IT	In malignant catatonia, bilateral treatments daily or twice daily for 3 to 5 days, then conventional frequencies until resolution, 5 to 20 treatments at expert-consensus grade. What buys the extra cognitive cost is mortality: 51 of 54 treated patients survived against 6 of 14 given antipsychotics and supportive care.
HOW MANY TREATMENTS, AND THE MID-COURSE THRESHOLDS	Not predetermined but based on individual need; the task force gives 6 to 12 sessions for depression. Two thresholds must not be merged: technique changes first, unilateral to bilateral or ultrabrief to brief pulse after four to eight sessions without improvement, while failure is declared later, at a minimum of 8 to 12. The United Kingdom handbook is stricter; both are printed. The endpoint is stable remission, not response.
CONTINUATION, MAINTENANCE AND THE INTERVAL PRINCIPLE	Continuation consolidates the index course, maintenance prevents a new episode, the line drawn at 6 months. Over 24 weeks relapse was 84 per cent on placebo, 60 on nortriptyline and 39 on the combination. The taper runs twice weekly to weekly, fortnightly, monthly, never prefixed. What is managed is cumulative exposure and the interval is how: extend it and minimise the cumulative number of treatments.

ASK	HOLD
CONCURRENT MEDICATION, AND THE THREE MOST EXAMINED	Anticonvulsants raise the threshold; chlorpromazine and clozapine are pro-convulsant; lithium raises the risk of postictal delirium; tricyclics raise cardiac risk. An interaction is never one fact: a direction on the seizure, a consequence, a management step. Benzodiazepines raise the threshold, shorten the seizure and decrease potential efficacy, the third mattering most. Theophylline is stopped 24 hours before in the Indian guideline while a second source gives no interval at all.
OTHER NEUROSTIMULATION THERAPIES	
RTMS: SUB-CONVULSIVE BY DESIGN	A high-voltage discharge drives a coil, producing a time-varying magnetic field of 1 to 2.5 Tesla under about 1 millisecond; parameters are chosen to minimise seizure risk, so a seizure here is an adverse event, not the mechanism. At therapeutic intensity it does not produce the amnestic syndrome that follows an induced generalised seizure, because it induces none, while an unintended seizure can still occur: the absence of the first neither abolishes nor excuses the second.
THE MOTOR THRESHOLD, FREQUENCY, COILS AND TARGETING	Rossini criterion: the lowest intensity, as a percentage of maximum stimulator output, inducing a motor evoked potential in 5 of 10 trials; resting and active thresholds differ, and a threshold read by eye comes out higher, inflating everything derived from it. Protocols divide at 1 Hz, low frequencies reducing excitability and faster ones raising it; the figure-of-eight coil is the most focal, and F3 by head measurement is the most practical targeting.
THE COURSE, THE SEIZURE RISK, AND THE CEILING	20 to 30 sessions over 6 weeks are very likely needed for results consistent with the regulatory trials. Seizure risk 7 per 100,000 sessions pooled and 33 at elevated risk. The most recent international update declined to update the safety tables, keeping one ceiling: the parameters used to induce a seizure deliberately must not be exceeded, usually 100 per cent of output at 25 Hz for up to 10 seconds.
TDCS: ENVELOPE, MECHANISM, POLARITY	A family defined by a parameter envelope rather than a mechanism: 4 mA or less, up to 60 minutes, electrodes 1 to 100 square centimetres, 0 to 10,000 Hz. It works by subthreshold polarisation, shifting membrane potentials without causing action potentials, so no step fires a neuron. Anode excites and cathode inhibits is a simplification: every montage is active at both ends, and electrode size is part of the dose.
THE TUPLE, AND A NEGATIVE TRIAL	In DepressionDC, a constant 2 mA for 30 minutes, 24 sessions within 6 weeks, added to a selective serotonin reuptake inhibitor, anode F3 and cathode F4. The investigators state their result plainly: no antidepressant benefit over sham and no difference in neurocognitive change, so the technique bought neither benefit nor cognitive cost.

ASK	HOLD
INDIA: A CLASSIFICATION IS NOT AN AUTHORISATION	The national risk-based list enumerates 131 devices in the Neurological category with no entry for a repetitive transcranial magnetic stimulation system, while electroconvulsive therapy systems, deep brain stimulators and vagus nerve stimulators are listed. That is classification and nothing more, establishing nothing about product licensing or indication-specific authorisation. The Act restricts psychosurgery but nowhere defines it, so whether an implanted system falls inside that restriction does not arrive from the statute's text.
VNS: THE SYSTEM, THE ROUTE, THE TRIAL	The implanted device whose electrode never enters the brain: a pulse generator in a subcutaneous chest pocket, a helical lead on the left cervical vagus. The vagus there is predominantly afferent, running nucleus tractus solitarius to locus coeruleus and raphe and on to limbic structures. In the acute trial 15.3 per cent responded against 10.0 on sham, not significant; approval rested instead on 12 month continuation results compared against a separate observational study.
DBS: THE TARGETS, AND THE WIDTH OF THE FIGURES	Not a reversible lesion but a circuit therapy that replaces a pattern. Obsessive-compulsive disorder: ventral capsule and ventral striatum and nucleus accumbens; depression: ventral capsule and ventral striatum, subgenual cingulate, medial forebrain bundle. Not the same set. Both sham-controlled depression trials failed their primary endpoints, 20 against 17 and 20 against 14.3 per cent, while obsessive-compulsive response ranges from 10 to 61 per cent, so a rate without its target and settings says nothing.
MAGNETIC SEIZURE THERAPY: SETTLED AND OPEN	Magnetic stimulation at parameters chosen to produce a seizure deliberately, under anaesthesia, demanding electroconvulsive therapy infrastructure. Settled: the induced electric field is much lower and much more focal, the site of initiation more restricted. Open: whether the ictus that follows propagates less widely. The guideline's bridge from focality to tolerability is a belief, not a finding.
PSYCHOSURGERY: THE GROUPS, HISTORY AND ABUSE	Lesioning destroys tissue, stimulation delivers current to tissue that remains intact. Moniz with Almeida Lima, 1936, 20 prefrontal leucotomies by free-hand injection of absolute alcohol, substantial improvement in 14 of 20 and apathy, abulia or personality change in others. Three features made it an abuse: indications so loose it was offered where no case existed, delivery outside the operating theatre, and sometimes without a neurosurgeon. Reform ended in Spiegel and Wycis's stereotactic frame.

ASK	HOLD
PSYCHOSURGERY: CURRENT SET, EVIDENCE, ETHICS	Anterior cingulotomy, anterior capsulotomy, subcaudate tractotomy, limbic leucotomy; since 1996 all three cingulotomy lesions per side are made simultaneously. The caveat is half the headline: ablative approaches are not SHOWN inferior to stimulation, response 50 to 60 per cent, but on largely uncontrolled studies with no direct comparative trials: not shown less effective, shown on weaker designs. Ethically acceptable only with strict respect for autonomy, beneficence, non-maleficence and justice; the named consent failure is therapeutic misconception.

References

Every specific in this chapter is bound to one of the sources below, and the count is the number of claim rows each carried. This chapter was grounded from PRIMARY sources read at origin rather than from any textbook or from the repo corpus, and the reason is specific to this chapter: the corpus carries no current guideline for the technique, no device manual and no regulator label, while this chapter's numbers are electrical parameters, anaesthetic doses, device authorisations and statutory provisions, where a textbook paraphrase is not good enough and a stale or summarised figure changes what a clinician does at the machine. Each of the 436 rows carries the verbatim quote it was read from, together with a receipt naming the issuer, the document, the version or year, the jurisdiction and the retrieval date. Four classes of primary source carry the chapter. Current clinical practice guidelines were read at the guideline text, the Indian Psychiatric Society guideline of 2023 controlling Indian practice questions and the Australian, South Australian, United Kingdom and international bodies printed beside it with their own bodies and years wherever they diverge, the divergences being recorded and not averaged. Regulator records were read at the regulator, meaning device approval and classification records and product labelling, and a classification is reported as a classification, never as an indication-specific authorisation, and never read across from one jurisdiction to another. Trial reports, meta-analyses and reviews were read at the published article rather than at a summary of it, so that a population, a comparator and a confidence interval travel with every effect size. And the statutory rows were read at the bare Act, on India Code and at the Legislative Department text, because a provision is what decides whether a lawful route exists; the Act's provisions touching this treatment are named in words throughout the chapter and never renumbered, their numbering belonging to the Mental health legislation and forensic psychiatry notes. Of the 436 claim rows, 319 are recorded at verified confidence and 117 at partial, the latter authored from established clinical knowledge or from a source read at abstract or at second reporting and checked by the adversarial content pass rather than bound to a single primary quote at origin; 4 rows are carried forward from the Mental health legislation & forensic psychiatry notes with their reuse declared on the row. Where a specific could not be grounded it was declared as a gap in the prose and taught around rather than supplied from memory, which is why several passages state plainly that no figure exists. The must-have-papers cross-check was NOT performed for this Paper III chapter,

because the paper lists do not yet exist in the intel index; for Paper III the topic bank plus the syllabus scaffolding, together with the inbound-promise sweep of the built corpus, is the completeness authority. This table records provenance, not proof: it says where each specific came from, not that the chapter's prose uses it correctly, which the content pass and the ship review test.

PAPER III

Perinatal and women's mental health, and emergency psychiatry

Eight bands . one complete notes document

Orientation: two doors, one patient

1 · Orientation: two doors, one patient

This chapter has two doors, and one patient walks through both. The first is the door of the antenatal clinic, the labour room and the postnatal ward, where the question is rarely whether a woman is unwell and almost always what may safely be done about it while she is carrying or feeding a child. The second is the casualty door at two in the morning, through which a patient arrives rigid, or confused, or fighting the people holding him, and through which no diagnosis has yet arrived. The chapter is built on the fact that the same woman can come through the second door weeks after leaving the first, and that nothing about the first door's caution is suspended when she does.

What follows is an **advance organizer** rather than a summary. It asserts no figure of its own, because every figure in this chapter belongs to the section that owns it, and it describes no syndrome, because not describing syndromes is the whole design. What it owns is the shape: the decision the chapter is organised around, the two seams that run through its halves, the order in which it runs, and the map of what it deliberately does not carry. The accompanying figure sets out the same architecture visually.

The act	The setting	The first hour	Two patients
WHAT EVERY SECTION HERE TEACHES, FROM THE FIRST MINUTE TO THE HANDOVER	WHERE IT IS DONE, ON WHOSE AUTHORITY, AND WHERE THE PATIENT GOES NEXT	THE SEAM RUNNING THE LENGTH OF THE EMERGENCY HALF OF THIS CHAPTER	THE SEAM RUNNING THE LENGTH OF THE PERINATAL HALF OF THIS CHAPTER

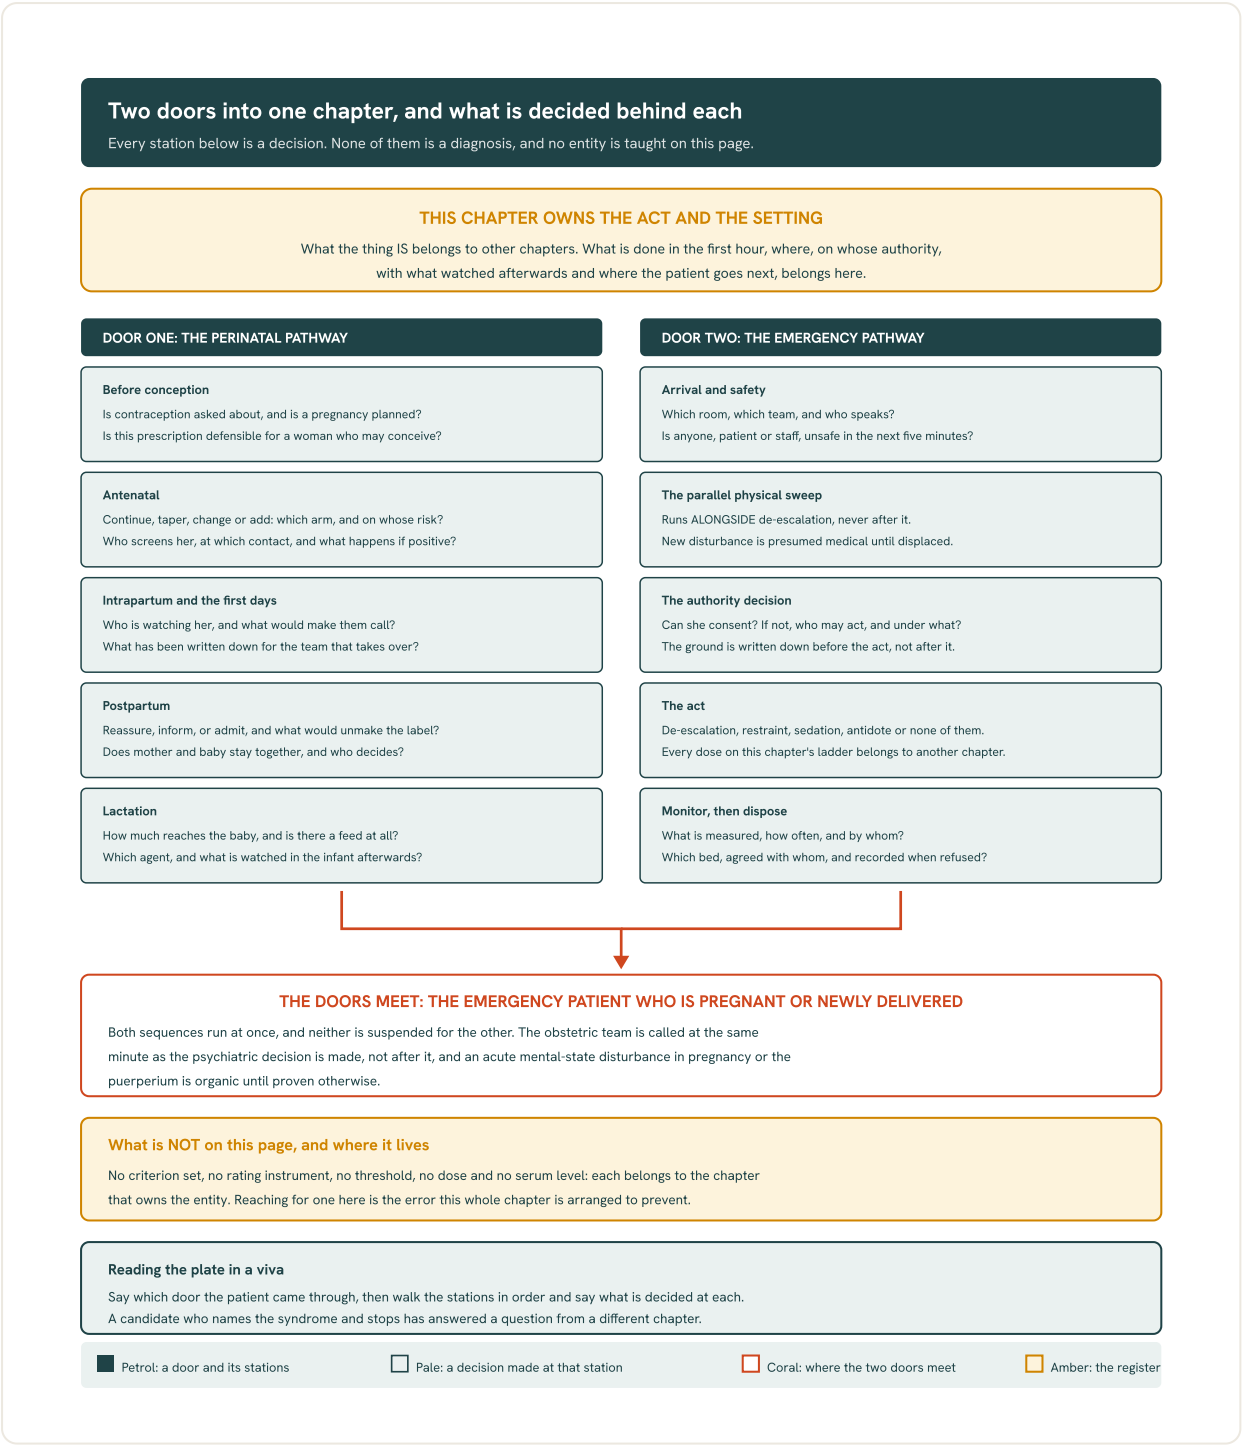

Fig 28.1. The chapter drawn as two doors the same patient may come through, the perinatal pathway from before conception to lactation set against the emergency pathway from arrival to disposition, with every station stated as a decision rather than as an entity, the point at which the two sequences run together in the pregnant or newly delivered emergency patient marked, and the criteria, instruments, thresholds and doses that belong to other chapters named as absent.

1.1 The decision this chapter is organised around

Almost everything named in this chapter has already been taught elsewhere, and taught properly: with its clinical features, its differential, its pathophysiology, its drug treatments and their doses. That body of work is the **entity**. What a syndrome is, what it looks like at the bedside, how it is told apart from the things it resembles, and which agent shifts it, all of that belongs to the chapters that own each disorder, and none of it is repeated here.

This chapter owns the other half, which nothing has yet carried. It is the **act** and the **setting**: what is done in the first hour, where it is done, on whose authority it is done when the patient cannot agree or will not, and where the patient goes afterwards. Reduced to a single contrast, the other chapters answer the question *what is this?* and this one answers *what do I do about it, here, tonight, and who allows me to?*

That division is not a compromise and it is not a shortage of material. It is the harder half of the question, and it is the half that is examined badly and practised badly. A registrar who names a hyperthermic drug reaction correctly and then leaves the patient on an open psychiatric ward has the entity right and the setting wrong, and it is the second error the patient carries. A woman whose antidepressant is stopped for exactly the right reason and in exactly the wrong manner is harmed by the manner. The **disposition** decision, the monitoring cadence, the authority question and the handover are where emergency and perinatal psychiatry are actually won or lost, and they are the content of this chapter.

RULE **Every section here answers what is done, where, on whose authority and where the patient goes next. None of them answers what the thing is.** Hold that while you read, because it decides what counts as a complete answer in this material. A section that says little about a disorder you already know is not thin; it has been written on the assumption that you know it, and everything it does say is content its owning chapter does not carry. The corollary is the one that costs marks. If you can describe a syndrome in this chapter but cannot say who you would call, what you would check before sedating, how often it would be checked afterwards and which bed the patient would be in at dawn, you have read the wrong half of the material.

1.2 The first hour, and how the emergency half is held together

Every emergency in this chapter is entered through one sequence. Recognise that something is wrong, make the patient and the room safe, establish who has the authority to act on someone who cannot consent, act, monitor what the act has done, and decide where the patient goes. That sequence is **the first hour**, and it is the seam that runs the length of the emergency half.

It is set out in full by the section on the assessment and management of the acutely agitated and aggressive patient, which owns it. Every other emergency section names it and enters it at a different point rather than restating it, and knowing where your section enters is most of what makes this half quick to read. The rigid, hyperthermic and toxidromic sections enter at the act, because recognition has happened elsewhere and their question is what the recognition selects. The sections on observation, monitoring and restraint occupy the stretch after the act, which is the stretch most often skipped. Triage and disposition own the two ends.

Two properties of the seam are worth carrying from the start. The first is that it is not a checklist to be worked through and ticked; the sections that own its steps will show you where two of them are meant to be running at the same time. The second is that establishing authority is a clinical step and not paperwork appended afterwards. It has a statutory frame, that frame is Indian, and it is taught in full by the Mental health legislation and forensic psychiatry notes and by the Forensic ethics, consent and legal procedure notes. What this chapter teaches is the decision itself: who is asked, what is recorded, and what is done when there is nobody available to ask.

1.3 The two-patient problem, and how the perinatal half is held together

The perinatal half has a seam of its own, and it is easier to state than to apply. Every decision in it is made for two people at once. That is **the two-patient problem**, and the framework for reasoning through it is set out by the section on prescribing psychotropics in pregnancy, which owns it; the remaining perinatal sections state which two patients their own decision is for and then get on with the decision.

Two things about the frame are worth fixing before you meet it. The first is that the second patient changes identity as the chapter moves: a fetus while she is pregnant, an infant at the breast while she is feeding, a relationship while that relationship is still forming, and, on the night she is acutely unwell, a baby who needs a named adult holding him. The second is that doing nothing is not the neutral option against which the others are scored. Untreated illness is itself one of the exposures being weighed, and the section that owns the framework builds that in from the first line rather than adding it as a caveat at the end.

GOOD TO REMEMBER

The four questions above are the ones this chapter answers, and they are worth carrying as questions rather than as an acronym: what is done now, where it is done, on whose authority, and where the patient goes next. A fifth runs the length of the perinatal half and is asked of every one of the other four, which is who else is the patient. The chapter's own memorable spine is cashed in at the close, built from what the sections actually taught, and it is not seeded here.

That is also why the sections ahead spend their space on sequence, cadence, authority and destination: those are the things rarely written down anywhere, and asked for every time. Four habits make the chapter read as one argument rather than as thirty-one:

- read every section for what it INSTRUCTS, and take the entity it names on trust from the chapter that owns it;
- where a section names another account by description, go and read that account before answering on the point it hands over;
- treat a declared gap as a finding rather than as an omission, because a stated absence is what stops a remembered number being written in;
- and hold the fifth question, who else is the patient, open across the whole perinatal half rather than asking it once.

Every section in this chapter answers four questions and leaves the fifth to the chapter that owns the disorder: what is done now, where it is done, on whose authority, and where the patient goes next. In the perinatal half all four are answered twice over, because two patients are in front of you; in the emergency half they are answered as one sequence, from the door to the handover.

Prescribing and treating in pregnancy and lactation

2 · Prescribing psychotropics in pregnancy (risk categories, teratogenicity)

Every prescription written in pregnancy is written for two patients, and only one of them can be asked what she wants. That asymmetry is the whole of the difficulty, and it is why this decision behaves unlike any other prescribing decision in psychiatry. Candidates prepare the topic as a list of safe and unsafe drugs and then answer the wrong question, because what is actually being examined is not a list. It is a method for reasoning about an exposure whose harm is uncommon, delayed, hard to attribute to any one cause, and measured against a background that was never zero. Get the method right and the agent-level figures become usable. Get it wrong and no quantity of memorised percentages will rescue you, because you will not know what any of them are percentages of.

The topic also carries a piece of currency that Indian teaching has been slow to absorb. The pregnancy risk categories that a generation of candidates learned as a five-rung ladder are no longer the labelling scheme they were drawn from, and a chapter written now has to say so with a date attached rather than quietly reprint the grid. Presenting the withdrawn system as current practice is the commonest way this topic is got wrong in print, and it is worth understanding why the regulator abandoned it, because the reasons are themselves the teaching.

Owned here in full: the two-patient frame that governs every perinatal decision in these notes; the withdrawn letter system and the labelling rule that replaced it; the general teratogenicity framework, meaning critical periods, background risk, and absolute against relative risk; kinetic change across the trimesters and its postpartum reversal; the pre-conception conversation; and the record a shared decision leaves behind. Named once and not re-derived: the agent-level malformation figures for individual mood stabilisers and antiepileptics, which belong with the agents in the Mood disorders: pharmacotherapy notes; electroconvulsive therapy in pregnancy, which belongs to the ECT and neurostimulation notes; and the milk-side exposure metric, defined in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and applied in the breastfeeding topic of these notes.

2 to 4 per cent
BACKGROUND MAJOR BIRTH DEFECT RATE THE REGULATOR CALLS A REASONABLE REPRESENTATION, IN DRAFT GUIDANCE

15 to 20 per cent
BACKGROUND MISCARRIAGE RATE REPORTED IN CLINICALLY RECOGNISED PREGNANCIES, SAME DRAFT GUIDANCE

3 to 16 weeks
POST-CONCEPTION, THE MOST CRITICAL PERIOD FOR BRAIN DEVELOPMENT, LONGER THAN ANY OTHER ORGAN

up to 330 per cent
RISE IN LAMOTRIGINE CLEARANCE IN PREGNANCY, THE CLEAREST WORKED EXAMPLE OF TRIMESTER KINETICS

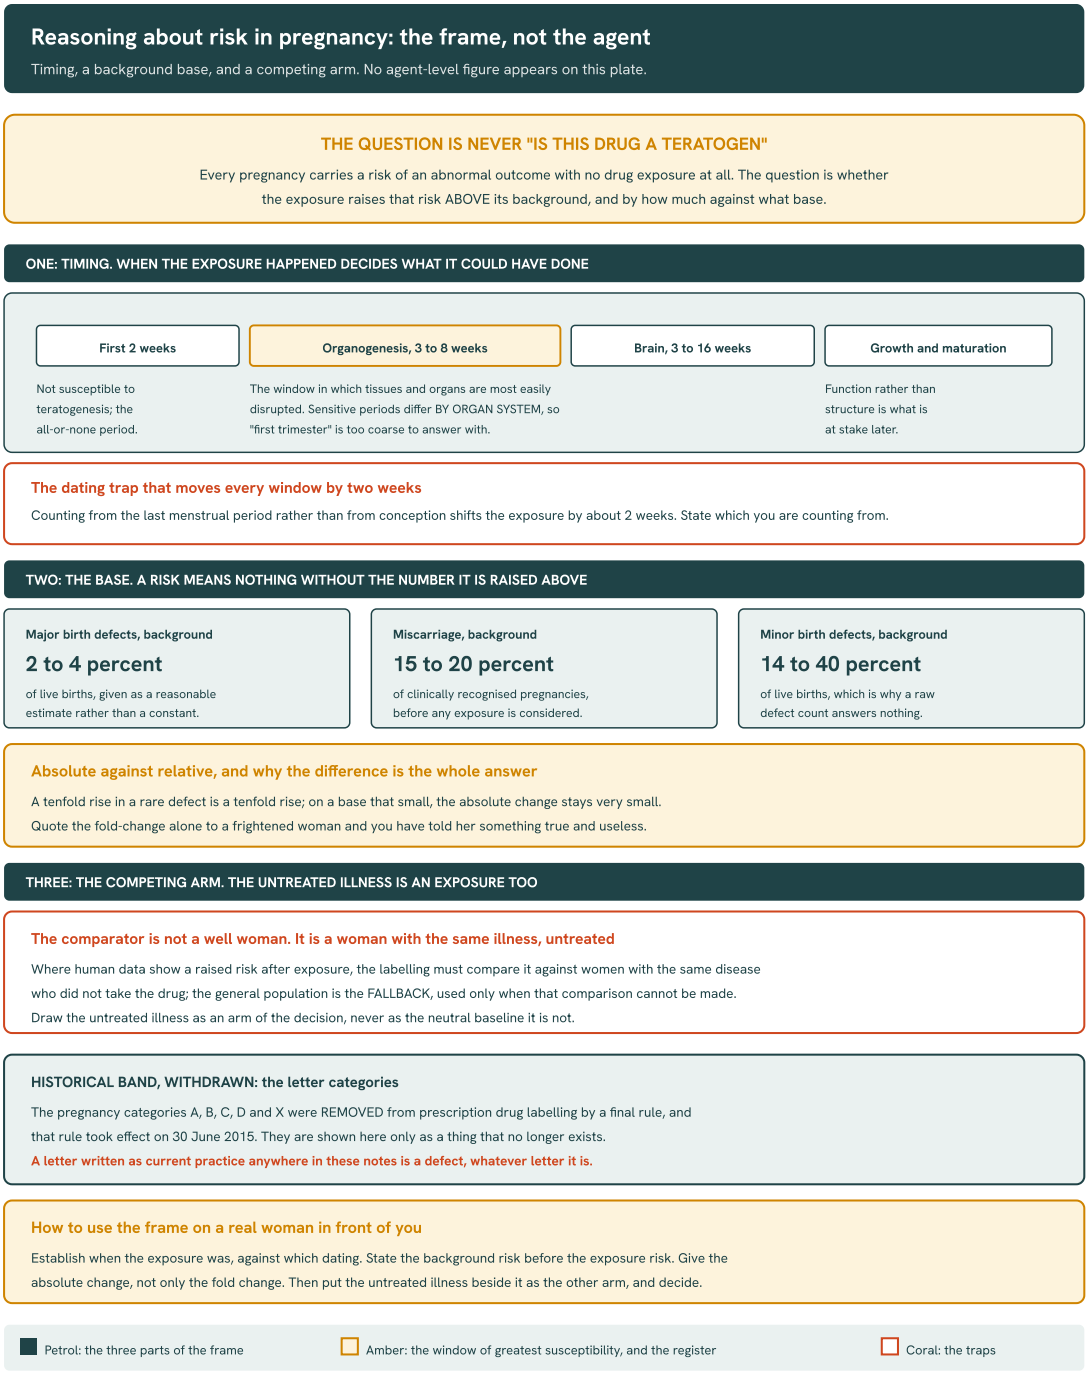

Fig 28.2. The general frame for reasoning about drug risk in pregnancy, drawn in three parts: the critical periods set against gestational age with the dating offset that moves all of them, the background rates of major and minor birth defects and of miscarriage that any exposure risk must be read against, and the untreated illness drawn as a competing arm rather than as a neutral baseline, with the withdrawn letter categories shown only in a dated historical band and labelled as removed.

2.1 Two patients, and the arm that has no drug in it

Start where the arithmetic starts. A woman with a serious mental illness who stops her medication has not moved into an unexposed condition. She has moved from one exposure to a different one, and the second is no better characterised than the first. The American College of

Obstetricians and Gynecologists states this as a recommendation rather than a sentiment in its clinical practice guideline on the treatment and management of mental health conditions during pregnancy and postpartum, issued in 2023: consider untreated or inadequately treated mental health disorders **an exposure**, and recognise the risks associated with inadequate treatment alongside the perinatal risks of any psychopharmacologic agent. Read that twice, because it inverts the way the question is usually asked in an outpatient department. The default framing puts the drug on trial and treats no-drug as the neutral condition. The guideline puts both arms on trial.

This is not a soft principle, and that surprises people. It is written into the labelling regulation itself. Where human data indicate an increased risk of a specific adverse developmental outcome after exposure in pregnancy, the United States regulation on labelling for use in specific populations requires that risk to be quantitatively compared with the risk of the same outcome in infants born to women who were not exposed to the drug but who have the disease or condition the drug is indicated to treat. The comparator the regulator mandates is the untreated ill woman, not the healthy population. Only when risk information for women with that condition is unavailable does the regulation permit the fallback of comparing with the rate at which the outcome occurs in the general population, and that fallback is explicitly second best, used because the better data are missing rather than because the healthy population is the right yardstick.

The same regulation carries the untreated illness onto the label as a required element rather than leaving it to the prescriber's conscience. Under clinical considerations, labelling must describe **any serious known or potential risk to the pregnant woman or to the embryo or fetus associated with the disease or condition for which the drug is indicated**. So when you open a current label to answer a woman's question about her medication, the document is built to tell you two things, not one: what the drug may do, and what her illness may do if it is left to run. Most clinicians read only the first half, which is precisely how a counselling conversation ends up numerically lopsided while feeling scrupulously cautious.

RULE **There is no unexposed arm in this decision, only two exposures.** The woman in front of you will carry either drug exposure or illness exposure, and usually some of each. Any counselling that quantifies one arm and leaves the other qualitative is not balanced counselling, however carefully the drug numbers are quoted. When you cannot quantify the illness arm, say so out loud rather than letting silence stand in for safety, because a number beside a blank always wins the argument.

2.2 The pregnancy risk categories, dated at both ends

Now the historical instrument, taught as history and dated on the page. The United States Food and Drug Administration adopted a pregnancy category system in **1979** to convey risk and benefit information about potential or documented human teratogenic risk and the potential maternal and fetal benefits of drug treatment in pregnancy. Under those regulations each drug product was identified with a pregnancy category: A, B, C, D or X. That is the grid Indian question banks still test, and it is the grid that no longer exists in current labelling.

It was dismantled deliberately. A final rule on the content and format of labelling for human prescription drug and biological products, referred to by the agency as the **Pregnancy and Lactation Labeling Rule**, requires the removal of the pregnancy categories A, B, C, D and X from all human prescription drug and biological product labelling. Removal is mandatory and it reaches all such labelling rather than only newly submitted products. The rule is effective **30 June 2015**, and that is the date from which the letter system ceased to be the applicable labelling scheme going forward. A system born in 1979 and struck out with effect from 2015 is a historical object, and it should appear in your answer with both of those dates attached or not at all.

What replaced it is a change of form, not a change of stringency. The agency's stated position is that **a narrative structure** for pregnancy labelling, rather than a category system, is best able to capture and convey the potential risks of drug exposure based on animal or human data or both. Concretely, the rule replaces the old subsections on pregnancy, nursing mothers, and labor and delivery with three subsections entitled Pregnancy, Lactation, and Females and Males of Reproductive Potential. A letter has become a description of the evidence, which is harder to memorise and far harder to misuse.

Two boundaries are worth holding, because both are commonly misstated. First, the letters never covered breastfeeding: the agency records plainly that the categories were not used to characterise the risks and benefits of drug treatment by lactating women. Anyone who quotes a lactation letter category is quoting something that never existed. Second, the instrument governs prescription products only. Labelling for over-the-counter medicines does not change, and over-the-counter drug products are not affected by the final rule, which matters in a country where a great deal of what a pregnant woman actually swallows was never prescribed to her.

The disappearance was staggered rather than instant, and this is where a confident single date would be an invention. Products submitted after the effective date use the new format immediately, while labelling for prescription drugs approved on or after 30 June 2001 is phased in gradually. For an application not subject to the earlier physician labelling rule, and therefore not required to adopt the new narrative content at all, the holder must still remove the pregnancy category from its labelling within 3 years after the rule's effective date. For an application that is subject to that earlier rule, the category is not removed until the product's labelling is revised into the new format, which may fall more than 3 years after the effective date. The letters therefore left product by product on a staggered schedule. No single calendar day on which every letter vanished can be quoted from the rule, and this account does not supply one.

TRAP **Answering a pregnancy prescribing question by reciting a letter.** Candidates do it because the grid is compact, memorable and still printed in old question banks, and because a single character feels like an answer. It is not an answer now and it was not a good one then. If a question asks for the category of an agent, the mark is in naming the system, dating its withdrawal, naming the narrative labelling rule that replaced it, and then reasoning about the actual evidence. A bare letter offered as current practice is a factual error, not a shortcut.

2.3 Why a letter could not carry the information

The reasons the regulator gave are the most efficient teaching in this whole topic, because each one is a general lesson about risk communication wearing regulatory clothes. The agency records that the system had long been criticised as confusing and overly simplistic, and then sets out what went wrong in specific terms.

- It was read as a grade. Through experience and stakeholder feedback the agency learned that the categories were heavily relied upon by clinicians but misinterpreted, misunderstood and erroneously used as a grading system in which fetal risk increased from A to X. The letters looked ordinal, so they were read as ordinal, and the underlying data never supported a single ranked axis of harm.
- It implied equivalence that did not exist. The categories gave the incorrect impression that drugs in the same category carried the same risk or potential for human adverse developmental outcomes. Two agents sharing a letter were never thereby comparable.
- It collapsed incommensurable evidence. The categories did not discriminate between risk information from non-clinical animal studies and from post-marketing human studies, and did not discriminate between drugs associated with adverse outcomes of differing severity or incidence. One character concealed both what kind of evidence existed and how bad the outcome was.
- It saw only structural harm. Stakeholders pointed out that the categories focused on structural abnormalities and so did not adequately address the full range of potential developmental toxicities. For psychotropics this is the decisive objection, since the harms that most concern a psychiatrist are functional and neurodevelopmental and a letter had no way to express them.
- No category system worked, including the alternatives. The agency explored a range of models to see whether the former system or a different one could communicate differences in degrees of fetal risk, and reports that when the criteria were applied to actual animal and human findings for drugs with known risk profiles, none of the models produced clinically informative and reliable differentiations of risk.

That last point is the one to carry into an answer, because it is the strongest and the least quoted. The failure was not that the wrong five letters were chosen. It was that the categorical form itself cannot hold the information, since a single ordered label has to compress evidence type, outcome severity, outcome frequency and gestational timing into one dimension, and those four dimensions do not lie on one line. Every subsequent element of a current label is an attempt to keep them apart.

2.4 What a current label must state, and how to read one in clinic

If the answer is no longer a letter, you have to know what the answer now looks like, otherwise the replacement is an abstraction. The regulation specifies required content, and reading a label for this decision means going after those elements deliberately rather than skimming the pregnancy paragraph for a reassuring adjective.

The single most useful requirement is the mandated comparator statement. The labelling must state the percentage range of live births in the United States with a major birth defect and the percentage range of pregnancies in the United States that end in miscarriage, regardless of drug exposure. Absolute against relative risk, which most clinicians treat as a matter of good communication style, is here a legal requirement of the document: the background sits on the page beside the drug figure so that the reader cannot see one without the other. The second is the required anatomy of the risk statement itself. Where human data establish the presence or absence of an adverse developmental outcome, the risk summary must summarise the specific outcome, its incidence, and the effects of dose, duration of exposure and gestational timing of exposure. Gestational timing is a required dimension, which is the critical-period principle written into law.

WHAT THE LABEL MUST CARRY	THE QUESTION IT ANSWERS BEFORE YOU PRESCRIBE
BACKGROUND RATES, STATED REGARDLESS OF EXPOSURE	The percentage range of live births with a major birth defect and of pregnancies ending in miscarriage, so the drug figure has a denominator on the same page
COMPARATOR FOR A HUMAN-DATA RISK	Unexposed women who have the same disease, with the general population only when data for diseased women are unavailable
DIMENSIONS OF THE RISK STATEMENT	Which outcome, how often, and how it varies with dose, duration and gestational timing
DISEASE-ASSOCIATED RISK, UNDER CLINICAL CONSIDERATIONS	Serious known or potential risk of the untreated condition to the woman or the embryo or fetus
DOSE ADJUSTMENT, UNDER CLINICAL CONSIDERATIONS	A summary of pharmacokinetic data supporting dose adjustment during pregnancy and the postpartum period
THE THREE NARRATIVE SUBSECTIONS	Pregnancy, Lactation, and Females and Males of Reproductive Potential, so pregnancy, feeding and contraception are answered from separate text rather than one letter

The practical consequence is a change in what you extract. The old act was to find a character and act on it, which took seconds and told you almost nothing. The new act takes minutes and gives you material for the actual conversation: the background rate you will quote first, the comparator the evidence used, whether the human data are informative or absent, the timing dependence, and whether the kinetics oblige you to plan a dose change. That is also why a label is no longer a substitute for judgement. It furnishes the arguments; it does not close them.

2.5 The denominator, before any drug is involved

Nothing in this topic can be interpreted without a background rate, and the first thing to establish with a frightened woman is that the alternative to her tablet is not a guaranteed normal baby. The framework begins from the premise that every pregnancy has a risk of an abnormal outcome regardless of drug exposure, and that reproductive toxicologists treat the major

manifestations of abnormal fetal development as growth alteration, functional deficit, structural malformation and death. Malformation is one member of that set and not the whole of teratogenicity, which is why a drug with a clean malformation record is not thereby a drug with a clean developmental record.

The regulator's own draft guidance on pregnancy, lactation and reproductive potential labelling, issued for comment in 2020 and non-binding, states that because various factors may affect the overall rate, a range of 2 to 4 per cent is a reasonable representation of the background major birth defect rate, and that miscarriage has been reported to occur in 15 to 20 per cent of clinically recognised pregnancies. Note the status carefully, because it is examinable in its own right: the requirement to print a background range is binding regulation, while these particular figures are a draft recommendation and must be quoted as such.

A rate means nothing until the numerator is defined. Most case reports and studies concern **major birth defects**, meaning those incompatible with life or requiring medical or surgical intervention, as against **minor birth defects**, the minor physical anomalies of less clinical importance that deviate from normal without obvious medical or surgical consequence. The minor category is enormous and elastic: minor defects occur in 14 to 40 per cent of live births, and the width of that range is itself the lesson, since what counts as a minor defect is substantially subjective. A study that widens its numerator definition can manufacture an apparent excess without a single extra child being harmed.

Two cautions travel with any background figure, and both come from the regulator rather than from commentary. All-inclusive background rates of major birth defects may include infants with genetic syndromes and chromosomal abnormalities not caused by a medication or other toxic exposure, so at best such rates constitute very crude comparisons. And population estimates can vary considerably by maternal age, race, geographic region, socioeconomic status and time period, including because the availability of diagnostic tools changes across eras. A background rate is a property of a named population, so carrying one across populations is a substantive assumption, not a neutral convenience.

IN INDIA

Three service realities change how this is used here. The letter categories were a United States labelling instrument and were never Indian law, yet they persist in Indian teaching, in older printed inserts and in question banks, which is why dating them matters more in an Indian answer than in an American one; no Indian labelling instrument governing pregnancy risk communication was available for this account, so nothing here should be read as a statement of Indian regulatory requirement. The background figures quoted above are United States estimates, and no Indian background malformation or miscarriage rate was retrievable for this account, so the denominator you quote to a woman in a district clinic is imported into a population with a different maternal age structure, different consanguinity, different nutrition and different ascertainment. Say that it is imported. Third, most women here present already pregnant rather than planning, and serum monitoring for the agents where it would help is often not obtainable outside a teaching hospital, so the follow-up plan has to be built out of clinical review at intervals a family can actually attend rather than out of assays.

2.6 Absolute against relative, and the study that reassures nobody

Here is the inferential target, stated by the regulator in one sentence: the purpose of collecting and evaluating data on drug exposure during pregnancy is to address whether a particular exposure increases the risk of abnormal fetal development above the background rate. The question is never whether a bad outcome occurred in exposed pregnancies. Bad outcomes occur in unexposed pregnancies at a rate that is not small. The question is whether they occurred more often than they would have anyway.

The worked illustration is the most useful arithmetic in the topic. A population experiencing a tenfold increase in a specific rare birth defect, **from 0.04 per cent to 0.4 per cent**, may still have a total birth defect rate across all malformations that is not measurably different from a reference population. Two conclusions follow and they point in opposite directions, which is why this example earns its place. A large relative increase on a tiny absolute base can be real and still invisible in aggregate data, so a reassuring study of total malformation rates does not exclude it. Equally, a tenfold relative risk quoted to a woman without its base sounds like a catastrophe when the absolute change may be a fraction of one per cent. The number that belongs in the consultation is the absolute one, with the background beside it; the relative figure belongs in the appraisal of the study.

Negative studies need reading with the same suspicion as positive ones. The regulator's appraisal rule is blunt: any study reporting no increase in the background rate of birth defects in exposed pregnancies can be viewed with scepticism unless the power of the study to detect or rule out a stated level of risk is also included. Pregnancy exposure cohorts are small, outcomes are rare, and a study with a hundred exposed pregnancies can exclude almost nothing while reading, in an abstract, as clean. When a colleague tells you an agent has been shown to be safe in pregnancy, the follow-up question is not which study, it is safe against what level of risk, with what power to exclude it.

GOOD TO REMEMBER

Write the background figures down before the consultation starts, not during it. The moment you are working out arithmetic in front of a frightened woman, you will quote whichever number you can retrieve, and the retrievable number is almost always the relative one. Two numbers spoken in the same breath, the background rate and the exposed rate, in the same units, do more counselling work than any amount of reassurance, and they are also what you will be able to defend later if the outcome is poor.

2.7 Timing: which clock, which window, which harm

The first thing to fix is the clock, because getting it wrong silently moves a drug into or out of the window that matters. The regulator warns that determining the gestational week of exposure from the date of the last menstrual period rather than the date of conception can produce a 2 week time difference that can be critical when evaluating an association between a birth defect and drug exposure, and states that in its own guidance gestational age means time since conception. Every window quoted below is post-conception. Obstetric practice in the clinic next door usually dates from the last menstrual period. If you carry a figure across without converting, you will be systematically out by a fortnight in the direction that makes exposure look earlier and safer than it was.

The organising principle is that sensitivity belongs to the organ rather than to the drug. Agents producing adverse fetal effects typically do so during discrete sensitive periods that vary with the particular teratogenic process and the target organ, and each part, tissue and organ of an embryo has a **critical period** during which its development may be disrupted. There is therefore no such thing as a safe trimester in general; there is only a window that is or is not critical for the structure you are worried about.

WINDOW, COUNTED FROM CONCEPTION	WHAT IS HAPPENING	WHAT EXPOSURE CAN PRODUCE THERE
FIRST 2 WEEKS	Cleavage of the zygote and implantation of the blastocyst, before differentiation	Not susceptible to teratogenesis, and exposures are not known to cause congenital anomalies in human embryos; interference with cleavage or implantation, or early death and spontaneous abortion
3 TO 8 WEEKS	Organogenesis, when the tissues and organs are forming, and when the embryo is most easily disrupted	Gross structural abnormalities readily seen at birth
3 TO 16 WEEKS	The most critical period for brain development, with susceptibility continuing beyond it as the brain differentiates and grows rapidly	Disruption of the organ with the longest window of any, which is why a first-trimester rule alone cannot govern psychotropic exposure
LATER GESTATION	Rapid fetal growth and maturation, with active cell growth, differentiation and migration, particularly in the central nervous system	A different class of harm rather than a smaller quantity of the same harm: growth and function rather than gross structure

Two clinical consequences follow, and both are commonly missed. The first is that the pre-differentiation window is also the window in which a woman is least likely to know she is pregnant, so an exposure that ENDED inside it is incapable of causing a malformation, though it is not incapable of causing a loss. That is a genuinely reassuring thing to be able to say, and it is worth saying precisely rather than vaguely, because the precision is what makes it true. Establish first which case you are in. A woman who stopped when the test turned positive has usually gone on dosing past this window and into organogenesis, since the window closes around the missed period, and the reassurance does not reach her exposure. Naming the clock is how you tell the two apart, and telling them apart is the whole point of naming it. The second is that the psychiatric agents we worry about act on a developing central nervous system whose critical period is the longest in the table and does not close when organogenesis does. A woman told she is past the dangerous phase at the end of the first trimester has been told something that is true of the palate and false of the brain.

MNEMONIC

Clock, window, harm

Three questions of any exposure, in order. **Clock:** is this week count measured from conception or from the last menstrual period, and have I converted. **Window:** which structures were in their critical period during the exposure, remembering that the brain's runs longest. **Harm:** which class of outcome that window can produce, since the same drug at a different point buys loss, malformation, or growth and functional harm rather than more or less of one thing.

2.8 Dose across the trimesters, and the reversal nobody owns

Once the decision to treat is made, the prescribing task changes character. The dose that was right at booking will frequently not be right at term, and this is a pharmacokinetic fact rather than a matter of the illness worsening. The obstetric guideline states that up-titration in pregnancy may be required with advancing gestation secondary to expected physiologic changes such as increased renal clearance and distribution volume, as well as changes in the activity of drug-metabolising enzymes. A woman whose symptoms creep back in the second half of pregnancy on a dose that held her for a year is not necessarily relapsing in the ordinary sense; she may simply be underdosed by her own physiology.

The direction of the change is broadly predictable from the elimination route, which is what makes this teachable rather than merely cautionary. A mechanistic pharmacokinetic review published in 2005 reports that renal excretion of unchanged drug is increased in pregnancy, and that metabolism catalysed by CYP3A4, CYP2D6, CYP2C9, UGT1A4 and UGT2B7 is increased, so that doses of drugs handled by those routes may need to rise to avoid loss of efficacy, whereas CYP1A2 and CYP2C19 activity is decreased, suggesting that reductions may be needed for their substrates. It is a narrative review rather than a primary study and no magnitude for an individual psychotropic should be taken from it, but the direction of travel is a usable heuristic when you are deciding which agents to watch hardest.

The magnitude, where it has been measured, can be startling. Lamotrigine is metabolised by **UGT1A4**, which is upregulated in pregnancy, increasing clearance of the drug by up to 330 per cent. That is the mechanism-to-magnitude chain the general principle needs in order to become real, and it is quoted here purely as kinetics. The malformation figures for this and every other agent, and the antiepileptic prescribing route, belong to their own chapters and are not extended here; the mood stabiliser numbers sit in the Mood disorders: pharmacotherapy notes.

Where there is no level to chase, the monitoring has to be clinical. Some psychiatric medications have therapeutic drug ranges requiring monitoring, whereas others such as the selective serotonin reuptake inhibitors have no established therapeutic concentration but do have **concentration-to-dose ratios** known to be dynamic across pregnancy and the postpartum. So the absence of an assay does not mean the absence of kinetic change; it means the change is invisible unless somebody is looking at the patient at planned intervals. No monitoring interval is asserted here, because none of the sources consulted for this account gives one, and an invented review cadence would be worse than an honest blank.

The step that gets forgotten is the reversal. The guideline is explicit that the dose needs to be carefully down-titrated again postpartum to avoid toxicity, with close clinical monitoring of the patient. Pregnancy kinetics unwind quickly after delivery, so a dose raised across gestation becomes a toxic dose within days of birth if nobody owns the review. This is a systems failure waiting to happen, because the antenatal dose rise is made by whoever is following the pregnancy and the postnatal fall belongs to nobody in particular. Name the person and the date before the woman delivers, and write it where the postnatal team will see it, not only in the psychiatric notes.

2.9 The pre-conception conversation, and the record a shared decision leaves

Almost everything above is more useful before conception than after it, which is why the conversation is owed early and broadly rather than at the first positive test. The United Kingdom guideline on antenatal and postnatal mental health directs that all women of childbearing potential with a new, existing or past mental health problem be asked about contraception and any plans for a pregnancy, and told how pregnancy and childbirth might affect the mental health problem including the risk of relapse, and how the problem and its treatment might affect the woman, the fetus and baby, and parenting.

- Contraception and any plans for a pregnancy, asked about rather than waited for, which is what converts this from a perinatal topic into a general adult prescribing habit.
- How pregnancy and childbirth might affect the mental health problem, including the risk of relapse, which is the illness arm of the two-exposure comparison made concrete for this woman.
- How the problem and its treatment might affect the woman, the fetus and the baby, kept as three separate questions because the answers differ.
- How the problem and its treatment might affect parenting, which is the element most often dropped and the one families ask about most.

The timing argument for holding this conversation early is the pre-differentiation window discussed above. By the time a woman with an unplanned pregnancy reaches you, organogenesis has usually begun, the exposure has already happened, and the only decisions left are downstream ones. Nothing about the framework changes, but the menu shrinks. A conversation at the point of prescribing, repeated when contraception or plans change, is the only version of this that is genuinely preventive.

The record is part of the clinical act, not an administrative afterthought. Shared decisions in this area are revisited, sometimes years later and sometimes by people who were not in the room, and the woman herself will not retain the arithmetic. What protects the decision is a note showing the reasoning rather than the conclusion. No documentation proforma from a professional body was available for this account, so what follows is derived from what the labelling regulation itself obliges a label to contain, and should be read as a structure rather than as a standard.

- Both arms named: the risks discussed for the agent, and the risks discussed for the untreated or inadequately treated illness in this particular woman, including her own relapse history.
- The comparator used, and whether it was other women with the same condition or the general population, since the two support different conclusions.
- The absolute figures actually quoted, with the background rate beside them, and the population those figures come from.
- The dating frame used for any gestational window discussed, since a note that says nine weeks without saying from what is not interpretable later.

- The kinetic plan: which direction the dose is expected to move with advancing gestation, who reviews it, and who is responsible for the postpartum down-titration and by when.
- What the woman decided, in her words, and what would change the decision, so that a future clinician can tell a settled choice from an unresolved one.

One boundary before leaving the topic. This framework tells you how to reason about an agent; it does not tell you which agent. The individual malformation and adverse-outcome figures for particular mood stabilisers are in live disagreement across published sources, and they are taught with their agents in the Mood disorders: pharmacotherapy notes rather than restated here. What travels from this topic to every other perinatal decision, including the feeding decision in the breastfeeding topic of these notes and the emergency decisions later on, is the frame: two patients, two exposures, an absolute number with its background beside it, and a clock you have named out loud.

> Every figure you quote in this conversation is an increase above a background that is not zero, on a clock you must name, for a woman whose untreated illness is itself an exposure.

3 · Drugs safe in breastfeeding (relative infant dose, agent selection)

Two people receive this prescription and only one of them is dosed. The mother's milligrams are chosen, titrated and written down. The infant's are inferred from a milk assay and a body weight, arrive at intervals nobody controls, and appear on no chart at all. That asymmetry is what this topic is about, and why the question asked is never "which drug is safe" but "which drug, for which infant, watched how, and what would make you stop".

The temptation is to memorise a ranked list of agents, and a ranked list is precisely what the published figures do not support. Several of the agents a candidate is most likely to name have no published figure at all. In two of the four classes the headline figure means something quite different from what it appears to mean, because it omits an active metabolite carrying most of the exposure. And the highest figure in the table belongs to a drug women take through lactation, under monitoring, every day. What is examined is whether a candidate can read a percentage, see what it excludes, and make a decision the percentage was never capable of making. The two-patient frame that governs this band, mother and infant weighed together, is developed in the pregnancy-prescribing topic of these notes.

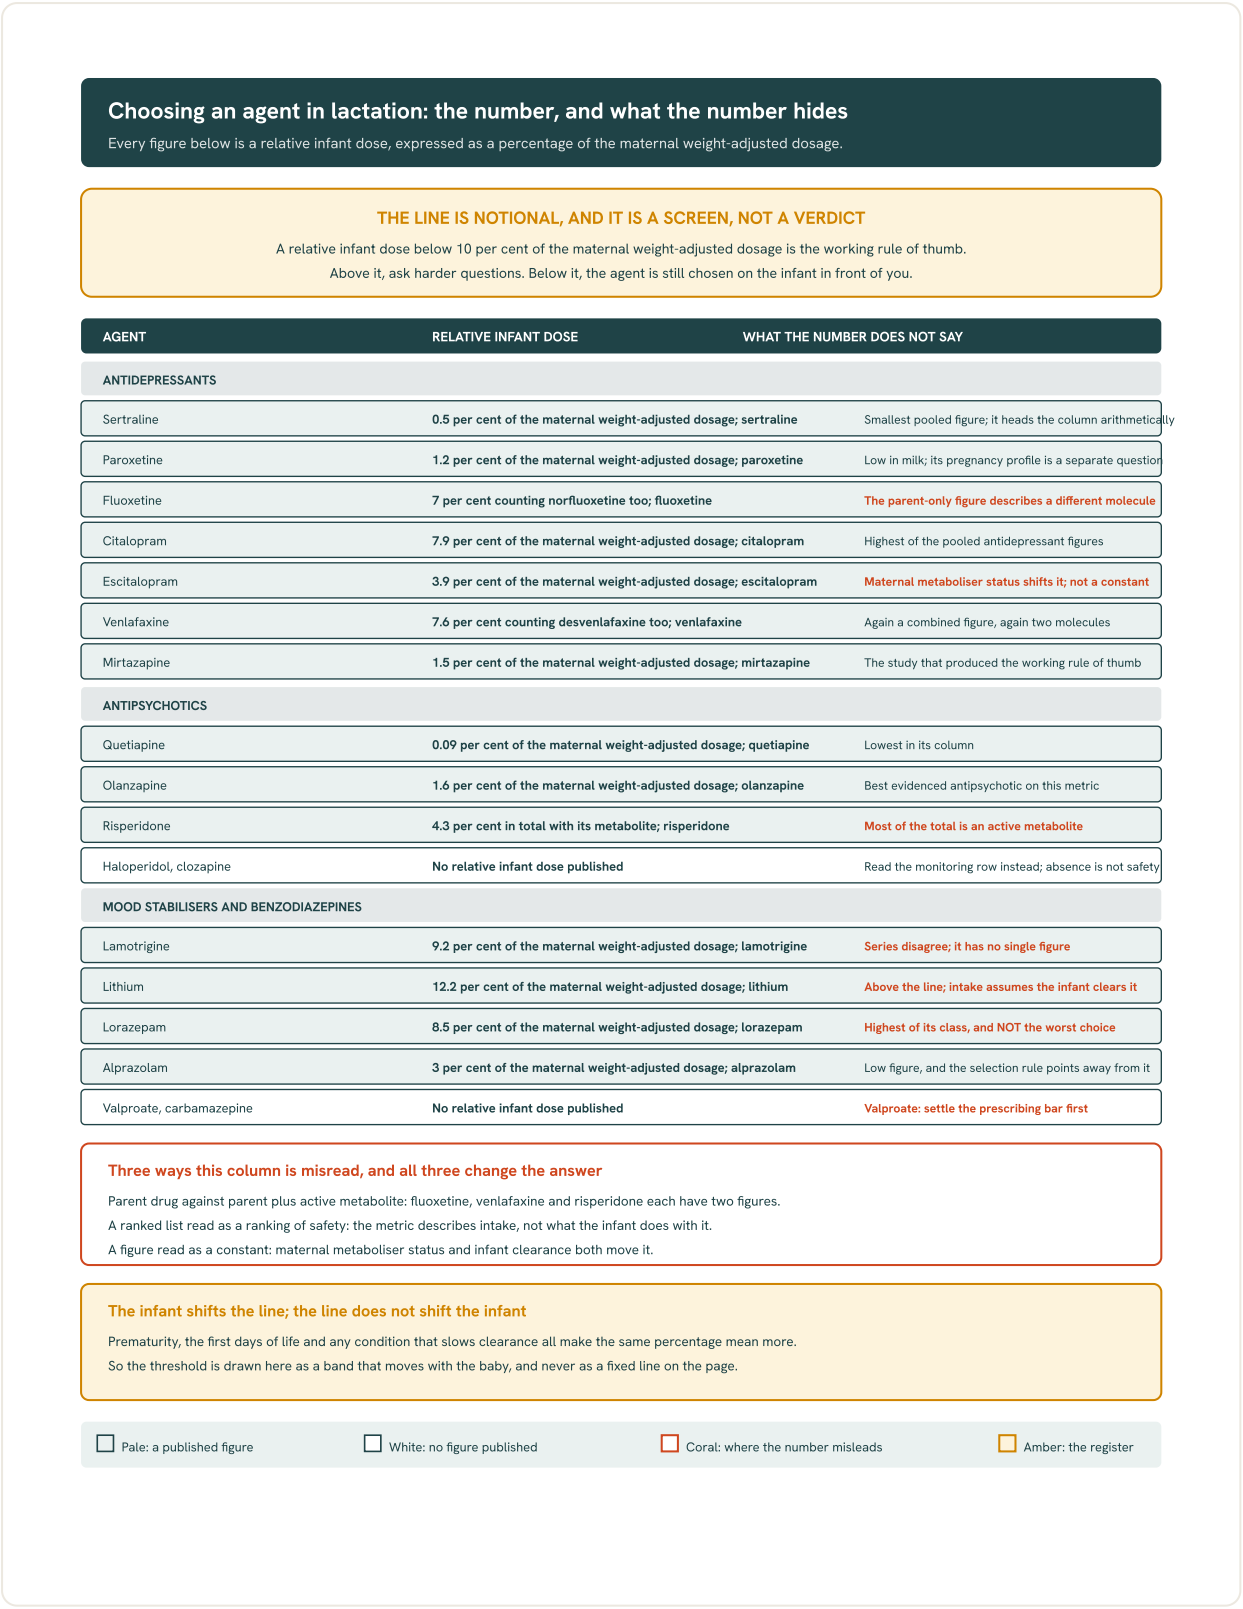

Fig 28.3. Agent selection in lactation, with the relative infant dose for each antidepressant, antipsychotic, mood stabiliser and benzodiazepine that has one, each figure naming in the same line what it is a dose of, set against the notional ten per cent working threshold, the agents for which no figure is published shown as such rather than omitted, and the three misreadings that change the answer named alongside the infant factors that move the threshold rather than the number.

3.1 The number you quote, and the half of the exposure it leaves out

The **relative infant dose** expresses what the breastfed infant takes in as a percentage of the mother's own weight-adjusted dose, and a value **below 10 per cent** of that maternal weight-

adjusted dose is conventionally taken as the notional level of acceptability. The derivation, the arithmetic and the worked exemplars are printed in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and are not repeated here. What belongs here is what the metric cannot do, and the primary sentence supplying the threshold supplies the caveat alongside it: the feeding decision remains an individual risk and benefit analysis rather than a threshold test.

Read literally, the metric is a statement about intake, and says nothing about what happens after the milk is swallowed. Two infants taking identical relative infant doses of the same agent can reach entirely different serum concentrations, because absorption, hepatic conjugation and renal clearance are all maturational and all slower in the first weeks of life than the adult pharmacokinetics behind the calculation assume. The exposure that matters clinically is intake set against clearance, and only the first of those is inside the number.

RULE **A relative infant dose is an intake figure, not an exposure figure.** It is calculated from what enters the infant and it assumes he can clear it. Every caveat in this topic, prematurity, the first postnatal days, dehydration, intercurrent illness and maternal genotype, is a statement about a clearance term the metric does not carry. A figure comfortably acceptable in a thriving infant of a few months can be the wrong figure in a jaundiced newborn on the same milk, and nothing on the page changes to tell you so.

3.2 The agent table, and how to read a blank cell

The figures that follow come from the Drugs and Lactation Database, a compilation of maternal serum and milk assays, together with the primary pharmacokinetic study of mirtazapine that supplies the working threshold. They are laboratory calculations on small samples of healthy, term, exclusively breastfed infants, not outcome data. A blank in the percentage column is neither reassurance nor warning: it means the calculation was not made, and the reason differs by agent. For the anticonvulsant mood stabilisers the database gives its own reason and it is methodological, which is worth teaching in itself.

0.09%

INFANT SIDE EFFECTS ON ATYPICALS, INDIAN MOTHER AND BABY UNIT

AGENT	RELATIVE INFANT DOSE, AS PERCENTAGE OF THE MATERNAL WEIGHT-ADJUSTED DOSE	WHAT THE FIGURE DOES NOT CONTAIN
SERTRALINE	0.5%, pooled dataset	Nothing material; this is the arithmetic reason it sits where it does
PAROXETINE	1.2%, pooled dataset	Discontinuation effects in the mother if it is stopped abruptly to permit feeding
FLUOXETINE	2.4% for the parent drug alone	The active metabolite; measured with it, about 7%, range 3 to 12%

AGENT	RELATIVE INFANT DOSE, AS PERCENTAGE OF THE MATERNAL WEIGHT-ADJUSTED DOSE	WHAT THE FIGURE DOES NOT CONTAIN
CITALOPRAM	7.9%, pooled dataset	Individual studies in the same record running both below and above this
ESCITALOPRAM	3.9%, with 1.7% more as desmethylcitalopram	Maternal genotype; modelled median 3.3%, range 0.8% to 11.3%
VENLAFAXINE	7.6% for drug plus metabolite, range 4.7 to 9.2%	Nothing; but it must be quoted as the combined figure, never as the parent alone
MIRTAZAPINE	1.5%, range 0.6 to 2.8%, plus 0.4% as the desmethyl metabolite	Maternal sedation, which is a feeding-safety issue in its own right
QUETIAPINE	0.09% on average; modelled worst case 0.43%	Nothing; the worst case already assumes every feed at the peak milk level
OLANZAPINE	1.6% on average, range 0 to 2.66%	Nothing material; the best-evidenced antipsychotic on this metric
RISPERIDONE	4.3% in total	Four fifths of it is 9-hydroxyrisperidone, itself a marketed antipsychotic
HALOPERIDOL	No figure published	A maternal oral ceiling statement instead: up to 10 mg daily gives low milk levels
CLOZAPINE	No figure published	The only agent here for which an infant blood count is the named action
LITHIUM	12.2%, range 0 to 30%, in the better-technique series	Infant clearance, which is the variable that actually decides the case
LAMOTRIGINE	9.2%, range 3.1 to 21.1%, in one series	A second series averaging 11.6%, range 5 to 31%
VALPROATE	No figure published	The calculation is held to be less meaningful for this class.

AGENT	RELATIVE INFANT DOSE, AS PERCENTAGE OF THE MATERNAL WEIGHT-ADJUSTED DOSE	WHAT THE FIGURE DOES NOT CONTAIN
VALPROATE, BEFORE THE LACTATION QUESTION ARISES AT ALL	Not a relative infant dose question	A woman who is breastfeeding is by definition of childbearing potential, so the bar on offering valproate to this group absent the conditions set out with contraception counselling in these notes applies to her before any milk calculation is reached. Settle that question first; it is not answered by this table.
CARBAMAZEPINE	No figure published	The same methodological reason as valproate
LORAZEPAM	About 8.5%, counting conjugated as well as free drug	Nothing; the conjugate is why this figure is the highest of its class, and the figure is not a verdict on the agent. It is short-acting and free of active metabolites, which is precisely what the selection rule in the row below asks for
ALPRAZOLAM	About 3%	Reported infant sedation, which drives the caution against repeated use in nursing and points instead to a shorter-acting benzodiazepine without active metabolites, especially with a neonate or a preterm infant
CLONAZEPAM	Maximum 2.5%, from a single mother and infant pair	Any population estimate; this is one report, not a mean
DIAZEPAM	No figure published	Accumulation of drug and metabolite in infant serum on repeated dosing

3.3 Antidepressants: the metabolite is the decision

Sertraline heads the antidepressant column for an arithmetic reason rather than a pharmacological one: its pooled figure is simply the smallest, and it carries no long-lived active metabolite to be added to it. Paroxetine follows closely, and mirtazapine is comparably low where sleep and appetite dominate the presentation.

Fluoxetine is where a single number misleads most reliably. The parent compound's pooled figure looks unremarkable, and the database flags in the same breath that the figure omits **norfluoxetine**, an active metabolite of equivalent antidepressant activity. Where both were measured together, in 14 mothers, the combined figure rose to about **7 per cent** of the maternal weight-adjusted dose, with the upper end of the range crossing the notional level. Long half-lives also mean the infant has no trough to be fed in. That is the whole clinical argument for choosing a

shorter-acting agent when treatment is started fresh in a breastfeeding mother, and emphatically not an argument for switching a woman already well on fluoxetine.

Citalopram gives the highest single-agent figure among the plain serotonin reuptake inhibitors, close enough to the notional level to matter when the infant is young or unwell. Escitalopram demonstrates why the column cannot be read as a table of constants at all. In a modelled analysis the median figure came with a range spanning more than an order of magnitude, and it split by maternal genotype: a **CYP2C19 poor metaboliser** mother produced a modelled relative infant dose of 5.5 per cent of her weight-adjusted dose against 3 per cent in other phenotypes. One agent therefore spans much of the column on its own, which should permanently discourage comparing two drugs on the second decimal place. Venlafaxine must always be quoted as drug plus **desvenlafaxine**, because the active metabolite carries most of it.

3.4 Antipsychotics: what is actually prescribed, and what is actually watched

Quetiapine gives the lowest published relative infant dose of any agent here, and the figure survives its own worst case: a model assuming that every single feed occurred at the peak milk concentration still returned a figure far below the notional level. That is a useful shape to recognise, because most published figures are averages across a dosing interval and a worst case is rarely offered. Olanzapine is the best-evidenced of the class and its published range extends down to zero. Risperidone is the trap.

TRAP **Quoting risperidone by its parent drug alone.** The parent contributes 0.84 per cent of the maternal weight-adjusted dose and **9-hydroxyrisperidone** a further 3.46 per cent, giving **4.3 per cent** in total. Candidates quote the first of those because it is the figure attached to the drug name they recognise, and thereby understate the infant's exposure roughly fivefold. A small series gives a mean of 3.3 per cent, range 2.2 to 4.7 per cent, which is consistent with the combined total and not with the parent figure. The general form of the error is the one that also catches fluoxetine and venlafaxine: where an agent has an active metabolite, the drug name and the number in front of you are describing different molecules.

Haloperidol has no relative infant dose in the database at all. What exists instead is a statement about the mother: doses of up to 10 mg daily by mouth during lactation produce low levels in milk and usually do not affect the breastfed infant, with very limited long-term follow-up showing no adverse developmental effect where haloperidol is used alone. That is a ceiling on the mother's oral daily dose offered in place of a figure for the infant, and it must be taught as exactly that. Clozapine likewise has no published figure, and the same database records that other agents are preferred and that some sources advise a woman taking it should not breastfeed at all.

IN INDIA

The most usable cadence available comes from an Indian tertiary-centre mother and baby inpatient psychiatry unit, published in the Indian Journal of Psychiatry in 2021, in which infants of 28 postpartum women taking atypical antipsychotics had medication side effects checked every alternate day for 1 to 2 weeks against a prepared checklist. Side effects including sedation and constipation attributable to the antipsychotic occurred in 17.85 per cent of that single-centre, uncontrolled, short-window sample. The exposure profile is Indian too: 15 of the 28 infants were exposed to olanzapine at maternal oral doses of 2.5 to 30 mg daily, 11 to risperidone at maternal oral doses of 4 to 8 mg daily, and 2 to quetiapine. The service point matters more than the percentage. An alternate-day check by the nurse at the cot is deliverable in a district hospital anywhere in the country. Serial infant serum levels and repeat white cell counts are not, and where the blood test cannot realistically be obtained, the agent choice itself must carry the safety the monitoring was supposed to provide.

3.5 Mood stabilisers: where the metric runs out

Lithium carries the highest central relative infant dose of any agent here, and the only central estimate sitting above the notional level. It also carries the widest disagreement between datasets. The better-technique series gives one figure; an older estimate from 6 infants, in reports published up to the start of the nineteen-nineties, gives about **26 per cent** of the maternal weight-adjusted dose, range 11 to 42 per cent, with the database noting that many of those case reports were of poor quality and that the reason for the gap between the two estimates is not apparent. Both have to be stated. Quietly choosing the lower because it supports a decision already made is the error, and so is quoting the higher to close a conversation down. Whether lithium prohibits feeding outright or permits it under monitoring is a separate argument with a substantial cohort literature behind it, and it is developed in the Mood disorders: pharmacotherapy notes rather than restated here.

Lamotrigine straddles the line rather than sitting on one side of it. One series gives a central figure just under the notional level with an upper bound at twice it; a second series averages above the line entirely. The honest teaching is that lamotrigine has no single relative infant dose, and that a mother asking for one is asking for a certainty the published data does not contain.

Valproate and carbamazepine have no figure at all, and here the database states its own reason rather than leaving the cell mysteriously empty. In the published lactation reports most women were taking **combination anticonvulsant therapy**, and because some of these agents induce and others inhibit the metabolism of the rest, the relationship between the mother's dose and the concentration in her milk becomes variable enough that the weight-adjusted percentage is less meaningful for this class than for other drugs in that database. That is a statement about the method rather than the drug, and it is why those two cells must stay blank rather than be filled from memory in a viva.

3.6 Anxiolytics: the agent for which timing the feed is useless

The benzodiazepine column contains the topic's most counter-intuitive result. Lorazepam has the practice reputation of being the most benign of the group and carries the highest published

relative infant dose of them, **about 8.5 per cent** of the maternal weight-adjusted dose. The reason is both methodological and clinically real: the figure counts **conjugated as well as free drug**, because infants can deconjugate and absorb glucuronides, so a metabolite an adult would have safely inactivated becomes available to the baby again. Alprazolam and clonazepam give lower figures, the clonazepam one from a single mother and infant pair rather than a population, which is the kind of provenance difference that disappears once figures are tabulated side by side.

Diazepam is the exception that governs the practical advice given later in this topic. Diazepam and nordiazepam accumulate in the serum of breastfed infants with repeated doses, and because both half-lives are long, timing breastfeeding with respect to the maternal dose is of little or no benefit in reducing infant exposure. Every timing manoeuvre a mother might be offered assumes a peak and a trough she can feed between. Diazepam on repeated dosing does not provide one.

Two further rules attach to this class, both population rules rather than agent rules. Because of reported infant effects including sedation, alprazolam is probably not the best benzodiazepine for repeated use during nursing, particularly with a neonate or premature infant, and a **shorter-acting benzodiazepine without active metabolites** is preferred. And the class as a whole has to be read against guidance that would rather it were not being prescribed to this population at all: the National Institute for Health and Care Excellence guidance on antenatal and postnatal mental health, which applies in England and Wales, advises considering gradually stopping benzodiazepines in women who are planning a pregnancy, pregnant or considering breastfeeding.

3.7 The infant who is not in the data

Every figure in the table was derived in a healthy, term, exclusively breastfed baby. The Indian cohort states this explicitly by way of its exclusions: preterm delivery, birth weight below 2 kilograms, major neonatal complications needing intensive care, major congenital anomaly and major medical or surgical illness were all excluded before a single infant was observed. Whatever reassurance that study offers, therefore, it does not offer it about the preterm infant, the small infant or the sick infant, and those are precisely the infants in whom clearance is worst. The reassurance and the risk have been separated by the study design, and a reader who does not check the exclusions will carry the reassurance across the gap.

The database makes the mechanism explicit for lithium and the shape generalises. Lithium in milk can harm the infant acutely where **elimination is impaired**, as in dehydration or in the newborn or premature infant, and a neonate may in addition be carrying transplacentally acquired serum lithium from before delivery. Consider what that does to the arithmetic. A baby with gastroenteritis and reduced feeding has an unchanged relative infant dose on paper and a rising serum concentration in reality, because the number describes what goes in and the illness has changed what comes out. The clinical habit follows directly: treat acute illness in the infant of a mother on a narrow-margin agent as a reason to reassess feeding that day, not at the next appointment.

MNEMONIC

Metabolite, Maturity, Malady, Mother

The four things a relative infant dose does not contain. **M**etabolite: the active metabolite frequently excluded from the headline figure. **M**aturity: prematurity and the first postnatal weeks, when clearance is immature. **M**alady: intercurrent infant illness or dehydration, which changes elimination without changing the number. **M**other: her metaboliser phenotype, which can move the figure several-fold on the same prescription.

3.8 What is watched in the infant, and who does the watching

Monitoring here is overwhelmingly clinical rather than laboratory, and where a blood test is named it is named for a reason a candidate should be able to give. The residual duty, covering every agent for which no panel and no figure exists, is a single line from the same English and Welsh guidance: where a woman is taking psychotropic medication while breastfeeding, the baby is monitored for adverse effects. No panel, no interval and no duration is specified there, so none should be invented to fill the silence.

AGENT	INFANT CLINICAL WATCH	INFANT BLOOD TEST NAMED BY THE SOURCE
LITHIUM	Dehydration, feeding, any acute illness	Serum lithium, creatinine, blood urea nitrogen and thyroid stimulating hormone, at intervals variously recommended from periodic to every 4 to 12 weeks, attributed to some investigators rather than to a guideline
LAMOTRIGINE	Apnoea, rash, drowsiness, poor sucking; stop feeding if a rash appears, until the cause is established	Infant serum level where there is concern; platelet count and liver function; levels before and after any increase in the maternal dose. Less extensive monitoring where the mother takes 150 mg daily or less
CARBAMAZEPINE	Jaundice, drowsiness, adequate weight gain, milestones; more closely in younger exclusively breastfed infants and on polytherapy	Serum carbamazepine, liver enzymes and a complete blood count, attributed by the source to one author rather than a guideline; no interval given
VALPROATE	Jaundice, unusual bruising or bleeding; sedation or withdrawal reactions where sedating agents are combined	None specified
CLOZAPINE	Close monitoring for excessive sedation	Periodic infant white blood cell count; the source gives no interval
HALOPERIDOL	Drowsiness and developmental milestones, more closely with concurrent antipsychotics; on the decanoate also excessive sedation, irritability, poor feeding and extrapyramidal signs	None specified
ANY OTHER PSYCHOTROPIC	Adverse effects, unspecified	None; the residual duty carries no panel

Three things are worth drawing out. Clozapine is the only agent for which a blood count on the infant is the named action, for the reason the reader already knows from the mother's own monitoring. Lamotrigine carries the most specific panel and the only monitoring-intensity threshold expressed as a maternal dose, on the stated logic that beneath it the infant is unlikely to have measurable serum drug at all. And the lithium panel is the only one with a named interval, attributed by the source to investigators rather than to a guideline and arriving with no target value and no action threshold: the reader is told what to send, not what to do with the result. An interval with no owner reads as universal, and none of these are.

3.9 Timing, expressing, and the decision the table cannot make

Mothers do not ask about relative infant dose. They ask whether to feed before the tablet or after it, whether expressing and discarding the milk helps, and whether to stop feeding altogether. The first two have arithmetic answers; the third does not. For sertraline the manoeuvre has actually been quantified: in one series the relative infant dose was 0.54 per cent of the maternal weight-adjusted dose, and **pumping and discarding** milk 8 to 9 hours after the mother's dose was calculated to reduce the infant's daily dosage by 17 per cent. A proportional reduction of that size, applied to an intake already among the smallest in the table, buys almost nothing at the cost of a discarded feed, a pump the family may not own, and a mother's sleep. Timing is not useless; its value must be computed against the figure it is applied to.

Timing is worth more where the peak is sharp and the baseline higher, nothing at all for diazepam on repeated dosing, and something quite specific after a single dose. After one dose of diazepam, for sedation before a procedure or for a seizure, there is usually no need to wait before resuming breastfeeding; with a newborn or preterm infant a cautious approach is to wait 6 to 8 hours before resuming nursing, and for that population other agents are preferred in the first place. That is one of the few genuinely timed acts here and it is worth carrying precisely.

The last question is the one no percentage answers. The English and Welsh guidance sets a default of encouraging breastfeeding in women with a mental health problem, and names its exceptions: carbamazepine, clozapine and lithium. Notice what that list is and is not. It is a service-level decision rule rather than a pharmacokinetic ranking, and most of the named agents have no published relative infant dose at all, so they appear on it because of the absence of a number rather than because of a high one. The same recommendation closes by requiring that each woman be supported in the choice of feeding method that best suits her and her family, which is what stops an exception list becoming a prohibition. It constrains what is encouraged; it does not decide for the woman.

The genuinely hard case is the woman already well on the agent with the worst milk data. The guidance names both sides without resolving them: the limited safety data on these drugs in milk, and the risk associated with switching from a previously effective medication, with specialist perinatal advice sought for specific drugs. Nothing in the percentage column tells you the second of those. A relapse in the early postnatal weeks costs the infant his mother's availability, frequently costs the feeding relationship anyway, and sometimes costs an admission, none of which appears in a milk assay. That is why the agent table is a set of inputs rather than a ranking of answers. One caution on jurisdiction: that guidance is English and Welsh, Indian guidance controls for Indian practice where it exists, and no Indian equivalent of the exception list was retrievable, so it structures the conversation rather than governing an Indian unit.

GOOD TO REMEMBER

Before the first dose, write down which infant this is: gestation at birth, current weight, age in weeks, whether feeding is exclusive, and whether the baby is well today. Then write down what will be watched and who will watch it. Every figure here assumes a term, healthy, exclusively breastfed baby, and the moment yours is not one, the number has stopped describing him and the plan is built from the infant instead.

- Name the metabolite before quoting the number: fluoxetine, venlafaxine and risperidone are each understated by their parent-drug figures.
- Read a blank cell as an absent calculation, never as reassurance, and be able to say why it is missing.
- Reassess feeding on the day an infant becomes acutely unwell, not at the next review, wherever the mother is on a narrow-margin agent.
- State whose an interval is. Where a source attributes a schedule to investigators rather than a guideline, say so out loud.

Quote no relative infant dose without naming the metabolite it excludes and the infant it assumes: a term, healthy, exclusively breastfed baby who can clear what he takes in.

4 · Mood and anxiety disorders in pregnancy

The commonest question about mood and anxiety disorders in pregnancy is not which drug is safe but what to do about the drug she is already taking. A woman maintained on treatment for depression, bipolar disorder or an anxiety disorder arrives either pregnant or planning to be, and something has to be decided in that consultation, on that afternoon, by whoever is sitting opposite her. Candidates prepare this as a teratogenicity table and then find that no table answers it, because the question on the table is not what an agent does to a fetus. It is what to do about a person who is currently well because of it. The two-patient frame is set out where these notes deal with prescribing psychotropics in pregnancy; what is added here is that the exposure being weighed on one side has a competitor on the other, and the competitor is her illness.

Owned here in full: the antenatal decision itself and the four arms it actually has, which are to continue, to switch, to reduce or to stop, each priced with what it costs; the relapse and recurrence evidence that turns stopping from a neutral act into a decision with a bill attached; the manner of stopping, where stopping is what she chooses; the detection of perinatal anxiety and perinatal obsessive-compulsive disorder, both of which are systematically under-recognised; and the narrow set of situations in which a non-pharmacological route is genuinely first-line rather than a way of postponing the decision. Named once and not re-taught here: the depressive, bipolar and anxiety syndromes themselves, which belong to the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes; and agent selection, comparative teratogenicity and dosing, which belong to the Mood disorders: pharmacotherapy notes.

RELAPSED IN PREGNANCY AFTER STOPPING THE ANTIDEPRESSANT	RELAPSED IN PREGNANCY ON THE ANTIDEPRESSANT MAINTAINED	HAD AT LEAST ONE RECURRENCE IN PREGNANCY IN A BIPOLAR COHORT	PERINATAL GENERALISED ANXIETY DISORDER, POOLED ACROSS LOW- AND MIDDLE-INCOME COUNTRIES

4.1 Who is in front of you, and what is actually being decided

Three consultations hide behind this heading and they are not the same problem. The first is the woman who is planning a pregnancy and has come to ask about it: the only version of this decision made with time in hand, where every arm is still open and nothing has been done that cannot be undone. The second, and by a distance the commonest, is the woman who is already several weeks pregnant when she finds out, whose exposure decision was made for her by biology before anyone was consulted. The third is the woman with no psychiatric history who becomes unwell during the antenatal period, where the question is whether to start rather than whether to continue, and where the reference point is a woman who has never been treated at all.

The decision itself has four arms, not two. She can continue what she is on; she can be switched to a different agent; the dose can be reduced; or the drug can be stopped. Examination answers and, more damagingly, real consultations collapse this into a binary of drug or no drug, and every collapse of that kind moves the conversation to the arm that feels safest rather than the arm that is safest. Each of the four is a positive act with a specific price, and a candidate who can name the price of each has understood the topic. The prices are not symmetrical and they are not all pharmacological: two of them are paid by the fetus, one is paid by the woman's mental state, and one is paid by both at once.

THE ARM	WHAT IT IS MEANT TO BUY	WHAT IT ACTUALLY COSTS
CONTINUE	Maintained control of an illness that is currently in remission on this agent	Steady exposure of the fetus to one drug for the whole of the antenatal period, and the review burden that goes with it
SWITCH	Exchange of an agent with worse evidence for one with better evidence	Exposure to two drugs across the changeover instead of one, plus destabilisation of a woman who was well
REDUCE	Less exposure while keeping some treatment	Possible loss of efficacy without a matching loss of exposure, which is the worst ratio of the four
STOP	Zero further drug exposure from the day it is stopped	Relapse or recurrence risk that is quantified, large, and largely borne in the antenatal period itself

MNEMONIC

Continue, Switch, Reduce, Stop - and name the bill for each

Four arms, four bills. Say all four aloud in the consultation, price each one in her hearing, and the conversation stops being a request for permission to stop and becomes a choice between four named positions.

4.2 Building the conversation the guidance actually requires

Before any arm is chosen there is a discussion, and the guidance specifies its contents rather than leaving them to the clinician's instinct. The National Institute for Health and Care Excellence, in guidance published in 2014 and last updated in 2020, requires that detailed advice about the risks of mental health problems and the benefits and harms of treatment in the antenatal and postnatal periods cover three things that clinicians routinely leave out.

- The **background risk of harm** to the woman and to the fetus or baby that comes from the mental health problem itself, and the risk to her mental health and to her parenting if she is not treated at all.
- The risks and harms attached to stopping or changing a treatment, which is a separate question from the risks attached to being on it.
- The need for prompt treatment, because of what an untreated mental health problem can do to the fetus or baby.

Notice what that list does to the arithmetic. The framework behind it, that the untreated illness is itself an exposure and that a relative risk must be read against its base rate, is set out where these notes deal with prescribing psychotropics in pregnancy, and is not re-derived here. What belongs to this decision is the direction it points. The American College of Obstetricians and Gynecologists, in its clinical practice guideline of 2023, directs that the **absolute risk** of adverse obstetric, perinatal and infant developmental outcomes, which for almost all psychiatric medications appears to be low, be set against the high risk of illness recurrence, and states that in general this balance favours continuing pharmacotherapy.

RULE **The default is not neutrality, and the burden of argument sits on stopping.** The same American guideline states that although pharmacotherapy is an exposure, for most individuals and most medications the risk of that exposure is lower than the risk of symptom exacerbation or relapse. Continuation is therefore the position that stands unless a case is made against it, and a clinician who stops a psychotropic in pregnancy is the one who owes the argument, not the one who keeps it going.

4.3 Pricing the stop option in unipolar depression

The counterweight to teratogenic risk is relapse risk, and unless it is quantified in the consultation it does not weigh anything at all. The best-known evidence comes from a prospective multicentre cohort of women with a history of major depression who were euthymic at conception and followed across the antenatal period. Of 201 women, 86, or 43 per cent, relapsed during pregnancy. That headline figure conceals the finding that matters. Among the 82

women who maintained medication throughout, 21, or 26 per cent, relapsed, against 44 of the 65 who discontinued, which is **68 per cent**. Expressed as an effect size across the whole of pregnancy, discontinuation carried a hazard ratio for relapse of **5.0**, with a 95 per cent confidence interval of 2.8 to 9.1.

The authors' conclusion is the sentence to carry into the consultation: pregnancy is not **protective** against relapse of major depression, and a woman with a depressive history who is euthymic on an antidepressant should be told that stopping it in pregnancy is associated with relapse. Many women and a fair number of clinicians hold the opposite belief, usually without ever having examined it, and the belief does real work: it makes stopping feel like a return to a natural, safer state rather than the removal of an active treatment from a person who has an illness.

Two honest qualifications travel with these numbers and a good candidate offers them before being asked. The design is naturalistic rather than randomised, so the women who discontinued were not allocated to do so; they chose, and the reasons a woman chooses to stop may themselves predict how she will fare. The direction of that bias is not obvious, because a woman with milder illness may feel safer stopping while a woman with more severe illness may be the one most frightened by exposure. What survives the qualification is the size of the gap and the fact that both arms were followed prospectively by the same investigators to the same endpoint.

4.4 Pricing the stop option in bipolar disorder

The bipolar figures are larger and the decision is correspondingly less balanced. In a prospective cohort of women with bipolar disorder who were euthymic at conception, the overall risk of at least one recurrence during pregnancy was **71 per cent**. Comparing those who discontinued a mood stabiliser with those who continued it, the discontinuers carried twofold the recurrence risk, a median time to first recurrence more than fourfold shorter, and a proportion of weeks spent ill during pregnancy that was five times greater. That last measure is the one to quote to a woman who is thinking in terms of a single feared event, because it describes not whether she becomes unwell but how much of her pregnancy she spends unwell.

An independent guideline summary of two cohort studies reaches the same place by a different route. Compared with continued use, discontinuing a mood-stabilising medication in pregnancy was associated with an increased risk of recurrence at an adjusted hazard ratio of 2.2 with a 95 per cent interval of 1.2 to 4.2, and with a reduced time to recurrence of 2 weeks against 28 weeks, at an adjusted hazard ratio of 12.1 with an interval of 1.6 to 91. Print the second interval whenever the point estimate is printed. An interval that wide says the direction is secure and the magnitude is not, and a candidate who quotes the point estimate alone has misrepresented the evidence in the direction of confidence.

Two further features of that cohort change what you do rather than what you think. Most recurrences were depressive or mixed, at 74 per cent, so the surveillance a clinician sets up should not be built around watching for mania; and 47 per cent of recurrences fell in the first trimester, which is exactly the window in which a woman who has just stopped is least likely to be under

psychiatric review and most likely to be attributing her symptoms to being pregnant. The investigators' own framing closes the argument: treatment planning here has to consider not only the relative risk of fetal exposure to a mood stabiliser but also the high risk of recurrence and morbidity that comes from stopping maintenance treatment.

4.5 Continue: the default, and the clock that governs any later stop

The American guideline sets two defaults that are worth memorising as a pair, because they are not the same default. In severe mental health conditions such as bipolar disorder and the psychotic disorders, pregnant and postpartum individuals should in general continue medication management. In depression or an anxiety disorder diagnosed in the antenatal or postnatal period, continued pharmacotherapy should be recommended for at least **6 to 12 months** of symptom remission before discontinuation is even considered. Note what that second default is a clock on. It runs from remission, not from delivery, not from the end of breastfeeding, and not from any gestational milestone. A woman who becomes well at some point in the antenatal period and delivers three months later has not finished the clock, and the postnatal request to come off is therefore usually a request made early rather than a request made at a natural end point.

The same guideline states plainly that discontinuing effective pharmacotherapy in pregnancy or the postpartum period increases relapse risk and is not recommended, and that where discontinuation is being considered it requires careful consideration of the risk of recurrence. For major depressive disorder it names two predictors of recurrence that a clinician can check in the room: **discontinuation before remission**, meaning before symptoms have completely resolved rather than merely improved, and an increasing number of lifetime depressive episodes. Both are answerable from the history in under a minute, and both convert an abstract worry into a statement about this woman.

Continuing is itself an act and not the absence of one. It commits the clinician to review, to a plan for what happens if she becomes unwell anyway, and to a decision about whether the dose that is right in the first trimester is still the right dose later, since the handling of a drug changes across pregnancy for reasons that belong to the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes. No review interval is asserted here, because none is carried in the sources used for this topic; what is asserted is that a decision to continue with no review date written next to it has not been fully made.

4.6 Switch: paying for one exposure with two

Switching is the arm that most often gets proposed by a clinician rather than requested by a woman, usually with the intention of moving her from an agent with worse reproductive evidence to one with better. Its cost is structural and easy to miss. A switch is executed as a **cross-taper**, the initial medication down-titrated while the newer agent is started and up-titrated, and the American guideline notes that this results in increased exposure, which is best avoided if a therapeutic effect can be reached with a single agent. For a period that may run into weeks the fetus sees two drugs where it previously saw one, and the woman spends that period on a subtherapeutic amount of the drug that was working and a not-yet-effective amount of the drug that might.

Two sequencing rules follow from that, and both are stated in the guideline rather than inferred. First, because a switch is expensive, careful assessment of what medication has actually been effective for this woman in the past is of particular importance; the agent with the best published reproductive data is of no use to a woman it has never worked for, and switching away from the one agent that has ever produced remission in her is the most consequential version of this error. Second, assuming that side effects are not prohibitive, dose optimisation should be considered before switching. Optimising is cheap in exposure terms and reversible; switching is neither.

4.7 Reduce: buying the exposure without buying the benefit

Reduction is the arm that feels like a compromise and has the worst ratio of the four. The British guidance directs use of the lowest effective dose, and adds in the same breath that this matters particularly where the risks of adverse effects to the woman, fetus and baby may be dose related. But it then states the cost explicitly: a **sub-therapeutic dose** may also expose the fetus to risks and not treat the mental health problem effectively.

The word carrying the weight in that recommendation is effective. Lowest effective dose is not the same instruction as lowest dose, and the two get conflated whenever a clinician halves a dose in the first trimester as a gesture towards caution. Exposure does not fall to nothing when a dose is halved; the drug is still crossing, still being metabolised, still detectable in the pregnancy. What may fall to nothing is the therapeutic effect that justified the exposure in the first place. A woman on a reduced dose who then relapses has ended up with both costs and neither benefit, and she has also lost the argument that the drug does not work for her, since it was never given a fair test at the dose that worked.

4.8 Stop: the taper is the instruction, not the decision

Stopping is two decisions wearing one word, and only the second is fully inside the clinician's control. The first is whether to stop, which is largely hers. The second is how, which is a technical act with evidence behind it. In the bipolar cohort described above, the median recurrence latency was 11 times shorter after abrupt or rapid discontinuation of a mood stabiliser than after gradual discontinuation. Same decision to stop, same drug, and an order-of-magnitude difference in how long she stayed well, determined by a variable the prescriber sets.

For the antidepressants the American guideline names the method directly: to avoid the discontinuation syndrome, a person who has been on a serotonin reuptake inhibitor or a serotonin and noradrenaline reuptake inhibitor should undergo a **progressive taper** over **2 to 4 weeks**. Two clinical consequences follow. An entry in the notes that reads only that the drug was stopped, with no taper written beside it, is half an instruction, and the missing half is the half that predicts the outcome. And because a discontinuation syndrome in a pregnant woman produces sleep disturbance, agitation, nausea and dysphoria, it is routinely misread as either an early relapse or as the pregnancy itself, which sends the consultation in the wrong direction at the worst moment.

Stopping is never the cautious option and never one decision: whether to stop belongs largely to her, how to stop belongs entirely to you, and the manner of stopping changes the outcome as much as the choice to stop.

4.9 When she has already decided to stop

Some women will decide to come off medication whatever is said, and the clinical task then changes from persuasion to damage limitation. The British guidance sets out what the conversation should contain when a woman with a severe mental illness decides to stop a psychotropic in the antenatal or postnatal period: discuss her reasons, and discuss the possibility of each of the following, then make sure she knows the risks to herself and to the fetus or baby of stopping.

- Restarting the medication, offered here without any precondition attached.
- Switching to a different medication, if the objection is to this agent rather than to treatment.
- A psychological intervention, which is a treatment and not a placeholder.
- Increasing the level of monitoring and support, which is the arm that stays available when every other one has been refused.

The parallel recommendation for a woman with depression or an anxiety disorder is worth putting side by side with that one, because it differs in exactly one place and the difference is examinable. There, the restarting option is conditioned: it applies if the depression or anxiety disorder is or has been severe and there has been a **previous good response to treatment**. No such condition appears in the severe mental illness recommendation. The threshold for pressing a restart is therefore explicitly higher in depression and anxiety than in severe mental illness, which is a proportionality judgement written into the guidance rather than a clinical preference, and it tells you where the guidance thinks the greater danger of undertreatment lies.

GOOD TO REMEMBER

Write the four arms and their costs into the notes, name which one was chosen, name who chose it, and write a date next to it. A decision recorded as "patient wishes to stop, medication stopped" cannot be defended, cannot be reviewed and cannot be handed over. A decision recorded as four options offered, relapse risk quantified in her hearing, her choice, taper plan, review date, is the same clinical act with the evidence of care attached to it.

4.10 When the pregnancy is already confirmed

This is the presentation that walks into most clinics, and it carries a correction that changes the first thing a clinician says. Where a pregnant woman has taken a psychotropic with a known teratogenic risk at any point in the first trimester, the British guidance directs that the pregnancy be confirmed as quickly as possible and that she be told, explicitly, that stopping or switching the medication after the pregnancy is confirmed may not remove the risk of fetal malformations.

The logic is uncomfortable and it is the point. By the time a routine test is positive, the exposure that would have mattered has usually already happened. Stopping today therefore buys much less

than it appears to on the risk that is being feared, while buying, in full and immediately, the relapse risk quantified earlier in this topic. That does not make stopping wrong; it makes stopping a decision that has to be justified on its own forward-looking terms rather than as a retrospective repair. The practical acts that follow are to confirm and date the pregnancy rather than assume it, to record what she actually took and when rather than what she was prescribed, and to route the exposure question to the people who can actually assess it obstetrically, instead of resolving it by withdrawing the treatment.

TRAP **Stopping the drug the day the test comes back positive, in the belief that this undoes the exposure.** It is made in good faith and it feels like the responsible act, which is why it is so durable. It usually cannot reverse a first-trimester exposure that has already occurred, and it adds a discontinuation to a woman in the very trimester in which recurrences cluster. The reflex substitutes an act that is visible for one that is useful.

4.11 Asking about antenatal anxiety, and why the number depends on how you ask

Perinatal services are built around depression, and the arithmetic does not support that design. In a Canadian cohort assessed by structured diagnostic interview, the prevalence of anxiety and related disorders was 15.8 per cent during pregnancy and 17.1 per cent in the early postpartum, against depression at 3.9 per cent and 4.8 per cent in the same sample. That is a single regional cohort, and only participants who screened positive went on to interview, so the authors describe their own estimates as conservative. Even discounted for both, a service whose only routine perinatal enquiry is about low mood is aimed at the smaller of the two problems.

The second thing to understand about these figures is that the number you find is partly a property of the method you used. Within one meta-analysis, generalised anxiety prevalence came out at 24.4 per cent when estimated from screening tools and 11.5 per cent when estimated from **diagnostic interview**, for the same construct in the same review. Roughly half the apparent prevalence of perinatal anxiety is instrument. That is not an argument against screening, which is doing what a screen is meant to do; it is an argument for never quoting a prevalence figure in an answer without saying how it was ascertained, and for never treating a positive screen as a diagnosis in the clinic.

WHAT WAS COUNTED	HOW IT WAS ASCERTAINED	STUDY BASE	THE FIGURE
ANTENATAL ANXIETY SYMPTOMS	Self-report	102 studies, 221 974 women, 34 countries	Self-reported anxiety symptoms in 18.2 per cent in the first trimester, 19.1 per cent in the second and 24.6 per cent in the third
ANY ANTENATAL ANXIETY DISORDER	Clinical diagnosis	The same global review	Any anxiety disorder in 15.2 per cent
ANTENATAL GENERALISED ANXIETY DISORDER	Clinical diagnosis	The same global review	Generalised anxiety disorder in 4.1 per cent

WHAT WAS COUNTED	HOW IT WAS ASCERTAINED	STUDY BASE	THE FIGURE
PERINATAL GENERALISED ANXIETY DISORDER	Pooled across all ascertainment methods	203 studies, 212 318 women, 33 low- and middle-income countries	Generalised anxiety disorder in 22.2 per cent, the most prevalent disorder in that review
THE SAME, SPLIT BY COUNTRY INCOME BAND	Pooled, subgrouped	The same low- and middle-income review	Generalised anxiety in 27.6 per cent in lower-middle-income countries, 24.0 per cent in low-income countries and 19.1 per cent in upper-middle-income countries

For an Indian answer, the pooled low- and middle-income figure is the more defensible comparator than a global pooled figure, because the studies behind it were done in economies that resemble the one the reader works in. One caution belongs with it and is stated rather than glossed: that review reports prevalence by World Bank income band, but it does not itself state which band India falls into, so no Indian figure is being asserted here by implication.

4.12 Asking about perinatal obsessive-compulsive disorder

Obsessive-compulsive disorder in the perinatal period is the clearest example in this topic of a diagnosis whose apparent frequency is determined by whether anyone asked. The older pooled estimates, drawn from studies using structured interviews, put prevalence at 1.08 per cent in the general female population, 2.07 per cent in pregnancy and 2.43 per cent postpartum, with regionally matched risk ratios of 1.45 in pregnancy and 2.38 postpartum and an aggregate risk ratio of 1.79. That much was established years ago: the perinatal period raises the risk, and it raises it more after delivery than before.

A later province-wide cohort of unselected women, interviewed directly and asked about perinatal-specific content, returned figures several times higher. Weighted **period prevalence** was 7.8 per cent prenatally and 16.9 per cent postpartum, with average point prevalence of 2.9 per cent prenatally and 7.0 per cent postpartum. Keep the two quantities apart when quoting them, since a period prevalence spanning months and a point prevalence at a single assessment are different measurements and the higher pair is not the more alarming version of the lower pair. The two estimates disagree substantially and the disagreement is unresolved; the honest position for a candidate is to quote both and to name the methodological reason they differ rather than to pick the more striking one.

The timing tells you when to ask. Point prevalence rose across pregnancy and the early postpartum to a peak of close to 9 per cent at approximately 8 weeks postpartum before declining, and the cumulative incidence of new diagnoses was estimated at 9 per cent by 6 months postpartum. Two things follow for the clinic. The peak sits in the early postnatal weeks, when most contact is obstetric or paediatric rather than psychiatric, so the enquiry has to be built

into whatever contact exists rather than into a psychiatric follow-up that has not been arranged. And a large share of it is new onset rather than pre-existing illness carried into the pregnancy, which means a negative psychiatric history is not a reason to skip the question.

The authors state the mechanism of under-recognition as a measurement fact rather than a clinical impression: when women are encouraged to report their **perinatal-specific symptoms** and current diagnostic criteria are applied, estimates come out higher than previously believed. Under-recognition here is a failure to ask about content, not a failure of the disorder to occur. The general enquiries most clinicians make do not reach obsessions whose content is about the infant, and a woman rarely volunteers them, for reasons that are obvious the moment you consider what she believes will happen if she says them aloud in an antenatal clinic.

PITFALL

Acting on the content of an intrusive thought about harm to the infant instead of on its form. The reflex is an emergency referral, a safeguarding entry, or a decision to keep mother and baby apart, and it punishes a woman for disclosing. What you ask about is the form. The discrimination itself, and the risk formulation that follows from it, are made in the section of these notes on mother-infant bonding and infanticide risk; the urgent-risk pathway belongs to the section on psychiatric emergencies in the perinatal period.

4.13 Choosing a non-pharmacological route where it is genuinely first-line

A psychological intervention appears in the guidance as one of the named options when a woman decides to stop medication, alongside restarting, switching and increased monitoring. It is a treatment arm in its own right, and there are three situations in which it is genuinely first-line rather than a way of deferring the decision.

- The woman not currently on medication whose symptoms are of low or moderate severity with no history of severe illness, where the comparison is between a psychological treatment and starting a drug rather than between a psychological treatment and continuing one.
- The woman who has firmly declined medication, where the real comparison is between a psychological intervention and nothing at all, and where the arm that is available beats the arm that is optimal.
- The woman who has stopped and accepted increased monitoring, where a psychological intervention is what turns a surveillance plan into an active one.

What makes any of these real is availability inside a clinically useful interval. A referral to a service that will assess her after delivery is not first-line treatment for antenatal illness; it is a deferral wearing a treatment's name, and the pregnancy will be over before the intervention begins. The honest test to apply before writing it in the plan is whether she will actually be seen while the problem is still the problem. Where the answer is no, saying so and choosing among the remaining arms is better practice than recording an intervention that will not arrive, because the record then reflects the decision that was actually made. No severity threshold, no named therapy and no efficacy estimate for psychological treatment in the antenatal period is asserted here;

none is carried in the sources used for this topic, and the principle is offered without a number rather than with an invented one. Where the illness is severe enough that no pharmacological arm is acceptable to her and psychological treatment is not sufficient, electroconvulsive therapy becomes the next question, and it belongs in full to the ECT and neurostimulation notes.

IN INDIA

A peer-reviewed analysis of Indian maternal mental health policy records that the National Mental Health Policy launched in 2014, directed at vulnerable populations and at de-stigmatisation, does not include women in the perinatal period among the populations it names as susceptible to psychiatric problems. That is a policy analysis rather than a government instrument, and it is cited as analysis. Its practical consequence is the one every reader will recognise: there is no funded pathway that puts a psychiatrist inside the antenatal clinic, so almost every contact this woman has during pregnancy is obstetric, and almost every opportunity to ask about anxiety or intrusive thoughts belongs to someone who has not been asked to ask. The arms of the decision above are all deliverable in that setting except one. Continuing, tapering properly, optimising a dose and increasing the frequency of review can all be done in a district clinic with a telephone number that works. A timely psychological intervention usually cannot. Where that is the local reality, it should change which arm is chosen, not be recorded as though it had been offered.

A closing note on jurisdiction, because it governs how the material above should be used. The four-arm structure, the required contents of the risk-and-benefit discussion, the remission clock, the taper interval and the option sets are British and American guidance. No Indian national guideline on the antenatal psychotropic decision was retrievable for this topic, and where an Indian instrument exists it controls for Indian practice. The relapse and recurrence figures come from North American cohorts of women who were in specialist follow-up and euthymic at conception, which is a more closely observed population than most Indian services can offer; the direction of that difference is that relapse in a less closely followed population is likely to be detected later rather than to occur less often. Use the structure as a way of organising the consultation, and the figures as the order of magnitude of what stopping costs, which is the part a woman needs in her hearing before she decides.

The postpartum period

5 · Postpartum blues (features, course)

Why the marks sit in the act and not in the description. **Postpartum blues** is judged quickly, usually by somebody who is not a psychiatrist, and then rarely revisited. What the state is, how it runs, and how it stands against a postnatal depressive episode and against a puerperal psychosis belong to the three-way treatment carried by the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes, and none of it is restated here. What belongs at the front door is different: the act performed in the room, the person into whose hands the judgment is given, and the condition under which it must be reopened.

Fig 28.4 The front-door distinction among postpartum blues, depression and psychosis is a disposition decision: reassure with a named review threshold, begin treatment, or arrange urgent admission and coordinated mother–infant safety.

The label is the easy part; the harm sits in how it is closed. A woman correctly judged to have blues may be depressed some weeks later: the first judgment was not wrong, the way it was ended can be. Every decision in this band is taken for **two patients** at once, the mother and the infant who depends on her, a frame belonging with prescribing in pregnancy and holding even though nothing is prescribed.

Reassure, inform, return	Reassurance and a named threshold	Mother and infant
THE THREE THINGS DONE WITH HER, AND ALL THAT IS DONE	THE TWO LIMBS OF THE TRIGGER, EACH INERT WITHOUT THE OTHER	WHO EVERY DECISION IN THIS BAND IS TAKEN FOR

5.1 The discrimination the front door actually makes

There are not three descriptions to choose between at the door so much as three **dispositions**, and the choice turns on what is safe to do next rather than on which picture fits best.

- **Reassure and review.** She is coping with the support she has, nothing needs treating tonight, and she can safely be seen again. That is the blues judgment: a disposition, not a description.
- **Treat now.** The state is deepening, or simply failing to lift, and function is going rather than holding. It has become a treatment question and enters the screening and referral pathway taught where postnatal depression is handled in this chapter.
- **Do not discharge.** Disorganisation, fluctuating awareness, perceptual disturbance, or any thought of harm to herself or to the infant takes her out of this category altogether and calls for same-day assessment and an admission decision. The branches then separate by destination, and getting them the wrong way round is the error. Fluctuating awareness or disorganisation is an organic question first, and goes to the emergency triage of the confused patient in these notes. A thought of harm goes to the risk assessment taught in the Somatic-symptom, sexual, impulse-control disorders and suicide notes. The presentation as a whole goes to this chapter's account of postpartum psychosis, which owns the same-day assessment and the admission decision it triggers.

Blues is therefore a **provisional judgment** by construction: it says treatment is not needed now, not that it never will be. And because the third branch is settled at the moment of contact rather than by watching, the examination that excludes it belongs to the first visit, not to the review.

5.2 The act in the room, and why each part fails alone

The response to blues has been set out as an act rather than as a description by the **IGEDEPP** prospective multicentre cohort, the cleanest available statement of the front-door task. **Three** things are done with the woman: her awareness of what she is living through is raised, so it has a name she recognises; she is reassured; and she is given information about postpartum depression and the symptoms by which it declares itself.

Take one away and the other two stop working. Awareness without reassurance medicalises an experience that does not need treating. Reassurance without information is heard as an instruction to disregard whatever comes next, so a woman whose state deepens reads that as her own failure. The information is what actually gets dropped, out of kindness: a woman never told a postpartum depressive episode exists cannot recognise she has crossed into one.

MNEMONIC

Reassure, Inform, Return

Reassure, with her awareness raised rather than her experience dismissed; **I**nform, about postpartum depression and the symptoms that announce it; **R**eturn, on a stated trigger held by a named person.

5.3 The trigger that reopens the judgment

RULE **Blues is managed by reassurance plus a named return threshold, and it ceases to be blues the moment the threshold is crossed.** Each half is inert without the other. Reassurance alone closes the encounter; a threshold alone, handed over flat, converts a settling experience into vigilance. Together they turn a judgment nobody can check today into one that checks itself later.

The condition attached is that the blues **worsens or is prolonged**, either of which requires management, so the trigger has **two** limbs and no third. That is what spares the clinician from having to predict: you have to be right about the trigger, not about the future. It stays coarse because it will be applied by an exhausted woman and by relatives with no clinical training.

How long counts as prolonged is fixed by no figure this section can assert, and inventing one would hand the family a false permission to wait. What the clinician can do instead is fix the review and let that date carry the meaning of prolonged: if the state has not lifted by the contact already arranged, the judgment is reopened there.

5.4 Handing the threshold to somebody who will still be there

Safety-netting is an allocation, not a sentence. A threshold given to the woman alone lands on the person least placed to act on it: the judgment about whether a state is worsening is being asked of the person whose state it is. **Safety-netting** means deciding, before she leaves the room, who else holds the trigger, and fixing a contact rather than issuing an invitation to return.

WHO HOLDS THE THRESHOLD	WHAT THEY ARE ASKED TO NOTICE	WHAT THEY DO WITH IT
The woman herself	That the state is deepening, or has not lifted	Present again, without waiting for the review
The relative in the room	The same change, which she may minimise	Bring her, having been told where and to whom
Whoever sees her at the next routine contact	Whether the judgment still holds	Escalate rather than reassure a second time

IN INDIA

The threshold assumes a clinician who stays reachable, and that is where this pathway breaks. The postnatal contact is commonly obstetric, or the frontline home visit by the auxiliary nurse midwife or the accredited social health activist, rather than anything psychiatric. Many women move to the natal home after delivery, often in another district, so whoever set the threshold is not whoever sees her next. Two adjustments cost nothing: give the trigger to the relative travelling with her, and name a destination where she is going.

TRAP **Writing postpartum blues into the record as a diagnosis instead of as a judgment with a trigger attached.** The label is correct when written, and correctness feels like a finished act, so it travels forward as a conclusion and the next clinician reassures a second time without ever seeing the condition the first reassurance depended on. In a viva the discriminating answer is what was said, to whom, and what was arranged.

GOOD TO REMEMBER

If the consultation is cut short, protect the trigger and the review before the reassurance. Warmth is remembered but not inherited; a threshold never stated is the part nobody downstream can reconstruct.

You are entitled to record postpartum blues only if you also state, out loud and in the notes, what would make you unmake it.

6 · Postpartum depression (assessment, EPDS, management)

Why the marks are here. Depression after childbirth is one of the few psychiatric conditions in which the diagnostic work is easy and the detection work is hard. A woman has more scheduled contact with health services in the perinatal year than at almost any other time in adult life, and she is still routinely missed, because being seen is not being asked. What this section teaches is not the illness but the machinery around it: who asks, at which contacts, with what, and what happens to the woman who answers yes. The entity itself, its specifier, epidemiology, recurrence risk and first-line treatment, belongs to the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes.

Two features make this a service question rather than a bedside one. Every decision in the perinatal band is taken for two patients at once, the mother and the fetus or infant, which is the frame these notes set out for prescribing in pregnancy: a missed diagnosis here is transmitted rather than contained. And screening is itself an intervention with a cost. It manufactures positives, and a positive that goes nowhere is worse than no screen, because it teaches a woman that disclosure achieves nothing.

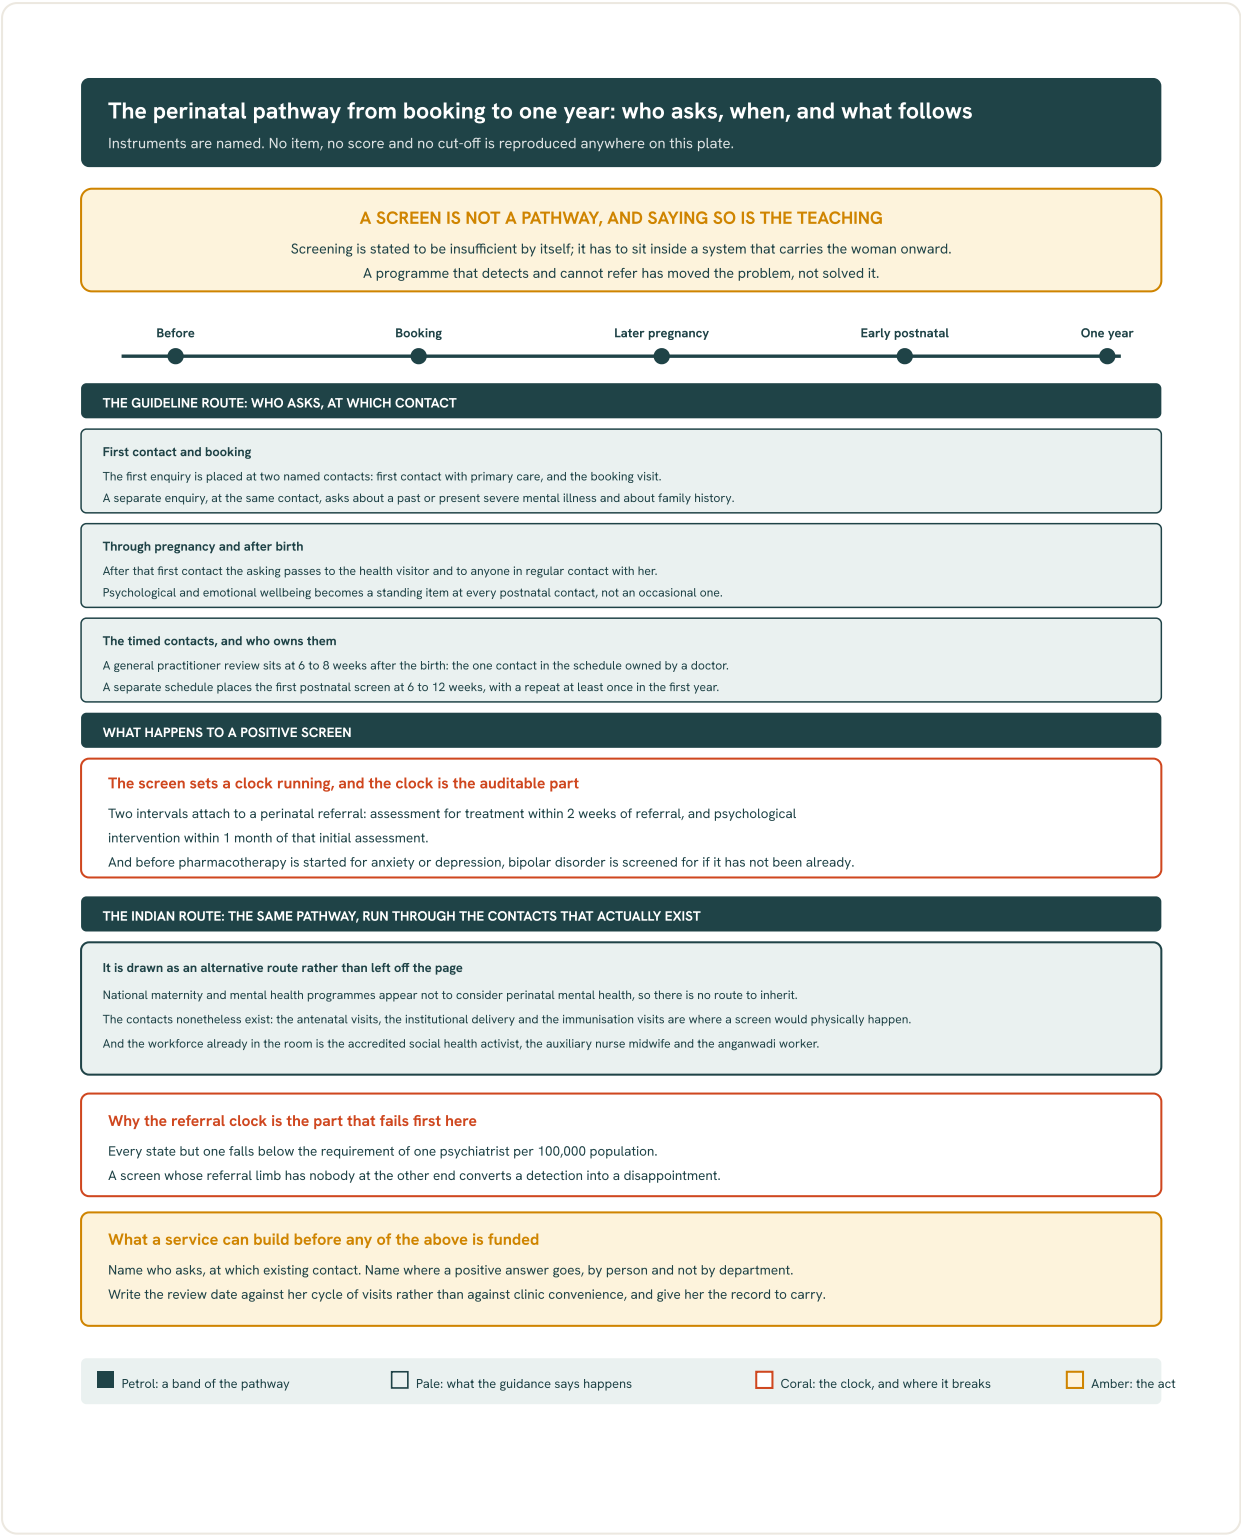

Fig 28.5. The perinatal screening and service pathway on a timeline from before conception to one year after birth, showing who asks at each contact, the timed reviews and the intervals a positive screen sets running, with the Indian route drawn as the alternative it has to be, through the antenatal, delivery and immunisation contacts that already exist and the workforce already in the room, and with the referral limb marked as the place the pathway fails first.

6.1 A screen is not a service

The governing principle comes from the American College of Obstetricians and Gynecologists, in its 2023 clinical practice guideline: screening is valuable but by itself insufficient, and earns its place only inside a system that carries a woman through the whole mental health pathway. That guideline names the stages in order: detection, assessment, triage and referral, treatment access

and initiation, symptom monitoring, and **measurement-guided treatment adjustments** continued until symptoms remit.

Read that as a chain of joins, not a list of activities, because the weakest join is almost never detection. Detection is cheap and easy to audit, which is why services install it first and why the unaccompanied screening programme is so common. Assessment costs clinician time; triage needs a destination with capacity; initiation needs it to accept and start; monitoring needs somebody to own the case after the referral letter leaves. Naming the stage at which a described service breaks answers the question; naming an instrument does not.

MNEMONIC

Who, When, With what, What next

The four questions a perinatal screening pathway must answer before it is worth running. **Who** is screened, and by which worker. **When** in the perinatal timeline the contacts fall. **With what** enquiry or instrument. **What next** when the answer is positive. Services specify the first three and improvise the fourth at the point of need, which is where the pathway fails.

RULE **Do not put a screening instrument into a service until the destination of a positive result has been named, and named as a person or a clinic rather than a category.** It is the easiest part of the pathway to install and the least useful alone. Where a service cannot say who assesses the positives, within what interval, and who follows the woman if treatment starts, a questionnaire increases documented distress without increasing treated distress.

6.2 Who is screened: a population defined by the care episode, not by risk

The first design decision is whom to ask, and the guidelines that have thought hardest about it define the population by the care a person is receiving rather than by risk stratification. ACOG makes screening for depression and anxiety universal across well-woman, prepregnancy, prenatal and postpartum care, using standardised and validated instruments. That is the difference between a programme and case-finding: a programme asks everyone inside a defined care episode.

The reasoning matters more than the rule. Risk-based screening sounds efficient and fails structurally: risk factors are unevenly documented, so the woman with the thinnest record is least likely to be flagged and often most exposed, and risk assessment inserts a judgement between the woman and the question, at which point bias and social distance select who is asked. A universal rule keeps judgement for the assessment rather than the front door.

The Australian clinical practice guideline of 2023 widens the population further than any other, offering screening to **non-birthing parents** early in pregnancy and again from 3 to 6 months after the birth, repeated when clinically indicated. That limb is missing from most teaching and almost every service, yet a depressed partner is both a risk to the infant and a determinant of whether the mother's treatment succeeds.

6.3 Which contacts carry the enquiry

The second decision is when, and every serious guideline answers with named contacts rather than a frequency, because a contact already exists in a schedule and a frequency has to be remembered. The NICE guideline on antenatal and postnatal mental health, published in 2014 and last updated in 2020, places the first enquiry at the woman's first contact with primary care or her booking visit, and again in the early postnatal period. Its form matters: the **depression identification questions** are asked inside a general discussion about mental health and wellbeing, not bolted on as a separate screening event, because an enquiry that arrives as a form feels like an audit.

NICE postnatal care guidance, issued in 2021 and updated in 2026, makes assessment of psychological and emotional wellbeing a standing item at every postnatal contact, routes the clinician to the mental health guidance for recognition and referral, and requires concerns to be followed by further assessment and follow-up. Screening thereby becomes part of routine postnatal care, the only form in which it survives a busy service.

ISSUER AND YEAR	WHO ASKS	ANTENATAL CONTACTS	POSTNATAL CONTACTS
NICE, antenatal and postnatal mental health, 2014, updated 2020	Primary care first; then the health visitor and any professional in regular contact	First contact with primary care or the booking visit, then later contacts	The early postnatal period, and contacts through the first year after birth
NICE, postnatal care, 2021, updated 2026	The postnatal care provider; the GP at the timed review	Outside scope	Wellbeing assessed at each postnatal contact; GP assessment 6 to 8 weeks after the birth
ACOG, 2023	The obstetric or well-woman provider	Initial prenatal visit, and again later in pregnancy	Postpartum visits
Australian clinical practice guideline, 2023	The perinatal care provider	As early as practical in pregnancy, repeated at least once later in pregnancy	First postnatal screen 6 to 12 weeks after birth, repeated at least once in the first postnatal year
American Academy of Pediatrics, 2019	The paediatric medical home	Coordination with prenatal providers where depression was diagnosed before birth	The 1-, 2-, 4- and 6-month well-child visits
India	No national requirement to screen; community health workers hold the contacts	Four incentivised antenatal care visits	Two incentivised postnatal care visits, plus institutional delivery

One point in the accompanying comparison is easily missed. These postnatal schedules are timed rather than merely repeated: the Australian schedule sets its first postnatal screen beyond the earliest weeks after delivery, when transient emotional change is expected and a screen would

largely detect that instead, so the timetable itself carries a discrimination the front door would otherwise make unaided.

6.4 Who does the screening, and for how long

The third decision is whose job this is, and the answer is uncomfortable for psychiatry: mostly not ours. NICE names the **health visitor**, with every other professional in regular contact during pregnancy and the postnatal period, defined as the first year after birth, as those who should ask the depression identification questions and the GAD-2 at contacts after the first, and use a rating instrument as part of monitoring. Screening is a repeated act distributed across a workforce, and the psychiatrist sits downstream of it.

The American Academy of Pediatrics gives the answer residents almost never do. Its 2019 policy statement puts postpartum depression screening inside the **paediatric medical home** at the early well-child visits, with three duties attached: coordinating with the prenatal provider where depression was diagnosed before birth, using community resources for the mother's treatment and referral, and supporting the mother-infant relationship including breastfeeding. The logic is attendance: after delivery the appointment reliably kept is the baby's, so the clinician who reliably sees the mother is the baby's doctor.

> **GOOD TO REMEMBER**
>
> A positive screen must be owned by a named person until it is closed, and the guidance builds that in rather than leaving it to goodwill: NICE requires the woman's GP to be told about a referral, and makes wellbeing a standing item at every postnatal contact so the finding is revisited by whoever sees her next. Your equivalent act is to record which contact the enquiry happened at, what the answer was, and who owns the next step.

6.5 The enquiry that no instrument performs

Alongside the depression questions, and frequently omitted, runs a second enquiry that is historical rather than symptomatic. NICE directs that at a woman's first contact with services in pregnancy and the postnatal period the clinician asks about three things:

- any past or present severe mental illness;
- any past or present treatment by a specialist mental health service, including inpatient care;
- any severe perinatal mental illness in a first-degree relative, named as mother, sister or daughter.

Note the strength of the instruction: the depression enquiry is framed as something to consider, this one as something to do. Note also what it is for. A symptom questionnaire describes today, and the women at highest risk here are frequently well when asked. No rating instrument detects a lifetime course or a family history, so this is the only route by which the highest-risk group is identified, and it runs through history-taking rather than screening in the technical sense.

What follows from a positive history does not wait for symptoms. NICE directs referral to a secondary mental health service, preferably a **specialist perinatal mental health service**, for

assessment and treatment of every woman who has or is suspected to have severe mental illness, and every woman with any history of one, whether from pregnancy, the postnatal period or any other time in her life. History alone triggers it, and the GP is told. This period compresses the interval between the first sign of relapse and a dangerous outcome, so the assessment must be in place before the sign appears.

6.6 What actually happens to a positive screen

The fourth decision is the one services skip, and NICE specifies it precisely. A positive answer to either depression identification question, a woman judged at risk, or clinical concern opens two branches, and the clinician chooses:

- use the **Edinburgh Postnatal Depression Scale** or the **Patient Health Questionnaire** as part of a full assessment; or
- refer to her GP, and to a mental health professional if a severe mental health problem is suspected.

Two structural points follow and they are the heart of this topic. The instrument is the second step of the pathway, not the first: the screening act is the conversational enquiry, and the rating scale enters afterwards, inside a full assessment, in a woman who has already said something. A service that inverts this hands the questionnaire out at a desk and scores it without a conversation. Referral is also an alternative to using the instrument rather than a consequence of it, which matters wherever the person who detects the problem is not the person who will assess it.

These notes name the instruments and stop there. What an examination can fairly ask is where an instrument sits in the pathway, who administers it, and what its result may decide.

TRAP **Starting an antidepressant on the strength of a positive depression screen.** ACOG requires screening for **bipolar disorder** before pharmacotherapy for depression or anxiety is initiated, if it has not already been done. This is a sequencing rule inside the pathway rather than a fact about either illness, and it is the front door's most consequential ordering decision: a depression screen is cross-sectional and knows nothing of lifetime course, so a pathway beginning with a positive screen can end in a precipitated episode of a different kind.

6.7 The intervals that make a positive screen mean something

A pathway with no clock is an aspiration. NICE attaches two intervals to a perinatal mental health referral: assessment for treatment within **2 weeks** of referral, and psychological interventions within **1 month** of the initial assessment. Both sit in the same guidance as the screening recommendations: the body that tells you to ask also tells you how fast you must answer for the reply.

They are short for a reason. The perinatal year is a moving target: the infant's developmental window does not pause while a waiting list clears, the mother's capacity to attend falls as the illness progresses, and the contact through which she was detected expires on its own schedule. A

wait unremarkable in general adult practice is useless here, because by the time it is reached she is no longer attending the service that found her.

4	6 to 8 weeks	0.05	1.2
MINIMUM SCREENING EVENTS ACROSS THE PERINATAL YEAR, AUSTRALIAN GUIDELINE	AFTER THE BIRTH, THE GP POSTNATAL ASSESSMENT, NICE	PSYCHIATRISTS PER 100,000 POPULATION, MADHYA PRADESH, LOWEST REPORTED	PSYCHIATRISTS PER 100,000 POPULATION, KERALA, HIGHEST REPORTED

6.8 The Indian position: the contacts exist, the instruction does not

Everything above describes systems that have decided to screen. India has not, and the absence is documented rather than assumed. A systematic review of Indian national maternity and mental health policies and programmes concludes that they appear not to consider perinatal mental health at all; its search yielded **11** relevant documents and no peer-reviewed publications, and identified no specific national policy or programme on maternal mental health. A policy analysis records that the **National Mental Health Policy**, launched in 2014 with a stated focus on vulnerable populations and de-stigmatisation, still fails to include perinatal women among the populations named as susceptible. Promising initiatives exist at state level; where they do not, need goes unrecognised and unmet.

Why the referral limb is the harder problem. Citing the national mental health survey of 2015 to 2016, the same analysis reports that every state except Kerala fell below the benchmark of **one psychiatrist per 100,000 population**, the reported figures spanning more than an order of magnitude between lowest and highest. Those figures are quoted in a policy analysis rather than read from the survey report, and are best taught as reported rather than settled. The conclusion does not turn on the decimal place: the referral limb every Western pathway assumes cannot exist at scale across most Indian states. That argues for a pathway built on task-shifted first-line management and brief psychological intervention by trained non-specialists, with specialist referral reserved for severe illness and for the history-based enquiry above. It is not an argument against screening; it is a decisive argument against installing an instrument and calling it a service.

IN INDIA

The contacts exist and are already funded. Cash benefits attached to four antenatal care visits, two postnatal care visits and institutional delivery create windows in which a woman is present, expected and identifiable, and the authors propose them as the natural sites at which healthcare workers could screen for perinatal mental illness. The workforce exists too: **accredited social health activists**, auxiliary nurse midwives and staff of primary and community health centres, credited by the same authors with the country's falling maternal and infant mortality. What is missing is the instruction to ask, and a named destination for the answer.

A perinatal screening pathway is judged by what happens in the fortnight after a positive answer, never by the instrument that produced it.

7 · Postpartum psychosis (presentation, emergency management)

Why it matters clinically. Nearly every other perinatal presentation is answered with an appointment. This one is answered with a clock, and the second patient in the room cannot report anything. What the service owes her is a same-day assessment by somebody with the authority to admit, a decision about where she sleeps tonight, and a written answer to who is holding the baby meanwhile. What postpartum psychosis is, how it declares itself and how its phenomenology separates from its neighbours belong to the Other psychotic disorders, delusional syndromes and catatonia notes, which own it as a psychotic disorder.

The examination question has the same shape: what you do, in what order, on whose authority, and where she and the baby go next. Candidates lose the marks by preparing it as a description and meeting it as a disposition. Every decision below is made for two patients at once, the frame set out where prescribing in pregnancy is taken up in these notes.

7.1 The classification that removes the discretion

The 2023 ACOG clinical practice guideline on mental health conditions during pregnancy and the postpartum classifies this presentation as an **obstetric and psychiatric emergency**, and as a severe mental health illness. The dual assignment is the operative part: it belongs to two services at once, so neither can hold it as a referral to the other and wait. It also sets a default for the time when you are still uncertain, since the trigger for everything that follows is a patient with possible or probable postpartum psychosis, not a confirmed one, which puts the threshold for acting below the threshold for diagnosing.

TRAP **Each service assumes the other owns her.** The obstetric team sees a psychiatric problem in an obstetric bed; the psychiatric team sees a recently delivered woman with a wound, a fundus and a feeding infant. The referral moves sideways while the clock runs, and both sets of notes honestly record that they referred on. Begin the act, then call the other team.

7.2 What "immediate" means once somebody writes it down

NICE guideline CG192 on antenatal and postnatal mental health, published in 2014 and last updated in 2020, is where the word acquires a number. A woman with sudden onset of symptoms suggesting postpartum psychosis is referred to a secondary mental health service, preferably a **specialist perinatal mental health service**, for immediate assessment **within 4 hours of referral**. No other perinatal presentation in that guideline carries a response time counted in hours. An emergency nobody has timed cannot be audited.

Three details are worth holding apart. The trigger is sudden onset of symptoms, so the referrer need not have made the diagnosis. The destination is a service, not a named individual, which puts the problem of finding somebody free on the receiving end. And the interval is a time to assessment, not to admission: it promises a competent pair of eyes, not a bed.

Assessed within 4 h	A psychiatric emergency	Staffed round the clock, all week
NICE CG192 STANDARD AFTER REFERRAL OF SYMPTOMS SUGGESTING THIS PRESENTATION	THE CLASSIFICATION THAT REMOVES THE DISCRETION, AND WITH IT THE OPTION OF A ROUTINE APPOINTMENT	DEDICATED MULTIDISCIPLINARY STAFF ABLE TO CARE FOR MOTHERS AND BABIES

Two honesties belong with that number. It and the postnatal window below are English NHS guidance, quoted with their owner attached rather than as a domestic obligation; no Indian national counterpart was available for the four-hour standard, and none requiring that the destination be a specialist mother and baby unit. The joint-admission default itself is a different matter and is NOT a gap: it is Indian statute, restated in Indian guidance, and it is taught with psychiatric emergencies in pregnancy and the postpartum period in these notes. And no source here states an observation cadence for the stretch between referral and assessment, so that gap is left open rather than filled with a plausible frequency.

7.3 The act at the point of contact, and the two rules about the infant

ACOG sets out the immediate act in one passage, written for whoever is standing there. The clinician encountering possible or probable postpartum psychosis obtains an **emergent psychiatric consultation**, or otherwise connects the patient with emergency medical or emergency mental health services; the condition then requires immediate emergent evaluation, admission and treatment, to assure the safety of the patient and the infant together. **Intensive monitoring** is required, and the guideline names what it is for: the risk of suicide and the risk of infanticide. No source available here attaches an interval or content to that monitoring, so it is left unstated rather than invented. Risk assessment as a framework belongs to the Somatic-symptom, sexual, impulse-control disorders and suicide notes; infanticide is a risk to ask about here, its classification belonging to the Mental health legislation and forensic psychiatry notes.

Two supervision rules close the passage: the patient should not be left alone, and she should not be left unattended with the infant. They are separate rules, and the second is not a separation order. It says the pair are not to be by themselves together, which a third person in the room satisfies, and it is compatible with feeding, holding and ordinary contact.

MNEMONIC

Never alone, never alone with the baby

The first covers the mother's safety, the second the infant's, and the second is about who else is present rather than where the baby is. Both bite from the moment the presentation is suspected: before the assessment, before the bed, before anyone has agreed a diagnosis.

7.4 What the admission actually buys

An admission is justified by what it delivers, and here that is a medical evaluation which cannot be completed in a corridor. Read the list below as an EXCLUSION SET rather than as a benefit of the bed: the question it answers is whether this presentation is organic, and that question is opened at the door and merely finished on the ward. The bedside acts that come first, and the order they come in, are set out with psychiatric emergencies in pregnancy and the postpartum

period in these notes. The **psychiatric inpatient evaluation** is described as one that may include:

- physical examination, and head imaging;
- complete blood count, and a complete metabolic panel;
- thyroid-stimulating hormone level, and ammonia level;
- lumbar puncture and electroencephalogram, which some clinicians add and others do not.

The strength is permissive: it may include these things, not must, and converting it into a compulsory battery invents a standard. No sequence, turnaround time or action threshold is given, and none is supplied here from memory. Each item needs a patient who stays put and a team that will chase the result, so an emergency department can start this work and only an admission finishes it. Treat the workup and the sedation decision as one plan with one owner: an evaluation abandoned because the patient was too disturbed, and never diarised again, has excluded nothing.

7.5 The risk formulation that has two subjects

At the first Indian mother and baby unit the admission decision is a formal step: every mother-infant dyad is assessed by the team for suitability, and that assessment has named limbs.

- a structured risk assessment covering self-harm and harm to the infant, carried out with a structured instrument, the **Formal Initial Risk Assessment for Mothers And Babies**, named here and not reproduced;
- infant health details;
- ruling out medical conditions in the mother;
- assessment of problems related to breastfeeding.

The shape of that list is the teaching: two limbs are about the baby and a third about the pair. A formulation that speaks only of the mother is not an abbreviated version of the right one but a different one, and it cannot answer what the team must close before admission, which is whether these two can safely be in a room together and on what conditions.

The 2023 Australian clinical practice guideline gives the test in usable form. Co-admission may not be appropriate for women who are severely unwell and incapable of caring for the infant, or where the safety of the infant may be compromised. Those are two independent gates, capability and danger, and they recover on different timescales, so collapsing them into one impression of how unwell she looks loses the decision. Against them sits the benefit the same guideline names, since co-admission assists the development of **mothercraft skills** and of a positive relationship with the infant.

GOOD TO REMEMBER

A supervision plan that names nobody is not a plan. Record who is with the mother now, who is with the infant now, who takes over at the next handover, and what would change the arrangement. The rules being absolute, the only variable is which named adult discharges them at any hour, and that is what goes missing between shifts.

7.6 Where she goes, and where the burden of proof sits

The destination is a decision, not a vacancy. The default is that mother and infant are admitted together, and separation is the deviation that has to be argued for, authored, dated and reviewed rather than arrived at because no cot was free. That is the whole of what this topic needs from the destination question, and it is the part a candidate is examined on: not what a specialist unit contains, but who carries the burden when one is not available.

What such a unit is, what its presence changes, the service specification behind it, the Indian answer to who cares for the infant while its mother cannot, and the availability position in this country are all set out with lactation and mother-baby unit care in these notes. This topic does not restate them, because a destination described twice in one chapter drifts, and the two accounts then disagree about the thing a reader most needs to be sure of.

The Indian statutory position on rooming-in and on the review clock that governs any separation is a different matter again, and it is not guidance but law. It is taught with psychiatric emergencies in pregnancy and the postpartum period in these notes. A clinician who separates a mother from her infant in India is working inside a statutory framework with an interval and a ceiling that are not the team's to set.

RULE **Joint admission is the default and separation is the deviation.** The clinical question is never whether to justify keeping them together; it is whether the reasons for parting them are good enough to be written down and reviewed.

7.7 The handover, and what this section hands on

What the receiving team needs is not the mental state examination, which they will repeat, but what is hard to reconstruct: when the clock started, what the risk assessment covered on both sides, who has been supervising each of them and under what instruction, and the reason for the destination chosen. A handover carrying the diagnosis but not the supervision plan has passed on the label and dropped the safety.

Three boundaries are worth naming. What changes about every other emergency when the patient is pregnant or newly delivered is taken up in the section of these notes on psychiatric emergencies in pregnancy and the postpartum period, which is built around this presentation. What the unit does across the rest of the admission sits with the section on lactation and mother-baby unit care, and agent selection in a breastfeeding woman with the section on drugs in breastfeeding, a decision that follows the destination rather than preceding it.

Postpartum psychosis is acted on before it is confirmed: same-day assessment by a service that can admit, an admission that buys the medical evaluation, and a supervision plan naming an adult for the mother and an adult for the infant, written before either is left alone.

8 · Mother-infant bonding and infanticide risk

Why the marks are here. A woman can be profoundly depressed after childbirth and remain warmly, competently attached to her baby. Another can pass every mood enquiry you put to her and feel nothing at all for hers. Almost every clinical error made in this area comes from assuming that one of those two sentences is impossible. The depressive syndrome itself, its specifier, its epidemiology and its first-line treatment belong to the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes. What is owned here is the relationship: how the bond is elicited and observed at the bedside rather than inferred from the mood, how far along the rejection and hostility gradient a given mother has travelled, and what the resulting formulation obliges you to arrange for the infant before she leaves your care. Every decision here is made for two patients at once, as the sections on prescribing in pregnancy set out, and the infant is the patient who cannot be interviewed.

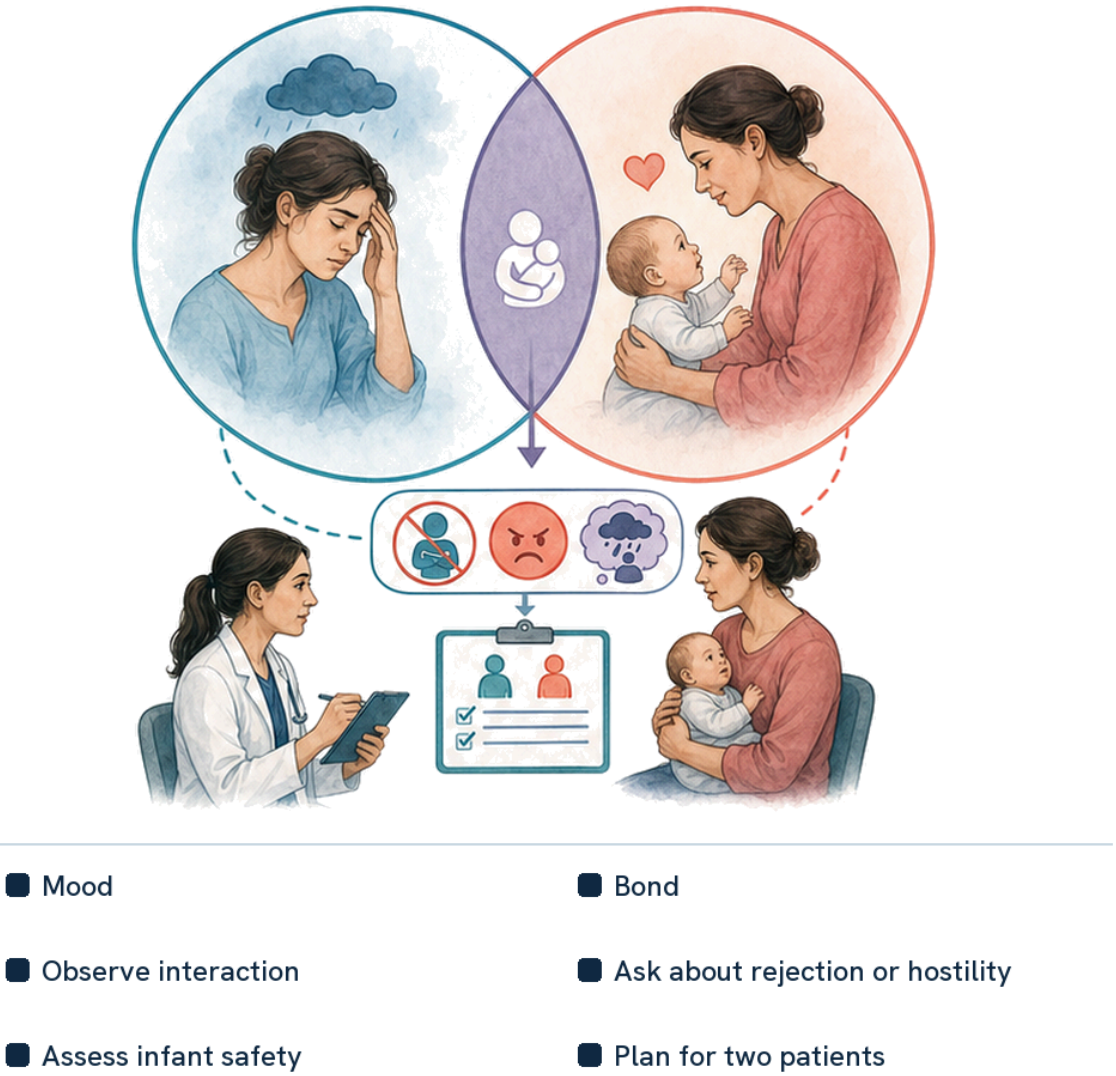

Fig 28.6 Maternal mood and the mother–infant bond are related but not interchangeable. Assessment elicits and observes the relationship directly, asks about rejection, hostility and thoughts of harm, and makes a safety plan for both mother and infant.

Infanticide enters this topic in one form only: as a risk to be asked about and acted on. The classification of filicide and neonaticide, and its forensic frame, belong to the Mental health legislation and forensic psychiatry notes, which also carry postpartum psychosis as the illness context in which infanticide is conventionally taught. That taxonomy is named here and not reproduced, for a clinical reason: a classification of completed acts is a retrospective instrument built for courts, and it does not tell you what to ask the woman in front of you on a postnatal ward.

8.1 Separate the bond from the mood before you ask anything else

The argument for treating a disturbed mother-infant relationship as an entity in its own right, rather than as a symptom of postnatal depression, opens with a claim about where the feeling points. A disturbed relationship is a distinct phenomenon whose **affective focus** differs from that of depression. That word carries the whole argument. Depressive affect is diffuse and self-

referred: everything is grey, and the woman herself is the worthless object. The affect of a bonding disorder is aimed, and it is aimed at one specific person who is in the room.

The claim is then supported in both directions, which is what makes it a dissociation rather than a preference. In one direction, maternal aversion to the infant is often disproportionate to depression and can occur without it. That half obliges you to ask about the bond in a woman whose mood enquiry is entirely negative, and it is why a depression instrument can never serve as a bonding instrument: it is not measuring the thing. In the other direction, only a minority of depressed mothers have a relationship problem with their infants, and what follows is both a clinical instruction and an ethical one. Select that minority for special treatment. Do not stigmatise the rest. Assuming that a depressed mother is a poorly bonded mother is wrong most of the time and harmful every time it is wrong, because the assumption reaches the woman, her family and often her notes.

The figure that makes the argument operational comes from women already diagnosed with postnatal depression, among whom a bonding disorder was present in **29%** of those depressed mothers. It sits in the right place to be useful: high enough that the bond must be asked about in every depressed mother, and low enough that it cannot be assumed in any of them. Two caveats travel with it: it is reported in a later paper citing an earlier study rather than generated by the paper that carries it, and it describes women referred for psychiatric help rather than a community.

RULE **Mood and bond are separate endpoints, so they are enquired about separately, recorded separately, and recovered from separately.** A mood enquiry that comes back negative has excluded a mood disorder and nothing else. A mood enquiry that comes back positive has raised the prior probability of a bonding disorder and settled nothing. In practice this means two passes at the same interview: one about how she feels in herself, one about how she feels towards this baby, in that order, because the second is harder to disclose and comes more readily once the first has shown that you are not there to judge her.

There is a genuine counter-position, and an examiner may know it. In the founding series, postnatal mental illness and recalled severe pain during labour were both significantly associated with these disorders, which in their severe forms did not occur in the absence of postnatal mental illness. Taken at face value that makes severe bonding disorder a complication of illness rather than an independent entity. The sampling caveat is load-bearing: the cohort was recruited among women who had suffered postnatal mental illness, so it was structurally incapable of demonstrating severe bonding disorder without it. The safe answer states both positions and says why they cannot be compared directly.

8.2 Establish that the disturbance belongs to one child

The clinical description that founded the field came from a series of self-selected women who reported absent affection, sometimes frank hate, rejection, neglect or impulses to harm, in relation to at least one of their children. Two features of it do the diagnostic work. The feelings often began immediately or very shortly after the birth, so this is not the slow erosion of a relationship across months of exhausted parenting. And, with a single exception in the whole

series, they were **specific to one child**, which is what produced the term maternal bonding disorder rather than any language about parenting capacity or personality.

Child-specificity is the most useful discrimination available at the bedside and the one a candidate most often misses. A woman who is affectionate with her older child and cannot bear to hold her newborn does not have a parenting problem or a failure of character. She has a disorder of one relationship, and the intact relationship sitting beside the disordered one is the evidence. It also reframes the conversation, because a mother who believes she is being assessed as a mother will conceal, while a mother who understands that you are asking about one particular bond will often tell you. So ask it plainly: whether she felt like this with her other children, and what is different about this one.

What the disorder contains has been described consistently across the literature: a distressing lack of maternal feeling, irritability, hostility and aggressive impulses, pathological ideas, and outright rejection. The list runs from an absence to an action. The absence, that flat and frightening nothing where the mother expected to find love, is the least likely to be volunteered without a direct question, because it carries more shame than any symptom in perinatal psychiatry. Its distressing quality matters diagnostically: these women are not indifferent to their indifference, and a mother who reports the absence with no distress about it is describing something else.

8.3 Place it in the classification, and know why it is missing from yours

A construct with a substantial clinical literature, a structured interview and inpatient admissions attached to it is nonetheless absent from most residents' differentials, and the reason given by the field's own originator generalises. Writing in 2004, he attributed the neglect of these disorders principally to their absence from ICD-10 and DSM-IV. That is a dated statement, since both classifications named in it have since been superseded. The mechanism it describes is not dated at all: a phenomenon with no code is not counted, so it is not audited, so it is not commissioned for, so it is not taught, so it is not looked for.

The current classificatory position is a partial answer at best. The nearest available category is **caregiver-child relationship problem**, defined as substantial and sustained dissatisfaction within a caregiver-child relationship, including a parental relationship, associated with significant disturbance in functioning. Read that against the clinical picture and the gap is obvious. Dissatisfaction and functional disturbance are captured; rejection of the infant is not, and pathological anger directed at the infant is not. The old complaint has been answered in form rather than in substance, and a candidate who says so, having quoted the definition accurately, is showing the judgement these questions are set to find. One limit is declared rather than hidden: that definition came from a coding reference mirroring the classification rather than from the classification's own browser, so the alphanumeric code is not printed here and should be verified at source.

The practical consequence is that nothing in the record will prompt you: no box to tick, no code that triggers a review. The enquiry has to be made deliberately, in free text, and a unit that wants

it done reliably must build the prompt into its own postnatal proforma.

8.4 Ask about rejection and about anger, in the words the literature uses

The gradient is useful only if it is expressed as behaviour a clinician can ask about by name, and it is. At the severe level of rejection the mother may try to escape; may seek permanent transfer of infant care within or outside the family; may express the wish that the baby be stolen, or succumb to cot death. Those last two are what candidates most often fail to ask about, because they sound too extreme to raise, and they are exactly what a woman will confirm if asked plainly and never volunteer. The question is not whether she wants to harm the baby. It is whether she has found herself wishing the baby were simply gone, by any route, including one that would not be her doing.

Presented separately in the same account, and the separation matters, is **pathological anger**: shouting, cursing or screaming at the infant, accompanied by impulses to strike, shake or smother the child. It is tempting to read them as two points on one severity scale, with anger further along. They are not described that way. **Emotional rejection**, the core concept of a bonding disorder, and pathological anger, which may harm the baby, can coexist, but they have different clinical features and require different intervention strategies. They are elicited by different questions, and the inference each supports differs: rejection points towards neglect, deprivation and relinquishment of care, anger towards an assault that could happen tonight. That last reading is clinical inference from the two descriptions rather than a sourced finding, and should be offered as such.

The category ladder and its proportions come from over 200 mothers referred to services in Birmingham and Christchurch, all interviewed with a semi-structured interview. **Established rejection** was present in **10.6%** of those referred mothers and threatened rejection in a further **14.6%** of them, while pathological anger of some degree was present in **28.6%** of the same referred mothers and was severe in 8.3% of them. Quote these with their denominator attached every time: they describe women already referred to specialist perinatal services, and an answer offering them as population prevalences has misread the study rather than merely rounded it.

CATEGORY ON THE GRADIENT	WHAT THE MOTHER DESCRIBES OR IS SEEN TO DO	WHAT IT SHOULD MAKE YOU ASK NEXT	WHAT IT CHANGES TODAY
Threatened rejection	Rejection voiced or approached rather than settled into. The source separates it from established rejection but does not describe its behaviours, and none are supplied here	What would have to happen for the threat to become a request, and whom she has already told	Frequency of contact, and whether the family have begun arranging a transfer of care
Established rejection	Attempts to escape; seeking permanent transfer of infant care within or outside the family; expressing the wish that the baby be stolen, or succumb to cot death	Who is physically caring for the baby now, and what happens when she is alone with the infant	Whether the infant's daily care can rest on her at all, and who else is named to provide it
Pathological anger	Shouting, cursing or screaming at the infant, accompanied by impulses to strike, shake or smother the child	Whether an impulse has ever come close to an act, what stopped it, and whether that brake still holds	Whether the infant can be unsupervised with her tonight, which is a disposition question rather than a formulation question

The two antenatal openings. The same referred series found rejection strongly associated with unwanted pregnancy and lack of interaction with the foetus. Both are askable before delivery, in an ordinary antenatal consultation, in ordinary language: whether this pregnancy was wanted, and whether she talks to, thinks about or has any sense of the baby she is carrying. That converts a postnatal problem into an antenatal enquiry, which is the only point in the pathway where anything can be arranged before the relationship starts badly.

8.5 Assess the relationship at every postnatal contact, and decide who supplies the information

The guideline-level bedside method is short enough to memorise and worth memorising. NICE guidance on antenatal and postnatal mental health, published in 2014 and last updated in 2020, requires clinicians to recognise that some women with a mental health problem experience difficulties with the mother-baby relationship, and to assess the nature of that relationship at all postnatal contacts along three named axes: verbal interaction, **emotional sensitivity** and physical care. It further requires that the woman's own concerns about her relationship with her baby are discussed, and that information and treatment for the mental health problem are provided. Read those last two duties as concurrent rather than sequential: the relationship is not parked until the illness is treated.

Its economy is the point. Verbal interaction is whether she talks to the baby at all, and in what register. Emotional sensitivity is whether she reads and answers the infant's signals, or handles a distressed baby as an object to be managed. Physical care is whether feeding, changing and

holding are done, and how. None of it needs an instrument, a room or an appointment, and all of it can be recorded in a line.

MNEMONIC

Ask her, watch them, ask them

The three sources of a bonding picture. **Ask her**: her own account of how she feels towards this baby, taken separately from the mood enquiry and after it. **Watch them**: the dyad observed directly, across the named axes, including what happens at separation. **Ask them**: the relatives and nursing staff who have watched the pair across a whole day and night. No single source is sufficient, and disagreement between them is data rather than noise.

Where a structured route is wanted, a semistructured interview containing a specific section for assessing perinatal bonding disorders exists in the form of **the Stafford Interview**, developed by the same author who advanced the construct. Where a self-report route is wanted, **the Postpartum Bonding Questionnaire** is the named instrument in this literature. Both are named here and nothing is reproduced from either: no item, no probe, no scoring rule, no threshold. An instrument reproduced piecemeal in a revision note gets used piecemeal in a clinic, and a bonding measure administered without its scoring yields a number that feels like a finding.

The important design question is not which instrument but who supplies the information. At the mother and baby unit at NIMHANS, Bengaluru, described in 2015, an objective bonding instrument was used to assess maternal infant safety, psychotic ideas about the baby, maternal care toward the baby and other aspects of maternal behaviour toward the infant, based on family and nurses observations rather than on what the mother said about herself. That is the only workable method in a woman too unwell to give an account, or too frightened of losing her baby to give an honest one, and those groups include most of the mothers about whom the question matters.

What that observation consists of was set out concretely by the same unit in a later outcome series, reported in 2021. Each mother-infant dyad was observed for:

- care for the baby's basic needs;
- affectionate behaviour;
- significant incidents;
- an overall assessment of safety;
- how the mother handles separation from the baby;
- whether the mother has been separated from the baby in recent days, and the reasons for it.

The last two are what a Western checklist usually omits and what carries most information in an Indian ward, where separation is often arranged informally by relatives long before a clinician has been asked. A mother relieved by separation, a mother distressed by it and a mother who does not register it are not the same formulation, and eliciting the difference costs nothing beyond a nurse who writes down what she saw.

ROUTE	WHO SUPPLIES THE INFORMATION	WHAT IT CAPTURES WELL	WHERE IT FAILS
The woman's own concerns, raised at every postnatal contact	The mother	The distressing absence of feeling, which nothing else detects, and her own reading of the relationship	Shame, and fear of losing the baby, both of which suppress disclosure
Direct observation of the dyad along the named axes	The clinician at the contact	Verbal interaction, emotional sensitivity and physical care, in minutes and with no equipment	A single brief window, and a mother who knows she is being watched
Structured clinical interview with a bonding section	The mother, with a trained interviewer	Category assignment on the rejection and anger gradient	Training and time; unavailable in most general settings
Third-party observational rating	Relatives and ward nurses across a whole day	Infant safety, care actually delivered, incidents, and behaviour at separation	Observer variability; needs a ward and a habit of recording

PITFALL

A reassuring self-report bonding questionnaire in a floridly unwell or a frightened mother is not reassurance, and filing it as such is the commonest way this assessment passes on paper while failing the infant in fact. Self-report assumes a respondent who can introspect and who believes that answering honestly is safe. A woman with active psychotic illness may satisfy neither condition, and a woman who has worked out that her answers decide whether she keeps her baby will satisfy the second only if you have told her, credibly, what happens next. Where self-report and observation disagree, the observation is the safer document, and the disagreement itself belongs in the notes.

8.6 Formulate the risk, and make the intrusive-thought discrimination first

Guideline risk assessment in the perinatal period is carried out with the woman and, if she agrees, her partner, family or carer, and is focused on self-neglect, self-harm, suicidal thoughts and intent, risks to others including the baby, smoking, drug or alcohol misuse, and domestic violence and abuse. The baby is written inside the risks to others limb, in a parenthesis, rather than given a heading of its own. That drafting is exactly how an infant gets missed by a clinician working down a proforma at speed, and it is why a bonding formulation has to be conducted as its own act rather than trusted to appear inside a general risk assessment.

What the formulation must consider is set out probabilistically and should be repeated in that register. The risks are higher in mothers with a disorder of the mother-infant relationship, and emotional deprivation, impaired cognitive and personality development, child abuse, child neglect and infanticide are probably commoner in this group. That is probability rather than established fact, and reproducing the hedge is what allows infanticide to sit among the outcomes to be asked about and acted on, rather than becoming the headline that turns every disclosure of

maternal ambivalence into a child protection emergency. The slow outcomes on that list happen far more often, and a formulation attending only to the dramatic one will miss the ones already under way.

The discrimination on which the whole formulation turns is between an intrusive thought and a psychotic idea. In its clinical practice guideline on screening and diagnosis of mental health conditions during pregnancy and postpartum, issued in 2023, the American College of Obstetricians and Gynecologists states that **intrusive thoughts** not associated with psychosis are common, that they can indicate severe distress and severe illness associated with depression, anxiety and obsessive-compulsive disorder, and that they most often do not indicate risk of actual harm to the infant, although they do merit further inquiry and evaluation. The discriminator is whether the thought is ego dystonic and distressing to her: an unwanted image of the baby being dropped, which horrifies her and which she manages by avoiding the stairs, marks illness severity rather than danger. Note the clause that survives the reassurance: common and non-predictive is not the same as ignorable.

TRAP **Reading a disclosed ego-dystonic intrusive thought of harm as evidence that the baby is in danger, and separating them on it.** The error is costly in both directions. The mother who has just described the most frightening thing in her head, having been told it was safe to speak, watches her infant removed, and she will not disclose again. Meanwhile the presentation that genuinely warrants urgency, an idea about the baby held with conviction and without distress, is quieter, is not offered spontaneously, and is missed by a clinician whose alarm has already been spent. Distress about the thought is reassuring; conviction is not; the enquiry continues either way.

8.7 Convert the formulation into supervision, surrogate care and a discharge plan

A bonding assessment that does not alter a plan has not been done, and there is Indian inpatient evidence for both of the ways it alters one. First, the disorder can stand alone as a reason for admission. In the Indian mother and baby unit series, three mothers were admitted for a primary mother-infant bonding disorder that was independent of the psychiatric problem. That is a small absolute number, offered as a demonstration that the category exists in practice rather than as a frequency estimate. Its force is that the bonding disorder was severe enough to justify an inpatient bed in its own right, in an Indian setting, without a mood or psychotic illness driving it.

Second, and more useful for everyday work, the bonding rating generates the discharge plan. Among 98 dyads in that unit who needed mother-infant bonding interventions, bonding was rated as normal at discharge in 88 of those mothers, while ten of those dyads needed close supervision or **surrogate infant care** even at discharge. Most dyads who need bonding work respond to it, which is the reason to do the work rather than plan around the relationship failing. A minority do not, and for them the discharge summary must name a person: who is supervising, when, and what specifically they are supervising against. A plan that says the family will help is not a plan. What a joint mother-and-baby admission is for, and how available such a facility is, is a separate question not taught here.

IN INDIA

Most of the assessment table assumes a service the average Indian unit does not have. A dedicated joint admission facility exists in very few centres, which leaves the method needing nothing but a ward, a nurse and the habit of writing down what was seen. In most Indian wards the person continuously with the mother and baby is a relative rather than a nurse, which makes third-party observation unusually available and unusually unreliable at once, since the relative may be the one who wants the baby transferred, or the one who will be blamed if anything goes wrong. Ask them separately, and record who said it. The same reality shapes the discharge decision: where close supervision or surrogate infant care is needed, the surrogate will almost always be a family member, so the plan names the individual, confirms that they have agreed, and sets a review date, rather than assuming a joint family absorbs the problem.

8.8 Re-examine the bond after the mood has recovered

The last act is the one most often skipped, and it is a timing rule rather than a technique. Where bonding difficulties are prominent, the instruction is to attend to the relationship problems in their own right and to assess whether they are still present beyond the recovery from depression. The timing is the whole of it: the re-assessment comes after mood recovery and not at the same sitting, because before recovery you cannot tell how much of the flatness towards the baby is the depression speaking. Treat the illness, look again at the bond, and treat what is left as a target in its own right. No interval is given in the source used here, so this is taught as a sequence and not as a number of weeks.

Indian prospective inpatient data make the same point as a null result. In dyads admitted to a mother and baby unit and assessed at admission, at discharge and again at follow-up, there was no correlation between maternal psychopathology and mother-infant bonding. The translation should be said plainly to teams: the woman whose psychosis has resolved is not thereby a woman whose bond has recovered. Symptomatic recovery and bonding recovery are separate endpoints, they move independently, and discharging on the first without measuring the second is a decision taken on the wrong variable.

GOOD TO REMEMBER

Book the second look before you need it. At the moment the mood is treated and discharge is being discussed, write two things into the plan: when the bond will be re-examined after recovery, and the named person who will do it. Both are trivial to record on the spot and impossible to reconstruct afterwards; without them the re-assessment becomes a good intention nobody owns. If the mother is going home to a district where nobody will see her again for months, make the re-assessment the stated reason for the follow-up appointment rather than bolting it onto a medication review.

29%	10.6%	14.6%	28.6%
OF MOTHERS DIAGNOSED WITH POSTNATAL DEPRESSION HAVE A MOTHER-INFANT BONDING DISORDER	ESTABLISHED REJECTION, AMONG OVER 200 MOTHERS REFERRED TO SPECIALIST SERVICES	THREATENED REJECTION, AMONG THE SAME REFERRED MOTHERS	PATHOLOGICAL ANGER OF ANY DEGREE, AMONG THE SAME REFERRED MOTHERS

A depression screen is not a bonding enquiry: ask about the mood and the bond separately, ask about the bond again after the mood has recovered, and let the answer to that second question, not the first, decide who is watching the baby at discharge.

9 · Lactation and mother-baby unit care

Why the marks are here. Ask a candidate what to do for a severely ill woman three weeks after her delivery and the answer arrives as a drug. Ask where she is to be nursed, who holds the baby while she is sedated, who decides whether the baby stays with her, and who picks up the telephone six weeks after she goes home, and the answer usually stops. That second set of questions is what this section owns: what a mother-baby unit is, what it is asked to do, how the joint admission and separation decisions are made and remade, what is physically done for a feed during acute treatment, and what an Indian team assembles when no such unit is within reach. Which drug to choose for a lactating woman is a different question with its own metric, and it belongs to the topic on drugs safe in breastfeeding in these notes.

Carry one idea through the section. A mother-baby unit is not a psychiatric ward that tolerates an infant on the premises. It is a service with a written specification, and every clause of it exists because something predictable goes wrong when it is missing.

9.1 The specification, and why each clause earns its place

The structural definition used by the Indian group that built the country's first such service is deliberately spare, and it teaches better than any description of the atmosphere on the unit. A mother-baby unit is an inpatient psychiatry service with at least **four** beds, physically separate from the other wards, configured for **joint admission** of the mother along with her baby, and staffed round the clock, every day of the week, by dedicated multidisciplinary staff who look after both of them.

Each clause earns its place. A minimum bed number exists because a smaller service cannot hold a rota, and one or two cots on an acute open ward is a gesture that collapses the first time the ward is full. Round-the-clock staffing matters because the hours in which an acutely unwell newly delivered mother is least able to care for her baby are the night hours, exactly when a general ward runs thinnest. And staff who care for both is what separates the model from every imitation of it: without someone competent and rostered to notice the baby is unwell, the service has an infant on the premises and nobody accountable for that infant.

What the unit is *for* is a separate specification from what it *is*, and the functional one is what candidates omit. Such a unit is expected to encourage breastfeeding, deliver specific interventions for parenting, provide psychotherapy, work on the mother's relationship with her infant, and educate her about the current illness and about preventing the next one; it must also support the spouse and caregivers and involve social services where the infant is at risk. Treating the mother's illness does not appear on that list, because treatment is the assumption rather than the purpose. The purpose is that a functioning dyad leaves the hospital, and a unit discharging a well mother and a relationship nobody has worked on has done the ward's job and not the unit's.

The English service guidance adds the limbs that make the specification auditable rather than aspirational. Specialist perinatal inpatient services should provide facilities designed specifically for mothers and babies, be staffed by specialist perinatal mental health staff and staffed to care appropriately for the babies, liaise effectively with general medical and mental health services, have the full range of therapeutic services available, and be closely integrated with community services so that continuity is preserved and the stay kept short. The last two limbs are what a new service forgets: without a therapeutic programme a unit is an admission ward with cots, and without community integration it produces long stays because there is nowhere safe to discharge into.

RULE **Joint admission is the default and separation is the deviation that has to be justified, recorded and reviewed.** Almost every ward runs the opposite assumption without ever having decided to, because the infant is not the ward's patient. The English guidance inverts it explicitly: a woman needing inpatient care for a mental health problem within 12 months of childbirth should normally be admitted to a **specialist mother and baby unit**, unless there are specific reasons for not doing so. Read that for its grammar: the burden of argument sits on whoever proposes to separate the pair, and that direction is worth more in an answer than the recommendation itself.

9.2 The arithmetic that decides whether such a unit can exist near you

Residents in India are routinely taught that mother-baby units are scarce here, in a tone implying the scarcity is a national failing. The service-planning parameter behind the model explains most of it. The same English guidance specifies that each **managed perinatal mental health network** should have designated specialist inpatient services covering a population in which there are between **25,000 and 50,000** live births a year, varying with the local rate of psychiatric morbidity.

The catchment for one unit is therefore defined by births rather than headcount or distance, and it is a large number of births. A service with that denominator is by construction regional or tertiary, never a district service, and it will sit in a handful of centres in any health system that builds it at all. So most severely ill postnatal women anywhere, and the overwhelming majority in India, will be treated by clinicians who have no mother-baby unit and never will. The model is therefore taught not as an ideal but as a specification you can partially reproduce, and the defensible answer to a district planning question names the unit as the regional referral destination and spends its words on what the district builds instead.

9.3 Who comes through the door, and what the case-mix demands of the design

The published series from India's first unit gives the denominator a resident actually needs. There were 237 admissions across a little over four years from July 2009; the mothers had a mean age of 24.25 years and a mean of 6.50 years of education, and most came from lower socio-economic status and rural backgrounds. Most of them, 80 per cent, stayed for three to four weeks, and the mean length of stay was 17.23 days.

That profile should change how the unit is run rather than merely being recited. Women admitted for weeks from rural homes with minimal schooling cannot be handed written

psychoeducation and a follow-up card and be expected to return: the family that travelled with them is part of the treatment and of the discharge plan. A stay of weeks is also long enough for a feed to be established or lost, which is why lactation here is an active programme and not a courtesy.

The risk case-mix dictates the physical design. In the same service, suicide risk was present in 36 mothers, 17 per cent of the series, and risk to the infant from the mother in 32 mothers, 16 per cent; problems in the mother's relationship with her infant affected 98 mothers, 41 per cent. Two of those percentages are the series' own and do not recompute against the series' own denominator: the first two work out nearer fifteen and thirteen and a half per cent. They are reproduced as printed rather than silently corrected, and the design argument is made from the counts, which are not in doubt. A unit admitting mothers together with their babies is therefore admitting, at any time, roughly one mother in seven who poses some risk to the baby sleeping beside her, and it must be built and staffed on that assumption rather than on the hope of filtering such women out at the door. Everything downstream follows: the sightlines, the observation arrangements, who may take the infant out of the bay, and the requirement that a member of staff rather than a relative is accountable overnight. The taxonomy of harm to infants by parents belongs to the Mental health legislation and forensic psychiatry notes; the design consequence belongs here.

The feed is in trouble at the door as often as the relationship is. Breastfeeding had stopped completely because of the maternal illness in 87 mothers, 36 per cent of that series, while 150 were still feeding at least partially on arrival. More than a third of the lactation work is therefore restoration, not maintenance, and a service that can only support a continuing feed will fail the sicker half of its intake.

ADMISSIONS IN THE INDIAN MOTHER-BABY UNIT SERIES	MEAN STAY, INDIAN MOTHER-BABY UNIT SERIES	MEAN STAY, FRENCH AND BELGIAN MOTHER-BABY UNITS	LACTATION RESTORED AMONG INDIAN MOTHERS WHO HAD STOPPED

9.4 How the unit is staffed, and the two posts an Indian service borrows

The first mother-baby unit in India opened in July 2009 at the National Institute of Mental Health and Neurosciences in Bengaluru, as a five bedded facility for mother-infant dyads. Naming the place and the date teaches better than a vague statement that such units are rare: it says where the Indian evidence comes from and gives the referral a destination.

Its staffing model is the transferable part. The unit is run by a multidisciplinary team of psychiatrists, psychiatric social workers and nurses; one psychiatry trainee is posted to it round the clock, and social work and psychology trainees provide part-time input. Two posts are not resident but available: a **lactation expert** is on call to respond to breastfeeding difficulties, and paediatric support is obtained from a neighbouring paediatric hospital rather than from an in-house paediatrician.

The design lesson in that sentence. An Indian unit does not solve the two-patient problem by employing two full establishments. It borrows the two competencies it cannot generate and

makes the borrowing formal rather than ad hoc. Telephoning the paediatric registrar when somebody happens to worry about the baby is not the same arrangement, because it depends on a psychiatric nurse recognising an unwell neonate. A named service, a route of referral and an expectation that the infant is reviewed as part of the admission converts a hope into a pathway.

IN INDIA

Those two on-call posts are exactly the two an ordinary Indian psychiatric ward lacks. Most district and many teaching hospitals have no identified lactation counsellor, and where one exists she is attached to the obstetric service and never comes to the psychiatry ward because nobody has asked her to. That is administrative rather than financial: one written arrangement with the obstetric or paediatric department buys the most useful non-psychiatric competency on the ward. If you cannot build a unit, build the two referral routes it borrows, because they are the cheap half of the specification.

9.5 The separation decision: safety, not diagnosis, and never final

This is the hard call in perinatal inpatient practice, because it is made about someone who is not your patient, on incomplete evidence, with consequences outlasting the admission. Two things must be held together: joint admission is the default, and a proportion of dyads cannot safely be admitted together on arrival.

The Indian series shows the decision being made and then unmade, which is the shape to reproduce. Ten mothers were refused admission to the unit initially because there was **serious risk to the infant** from the mother, and were cared for on a different ward away from the baby; they were moved into the unit with their infants once the high-risk status had improved. Three features of that practice are what to take. The criterion is the infant's safety as it stands now, not the mother's diagnostic label. The separation is an interim arrangement with an expected end rather than a disposal. And somebody must own the review, because a separation nobody is scheduled to reconsider becomes permanent by default.

Joint admission is not, however, a promise that the pair goes home together, and teaching it as one is dishonest. In a French mother-baby unit series, separation at discharge occurred in **23 per cent** of joint admissions; women admitted with acute postpartum psychoses and with major depressive disorders had better outcomes than those with chronic psychoses, and the latter were more often separated from their children at discharge. The authors make the point any good answer should: where separation occurred, the admission had bought the time in which to arrange the best available placement for the child. An admission ending in separation is therefore not a failed admission but one in which a considered decision replaced an emergency one.

The gradient replicates in a multi-unit national dataset from France and Belgium: women with schizophrenia or chronic delusional disorders, and women with personality disorders or intellectual disability, stayed longer, improved less, and were more often separated from their babies or discharged with supervision than women with other diagnoses. It is a robust finding and the most misused one in this topic.

TRAP **Converting the diagnostic gradient into a decision rule.** Candidates read that chronic psychosis predicts separation and then write that a mother with chronic schizophrenia should be separated from her infant. That inverts an observed association into a policy, and it fails both ways: it separates dyads that were manageable, and it reassures the team about a benign-sounding diagnosis attached to a frankly unsafe home. Diagnosis is not the criterion. What it legitimately does is tell you where to look hardest, how long to plan for, and when to open the placement conversation early, so the option is prepared and not forced.

When separation happens the infant goes somewhere, and the routes differ by jurisdiction. In the French series the separated children fell into two groups: those removed by judicial order into foster care, and those placed in the **unofficial custody of another family member**, an arrangement the children's court judge usually confirmed afterwards. The second route is the one that matters for Indian practice, where family placement is the norm and a court order the exception. That machinery is French, however, and the Indian legal route for a child in need of care and protection belongs to the Mental health legislation and forensic psychiatry notes rather than being asserted from a European series.

AXIS	SEPARATION DECIDED AT ADMISSION	SEPARATION DECIDED AT DISCHARGE
What triggers it	Serious risk to the infant from the mother, assessed on arrival	Persistent inability to care safely for the infant once the acute episode is treated
Expected course	Interim and reversible; the Indian series moved such mothers in once the risk state improved	May be durable; in a French series it occurred in 23 per cent of joint admissions
What the admission buys	A safe place to treat while the risk is reassessed	Time to arrange the best placement rather than an emergency one
Commonest error	Making it once and never scheduling the review	Reading it off the diagnosis instead of the observed caregiving

9.6 Managing lactation during acute treatment: the package, not the principle

Everyone agrees breastfeeding should be supported during psychiatric treatment. Almost nobody can say what supporting it consists of, which is why the itemised package from an Indian unit is the most useful content here. The interventions delivered were: dispelling myths about feeding during treatment; helping with positioning at the feed; educating the mother on timing the feed against the peak level of the psychotropic in her milk; encouraging electric breast pumps and **expressed breast milk** where sedation, agitation or a treatment session stopped her feeding; and seeking a lactation expert's advice for severe difficulties. Of the 87 mothers who had stopped breastfeeding because of mental illness, lactation was restored in 75, **86 per cent**.

Read that outcome twice. A feed stopped by maternal mental illness is in the great majority of cases recoverable, and it is recovered by unglamorous physical and educational work rather than by any decision about the drug. So "has stopped breastfeeding" at admission is a problem to be

worked on, not a fact to be recorded and left. The pump keeps the option open while she is too unwell to feed, and its absence in the first days makes the loss permanent.

MNEMONIC

Myths, Position, Timing, Pump, Expert

The five moves of the lactation package, in the order usually needed: dispel the **myths** that treatment forbids feeding; correct the **position** at the breast; teach the **timing** of the feed against the peak drug level in milk; use the **pump** and expressed milk when sedation, agitation or a treatment session stops her feeding; call the lactation **expert** for severe difficulties. The first two need no equipment and no prescription, and are the two most often skipped.

THE OBSTACLE AT THE BEDSIDE	WHAT IS ACTUALLY DONE	WHO DOES IT
The family believes any psychotropic makes the milk unsafe and has stopped the feed	The myth is addressed directly, with the family present, before anything else	Treating team, at admission
She is willing but the infant is not latching and the feed is failing mechanically	Hands-on correction of positioning and attachment at the feed	Nursing staff, repeatedly, not once
She is feeding but anxious about drug in the milk at every feed	Education on timing the feed against the peak psychotropic level in milk	Treating team, with agent-specific information
She is too sedated or agitated to feed, or is off the ward for a treatment session	Electric pump and expressed breast milk, preserving supply and option	Nursing staff, on a schedule not on request
Severe or persistent difficulty that ward measures have not solved	Formal referral for specialist lactation advice	Lactation expert, on call
Nobody has decided whether her drug is compatible with the feed at all	An explicit agent-level decision, written down rather than assumed	Treating psychiatrist; the agent table sits outside this section

Two boundaries around that last row keep the answer clean. Which drug is acceptable in lactation, judged by how much of the maternal dose reaches the infant, belongs to the topic on drugs safe in breastfeeding in these notes, and the metric behind that judgement is defined in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes. And where the reason she is off the ward is a course of electroconvulsive treatment, that licenses no teaching here about the treatment in the perinatal period, which sits in the ECT and neurostimulation notes.

9.7 The milk supply question the ward actually asks

A second lactation question, quite separate from infant exposure, is the one asked out loud on ward rounds: will this antipsychotic wreck her supply? It is about the mother's prolactin axis rather than the baby's blood, and confusing the two is the commonest muddle here.

The mechanism is straightforward. The rise in prolactin on haloperidol follows from blockade of dopamine in the **tuberoinfundibular pathway**, dopamine being the tonic inhibitor of prolactin release. The answer, stated plainly by the lactation database, is that a raised maternal prolactin level in a mother whose lactation is already established may not affect her ability to breastfeed. That is narrower than it first appears, and the narrowness is the teaching point: the source says it of established lactation and does not extend it further. In a woman admitted in the first days after delivery, before the feed is running, the same reassurance is not available and the question is unsettled.

The axis is also not loaded equally by every agent, which gives the ward a real selection axis when the feed itself is under threat. **Olanzapine**, unlike the phenothiazines, has a minimal effect on serum prolactin levels. That is a group tendency and not an absolute, since the same record notes hyperprolactinaemia and galactorrhoea have been reported with it. Note what this axis does not do: it says nothing about how much drug the infant receives, and an agent chosen on it must still clear the exposure question in the topic on drugs safe in breastfeeding in these notes.

> The two lactation questions are separate and both must be answered explicitly: how much drug reaches the baby, which decides whether the feed is safe, and what the drug does to the mother's prolactin axis, which affects whether there is a feed at all.

9.8 What joint admission changes, and how strong the evidence actually is

The argument usually offered for the model is a chain of consequences following from separation of a mother from her infant: mothers refuse admission, the feed fails, the diagnostic picture is harder to read, dyadic psychotherapy becomes impossible, stays run longer, relapse after discharge rises, and infant care falls on the husband and extended family. Its own source states that chain as what the absence of a unit *may* produce. It is a mechanism argument, not a measured effect, and presenting it as measured is overclaiming.

The measured evidence is narrower than the enthusiasm around it. In an Australian cohort assessed at admission and at discharge, joint admission was highly beneficial in the short term across clinical, functional and parenting outcomes, with the authors noting that follow-up studies are needed before longer-term benefit to the dyad can be claimed. Within that cohort 73.3 per cent recovered symptomatically, and recovery was associated with increasing maternal age and with lower psychosocial risk at admission. Both are observational, and the second is the interesting one: psychosocial risk, not diagnosis, does the predictive work, which is the lesson the separation literature teaches from the other end.

Length of stay is where the international and Indian pictures diverge most sharply. Across the French and Belgian units the mean duration of hospitalisation was 11 weeks, and units also offering day-care admission in the same or a nearby unit had shorter mean admissions. The Indian mean quoted earlier is measured in days rather than months. Some of that gap is case-mix and some is what the receiving community can hold; the reproducible lever is the day-care arm.

Finally, the honest statement about the evidence base, which a good answer includes rather than avoids. A systematic review of research in psychiatric mother-baby units found that most studies of the impact of admission showed favourable results, but that few follow-up studies had been done and few had compared outcomes on such units against other clinical settings; it also reports a shortage of research on infant outcomes. The model rests on before-and-after data and a strong mechanism argument, not on comparative data, and saying so defends it better than implying a trial that does not exist.

9.9 Where there is no unit: the alternate model, and the variants that scale down

The plainest statement of the Indian position comes from the group that runs the country's first unit: in many low-resource settings the absence of specialised mother-baby units necessitates **alternate models of care**. The unit is the standard; the alternate model is the norm, and teaching only the standard teaches most Indian readers about a facility they will never work in.

The components named in its place by the same group are:

- family engagement, which in Indian practice means an admitted attendant rather than a visiting relative;
- telepsychosocial support and caregiver education, which are how expertise reaches a district where none is resident;
- safety planning, and community-based care that continues after the ward has finished.

The same source names multidisciplinary team working and a medication plan compatible with breastfeeding as further elements. Two of these are notably cheap and notably omitted: caregiver education and safety planning need time and a written record and nothing else.

There is also a documented intermediate between a full unit and nothing. The French unit had capacity for four families day and night through the week, and additionally treated a limited number of mother-baby pairs in day or even **half-day hospitalisation** from Monday through Friday. Partial admission of a dyad is therefore an established configuration rather than an improvisation; it maps onto Indian day-care infrastructure far better than a residential unit does, and it needs no night establishment, the most expensive part of the specification.

One indication for joint admission is worth knowing precisely because nobody expects it. The French unit's fourth category of situation in which mother-baby hospitalisation may be proposed is child-led: children with functional symptoms such as sleeping or eating disorders, or with developmental delay, admitted for short-term inpatient treatment in a mother-child setting, where the parents are normally not mentally ill and it is the child who has the disorder. Held alongside the maternal indications, that makes the point that what is admitted and treated here is a relationship, which is why the unit needs staff competent in both halves of it.

9.10 Where the patient goes next: discharge is not the end of the episode

A service model is only as good as its disposition, and this one is demanding: two people go home, one of them cannot report her own condition, and the mother's illness carries a relapse

risk in the months ahead. The community integration clause exists for exactly this, and where it is absent the gains of the admission are lost within weeks.

An Indian unit's answer is instructive because it is affordable. Mothers discharged were given a mobile telephone helpline number answered by a social worker. Of 113 mothers, 51, 45 per cent, made 248 calls between them. What they called about lists everything a discharge plan should have anticipated and usually has not:

- medication, sleep problems and symptom exacerbation;
- appointments, and planning future pregnancies;
- suicidal ideation, with separate calls about domestic violence and about infant health and breastfeeding.

Three things follow. Nearly half of discharged mothers used a channel costing one social worker's time, so this tail is real and cheap to catch. The content spans psychiatry, obstetrics, paediatrics and safeguarding, so whoever answers must be able to route and not merely reassure. And the reported limitation is what an Indian service must design around: some women could not use it for want of a telephone, so a helpline supplements a follow-up appointment and never replaces it.

GOOD TO REMEMBER

Four things to put in the notes of any acutely ill postnatal woman you admit, unit or no unit. Write the separation decision as a decision, with the reason, the person who made it and the date it will be reviewed, because an unreviewed separation becomes permanent. Write the feeding status as a plan and not a fact, since more than a third arrive having already stopped and most of those feeds can be brought back. Book the infant's paediatric review at admission, not when somebody becomes worried. And name, before she leaves, whom she or her family will telephone and what will happen when they do.

Women's mental health across the lifespan

10 · Premenstrual dysphoric disorder (criteria, management)

The disorder the classification hides. A woman describes a week of irritability, hopelessness and conflict at home that lifts within a day or two of her period starting. The first question is not which drug. It is which clinic she belongs to, what must be documented before anyone commits to a label, and who holds her meanwhile. **Premenstrual dysphoric disorder** earns its place here for reasons unrelated to its symptom list: the classification does not file it where a psychiatrist would look, most of these women are already in another specialty's clinic when the question is asked, and the step that settles it is a service step, not a bedside one.

10.1 Filed under gynaecology: what the code tree does to your pathway

In the World Health Organization's current international classification the disorder carries the code **GA34.41**. It sits under a parent grouping of **premenstrual disturbances**, coded **GA34.4**, and its immediate neighbour there is **premenstrual tension syndrome**, coded **GA34.40**. That

grouping resides in the **genitourinary chapter**, among the diseases of the female genital system, in the same company as endometriosis and the menopausal disorders. It is not filed there and forgotten. The classification's own clinical manual for the mental, behavioural and neurodevelopmental disorders cross-lists the disorder into its depressive disorders grouping as a secondary-parented category, and prints the reason: the prominence of mood symptoms in its clinical presentation, and to assist in differential diagnosis. One code, two homes, and the two do different work.

GA34.41	GA34.4	GA34.40
PREMENSTRUAL DYSPHORIC DISORDER	PARENT GROUPING	SIBLING CODE

Where a disorder is coded decides who meets it, who counts it and who is expected to treat it, and each consequence lands on the psychiatric service rather than on the coder:

- the record leaves the hospital tagged to a gynaecological chapter, so an audit or a registry built from the mental disorders codes never retrieves these women;
- the specialty that sees her first is the one the code sits with, so the psychiatric opinion arrives as a referral, not as a first contact;
- a service planning clinics from mental-chapter workload data cannot see the demand, and will not staff for it.

TRAP **Finding the disorder in the mental-disorders manual and assuming the coded record will therefore be found among the mental disorders.** The manual does carry it, deliberately, with its reason printed. The code does not move. What leaves the hospital is a genitourinary code, so a registry, an audit or a workload return assembled from mental-disorder code ranges retrieves none of these women however the manual is arranged. Read the manual for the diagnosis and the code for the count, and never let one stand in for the other.

10.2 The front door: which clinic she is in when the question reaches you

The referral route changes the first act. These complaints reach psychiatry along four paths, and running the same interview on each produces a treatment discussion in a patient whose complaint has not been shown to be cycle-bound at all.

WHERE THE QUESTION REACHES YOU	THE FIRST ACT	WHERE SHE GOES NEXT
Obstetrics and gynaecology outpatient, referred for mood symptoms before menses	Establish whether the complaint is confined to the premenstrual window; issue the record and fix the review	Joint review with the referring clinic once the record exists
Primary care or general outpatient, presenting as irritability and conflict at home	Ask directly whether the complaint tracks the cycle	Full psychiatric assessment if symptoms cross the whole cycle; forward-looking record if not
Already under psychiatric follow-up, worse premenstrually	Do not relabel on the timing alone; record where in the cycle each review falls	Stays with the treating team; the discrimination from **premenstrual exacerbation** is taught by the Endocrine and metabolic psychiatry notes
Crisis contact with distress the family attributes to the cycle	Risk assessment first and on its own terms, timing question second	Disposition on the risk, never on the presumed cycle attribution

RULE **A premenstrual complaint is a routing decision before it is a diagnosis, and a diagnosis before it is a prescription.** What decides the routing is information about time, which cannot be had in the consultation where the question is first asked. The service must build around that: a record collected across cycles, a named reviewer, a plan for the interval. Compressing those steps into one sitting substitutes recall for observation.

10.3 The act this section owns: documenting the timing forward, not backwards

Confirmation rests on **prospective charting**: the patient records symptoms as the cycle runs rather than reconstructing them at the clinic. The instrument, the number of cycles it must cover and the rules for reading it belong to the Endocrine and metabolic psychiatry notes. What a service chapter owns is what that requirement costs and how a clinic delivers it. Before she leaves the room:

- the review appointment is fixed and written down, its date chosen against her cycle rather than clinic convenience;
- she is told what she is bringing back and what will be decided when she does, so the second visit has a purpose she can weigh against its cost;
- a named plan covers deterioration before review, including whom she contacts if the worst part of the cycle brings a safety concern, assessed on the principles set out in the Somatic-symptom, sexual, impulse-control disorders and suicide notes.

IN INDIA

The prospective record assumes a second visit, and that is where this pathway breaks. She is often attending a district or teaching hospital far from home, with a relative whose permission and lost wages the trip costs, for a complaint the family has already filed as a normal period problem rather than illness. The visit for charting alone is the one that gets dropped. Two adjustments cost nothing: fix the review to a date she can keep, and give the record in a form she can carry, in her own language. Where psychiatric opinion sits inside the obstetrics and gynaecology clinic rather than behind a referral, charting is likelier to be completed.

10.4 Handing on: who holds this patient, and where the rest is taught

Two chapters carry premenstrual dysphoric disorder in full between them, and this section adds no third account. Its nosological position, meaning how it stands in relation to the depressive disorders, belongs to the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes. The working clinical material, meaning the criteria set, the rating record and how it is read, the discrimination from premenstrual worsening of an existing disorder, the epidemiology and the treatment ladder with its starting doses, belongs to the Endocrine and metabolic psychiatry notes. No criterion and no dose is printed here.

What remains is the **disposition** decision, and it is usually shared rather than transferred. Once the diagnosis is established most of these women are managed in the clinic that first saw them, with psychiatric input reserved for comorbid mood or anxiety disorder, for failure of first-line treatment, or where risk rather than distress leads. Psychiatry retains her outright when the cycle-linked worsening proves to sit on a disorder running through the month.

GOOD TO REMEMBER

Write the cycle position into the note at every review, for any woman of reproductive age under follow-up for a mood or anxiety disorder, whether or not premenstrual symptoms have been raised. Without it, a year of notes cannot answer the timing question later.

Premenstrual dysphoric disorder is coded in the genitourinary chapter and cross-listed into the depressive disorders: the manual will hand it to a psychiatrist and the code will not, so the service has to go and collect it, and the diagnosis is settled by a record kept forward across cycles.

11 · Menopause and perimenopausal mental health

Why a transition filed outside psychiatry gets a psychiatric section. A woman in midlife presents with low mood, broken nights and flushing, and the explanation is agreed before she arrives: it is the change. Almost none of the work that follows is endocrinology. Staging, the endocrine markers, the size of any risk the transition carries, the oestradiol evidence and endometrial protection belong to the Endocrine and metabolic psychiatry notes, and the hypothalamic-pituitary-gonadal axis beneath them to the Neurochemistry, Neuroendocrinology,

Neuroimaging and Basic Psychopharmacology notes. What is left over is a consultation, and that is what gets examined.

11.1 Where the transition sits, and what its placement instructs you to do

The World Health Organization's current international classification carries the transition as one grouping, **GA30 Menopausal or perimenopausal disorders**, filed among the diseases of the female genital system in the genitourinary chapter rather than among the mental disorders. What that placement does to a psychiatric pathway is worked out with premenstrual dysphoric disorder elsewhere in these notes and is not re-derived here. Its neighbours are the other reproductive events of adult life: **GA31** female infertility, **GA32** complications associated with medically assisted reproduction and **GA33** recurrent pregnancy loss, whose psychiatric side is taken up in the section of these notes on infertility, abortion and contraception. The transition has a nosological home, and it is not psychiatry's.

Read that as a clinical instruction, not a filing detail. There is no label called menopausal depression to reach for: you identify the mental disorder that is present, diagnose it on its own terms, and record the **menopausal transition** as the setting in which it appeared. Where the complaint genuinely is a symptom of the transition, the clinician who treats it sits outside psychiatry and the correct act is a referral, not a prescription.

RULE **The perimenopause is a context, not a diagnosis.** A context tells you what else to ask about and whom to involve, not what to treat. Collapse it into the diagnosis and two opposite errors open at once: a depressive episode goes untreated because it has been explained away, and a transition needing a gynaecological opinion is absorbed into a psychiatric formulation.

11.2 Establishing the episode before attributing it

Identification is the whole of the psychiatric task here. An expert panel convened by the North American Menopause Society and the National Network of Depression Centers Women and Mood Disorders Task Group framed the perimenopause as a **window of vulnerability** for depressive symptoms and for major depressive episodes, and recorded that clinical recommendations on identifying and treating depression in that window were lacking. Both halves are usable: raise the index of suspicion where nobody screens, and do not wait for a bespoke pathway, because what you have is the ordinary assessment done early.

The difficulty the panel names is **overlap**. Symptoms of the transition complicate the presentation of depression, run alongside it and overlap it, so the same broken sleep and fatigue read either way. Establish the episode on its own core features and course, not on the symptoms the two conditions share, since a shared symptom cannot arbitrate between them. How far the risk of depression rises across the transition is a question this section does not answer; it sits with the entity in the Endocrine and metabolic psychiatry notes. The framing above is North American expert-panel guidance, not Indian practice.

TRAP **Waiting for the transition to finish.** It is the most comfortable error available, because the patient offers it herself: review is set a long way out, and a woman with recurrent depressive illness goes untreated on an explanation her history does not support. An episode diagnosed in the perimenopause is treated on the same terms as one diagnosed at any other point: the timing changes what else you look for and whom you involve, never whether you treat.

11.3 The history that decides the formulation

The decisive fact about this window is historical rather than endocrine. The same panel concluded that most midlife women who have a major depressive episode during the perimenopause have had a **prior episode of depression**, and that they present with a classic depressive picture combined with menopause symptoms, **vasomotor symptoms** and sleep disturbance among them, plus the psychosocial pressures of midlife. The lay picture, of a fresh illness with a purely hormonal cause, is what the family arrives holding; correcting it is this section's work. So the **lifetime mood history** comes before the flushes. What the answer changes:

- if there were earlier episodes, this one is a recurrence, and her own record is the most useful thing in the room: what she was given, whether it worked, why it stopped;
- if there were none, a first episode in later life earns a physical review and a look at what she already takes before anything is attributed to the transition;
- ask separately about mood at earlier reproductive events, because many women do not file those episodes under depression and answer no to the general question, yes to the specific one.

11.4 Dividing the decision, and working where there is nobody to divide it with

This is a two-clinic presentation, and saying which decision belongs where is most of what a psychiatric opinion adds; the handoff fails quietly when each clinician assumes the other is deciding.

THE QUESTION	WHOSE DECISION	WHERE IT IS TAUGHT
Is she in the transition, and does a hormonal measurement help?	Gynaecology or the physician	the Endocrine and metabolic psychiatry notes
Is hormonal treatment indicated, and what protects the endometrium?	Gynaecology	the Endocrine and metabolic psychiatry notes
Is a depressive episode present, and is it a recurrence?	Yours, in this consultation	the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes
Which antidepressant, and for how long?	Yours	the Mood disorders: pharmacotherapy notes

Notice what the table does not contain: a second patient. Every other decision in this band is made for a mother and a fetus or infant at once, a calculus set out with prescribing in pregnancy

earlier in these notes; here the risk is hers alone. Three things must be explicit when you write:

- which symptoms you have assigned to the mood episode and which you have left with the transition, so two clinicians do not treat one complaint;
- whether an episode is established, suspected or excluded, in those words, because menopausal symptoms with low mood commits nobody to anything;
- the single decision you want made, and who reviews her next, so that a woman who improves on hormonal treatment alone is not discharged by both clinics.

IN INDIA

Plan the consultation on the assumption that you cannot refer. The perinatal period has scheduled contacts and this transition has none, so no appointment obliges anyone to ask about her mood: these episodes are missed for structural rather than clinical reasons. Dedicated menopause services are gynaecology-led where they exist and cannot be assumed at district or taluk level, so outside a teaching hospital, whoever sees her first asks the mood questions.

GA30	Genitourinary	Overlap	Prior episode
GROUPING FOR THE TRANSITION	CHAPTER IT IS FILED IN	WHY IDENTIFICATION IS ACTIVE	THE USUAL HISTORY

Most depressive episodes in the perimenopause occur in women who have been depressed before: the transition is where the episode happened, not what it is.

12 · Gender and mental health, intimate partner violence

Why this earns a section of its own. Two facts about who becomes unwell, and who is reached, are stable enough to plan a service around: common mental disorders are commoner in women, and a substantial minority of those women are being hurt at home by the person they live with. Neither is a diagnosis; both change what is done in the room. Whom you ask, what has to be in place before you are entitled to ask, what you say in the first minutes after the answer is yes, and who in the Indian system is legally supposed to do the rest: that is this section. The syndromes themselves are taught in the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes and in the Somatic-symptom, sexual, impulse-control disorders and suicide notes.

It is examined because an epidemiological finding, a guideline recommendation with a stated strength and an Indian statute bear on the same five minutes of consultation. A candidate who can quote a prevalence but cannot say who may be asked, on what trigger and with what arranged beforehand, has learned the wrong half.

12.1 The size of the sex difference, and the shape that constrains its explanation

The reference estimate comes from meta-analyses restricted to nationally representative samples, which matters because clinic samples are shaped by who reaches a clinic. Pooled, the female-to-male odds ratio for depression is **1.95**, with a confidence interval of 1.88 to 2.03, and the

standardised mean difference for depressive symptoms is 0.27. Hold both. The odds ratio says a woman is roughly twice as likely to carry the diagnosis; the standardised mean difference says the symptom-score distributions overlap heavily. Those are compatible, and quoting only the first teaches a difference between two kinds of person rather than a shift in one population.

The shape across the lifespan is where the teaching sits, and it is not a constant. It is detectable in late childhood, with an odds ratio of 2.37 at age 12, reaches its maximum in adolescence at 3.02 for ages 13 to 15, then falls back and stays broadly stable through adult life. A difference that switches on around puberty, peaks and partially resolves fits neither a fixed constitutional account nor a pure ascertainment account. The pooled base spans over 90 nations, which is why it is carried in preference to any single survey.

12.2 Testing the explanations, and the mirror error that follows them

Dispose of the reporting-artefact account first. Its logic is familiar: women consult, disclose and are labelled more readily, so the excess is partly manufactured at measurement. That makes a checkable prediction: if the excess were mainly men under-reporting, it should shrink where disclosure is least constrained. The cross-national moderator analysis in the same meta-analytic programme found the opposite: larger female-to-male differences in major depression in nations with greater gender equity, though not for depression symptoms. Measurement bias is not abolished by that, but the simplest artefact story runs the wrong way, and a candidate who offers it as the whole explanation can be asked why the difference is largest where women are freest to speak.

The social-role account has been tested directly. Across cohorts and countries in the World Health Organization's World Mental Health Survey Initiative, the directions were consistent: women carried more anxiety and mood disorders, men more externalizing and substance use disorders. What moved was the size: in more recent cohorts the difference narrowed for major depressive disorder and for substance use disorders, tracking variation in **gender role traditionality**, indexed by aggregate patterns of female education, employment, marital timing and use of birth control. A difference that moves when social roles move is, to that extent, made rather than found.

Then the mirror error, which those authors named themselves: the magnitude of the difference does not license overlooking depression in men. The male excess of externalizing and substance presentations is how a male depressive episode gets rerouted away from a mood assessment, so the difference becomes partly self-fulfilling at the clinic door.

12.3 The Indian figures, and the half of the disparity that is about who is reached

An Indian chapter cannot run on cross-national odds ratios. National survey data give a weighted current prevalence of common mental disorders in adults of 5.1 per cent, and a higher prevalence in women at 5.79 per cent. Check what the label covers first: common mental disorders here means depressive and anxiety disorders, the anxiety group including generalized anxiety disorder, social phobia, agoraphobia, panic disorder, obsessive-compulsive disorder and post-traumatic stress disorder, ascertained by structured interview. On multiple logistic regression,

with age, education, occupation, marital status and residence in the model, the risk in women was **1.53** times that in men.

Set a second adjusted figure from the same model beside it: people in metro urban cities carried 1.86 times the risk of those in rural areas. Sex is one structural driver among several, and treating it as the only one misses the urban, displaced, low-income patient in front of you.

The service half is left out of most answers. The **treatment gap** for common mental disorders in the same data was about 80.4 per cent overall and slightly greater in women, at **81.5 per cent**. Teach the female excess in prevalence and stop, and you have taught half a disparity: it sits inside a population that is overwhelmingly untreated. That is the argument for asking well when contact happens, because for many of these women it will not be repeated.

12.4 Reading a violence prevalence figure: the denominator is part of the number

Global estimates from the World Health Organization put lifetime exposure to physical or sexual intimate partner violence, or non-partner sexual violence, at about one in three women worldwide. It is also the most misquoted, because a second sits beside it on a different denominator: among women ever in a relationship, 25.8 per cent of those aged 15 to 49 years and 24.7 per cent of those aged 15 years and older have been subjected to physical or sexual violence by a current or former husband or male intimate partner. The first denominator is all women and includes non-partner violence; the second is ever-partnered women only.

The highest lifetime prevalence of intimate partner violence is reported in Oceania at 37 per cent, Sub-Saharan Africa at 32 per cent and Southern Asia at 31 per cent. Southern Asia is a regional aggregate, not an Indian figure. Over twenty years the average annual decline has been 0.2 per cent, and the one-in-three figure has stayed effectively stagnant.

22.3%	2.7%	31.6%	0.2%
EVER-MARRIED INDIAN WOMEN 18 TO 49 WHO HAVE EVER EXPERIENCED SPOUSAL VIOLENCE	THE SAME WOMEN, PHYSICAL VIOLENCE DURING ANY PREGNANCY	WOMEN WORLDWIDE, LIFETIME PHYSICAL OR SEXUAL PARTNER VIOLENCE, OR NON-PARTNER SEXUAL VIOLENCE	AVERAGE ANNUAL FALL IN PARTNER VIOLENCE OVER TWENTY YEARS

The Indian figure comes from the key-indicator table of the National Family Health Survey, whose latest round has fieldwork in 2023-24 and gives urban, rural and total columns beside a single total for the previous round, 2019-21. Ever-married women aged 18 to 49 ever experiencing spousal violence run at 22.3 per cent nationally, against 29.2 per cent nationally in the previous round; the same women reported physical violence during any pregnancy at 2.7 per cent nationally, against 3.1 per cent nationally in the previous round. Both comparisons are national against national, which is what makes them comparisons; the disaggregation is a separate reading, and the rural column runs higher than the urban on both indicators, at 24.4 per cent against 17.5 per cent for spousal violence ever. Two cautions travel with the fall: the issuing institute states these fact-sheet results to be provisional, and a fall in a disclosure-dependent indicator is not by itself a fall in the behaviour.

PITFALL

Quoting the Indian national figure as a measure of domestic abuse in general. The survey's own footnote defines **spousal violence** as physical and sexual violence, so emotional abuse, economic abuse and controlling behaviour sit outside the headline number. A woman who is not hit, not sexually coerced and comprehensively controlled therefore falls outside the indicator altogether, and a resident who learned the number as a measure of abuse will hear her account as something lesser than what the statistics describe.

12.5 Intimate partner violence as a risk factor, and as the presentation itself

The World Health Organization's statement of consequences is the bridge from a social fact to a psychiatric one. Violence against women is listed as leading to depression, post-traumatic stress and anxiety disorders, sleep difficulties, alcohol use disorders and suicide attempts, and to increased smoking, substance use and risky sexual behaviours. In women subjected to intimate partner violence during pregnancy it is listed as increasing the likelihood of miscarriage, stillbirth, pre-term delivery and low birth weight, which ties this material to the antenatal and postnatal decisions taken elsewhere.

Two quantitative anchors answer different questions. The first is direction. A systematic review of longitudinal studies found, in women, a pooled odds ratio of **1.97** for intimate partner violence predicting incident depressive symptoms, with a confidence interval of 1.56 to 2.48 across six studies, and 12 of 13 studies pointing the same way. It found the reverse path too, depressive symptoms predicting incident violence, at 1.93 across four studies, and violence was also associated with incident suicide attempts. The relationship is bidirectional, so a depressive episode in a woman being abused is neither purely reactive nor safely treated as though the exposure had stopped.

The second anchor justifies enquiry in a psychiatric clinic specifically. Compared with women without mental disorders, the odds of adult lifetime partner violence were 2.77 in women with depressive disorders, 4.08 in women with anxiety disorders and **7.34** in women with post-traumatic stress disorder, with individual studies reporting raised odds across all diagnostic categories including the psychoses. Those authors could not investigate causal direction, having too few longitudinal studies to pool. The operational point survives that, because it is about base rates: a psychiatric outpatient population is enriched for exposure, so asking only when it is volunteered misses most of it.

12.6 The enquiry decision: not everyone, and not by accident

Instinct gets this backwards. The World Health Organization's clinical and policy guidelines recommend that **universal screening**, also called routine enquiry and meaning asking women in all health-care encounters, should not be implemented; the quality of evidence was graded low to moderate and the recommendation is conditional. The reasoning is examinable. Screening increases identification but has not been shown to reduce violence or improve health outcomes; where referral options are limited the burden is real, women find repeated asking difficult when nothing follows, and the question degrades into a tick-box.

The positive half is stronger. The same guidelines make a strong recommendation, on indirect evidence, that providers undertake **clinical enquiry** about exposure to intimate partner violence when assessing conditions that violence may cause or complicate, to improve identification and subsequent care. The example conditions listed are psychiatric: symptoms of depression, anxiety, post-traumatic stress disorder and sleep disorders, and suicidality or self-harm. Read the two together and the rule for a psychiatrist is not conditional. Routine, for us, means routine within the presentations that trigger it.

THE SITUATION	WHAT THE GUIDELINE SAYS TO DO	HOW STRONGLY
Every woman attending any health-care encounter	Do not implement universal screening or routine enquiry	Conditional; evidence low to moderate
A woman assessed for a condition violence may cause or complicate	Ask about exposure, to improve identification and subsequent care	Strong, on indirect evidence
A woman presenting with depression, anxiety, post-traumatic stress disorder, self-harm or a suicide attempt	She could be asked as good clinical practice, since exposure may change her care	A remark, not a graded recommendation
Antenatal care	An opportunity to enquire routinely, given the vulnerability of pregnancy and the possibility of follow-up	A remark, conditional on minimum requirements; evidence limited and from high-income settings

The antenatal exception is the seam to every perinatal decision. Routine enquiry is permitted there because pregnancy creates a **dual vulnerability**, because interventions following identification may improve outcomes, and because the antenatal schedule uniquely offers repeated contact. It is conditional on the guideline's minimum requirements for a health sector response, and a clinic that asks without them takes the risk of asking and none of the benefit.

TRAP **Answering "screen every woman" because it sounds like the caring answer.** It is the answer the guideline explicitly rejects, and rejecting it is not a counsel of neglect. The distinction tested is between asking everybody once and asking the right patients properly: enquiry is targeted by presentation, unconditional inside those presentations, and routine in antenatal care alone. A candidate who cannot state the negative recommendation cannot explain why the positive one is graded strong while the negative one is only conditional.

12.7 The preconditions, and the manner of asking

Before the question is asked at all, conditions have to hold. The guideline states them as a minimum, not as good form:

- it is safe to ask, which the guideline operationalises as the partner not being present;
- the provider is trained in the correct way to ask, and in how to respond to a woman who discloses, at least to first-line support;
- the provider is aware of and knowledgeable about the resources she can be referred to, before the question is put.

The companion clinical handbook sharpens the first into an absolute: never raise the issue of partner violence unless a woman is alone, and note the reason: even if she is with another woman, that woman could be the mother or sister of an abuser. This is the rule most often broken in an Indian outpatient department, where the accompanying relative is a fixture and separating a patient from her attendant reads as rude. Build it into clinic routine, because improvising it in front of the family announces the question you were trying to ask privately.

The manner is specified too. Ask in an empathic, non-judgmental way, in language appropriate to the culture and community you work in, and use the words the woman herself uses rather than the words violence and abuse, which many women do not accept for what is happening to them. The question is therefore built out of her own account: what happens at home when he is angry, whether she is ever frightened, whether anyone stops her going out. The construct is coercion and injury; the vocabulary is hers.

MNEMONIC

Alone, trained, and somewhere to send her

Alone: no partner present, and no accompanying person at all before the topic is raised. **Trained**: to ask, and to respond to a disclosure at least to the level of first-line support. **Somewhere to send her**: referral resources known before the question, not after the answer.

RULE **Asking is a commitment, not a question.** Every element of the minimum condition is about the capacity to answer the answer, which is why a service can be criticised for asking as readily as for not asking. Enquiry with nowhere to refer, no privacy and no trained response converts a disclosure into new risk the woman carries home, and that is the mechanism behind the guideline's objection to universal screening where referral options are limited.

12.8 First-line support, and what changes when the room is an emergency department

What follows a disclosure has a name and a fixed content. The guideline makes a strong recommendation, on indirect evidence, that women who disclose any form of violence by an intimate partner or other family member, or sexual assault by any perpetrator, are offered immediate support, and that providers offer **first-line support** as a minimum. Learn the components as acts rather than attitudes.

COMPONENT OF FIRST-LINE SUPPORT	WHAT IT REQUIRES OF YOU
Consultation conducted in private	Arranged before the topic is raised, not once she has started
Confidentiality ensured, and its limits stated	She is told what would have to be passed on, for example where reporting is mandatory, before deciding how much to say
Non-judgmental, supportive, validating	Her account is treated as an account of events, not a symptom to interpret
Practical care responding to her concerns without intruding	Her stated priority sets the agenda, not the one you would choose
Asking about her history of violence, listening without pressure	Silence is allowed; with an interpreter, care over sensitive material
Helping her access information about resources	Named legal and other services, not an assurance that help exists
Assisting her to increase safety for herself and her children	The children sit inside the safety question, not a separate referral
Providing or mobilising social support	Someone in her own network, identified with her

Two structural points sit around that table. First, a fallback: a provider who cannot give first-line support must ensure someone else, in that setting or an easily accessible one, is immediately available. It is not permission to defer. Second, the setting rule that makes this an emergency topic. In settings such as emergency care departments, as much as possible is done at first contact because the woman may not return, and safe, accessible means of follow-up are negotiated with her. Three principles run underneath: do no harm, the safety of the woman and her children is uppermost, and the woman always decides.

12.9 The safety assessment as a repeated act

It is a process, not a form. The clinical handbook frames safety assessment as ongoing rather than a single conversation, revisited each time she is seen because her situation changes, and instructs the clinician to say plainly that partner violence is not likely to stop on its own. That sentence does work: a woman who expects the violence to resolve will decline planning she would otherwise accept, and the family urging her to be patient shares the expectation.

The judgement is narrow, and should be stated narrowly: whether there is an immediate and likely risk of serious injury. If she is worried about her safety she is taken seriously, her appraisal being evidence rather than anxiety to be reassured away. Where immediate high risk is apparent, the handbook names the concern to her in plain words and puts concrete options on the table:

- contacting the police;
- arranging for her to stay that night away from home;
- where it is not safe to return home at all, referral for shelter or safe housing, or identifying a safe place with her.

One omission is declared rather than left silent. The handbook's job aid for assessing immediate risk carries a fixed list of questions and a numeric answer threshold, adapted from a published violence-risk instrument. Neither items nor threshold is reproduced here, and no violence-risk instrument appears in item or score form anywhere in these notes. What transfers is the judgement, the options and the revisiting.

GOOD TO REMEMBER

Four things should exist before she leaves that did not exist when she arrived: a record of what she disclosed, kept where her partner cannot request it; a named person or service she can contact, written somewhere she can safely carry; a plan for tonight if tonight is the risk; and a next appointment she has agreed is safe to attend. In an emergency department all four are done at that contact.

12.10 The Indian legal and service frame, named and not renumbered

The governing instrument is the Protection of Women from Domestic Violence Act, 2005, whose long title describes it as an Act to provide for more effective protection of the rights of women guaranteed under the Constitution who are victims of violence of any kind occurring within the family. Two features matter clinically. It is a civil protective statute, so its purpose is protection and relief rather than conviction, and a woman can want the first without the second. And it builds a service architecture: it creates the **Protection Officer**, recognises registered service providers, provides for notified shelter homes and places duties on medical facilities. Its reliefs are a **protection order**, monetary relief, a custody order, a residence order and a compensation order.

The provision a psychiatrist is personally bound by is short. If an **aggrieved person**, or a Protection Officer or service provider on her behalf, requests the person in charge of a medical facility to provide medical aid, that person shall provide it in the facility. The duty is triggered by a request. It is not conditional on a police complaint, and a refusal on the ground that the police are not involved has no basis in the Act.

The information duty sits on a police officer, Protection Officer, service provider or Magistrate who receives a complaint of domestic violence, is present at the place of an incident, or has an incident reported to them. They are to inform her of her right to apply for those reliefs, of the availability of service providers and Protection Officers, and of her right to free legal services. Note that a treating clinician is not among the named duty holders unless the facility is registered as a service provider. It is still the referral information a psychiatrist should be able to give from memory, but an answer saying a doctor must inform her under the statute is an over-claim.

IN INDIA

The statute creates the roles; it does not staff them for you. Three local facts have to be known by name before this material is usable in your department, and none is in any book: who your district's Protection Officer is and how they are actually reached, which organisations near you are registered service providers rather than merely helpful, and where the nearest notified shelter is and whether it admits at night. The guideline precondition that a provider know the referral resources before asking is, in an Indian district hospital, an administrative task somebody does once for the whole unit. A service that has not done it cannot yet run enquiry, however willing its residents are.

12.11 Obligations on disclosure, and where the settled ground ends

The reporting question is most often answered from memory and answered wrongly, so state exactly what is sourced. Government of India guidance for medical practitioners on medico-legal care in cases of sexual violence, issued through the Ministry of Home Affairs, records that the examining registered medical practitioner or hospital is required to inform the police about a sexual offence. It records in the same breath that if the survivor does not wish to lodge a first information report or take part in a police investigation, the practitioner is bound to provide medical treatment, and that **informed refusal** is documented in such cases. It further records that every hospital and doctor is bound to provide free first aid or medical treatment to victims of rape and to intimate the police, and that the victim, or the person in whom she reposes trust, may refuse medico-legal examination or evidence collection or both, with that refusal never taken as denial of treatment.

Two limits travel with that paragraph. The first is scope: the guidance addresses sexual offences. It does not settle what a clinician must report when an adult woman discloses non-sexual intimate partner violence and asks that nothing be done, which is the commoner situation by a wide margin. That position is not sourced here and is not asserted. The practical course is to state the limits of confidentiality to her before she decides how much to say, as first-line support requires, and to take the doctrine of confidentiality and its exceptions from the Forensic ethics, consent and legal procedure notes. The second limit is currency: the guidance cites a code of criminal procedure and a penal code since replaced, and the successor provisions are not carried here. Name the duty, and do not translate an old section number into a new one from memory.

12.12 Sexual and gender minority patients at the same doors

The same logic extends to a group the epidemiology reaches less reliably. Pooling population-based studies, lesbian and gay people carried odds ratios for common mental disorders between 1.97 and 2.89 compared with heterosexual people, across every diagnostic category investigated, and bisexual people higher odds still, between 2.70 and 4.81, their excess over lesbian and gay people concentrated in depression and suicidality. Exploratory analysis found no narrowing in recent years except for alcohol use disorders. One limitation governs Indian use of these figures: the evidence base is predominantly Western, so the direction transfers more safely than the magnitude.

In India the obligation is statutory as well as clinical. The Transgender Persons (Protection of Rights) Act provides that no person or establishment shall discriminate against a transgender person on grounds that include the denial or discontinuation of, or unfair treatment in, healthcare services, and bars the same in access to any facility available to the general public. Read that against what an emergency department does. A refusal of registration, a refusal to admit, a ward placement made on documents rather than the patient's stated gender, or unequal treatment at triage is a statutory matter in India, not only an ethical one. The Act also requires the appropriate Government to provide medical care including sex reassignment surgery and hormonal therapy, counselling before and after both, a health manual in accordance with the **World Professional Association for Transgender Health** guidelines, review of the medical curriculum, and access in hospitals. The counselling obligation is directly psychiatry's.

The Indian professional position has a date, and dating it teaches better than presenting it as timeless. A peer-reviewed account records that in 2018, a day before the Supreme Court of India began hearing the curative petition on the penal provision then criminalising carnal intercourse against the order of nature, the Indian Psychiatric Society issued an official statement that homosexuality is not a mental pathology, and that in 2014 the then President had termed it a pathology requiring treatment. That is a secondary account rather than the Society's own instrument and should be quoted as such, and the penal provision it refers to has itself been replaced, with no successor number given here. The profession's position in India was therefore contested within living professional memory, which is why a patient may arrive expecting to be pathologised and will read your first questions as a test of whether she is safe with you.

> Do not raise intimate partner violence unless she is alone, you are trained to respond and you already know where she can be referred; and in an emergency department, do everything at that contact, because there may not be another.

13 · Psychiatric aspects of infertility, abortion and contraception

Why the marks are here. Reproductive medicine hands psychiatry three separate tasks, and candidates lose marks treating them as one. In infertility the psychiatrist is asked to keep two people functioning through a long, expensive, invasive treatment that may not work. In abortion the psychiatrist may be asked for an opinion a statute names as a precondition of a lawful procedure. In contraception the psychiatrist is the prescriber whose own drug is why the conversation cannot be left to the gynaecologist. Three acts, three sources of authority, three destinations.

The characteristic error is to arrive with a view about whether fertility treatment, or termination, or a contraceptive decision is psychologically good or bad for women. None of the three settings asks that. Each asks a procedural question with a defined answer: what must be discussed and by whom, what opinion the law requires and on what ground, and what must be in place before a prescription is defensible. Get it wrong and a careful formulation answers a question nobody asked, while the real question goes back unanswered to a clinic working against a clock. The

disorders that present inside these settings are taught in the chapters that own them and are named here rather than restated.

13.1 Taking the referral: what infertility is, whose it is, and who is asking

Infertility is defined by the World Health Organization as a disease of the male or female reproductive system, established by failure to achieve a pregnancy after **twelve months or more** of regular unprotected sexual intercourse, and it may arise from male, female or unexplained factors. Two things in that definition matter at the point of referral: it is framed as a disease of a reproductive system rather than as a failure of a person, and it is explicitly not assumed to be the woman's. Estimates on the same authority suggest approximately **one in every six** people of reproductive age worldwide experience infertility in their lifetime. This is not a niche referral.

The classification reinforces this. The international classification of diseases carries female infertility at GA31 and, as a separate entry, **complications associated with medically assisted reproduction** at **GA32**, both filed among the diseases of the female genital system in the genitourinary chapter alongside recurrent pregnancy loss. A treatment given its own morbidity entry, distinct from the condition it treats, is one whose burden the classification has already conceded. Much of what you are asked to manage is generated by the treatment, not by the infertility.

The first act on receiving the referral is therefore to establish which question is being asked, because the letter will rarely say. Is this couple in a state to start or continue a cycle. Is a mental disorder present that needs treatment in its own right, irrespective of the fertility work. Does an existing illness or its medication change what the service can safely offer. Each has a different output and destination, and answering the wrong one is how this consultation is wasted. Note too that the referral will almost always name the woman even where the factor is the man's or unexplained, and correcting that framing is part of the first consultation.

IN INDIA

The World Health Organization records in the same fact sheet that equal and equitable access to fertility care remains a challenge in most countries, particularly in low and middle-income countries, and that fertility care is rarely prioritized in national universal health coverage benefit packages. Read that as a clinical fact, not a policy one. Where treatment is paid for privately and cycle by cycle, continuing is also a household financial decision, often with in-laws holding the money, and the distress you are asked to treat is partly a debt and partly a loss of standing. Who is paying, and what happens in the family if the next cycle fails, is material the formulation is built from, and the question most reliably omitted.

13.2 Mapping the cycle: what to ask before, during and after treatment

The most useful structure for this work is not a psychiatric one. **Routine psychosocial care**, as the European Society of Human Reproduction and Embryology guideline for fertility staff sets it out, organises the emotional course of treatment as needs experienced across the treatment pathway, before, during and after treatment, and sorts those needs into four kinds: behavioural, relational, emotional and cognitive. The table below carries what the guideline places in each.

Learn it as a grid rather than a list, because the grid turns a vague enquiry about coping into a structured interview. The same four domains carry different content at each phase. Before treatment the cognitive domain is dominated by what the couple has understood about their chances; during treatment by what each injection, scan and result means; afterwards by whether to go again. The relational domain moves the same way, from disclosure and whom to tell, through the erosion of a sexual relationship that has become scheduled, to the anniversary of a failed cycle.

MNEMONIC

Be Real Every Cycle

Behavioural, **R**elational, **E**motional, **C**ognitive: the four psychosocial need domains, asked at each of the three phases of the pathway. Four questions, three times, and the interview is covered.

NEED DOMAIN	WHAT THE GUIDELINE PLACES IN IT	WHAT THAT TURNS INTO AT THE BEDSIDE
Behavioural	Lifestyle, exercise, nutrition, compliance	Whether the regimen is actually being taken as prescribed, and what has been given up to take it
Relational	The relationship with the partner where there is one, family, friends and the wider network, and work	Who knows, who is asking, who is paying, what leave has been used
Emotional	Wellbeing, including anxiety, depression and quality of life	The screen for a treatable disorder, and whether this is distress or illness
Cognitive	Treatment concerns and knowledge	What the couple believes the odds are, and whether that matches what the clinic has told them

The guideline's other structural instruction is about who does this. It directs that fertility clinic staff detect and address these needs, making routine psychosocial care a responsibility distributed across the team rather than a referral generated when someone cries in the waiting area. The durable act is therefore to teach the four domains to the nursing and embryology staff who see the couple far more often than you do, and to keep the psychiatric consultation for the questions that need one.

13.3 Why the burden is a treatment outcome and not a side issue

The argument that psychological care in a fertility unit is a luxury collapses against the discontinuation data. A systematic review of why patients stop fertility treatment, pooling studies across several countries, found that **discontinuation** is not driven mainly by treatment failure or by cost alone. The reasons selected most often were postponement of treatment, then physical and psychological burden, then relational and personal problems, then rejection of the treatment itself, with organizational and clinic problems behind.

39.18%	19.07%	16.67%	13.23%
STOPPING FERTILITY TREATMENT: POSTPONEMENT	STOPPING FERTILITY TREATMENT: BURDEN	STOPPING FERTILITY TREATMENT: RELATIONAL	STOPPING FERTILITY TREATMENT: REJECTION

The split within that burden category is instructive: the psychological component accounted for 14 per cent of reasons selected for discontinuing fertility treatment and the physical component for 6.32 per cent. The mind is carrying more than twice the load of the body in the decision to stop, and adding the relational and personal figures makes the psychosocial share the largest identifiable block after simple postponement. The same authors report that none of the predictors they examined was consistently associated with discontinuation, and that finding has the sharpest operational consequence: you cannot select in advance who will drop out and support only them. Support has to be routine, which is exactly what the guideline above calls it.

GOOD TO REMEMBER

Ask directly, at every review, whether the couple has considered stopping, and treat the answer as clinical data rather than as a failure of morale. People who stop treatment that might still have worked usually stop after a period in which nobody asked. The question does not push them towards stopping; it converts an unspoken drift into a decision made deliberately, with the psychological burden named as one of the things being weighed.

13.4 The counselling duty Indian law places on the fertility clinic

India answers the European guideline with a statute rather than guidance. The Assisted Reproductive Technology (Regulation) Act places on assisted reproductive technology clinics a duty to counsel, and specifies its content. The clinics must:

- provide **professional counselling** to the commissioning couple and woman about all the implications and chances of success of assisted reproductive technology procedures in the clinic;
- inform them of the advantages, disadvantages and cost of the procedures, their medical side effects and risks including the risk of multiple pregnancy;
- help them arrive at an informed decision on the matters most likely to be best for them.

The Act further requires that they be made aware of the rights of a child born through assisted reproductive technology, and a companion provision requires the written informed consent of all the parties seeking it before treatment. Counselling in Indian assisted reproduction is therefore an obligation with a statutory duty holder, and the duty holder is the clinic. It is not an extra a busy unit may drop, and it is not, by default, the psychiatrist's.

Hold that distinction: the two get conflated in practice and the conflation harms both. The clinic's statutory counselling is informational and decisional, covering implications, success rates, costs, side effects, risks and support to a decision. A psychiatric consultation is diagnostic and therapeutic, triggered by a question about mental state, capacity, medication or risk. When a unit sends a couple to you and calls it counselling, clarify in writing which is being requested, because the record must show whether the clinic has discharged its statutory duty and, separately, what

psychiatric opinion was given. A note that blurs them leaves the clinic exposed and leaves you carrying a duty that is not yours.

13.5 Saying honestly what psychosocial care can and cannot deliver

Residents oversell this work in vivas, and the guideline itself does not. Its own summary is that the evidence presented shows that providing routine psychosocial care is associated with, or has the potential to, reduce stress and concerns about medical procedures and to improve lifestyle outcomes, fertility-related knowledge, patient wellbeing and compliance with treatment. Read the verbs: association, or potential, is not demonstrated causation. It then quantifies its own foundations: only 45 of the 125 recommendations in that guideline, 36.0 per cent of them, were based on high-quality evidence, and the guideline group wrote recommendations aimed at generating the research the rest of them need.

Two consequences follow. First, the outcomes on that list are stress, procedural concern, lifestyle, knowledge, wellbeing and compliance. A pregnancy outcome is not among them, and you should not imply one. A couple told that counselling improves their chance of a baby has been given a false reason to attend, and will read the next failed cycle as a failure of their own psychological effort, which is the attribution this work exists to prevent. Second, compliance and treatment concerns are on the list, and compliance is what the discontinuation data says is at stake. The defensible claim is that psychosocial care makes an arduous treatment tolerable enough to complete, and that distress is worth treating in its own right, not that it is fertility treatment by another route.

13.6 The termination request: which statutory question you are being asked

The Indian frame is the Medical Termination of Pregnancy Act, 1971, as amended by the Medical Termination of Pregnancy (Amendment) Act, 2021, which defines termination of pregnancy as a procedure to terminate a pregnancy by medical or surgical methods and introduces the Medical Board as a statutory body. Name the Acts; do not carry their section numbers into an answer, because a wrong number reads worse than none.

Under the statute as amended, a pregnancy may be terminated by a registered medical practitioner on the opinion, formed in good faith, that continuance would involve a risk to the life of the pregnant woman or of **grave injury to her physical or mental health**, or that there is a substantial risk that the child, if born, would suffer from any serious physical or mental abnormality. How many practitioners must hold that opinion depends on the length of the pregnancy, and that two-tier structure is the part most often mangled in written answers.

LENGTH OF PREGNANCY	OPINION THE STATUTE REQUIRES	WHERE THE PSYCHIATRIST ENTERS
Not exceeding twenty weeks of pregnancy	The opinion of one registered medical practitioner, formed in good faith	As the practitioner forming that opinion where the ground is mental health, or as the source of the evidence the treating practitioner relies on
Exceeding twenty weeks but not exceeding twenty-four weeks of pregnancy, for a prescribed category of woman	The opinion of not less than two registered medical practitioners, formed in good faith	Commonly as one of the two, since one of the prescribed categories is itself psychiatric
Where termination is necessitated by substantial foetal abnormalities	Diagnosis by a Medical Board, on which the length-of-pregnancy limits do not apply	Not the psychiatric route; recognise it so a case is not misrouted through a psychiatric opinion

RULE **The statutory question is prospective, and it is about continuance.** The Act asks whether continuance of the pregnancy would involve grave injury to mental health. It does not ask whether termination will damage mental health, and it does not ask you to predict outcome after the procedure. An opinion that discusses post-abortion regret, or weighs whether she will cope afterwards, answers a question the statute does not pose and can defeat a lawful request while appearing thorough. Write about continuance.

13.7 The two presumptions, and the categories that open the extended window

The statute does not leave grave injury to mental health entirely to case-by-case judgment. Two explanations attach to it, and the difference between them is the most examinable psychiatric content in the Indian abortion frame. Where a pregnancy results from failure of any device or method used by any woman or her partner to limit the number of children or prevent pregnancy, the anguish caused by such pregnancy may be presumed to constitute grave injury to the mental health of the pregnant woman. Where a pregnancy is alleged by the pregnant woman to have been caused by rape, the anguish caused by the pregnancy shall be presumed to constitute grave injury to her mental health.

Three things follow. The verbs differ, and permissive is not mandatory. The reach differs: the contraceptive-failure explanation is expressed for the first gestational clause, the rape explanation for both. And the trigger for the second is the woman's own allegation, not a police finding, corroboration or a conviction; requiring proof first is a misreading with real consequences for a woman against a deadline. Note also that the amendment replaced the older married-woman-and-her-husband framing of the device-failure explanation with any woman or her partner, removing marital status from that route entirely.

> Grave injury to mental health is a statutory ground for termination in India, and where the woman alleges the pregnancy was caused by rape the anguish shall be presumed to constitute it.

The extended window depends on being within a **prescribed category of vulnerable women**. Answering in Parliament, the Government of India stated that the amendment rules define these categories, eligible for termination beyond twenty weeks till twenty-four weeks of gestation with the permission of two doctors, as survivors of sexual assault or rape or incest; minors; change of marital status during the ongoing pregnancy, namely widowhood and divorce; women with physical disabilities meeting the major disability criteria laid down under the Rights of Persons with Disabilities Act, 2016; mentally ill women, the Government's own wording adding the phrase including mental retardation; foetal malformation carrying a substantial risk of being incompatible with life or of the child being seriously handicapped; and women with pregnancy in humanitarian settings or disaster or emergency situations as declared by the Government. Two caveats belong with that list. The wording quoted for the fifth category is the Government's and reflects superseded terminology. And the categories come from an official parliamentary answer restating the rules rather than from the rules as separately retrieved, so name the categories and the rules and do not cite a rule number.

Mentally ill women being a named category is what most often brings an Indian psychiatrist into this decision, and it carries a trap. Membership of the category opens the extended window; it does not establish the ground, and it does not answer whether this woman can consent. Capacity and consent are set out in the Forensic ethics, consent and legal procedure notes, and where the woman is a minor, or a reporting obligation may bite, protective legislation belongs with the Mental health legislation and forensic psychiatry notes. Establish category, ground and capacity as three separate findings and record them separately.

13.8 Answering on the evidence, not on the politics

Whether abortion damages mental health is treated in public debate as an open scientific controversy. It is better understood as a methodological artefact, which is the most useful thing to carry out of this topic. A systematic review of studies of abortion and long-term mental health outcomes rated each study on the methodological features needed to answer the question, and found **a clear quality gradient**: the highest quality studies had findings that were mostly neutral, suggesting few if any differences between women who had abortions and their comparison groups in terms of mental health sequelae, while the studies with the most flawed methodology were the ones that found negative mental health sequelae of abortion. No study in that review reached the top rating.

TRAP **Reading the abortion literature as a genuine disagreement between equally good studies.** Candidates write that the evidence is conflicting and leave it there, which sounds balanced and is wrong. The direction of a finding in this literature tracks methodological quality, and the weakest designs generate the strongest claims of harm. The comparison group is where most fail: women who have an abortion are compared with women never pregnant, or who carried to term by choice, leaving the unwanted pregnancy itself, the exposure that predicts distress, uncontrolled.

The design that solves the comparison-group problem compares women who obtained an abortion just under a facility's gestational limit with women turned away because they had passed it. In that prospective longitudinal cohort, being denied an abortion was associated with greater

risk of initially experiencing adverse psychological outcomes compared with having one: at the first assessment after seeking the abortion the women who had been denied it reported more anxiety symptoms, lower self-esteem and lower life satisfaction, with similar levels of depression in the two groups. Over the follow-up, psychological wellbeing improved and the two groups eventually converged. The authors state that their findings do not support policies restricting access to abortion on the basis that abortion harms women's mental health.

Handle the transfer honestly. That cohort was recruited in a jurisdiction whose statutory and service model is not India's, so the psychiatric finding transfers and the service model does not. What it gives an Indian psychiatrist is a defensible answer to the question a family, a colleague or an examiner will put: the mental-health case against access is not supported by the strongest available design, and the acute psychological cost in these data sits with denial rather than with the procedure. It is not licence to promise any woman a particular emotional outcome. Where a woman denied a termination presents with active suicidal ideation, assessment and disposition are those in the Somatic-symptom, sexual, impulse-control disorders and suicide notes; a legal refusal as the stressor changes the urgency, not the method.

13.9 Writing the opinion, and protecting it

The output of this consultation is a document, and its quality is what gets examined and, occasionally, litigated. Four features distinguish a usable opinion from an essay. It states the ground in the statute's own terms rather than in diagnostic shorthand, because a diagnosis is evidence for the ground and is not the ground itself. It addresses continuance rather than outcome after the procedure. It records capacity and voluntariness as separate findings with reasons for each, since coercion runs both ways and a woman pressed towards termination and one prevented from it both present as ambivalence. And it is dated against the gestational age at the time of writing, because the window it opens is closing while the note is being typed.

Speed is therefore part of the standard of care here in a way it is not in most psychiatric opinions. A request left in an outpatient queue for a fortnight can convert a first-tier decision requiring one practitioner into a second-tier decision requiring two, or take the case outside the window entirely; where the service cannot see the woman quickly, saying so in writing and escalating is itself the clinical act.

The last element is confidentiality, and here the statute is unusually direct. **The confidentiality provision** of the Act as amended states that no registered medical practitioner shall reveal the name and other particulars of a woman whose pregnancy has been terminated under the Act except to a person authorised by any law for the time being in force, and that contravention is punishable with imprisonment which may extend to **one year**, or with fine, or with both. Note what that means for a consulting psychiatrist: the duty is on the registered medical practitioner, not only on the operating gynaecologist, and it attaches to the woman's identity rather than to the clinical detail.

PITFALL

The breach in this area is almost never a deliberate disclosure. It is a case discussed by name in an open ward round, a shared register carrying the woman's name against the indication, a case sheet photographed and sent to a colleague for advice, or a relative told at the door what the appointment was for. Each discloses name and particulars, and the sanction here runs to imprisonment. Decide how a termination case will be recorded, presented and handed over in your unit before the first such case, not after.

13.10 Contraception counselling as a psychiatric responsibility

Why it matters clinically. The commonest way psychiatry harms a pregnancy is not by mismanaging one. It is by never having the conversation that would have made the pregnancy a planned event. The four-limb pre-conception recommendation itself, its wording and the record it leaves behind, is set out with prescribing psychotropics in pregnancy elsewhere in these notes and is not restated here. What this topic owns is the contraceptive limb of it, which is the one a general psychiatric clinic acts on every week and the one that has a prescribing bar attached.

Read the population before the content, because it is not the population the topic's name suggests. Not pregnant women. Not women already on a teratogen. All **women of childbearing potential** with a new, existing or past mental health problem, which in a general psychiatric clinic is most of the women on the list. Contraception is placed first of the four limbs, ahead of relapse risk and parenting, making it the entry point to the conversation rather than an afterthought once a pregnancy is announced. That conversation is a decision made for two patients at once, one of whom does not yet exist; the framework for weighing treatment risk against the risk of the untreated illness belongs with prescribing in pregnancy and is not re-derived here.

The prescribing rule that pairs with it is deliberately not a number. The same guideline recommends that, when prescribing psychotropic medication or anti-epileptics for women or girls of childbearing potential, including young girls likely to need treatment into their childbearing years, the prescriber takes account of the latest data on the risks to the fetus and baby and follows **the medicines regulator's current safety advice** on anti-epileptic drugs in pregnancy. That is an instruction to consult the live regulatory position rather than a remembered figure, which is the right discipline: agent-level teratogenicity figures move, disagree between sources, and belong with the chapters that own each agent.

One prescribing bar makes contraception a formal precondition rather than advice. The same guideline recommends not offering valproate for acute or long-term treatment of a mental health problem in women or girls of childbearing potential, including young girls likely to need treatment into their childbearing years, unless other options are ineffective or not tolerated and the **pregnancy prevention programme** is in place. Both limbs are required, not either. Contraception here is not a conversation the prescriber ought to have; it is a condition of the prescription being defensible at all, whatever the indication. The regulator's current requirements

under such a programme were not retrievable for this section and are not stated; check the live position.

Finally, name the pharmacology and do not re-derive it. Enzyme-inducing psychotropics can reduce the effectiveness of hormonal contraception; the mechanism, the agents involved and the hormonal thresholds at stake are taught in the Mood disorders: pharmacotherapy notes and in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes. What belongs here is the act the mechanism obliges: when you start or change such a drug in a woman of childbearing potential, the contraceptive method is reviewed in the same consultation and the review is documented. The failure in practice is never ignorance of the interaction. It is that the psychiatrist knew it and treated contraception as somebody else's department.

No Indian recommendation equivalent to that discussion duty was located for this section, so it is cited as United Kingdom guidance and the Indian reader substitutes the current advice of the national medicines regulator on the anti-epileptic limb. The practical Indian gap is not knowledge but access: the conversation names a method the woman must then obtain, often from a different service, sometimes without her family knowing, and usually at her own cost. A referral that ends at the door of a clinic she cannot reach unaccompanied has discharged nothing. Ask how she will get the method, and where follow-up will happen, before the consultation ends.

The behavioural emergency

14 · Assessment and management of the acutely agitated and aggressive patient

Why the marks are here. Asked how to manage an acutely agitated and aggressive patient, most candidates produce a ladder: talk to the patient, offer oral medication, tranquillise, restrain. The ladder is correct, it is taught in full by the Mental health legislation and forensic psychiatry notes and by the Schizophrenia: management, antipsychotics and adverse effects notes, and it is not restated here. The trouble is that it answers only the second half of the question. It begins once the clinician has decided this is an agitated psychiatric patient who needs calming, and says nothing about the minutes before that decision: which room the patient is in, how many people are in it, who may speak, how far away they stand, what is measured while the talking happens, and which physical causes are excluded at the same moment. That is the assessment half, and where the examinable difficulty sits.

What follows is act and setting rather than entity. The sequence it belongs to is the one every other emergency invokes: recognise, make safe, decide who has authority to act, act, monitor, dispose. This section owns the front of that sequence, from arrival to the moment a treatment decision is taken, and owns it for the undifferentiated patient, whose diagnosis is not yet known and may never turn out to be psychiatric. The organising commitment is that assessment and calming are not consecutive. They run at the same time, in the same room, performed by different members of the same team, and a candidate who describes them sequentially has described something that does not happen.

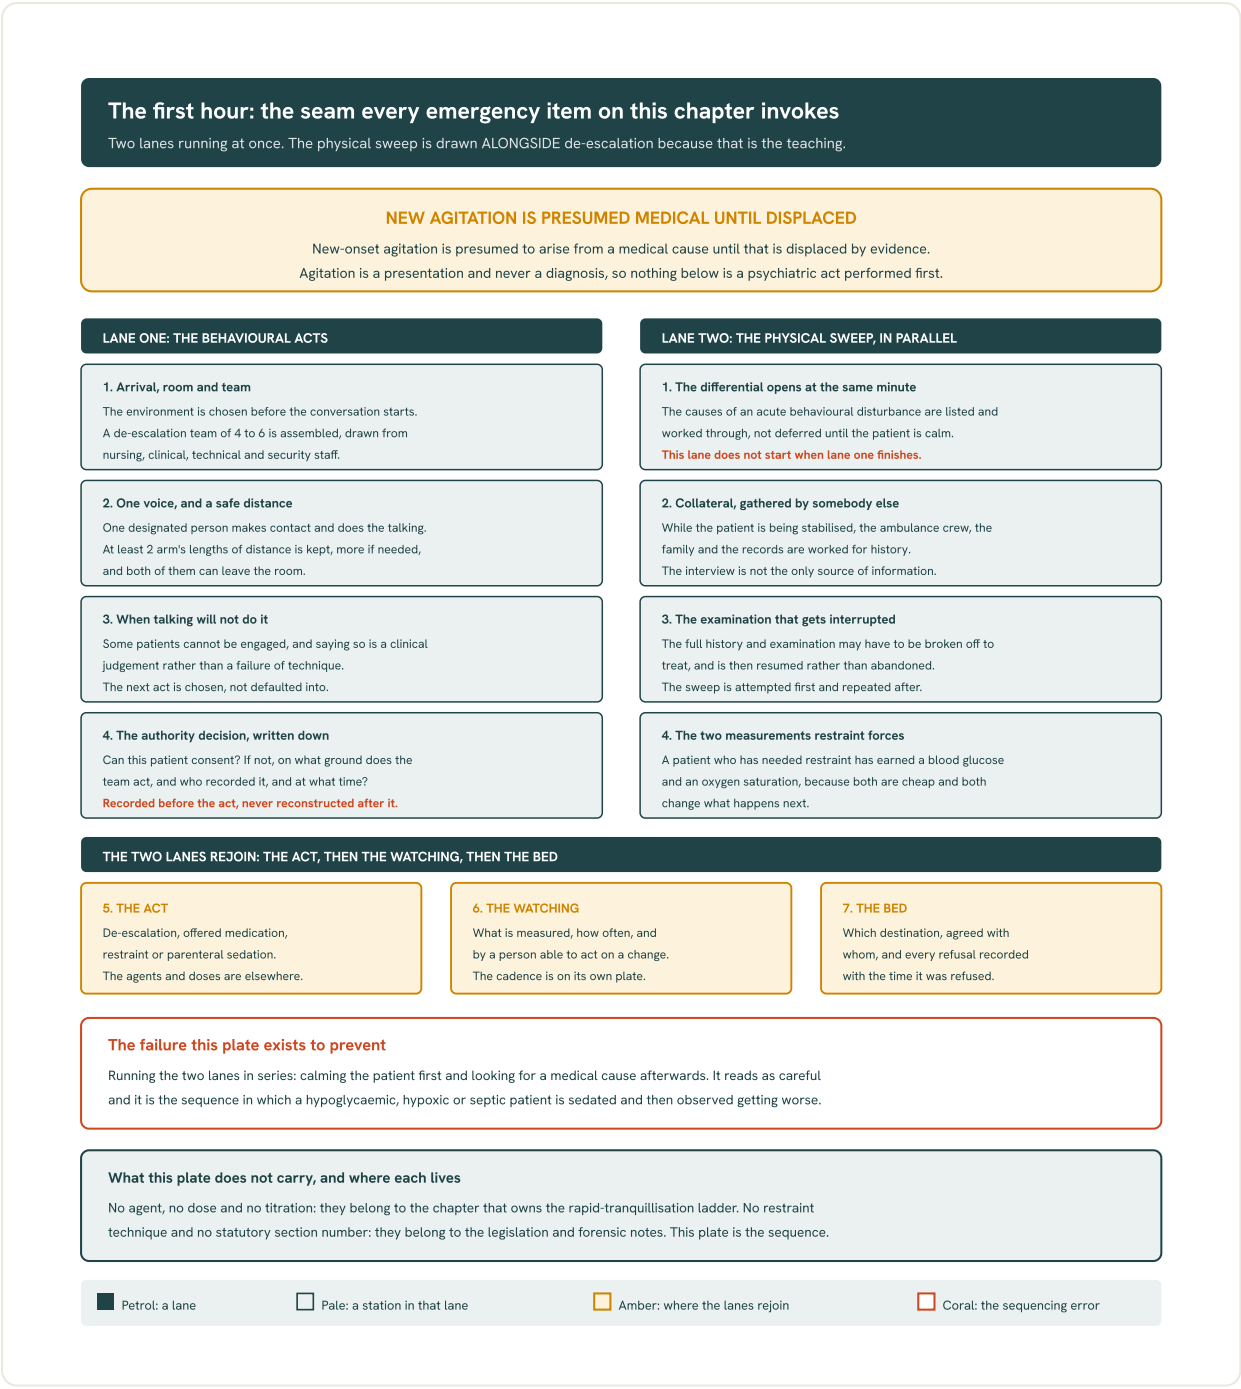

Fig 28.7. The first hour drawn as two lanes running at once, the behavioural acts of environment, one designated voice, safe distance and the authority decision set beside the physical sweep of differential, collateral, the interrupted examination and the two measurements that restraint compels, with the lanes rejoining at the act, the watching and the bed, and the sequencing error of running them one after the other named as the failure the arrangement exists to prevent.

14.1 Agitation is a presentation, and never a diagnosis

The most consequential error in this area is to treat agitation as though it were itself the thing to be treated. It is a final common pathway. The consensus statement of the American Association for Emergency Psychiatry, produced by its **Project BETA** medical evaluation workgroup, puts this as a formal consensus position rather than as advice: agitation that is **new in onset** is to be presumed to arise from a general medical condition. The presumption runs that way deliberately, and it does not wait for a positive finding to activate it. The clinician who wants to conclude that this is psychiatric carries the burden of excluding the medical cause first.

Two riders come with it. The first is about testing: the same consensus states that routine laboratory testing is not indicated, and that **directed testing** chosen from the most likely diagnosis is what is indicated instead. The reflex in a busy casualty runs the other way, and a standard panel sent from the trolley is expensive, slow, frequently uninterpretable, and above all a substitute for thinking. A directed test follows a hypothesis; a routine panel replaces one.

The second rider names when to hold the presumption most tightly. Suspicion rises where the past medical history is concerning, with immunosuppression given as the example, and where onset falls outside the normal age ranges of psychiatric disease. The second is the more useful at the bedside, because it is available before any test result and often before any history: first-onset agitation in a man in his seventies, or in a child, is a medical presentation until proved otherwise, whatever the referral letter says.

TRAP **Reading a known psychiatric history as the explanation for new agitation.** The patient with an established diagnosis is the exact patient in whom the medical cause is missed, because the history supplies a ready-made account that closes the question before it is asked, and the presumption rule carries no exemption for people already known to services. Candidates make this error because the vignette gives the diagnosis in its first line and they read it as the answer rather than the distractor. The discipline is to notice that the history explains why this patient might become agitated, which is a different question from why they are agitated today.

14.2 Reading risk at the door, with what the first minutes actually give you

Prediction at the front door is where the honest answer is uncomfortable and should be given anyway. The available evidence-based recommendation is not about the emergency room. The National Institute for Health and Care Excellence guideline on the short-term management of violence and aggression recommends considering an **actuarial prediction instrument** rather than unstructured clinical judgement alone, to monitor and reduce incidents of violence and aggression and to help develop a risk management plan, and it names two: the **Broset Violence Checklist** and the **Dynamic Appraisal of Situational Aggression, Inpatient Version**. Neither is reproduced here, and no item, anchor or threshold from either belongs in an answer; they are named, and naming them is the whole of what a candidate should do with them.

The recommendation carries a scope restriction that is routinely dropped when it is quoted, and dropping it is a real error. It is written for inpatient psychiatric settings, where a known patient is observed continuously by staff who saw them yesterday and can score a change. The emergency door is a different problem: a stranger, no baseline, no serial observation, minutes rather than shifts. No instrument validated for that position is quoted here because none was available to quote, and the correct answer says so rather than transplanting an inpatient tool to the door and calling the transplant evidence.

What remains is what the first minutes genuinely supply: behaviour observed in real time, and an account from whoever brought the patient. What makes a prediction from that defensible is not a score but a stated basis. What specifically is being predicted, over what period, from which observed features, and what would change the answer. That formulation is transferable at handover and survives the question an incident review actually asks, which is never what the risk

level was but always what it rested on. The framework for assessing risk to self, and the instruments used for it, belong to the Somatic-symptom, sexual, impulse-control disorders and suicide notes.

14.3 The room: exits, doors, stimulus and ligature points

The environment is the only part of this problem that can be fixed before the patient arrives, and the part candidates never mention. The Royal College of Emergency Medicine best practice guideline on **acute behavioural disturbance** in emergency departments specifies the ideal space for verbal and environmental de-escalation. It is a United Kingdom emergency department specification and should be attributed as one; no equivalent Indian specification is quoted here because none was found. Read its features as events they are designed to prevent, because each removes something that has actually gone wrong somewhere.

WHAT THE SPECIFICATION ASKS FOR	WHAT ITS ABSENCE PRODUCES
Adequate and appropriately located exits, so staff can leave without being trapped by the patient	A clinician cornered between the patient and the curtain, whose attention is on their own escape and who is read accurately as afraid
Doors which open outwards	A door wedged shut from inside, so that entry becomes forced entry with no intermediate step
A quiet, low-stimulus space that is not too warm	De-escalation attempted against a continuing provocation, so its failure is misattributed to the patient
No equipment, furniture or moveable object usable as a weapon or to barricade an exit	Injury and a barricaded room, and a threshold for restraint that falls because waiting has been made costlier
No potential ligature points	Self-harm in the interval when nobody is in the room, so staffing rather than fabric becomes rate-limiting
Constant observability, and staff able to signal for additional support easily	An incident found late, and help that arrives after the event rather than in time

Where the department cannot supply the room, the specification becomes a checklist for choosing the least bad space and stating what has been accepted. Observability and the ability to signal are the two that must be met somehow, because both are about the arrival of help, and both can be met with people when they cannot be met with architecture.

14.4 Where you stand: distance, positioning and your own way out

Personal safety at this stage is a matter of geometry, and the geometry is specified. The Project BETA de-escalation consensus directs the clinician approaching an agitated patient to keep a minimum of **2 arm's lengths** between themselves and that patient. The unit is deliberate and should not be converted into metres: an arm's length scales with the two people in the room, and what is specified is the distance at which a strike cannot land. The stated reasoning is double: it gives the patient the space they need, and gives the clinician room to move out of the way if the patient kicks out or otherwise strikes.

Three refinements follow, each examinable. The clinician may take more distance in order to feel safe, which makes the parameter a floor rather than a prescription and legitimises the clinician's own discomfort as data. If the patient tells the clinician to get out of the way, the clinician does so immediately, because complying with a request that costs nothing is itself de-escalation, and refusing converts the clinician into the obstacle. And both people must be able to leave the room without feeling that the other is blocking the way, which is the sentence that decides where everybody stands: neither party is between the other and the door. In a cubicle with one exit this cannot be perfectly satisfied, and the practical resolution is to stand off the direct line to the door rather than on it, so neither has to move the other to leave.

MNEMONIC

Room, Team, Voice, Sweep

Room: the space and its exits, settled before the patient is in it. **Team**: enough people, and the right ones, present before the approach. **Voice**: one designated person makes and keeps verbal contact. **Sweep**: the physical differential runs in parallel with the talking, not after it. Everything the escalation ladder teaches begins only once these four are settled, which is why an answer that starts at the ladder has skipped the examinable half.

14.5 The team: how many, who, and who is allowed to speak

Working with an agitated patient is a team activity, and the Project BETA de-escalation consensus is specific about size: in a busy emergency service the **de-escalation team** should consist of **4 to 6 team members**, made up of nurses, clinicians, technicians, and police and security officers if available. The stated purpose explains why the figure is not arbitrary: enough people to provide verbal de-escalation, to offer the possibility of voluntary medication, and to maintain safety if agitation escalates to violence. Sufficient numbers also communicate non-verbally that violence will not be acceptable, and this is easy to get wrong in both directions. Too few, and the patient correctly perceives that the room can be dominated. Too many, or too close, and the same presence reads as a threat and drives the escalation it was assembled to prevent.

The rule about who speaks is one sentence and it is the most useful sentence here. The **first person to make contact** should be the person designated to de-escalate the patient, and if that person is not trained or is otherwise unable to take the role, another should be designated immediately. Two things are fixed at once. Only one person interacts verbally, because an agitated person receiving instructions from several directions has been given a task they cannot perform and will experience the room as an assault. And the designation is a live decision rather than an accident of who reached the trolley first: if the nearest person cannot do it, the role moves, at once and out loud, so everyone else knows to stop talking.

The rest of the team therefore have jobs which are not talking. Someone obtains the bedside physiology, someone interviews the people who brought the patient, someone is positioned so help can be signalled and reached. In a well-run department this is choreographed and almost silent, and the loudest failure mode is a room full of staff all reasoning with the patient at once.

IN INDIA

None of the numbers above describes a district hospital casualty at two in the morning, where the available team may be one postgraduate resident, one nursing officer with a whole department to run, and one security guard whose training is in guarding rather than de-escalation. The honest position is not to pretend the specification is met but to state what is substituted and what that costs. The designated-de-escalator rule becomes easier rather than harder to keep when there are only two staff: one talks, one does everything else. But the missing team members are exactly the people who would have run the parallel physical sweep, so where numbers are short the sweep is the first thing silently dropped and the last thing that should be. Accompanying relatives are almost always present, and they are at once the collateral source, a calming influence in some cases and an inflaming one in others, and people whose own safety the team is responsible for. Which relative stays in the room is a clinical decision taken by the person leading.

14.6 The parallel sweep: what is measured while somebody else is talking

The rule that organises the whole hour. The Project BETA medical evaluation consensus states that the complete history and physical examination may have to be interrupted to treat the patient's agitation, and resumed once the patient is less agitated. Two clauses make this coherent: the patient may need treatment to reduce agitation without a definitive diagnosis, and the goal of medication is to calm the patient enough to allow a thorough evaluation. Read the last one carefully, because it inverts the usual framing. Sedation is not the end of the assessment; it is an instrument of it. A patient who has been calmed and then left alone has received half a treatment, and the half omitted is the reason the other half was given.

What is swept is set out most usefully for a resource-realistic setting by the World Health Organization mhGAP Intervention Guide, written for non-specialised health settings, whose table on the person with agitated or aggressive behaviour directs the clinician to attempt to communicate with the person and, in the same breath, to evaluate for an underlying cause:

- check blood glucose, and give glucose if it is low;
- check vital signs including temperature and oxygen saturation, and give oxygen if needed;
- rule out delirium and medical causes including poisoning;
- rule out drug and alcohol use, considering stimulant intoxication and alcohol or sedative withdrawal specifically;
- rule out agitation due to psychosis or a manic episode.

The order of that list is the teaching. The psychiatric attribution comes last, reached by exclusion rather than by recognition. Note also how little equipment the sequence needs: a glucometer, a thermometer, a saturation probe and a pair of hands. This is a protocol a district hospital can actually run, which is why it is the one worth memorising.

The Royal College of Emergency Medicine guideline supplies the same idea as causes to exclude rather than acts to perform, naming substance intoxication and mental health conditions as the most common factors, alongside substance withdrawal, head injury, hypoglycaemia, seizures, heat

stroke and hypoxia. Serotonin syndrome and anticholinergic syndrome appear on the same list and are named here only; their recognition, discriminating features and treatment belong to the Schizophrenia: management, antipsychotics and adverse effects notes, and nothing resembling a grid comparing them belongs here. Taken as acts, the five this section owns are quick. Hypoglycaemia is excluded by a bedside stick, which takes less time than the argument about whether to do it. Hypoxia is excluded by a probe, which also detects the deteriorating patient nobody is watching because everybody is watching the behaviour. Head injury is excluded by looking, feeling the scalp, and asking whoever brought the patient about a fall or a blow, a question that stops being answerable once those people leave. Intoxication and withdrawal are excluded by history and examination, their entities belonging to the Substance use disorders notes, and delirium by cognitive assessment as far as the patient permits, the syndrome belonging to the Stroke, TBI, delirium and focal brain syndromes notes.

RULE **Assessment and calming are interleaved, not sequential.** The examination may be interrupted by treatment and then resumed, and treatment may precede the diagnosis, because the alternative is a patient who is neither evaluated nor calmed while the team waits for one to permit the other. The corollary is what makes this examinable: because the assessment is interrupted rather than abandoned, somebody must own resuming it. The commonest real failure is not that the sweep is refused but that it is deferred to a moment nobody owns, and the patient is found hours later, calm, undiagnosed, hypoglycaemic and still in the corridor.

LANE RUNNING IN THE FIRST MINUTES	WHAT IS DONE	WHAT IT MAY NOT WAIT FOR
Verbal contact	One designated person makes contact and holds it; if that person is untrained or unable, another is designated immediately	A diagnosis, or a more senior clinician arriving
Team and space	4 to 6 team members in a busy emergency service, drawn from nurses, clinicians, technicians and police and security officers if available	The patient becoming more disturbed before help is called
Bedside physiology	Blood glucose checked and glucose given if low; vital signs including temperature and oxygen saturation checked and oxygen given if needed	The patient becoming cooperative
Physical differential	Delirium and medical causes including poisoning excluded, and drug and alcohol use excluded	Laboratory results, which are directed rather than routine
Collateral	Ambulance crew, police, family, friends, relatives and nursing home personnel interviewed during behavioural stabilisation	The patient becoming interviewable
If restraint occurs	Oxygenation level and finger stick blood glucose done immediately, where they could not previously be obtained	The post-restraint review, or the next shift
History and examination	Interrupted to treat the agitation, then resumed once the patient is less agitated	A definitive diagnosis before any treatment

GOOD TO REMEMBER

Restraint is the moment the two easiest measurements finally become obtainable, and the moment they are most often forgotten. If a patient must be restrained because de-escalation was impractical or ineffective, then oxygenation level and finger stick blood glucose are done immediately where they could not previously be obtained. Build it in as a fixed pairing: hands on, probe on, stick done, before anybody leaves the bedside to write. Restraint converts two impossible tests into two immediate ones, and a team that does not take them has thrown away the one benefit it conferred.

2 arm's lengths MINIMUM DISTANCE ON APPROACHING AN AGITATED PATIENT	**4 to 6** DE-ESCALATION TEAM MEMBERS IN A BUSY EMERGENCY SERVICE	**1** PERSON DESIGNATED TO HOLD VERBAL CONTACT	**Immediate** OXYGENATION AND FINGER STICK GLUCOSE ONCE A PATIENT IS RESTRAINED

14.7 Collateral is taken now, while the patient is being stabilised

Collateral history here is not a step that follows assessment. The Project BETA medical evaluation consensus places it inside the stabilisation itself: during the time the patient is being behaviourally stabilised, the **ambulance crew, police, family, friends, relatives and nursing home personnel** should be interviewed to obtain a history or collateral information. Learn that as a list, because it is a list of people physically present at that moment and at no other.

This is the most perishable resource in the encounter. The ambulance crew has another call; the police stop being responsible once they have handed over. Each holds information nobody else has and the patient, by definition, cannot supply: what the person was like yesterday, when the change began and how fast, whether there was a fall, what was taken and how much, whether the tablets in the house have gone. An hour later, when the patient is calm and the clinician is free to take a history, all of them have gone and the information with them.

The operational answer is to assign it. The team member not holding verbal contact interviews the accompanying people while de-escalation is still running, and before releasing anyone. Two questions justify the exercise even when time is shortest: what is different about this person compared with yesterday, and what could they have taken or been given. In Indian practice the accompanying group is large and its members frequently disagree, and that disagreement is itself information about the timeline. The task is not to arbitrate but to record who said what, because a discrepancy about time of onset is often the first sign that the story offered is not the story that happened.

14.8 When de-escalation has not worked yet, and when it cannot be attempted at all

Two situations look identical from the doorway and demand opposite responses, and telling them apart is the discrimination this section exists to teach. The Project BETA de-escalation consensus states both. There are patients who cannot be effectively engaged and verbally de-escalated, and the example given is the **delirious patient**. Against that, training should emphasise that a patient may not respond to initial efforts at engagement and that **persistence** is indicated, especially where the patient is not showing signs of further escalation towards violence.

The distinction turns on capacity to engage rather than degree of disturbance. The delirious patient is the exemplar because the medium itself has failed: attention cannot be held, so a sentence does not arrive intact, and repeating it more calmly does not repair the channel. Verbal de-escalation there is not merely ineffective, it consumes the time in which the reversible cause should have been found. The syndrome and its assessment belong to the Stroke, TBI, delirium and focal brain syndromes notes, and the front-door management of the confused patient is dealt with elsewhere in this chapter.

The opposite error is commoner and more damaging. A patient who has not answered the first two attempts is frequently written off as unresponsive, when the guidance is explicit that failure of initial efforts is not the end point. The condition attached to persistence is behavioural rather than temporal, which makes it usable without a clock. If the patient is disturbed but not

escalating, keep going, because that is time in which the physical sweep and the collateral are being completed by everyone else in the room. If the patient is escalating despite engagement, or cannot engage at all, the situation has changed category and the response moves to the staged escalation that the Mental health legislation and forensic psychiatry notes and the Schizophrenia: management, antipsychotics and adverse effects notes set out in full, with every agent and dose. The authority under which that is done for a patient who cannot consent is a separate question, addressed with the rapid tranquillisation and legislation material.

One further point, because it is where good answers lose marks. Deciding that de-escalation cannot be attempted is a clinical judgement that must be recorded with its reason, like any other move to a more restrictive intervention. The reason is not that the patient was agitated. It is that this patient could not sustain attention on a sentence, or that a designated person attempted engagement and the behaviour escalated during it. That separates a considered escalation from an impatient one.

14.9 What must be true before the first hour ends

The end of this section is the beginning of everything else, and the handover is best stated as conditions rather than narrative. Before the patient leaves the resuscitation area or assessment room, the following should be true and recordable.

- A glucose and a saturation exist, with a time against each, and if the patient was restrained they were taken at that moment.
- Somebody has been interviewed who saw the patient before this episode, and their name is written down.
- A named person led the verbal contact, and a named person is responsible for resuming the interrupted examination.
- The medical presumption has been tested rather than assumed away, and if set aside, the reason is written.
- The level of care, the level of observation and the disposition have been decided by somebody rather than defaulted to by nobody.

The last of those is where this section hands over. Observation levels and the admission decision, the rapid tranquillisation protocol with its authority question and its monitoring, and the physical safety of a person in restraint each have their own place in this chapter. What has been established here is the material all three depend on: the room was chosen, the team assembled and one voice designated, physical causes excluded while the talking was happening, the people who knew the patient spoken to before they left, and the presumption of a medical cause carried until actively displaced. An answer that reaches the escalation ladder without any of that has described the treatment of a diagnosis nobody has yet made.

> Agitation is a presentation and never a diagnosis: the physical sweep runs alongside the talking rather than after it, and the psychiatric attribution is the last one made, not the first.

15 · Rapid tranquillization protocols

Why the marks are here. Rapid tranquillisation is examined as though it were a pharmacology question, and answered as one: which agent, in what order, at what dose. Those belong to the Schizophrenia: management, antipsychotics and adverse effects notes, which print the sequence and every first dose in it, and they are not repeated here. Take the drug chart away and what remains is the part that actually goes wrong on a ward. Rapid tranquillisation is a procedure. Like any procedure it has an indication statable in one sentence, an authority that must exist before it begins, a practitioner competent to manage what it may cause, a brief that fixes who does what, a written order whose form determines who thinks next, and a monitoring plan that outlives the drug by hours. Not one of those is a milligram.

The front of the emergency sequence, including the environment, the team, verbal de-escalation and the physical differential that runs in parallel with it, is set out with the assessment of the acutely agitated and aggressive patient elsewhere in these notes and is assumed rather than restated. What follows begins once the decision to sedate has been taken. The organising commitment is that the drug is the smallest and least dangerous component of the act, and that the avoidable deaths in this area happen in the hour after the injection rather than at the moment of it.

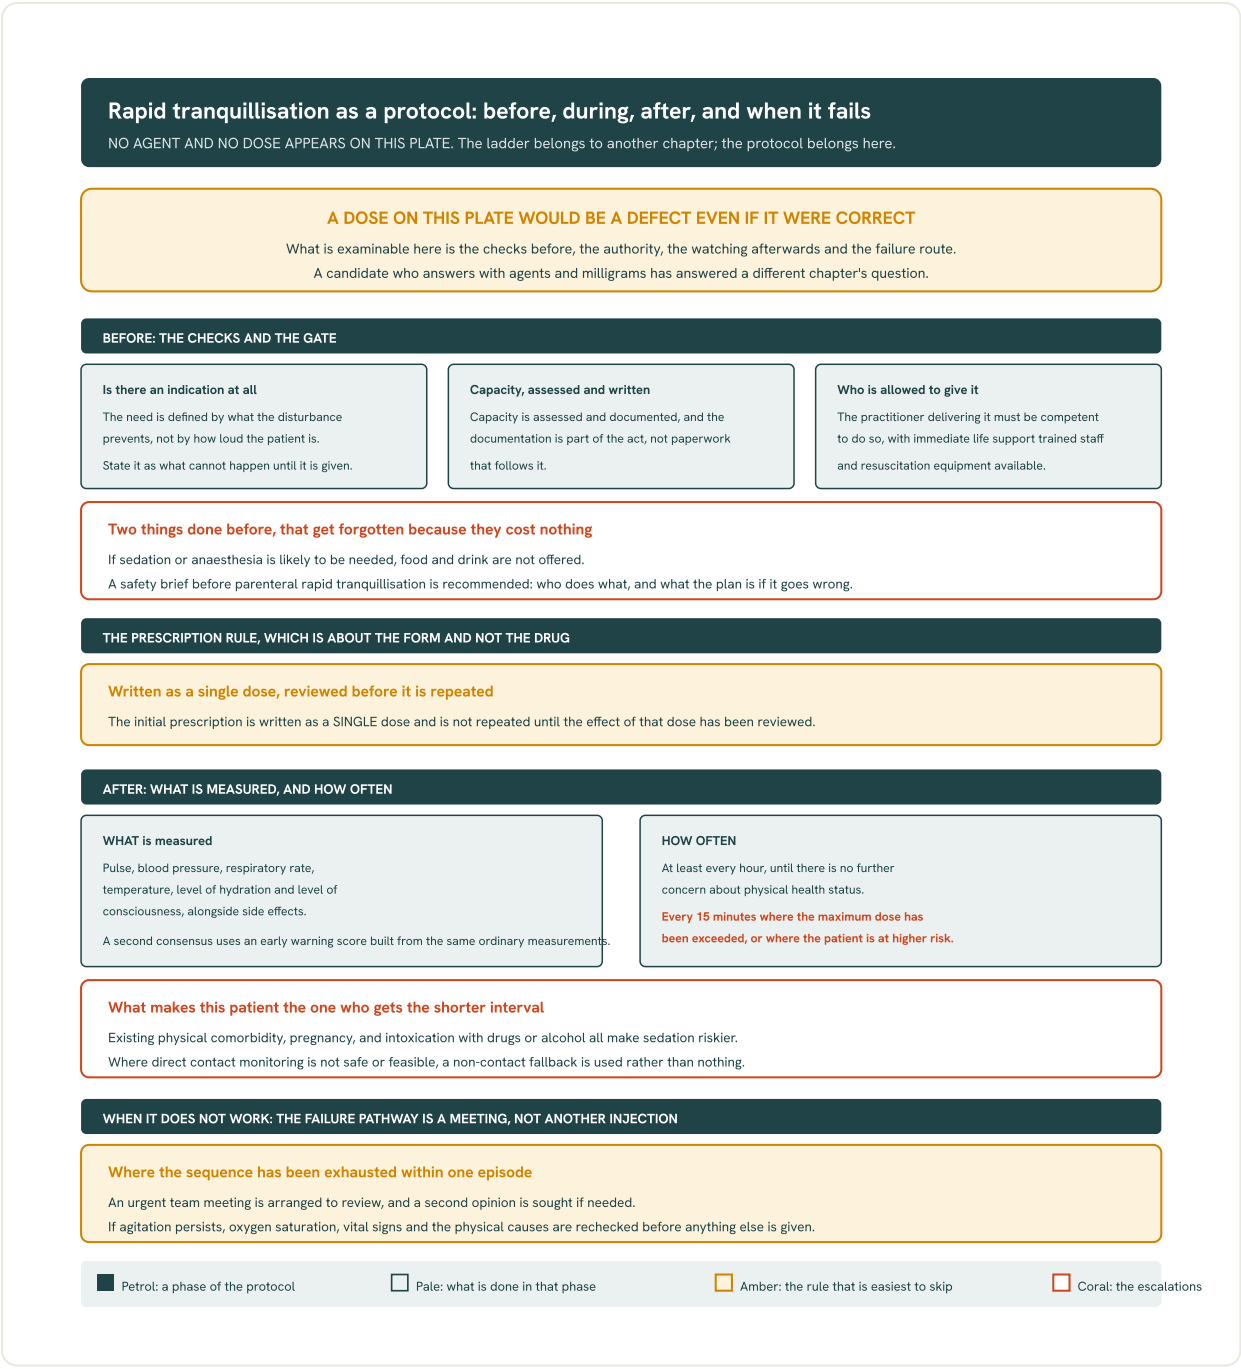

Fig 28.8. Rapid tranquillisation drawn as a protocol rather than as a drug ladder, with the indication test, the capacity assessment and the competence and resuscitation requirements before it, the single-dose prescription rule, the parameters measured afterwards and the two cadences that govern them, the patient factors that shorten the interval, and the failure pathway stated as an urgent team review rather than as a further injection. No agent and no dose appears anywhere on the plate.

15.1 The indication is what the disturbance prevents, not how disturbed the patient looks

The most useful answer to when this is indicated is a definition rather than a threshold. The Royal College of Emergency Medicine, in its best practice guideline on acute behavioural disturbance in emergency departments (version 2, October 2023), defines the need for rapid tranquillisation as the **inability to provide safe assessment or essential treatment**. That deserves a slow reading for what it declines to do. It does not define the indication by the patient's behaviour, by a level of arousal, by how frightened the staff are, or by a score on any instrument. It defines it by what the clinician cannot do while the disturbance continues.

The definition cuts both ways, and both cuts are examinable. A patient who is loud, threatening and frightening to be near, but who can be examined and whose essential treatment can be given, does not meet it. Noise is not the indication, and a department that sedates noise will sedate distress, grief and cultural difference along with illness. Conversely a patient who is barely raising his voice, but who will not permit the examination his physical presentation demands or is pulling out the line that is treating him, does meet it. The quiet obstructive patient is the one this definition catches and intuition misses.

It also imposes a discipline of statement. If the indication is an inability, the clinician must say what it is an inability to do: this assessment, this investigation, this treatment. That sentence belongs in the record before the drug is drawn up, and it does a second job at review, because the question afterwards is not whether the patient is calmer but whether the thing that could not be done can now be done. Where nobody can complete the sentence, what is being treated is the department's distress.

RULE **Rapid tranquillisation is indicated by what the disturbance prevents, never by how disturbed the patient appears.** Everything else in the protocol follows. The indication states a purpose, the purpose sets the endpoint, the endpoint is what the post-dose review tests, and the monitoring exists to keep the patient alive until that review can be made. A protocol entered without a stated purpose has no endpoint, and sedation without an endpoint becomes sedation renewed by habit.

15.2 Authority: capacity is assessed and written down, never assumed

The act contemplated is giving a drug to an adult who has not agreed to it, which requires an authority, and the authority has two halves that candidates collapse into one: legal permission to treat without consent, and clinical competence to carry the treatment out. The second is the next section. The first begins with capacity, and the guidance is blunt about how it is handled. The Royal College of Emergency Medicine states that patients presenting with severe acute behavioural disturbance are likely to lack capacity to make treatment decisions and may require emergency treatment, and that this should be **formally assessed and documented**.

The two clauses pull against each other deliberately, and that tension is the teaching. The first is an empirical expectation: in this population incapacity is the likely finding. The second forbids acting on the expectation without checking it, because a likelihood is not a finding. The error runs both ways. The commoner one treats the disturbance as self-evidently establishing incapacity, so no assessment is made and the record contains a drug and no reasoning. The rarer one accepts a fluent refusal as evidence of capacity, because the patient is talking in sentences, and withholds treatment from someone who cannot retain or weigh what he is being told.

Formal assessment here does not mean an unhurried capacity interview, which the situation does not permit and the guidance does not demand. It means an assessment was attempted and its result recorded: what the patient was told, what he was able and unable to do with that information, and the conclusion. Two or three contemporaneous lines will do; nothing will not. The documentation is load-bearing rather than bureaucratic, because the record is the only later

evidence that the injection was a treatment decision rather than a convenience, and every subsequent review or inquiry begins by reading it.

One jurisdictional caution must be stated rather than smoothed over. The rule above is a United Kingdom statement of the step. The statutory basis on which a patient may be treated without consent in an emergency in India, and the position of restraint within that law, are set out in the Mental health legislation and forensic psychiatry notes, with the consent doctrine itself in the Forensic ethics, consent and legal procedure notes. They are named here and not restated, and no Indian statutory provision is asserted in this section. What survives translation is the structure of the obligation: identify the ground you are acting on, satisfy yourself it applies to this patient now, and write down that you did.

TRAP **Treating the disturbance as though it were the capacity assessment.** Candidates write that the patient was agitated and therefore lacked capacity, which reverses the logic: severe disturbance makes incapacity likely, and likelihood is exactly what an assessment is for. The error is attractive because it saves time in a situation that has none, and because the conclusion is usually correct, which is what makes it dangerous. A correct conclusion reached without an assessment is indistinguishable in the record from no conclusion at all, and it is the record that is examined afterwards. State the assessment and its documentation as a discrete step with its own place in the sequence, before the drug rather than after it.

15.3 Competence: who may give it, and who must be within reach

The second half of the authority question is clinical, and no legal framework answers it. The same emergency medicine guideline states that the practitioner delivering rapid tranquillisation must be **capable of managing those complications** if they arise, that care of the patient presenting with acute behavioural disturbance should be provided by a senior emergency medicine practitioner, and that early critical care support should be considered. The complications in view are recorded in the same source as apnoea, airway obstruction and a subsequent requirement for intubation, associated with most of the sedative agents used in this situation.

Put plainly: whoever gives a drug that may stop the patient breathing must be able to manage a patient who has stopped breathing. This is not about hierarchy or prescribing rights. It is about which skills are physically present in the room when the plunger goes down, and it has an uncomfortable implication for the common arrangement in which the decision is taken by a senior over the telephone and executed by whoever is on the floor. The decision may be delegable. The airway is not.

The standard is stated again from a different direction by the National Institute for Health and Care Excellence in its guideline on the short-term management of violence and aggression, NG10, published in 2015: staff trained in **immediate life support**, and a doctor trained to use resuscitation equipment, should be immediately available to attend an emergency wherever restrictive interventions might be used. Read the limbs together, because the standard is equipment plus a person competent to use it and neither discharges it alone. A resuscitation trolley behind a locked door, and a nurse trained in life support on a ward whose defibrillator is three floors away, both fail it while appearing on paper to meet it.

Note also that the standard attaches to the possibility of a restrictive intervention rather than to its occurrence. It is a rostering and geography requirement settled before any particular patient arrives, which is why it cannot be improvised at the moment of need. The same logic explains considering critical care support early: an early call is made while there is still time for someone to walk to you, whereas a call made once the saturation is falling has become an emergency referral.

15.4 Before the drug: who is less safe to sedate, and the check everyone forgets

Pre-sedation assessment here is compressed and often uncooperative, so it has to be selective. The joint consensus guideline of the British Association for Psychopharmacology and the National Association of Psychiatric Intensive Care and Low Secure Units, published in 2018, names the factors conferring additional risk on the act of sedation itself:

- pre-existing physical health comorbidity, which converts a transient respiratory or haemodynamic effect into a decompensation;
- pregnancy, where the decision is being made for two patients at once and restraint positioning changes as well, taken up with the perinatal emergencies elsewhere in these notes;
- intoxication with, or withdrawal from, drugs or alcohol, the commonest unknown at the front door and the one most likely to be additive with what you are about to give;
- the potential for medication interactions, which in a patient whose regular prescription is unknown is a risk accepted rather than assessed.

The same source adds a category easy to miss because it is not pharmacological at all: non-medication risks are also a factor, and they include **the process of restraint** itself. This changes how the decision is framed. Clinicians weigh sedation against restraint as though they were alternatives and only one risk were being taken; in practice parenteral rapid tranquillisation in a resisting patient is delivered under restraint, so the two risks are additive and arrive together. The physical hazards of holding a person, and the observation that person needs during and after the hold, are taken up separately in these notes.

One further instruction deserves separate billing as the most reliably forgotten line in the protocol. The emergency medicine guideline directs that where sedation or general anaesthesia is likely to be required, the patient should be offered **no food or drink**. It is a short rule with a large consequence, and its difficulty is that it runs against the instinct that de-escalation trains into a good clinician.

PITFALL

De-escalation works partly through ordinary kindness, and the commonest ordinary kindness in an Indian casualty is a cup of tea or a glass of water brought by a relative who has been waiting outside for hours. If the patient is on a path towards parenteral sedation, that kindness fills the stomach of a person who may shortly be obtunded, unable to protect the airway and supine under restraint. The instruction is not to be unkind. It is to decide early whether sedation is likely, say so to the team and to the family in the same breath as the explanation of what is happening, and substitute a kindness that does not enter the stomach. A team that has not made this decision explicitly makes it by default, and the default is the tea.

15.5 The safety brief, and the three elements that make it more than a formality

Parenteral rapid tranquillisation is a team procedure performed at speed on a resisting person, which is the exact configuration in which tasks get duplicated, tasks get dropped, and nobody notices either. The emergency medicine guideline answers this with an instrument borrowed from surgery and resuscitation: it recommends considering a **safety brief** before parenteral rapid tranquillisation where practicable, covering roles, the intended plan, anticipated problems, restraint considerations, the intravenous access plan, the plan for moving to a resuscitation environment, and responsibility for the decision to relax restraint.

Each element removes a specific failure. Roles removes duplication: who holds which limb, who protects the head and airway, who draws up and gives, who keeps time, who continues talking to the patient, and who is doing none of these because they are watching the whole room. The intended plan removes the situation in which two people execute different plans in good faith. Anticipated problems converts a foreseeable crisis into a contingency somebody has already been assigned. Restraint considerations settles position and duration before adrenaline rather than during it.

The last three separate a brief from a formality. The intravenous access plan is settled beforehand because access gets harder as the patient becomes more disturbed and then more sedated, so the moment you urgently need a line is the moment you are least able to get one. The plan for moving to a resuscitation environment is a route, a trolley, a door and a person, worked out while there is time to walk it; a team that has not settled it discovers the lift is on another floor while carrying a patient who is not breathing. Responsibility for the decision to relax restraint is the element most often left unassigned, at the moment it matters most, because releasing too early and holding too long are both harmful and a team with no named owner does neither deliberately.

The guidance qualifies the brief with the words where practicable, and that should be taught honestly rather than quietly dropped. Some situations do not permit a huddle. They do permit a compressed version delivered in the corridor: roles, plan, who calls the release. The brief is a distribution of attention rather than a document, and a shortened brief distributes far more of it than none.

MNEMONIC

Who, What, What if, Hold, Access, Exit, Release

The seven elements of the brief in the order they are needed. **Who**: roles. **What**: the intended plan. **What if**: anticipated problems. **Hold**: restraint considerations. **Access**: the intravenous plan. **Exit**: the route to a resuscitation environment. **Release**: the named owner of the decision to relax restraint. Teams that skip one skip the last, and the last is the one whose absence is felt at the most dangerous moment.

15.6 The order is written as one dose, and the review is what makes it a protocol

How the prescription is written determines who makes the next decision, which makes the form of the order a clinical matter and not a clerical one. The national guideline on violence and aggression recommends that the initial prescription for rapid tranquillisation is written as **a single dose**, and is not repeated until the effect of that dose has been reviewed.

The rule is doing something precise. An order written open, in the familiar form permitting repetition as required, silently transfers the next decision to whoever holds the chart when the patient is next disturbed. In practice that is the most junior person on the floor, at night, under pressure from a ward that wants quiet, assessing a patient who by then is least able to object. A single-dose order makes repetition impossible without a clinician returning to the patient, which is the point: it forces a fresh act of judgement at the moment the risk of accumulation begins.

It is also what makes the monitoring meaningful, so the two are always taught together. Observations recorded with no decision attached are chart-filling, and wards produce a great deal of it. The review of effect is what the observations are for, and it has two limbs that must both be answered. The clinical limb returns to the stated indication: can the assessment now be made, can the essential treatment now be given. The physiological limb asks what the drug has done to breathing, circulation and conscious level. A review answering only the first is how a patient becomes calm, monitored and dead.

GOOD TO REMEMBER

Write four things into the same entry as the order and it becomes a protocol rather than a prescription: the indication in the inability form, the single dose given, the time the effect will be reviewed, and the name of the person who will review it. A team that writes only the drug has documented an event. A team that writes all four has documented a decision, and has left the only instruction that survives a shift change.

15.7 After the dose: what is measured, how often, and until when

This is the genuinely owned part of the topic and the part most often missing from an answer. After rapid tranquillisation, the national guideline on violence and aggression directs that side effects and the patient's pulse, blood pressure, respiratory rate, temperature, level of hydration and level of consciousness are monitored at least **every hour**, until there are no further concerns about the patient's physical health status. The interval shortens to **every 15 minutes** where the maximum dose has been exceeded, or where the patient:

- appears to be asleep or sedated;
- has taken illicit drugs or alcohol;
- has a pre-existing physical health problem;
- has experienced any harm as a result of any restrictive intervention.

The first trigger is counter-intuitive and is the one wards get wrong: the more successful the sedation looks, the closer the monitoring gets. A sleeping patient reads to a busy team as a solved problem and to this protocol as an escalation, because sleep and over-sedation are indistinguishable from the end of the bed and the difference between them is the airway. The fourth trigger matters too, because harm sustained during restraint escalates the monitoring of the sedation, which is the protocol acknowledging that the two interventions have combined into one physiological insult.

Every hour	Every 15 min	4	97%
MINIMUM MONITORING INTERVAL AFTER RAPID TRANQUILLISATION, NICE NG10	NICE INTERVAL WHEN ANY ESCALATION TRIGGER IS PRESENT	BAP AND NAPICU MONITORING LEVELS, LOW TO CRITICAL	OF 44 UK RAPID TRANQUILLISATION DOCUMENTS NAMED MONITORING PARAMETERS

Notice what is missing. This cadence has no fixed end. It runs until there are no further concerns about physical health status, which is a clinical stopping rule and not a duration, and the omission is deliberate. A fixed period invites a team to stop at the end of it, and the risk from a sedative does not expire on a clock; it expires when the physiology says so. The corollary is that somebody must be nominated to decide the concern has ended, because a stopping rule with no owner does not stop, it lapses.

The parameter set is worth comparing with the one the other major consensus uses, because they differ instructively. The joint BAP and NAPICU guideline monitors using the **National Early Warning Score**, which it defines as comprising temperature, pulse, systolic blood pressure, respiratory rate, oxygen saturation and level of consciousness. The instrument is named and its constituents are ordinary clinical measurements; no scoring, weighting or trigger threshold from it belongs in an answer.

PARAMETER	WHICH SET NAMES IT	WHAT IT IS WATCHING FOR
Respiratory rate	Both sets	Respiratory depression, and the earliest bedside warning of it
Level of consciousness	Both sets	Depth of sedation, and whether the airway is still protected
Pulse	Both sets	Rate and rhythm disturbance, and the cost of the preceding struggle
Blood pressure	Both sets, systolic specified in the early warning score	Hypotension, including the postural drop seen only on sitting up
Temperature	Both sets	Pyrexia, which after antipsychotic exposure changes the diagnostic frame
Oxygen saturation	Early warning score only	Hypoxaemia, and the measurement a resisting patient will usually tolerate
Level of hydration	NICE set only	Prolonged struggle, refused fluids and a period nil by mouth
Side effects	NICE set only	Drug effects no physiological number displays, found only by looking

15.8 Stratifying the monitoring: level set by route and by state, not by drug

The joint BAP and NAPICU consensus goes beyond a single interval and stratifies direct contact monitoring into **four** levels, each pairing a physical cadence with an observation intensity. Only the physical cadence is taught here. The observation intensity is a sixth vocabulary for a construct that already has five in print, and both the levels and the fact that their names do not agree across documents belong with observation after self-harm elsewhere in these notes; naming an intensity in this consensus's words to a nurse working in another document's words communicates nothing. Its own statement of status travels with it: the source records that these levels rest on the consensus of experts, given the dearth of available evidence. That label is not a reason to discount them. It tells the reader what kind of authority an interval carries, and it is why a local protocol may legitimately differ from this one while a local protocol that differs from a physiological principle may not.

LEVEL	WHICH PATIENTS	PHYSICAL MONITORING	OBSERVATION
Low	Following pre-tranquillisation medication	Early warning score or equivalent every hour, minimum one hour	Standard psychiatric observations every hour
Medium	After intramuscular rapid tranquillisation, no higher level required	Early warning score or equivalent every 15 minutes, minimum one hour	Intermittent psychiatric observations every 15 minutes
High	After intramuscular rapid tranquillisation, over-sedated, asleep or significantly physically unwell	Early warning score or equivalent every 15 minutes, minimum one hour, with pulse oximetry until ambulatory	Continuous, within line of sight
Critical	After intravenous rapid tranquillisation, or unconscious and not rousable, or severely physically unwell	Continuous monitoring, resuscitation facilities essential	Continuous, within arm's length

Two design features are the transferable part. First, the level is set by the route of administration and by the patient's state, never by which agent was used: intravenous administration goes to the top level regardless of what was given, and unrousability does the same. A candidate reasoning from the drug to the monitoring has the logic inverted. Second, the recovery marker at the high level is that the patient is ambulatory rather than talking. Walking tests conscious level, coordination, standing blood pressure and postural airway control at once, which makes it a better endpoint than conversation and available on any ward without equipment.

The observation column belongs to a construct taught in full with the emergency management of suicide risk elsewhere in these notes, where the levels, who sets them, who reviews them and what the handover carries are set out. What this section owns is the pairing: after rapid tranquillisation a physical cadence and an observation intensity are prescribed together, and prescribing one without the other leaves a patient either watched but not measured, or measured but not watched.

15.9 When the monitoring the protocol assumes does not exist

The honest problem. Every cadence above assumes a working pulse oximeter, a cuff the patient will tolerate, a thermometer, a member of staff who can stay in the room, and a resuscitation capability within reach. That set is frequently incomplete, and pretending otherwise produces an answer that is correct and useless. The consensus guideline addresses incompleteness directly, though from a different starting point: for patients in whom direct contact physical monitoring is not safe or feasible, it directs that **non-contact physical monitoring** be conducted until direct contact monitoring can be established, comprising:

- respiratory rate;
- level of consciousness;

- pallor;
- signs of pyrexia;
- evidence of dystonia or akathisia;
- signs of dehydration.

Notice the design of that set. Every item is obtainable from the end of the bed by a clinician with no equipment and no cooperation, which makes it usable both in the situation the guideline describes, where touching the patient is unsafe, and in the situation an Indian ward more often faces, where the equipment is elsewhere. The extension from one to the other should be made explicitly rather than smuggled: the source frames the constraint as safety or feasibility, not as resource scarcity, and a candidate who cites it as guidance about under-resourced settings has overstated it. What transfers legitimately is the principle that when the measured set is unavailable the answer is a different observation set, not an absence of observation. Two further features matter. The fallback is temporary by construction, since it runs until direct contact monitoring can be established, so adopting it carries a standing obligation to keep trying. And it is not a diluted version of the full set but a differently chosen one, weighted towards what a human observer detects reliably without instruments.

Protocol variation in this area is real and has been measured, rather than being a complaint. In national surveys of United Kingdom mental health organisations reported by the same consensus guideline, nearly all of the rapid tranquillisation documents examined specified monitoring parameters, but **14** different parameters appeared across them. Those were United Kingdom documents and say nothing about Indian practice, so the figure establishes only that having a protocol is not the same as having a standard. The consequence for a case sheet is that the phrase as per protocol records nothing: name the parameters actually measured and the interval actually used.

IN INDIA

In a district hospital casualty at night the full monitoring set is often not assembled, and the honest response is neither to recite the guideline nor to abandon it, but to state what is being substituted and what that costs. Name the observer: a cadence assigned to the ward is assigned to nobody, and where staff are few the single most effective act is to write one person's name against the observation until relieved. Run the non-contact set from the bedside, since it needs nothing and can begin the moment the injection is given rather than when a trolley is found. Prioritise the pulse oximeter above every other instrument if only one can be brought, because it is continuous, tolerated by a resisting patient, and directly relevant to the complication that actually kills. And record what was not available, in plain terms. That record is both an honest account of the care given and the only thing that has ever changed what a ward is equipped with.

15.10 Failure: what is done when the patient is still disturbed

Sedation that does not work is a common examination scenario and a dangerous clinical moment, because the instinctive response is to give more of the same and the guidance says something else. Where the sequence of intramuscular options has been exhausted within an episode, the

national guideline on violence and aggression directs that **an urgent team meeting** be arranged to carry out a review, and that a second opinion be sought if needed. The agents and their order belong to the Schizophrenia: management, antipsychotics and adverse effects notes and are not reproduced here; what is owned here is the terminal step, and the striking thing about it is that it is not pharmacological. At the end of the ladder the recommended intervention is more clinicians, not more drug.

The World Health Organization mhGAP Intervention Guide, version 2.0 (2016), written for non-specialised settings, reaches the same destination by a different road. If the person remains agitated it directs the clinician to recheck oxygen saturation, vital signs and glucose, to consider pain, and to refer to hospital; and once agitation subsides, to move to the assessment that identifies what is actually wrong. Failure is treated as a reason to repeat the physical sweep, not to escalate the dose.

Held together, the two pathways teach one thing: failure of sedation is a diagnostic event. One response escalates the number of people making the decision, the other escalates the examination, and neither escalates the syringe. That is clinically right as well as procedurally safe, because the commonest reasons a correctly given sedative fails are that the cause of the disturbance is not the one assumed, that a physiological derangement is driving it, or that something is hurting.

Pain deserves its own sentence, since the instruction to consider it sits in a guideline written for clinicians with the fewest resources and is the cheapest thing on this page. The patient who cannot give a history is the patient whose pain is never asked about: retained urine after hours of restraint and immobility, an injury sustained in the struggle, a surgical abdomen underneath the agitation. An analgesic and a bladder scan have settled patients two rounds of sedation did not. The disposition follows from the same logic. Once the disturbance subsides the assessment begins rather than ends, and where the patient goes next is set by the monitoring level he currently needs rather than by which ward has a bed.

> Rapid tranquillisation is a procedure, not a prescription: an indication stated as something you cannot do, a capacity assessment written down, a practitioner who can manage the airway, one dose with a named reviewer, and a monitoring cadence that runs until someone decides the physical concern has ended.

16 · Suicide risk assessment and emergency management

Why the marks are here. The suicidal patient is examined as though suicide risk were an assessment problem alone, and it is half of one. Assessment produces a judgement; the judgement then has to become something a ward can deliver over the next several hours: a level of observation, decisions about the room and what is in it, an admission decision, and conditions that must hold before the patient leaves. The framework for estimating risk, the disposition ladder and the counselling of patient and family about access to lethal means at home belong to

the Somatic-symptom, sexual, impulse-control disorders and suicide notes and are not repeated here.

One warning governs everything below. The documents that create observation levels do not agree with each other: they use the same word for different things and different words for the same thing, and most decline to fix an interval at all.

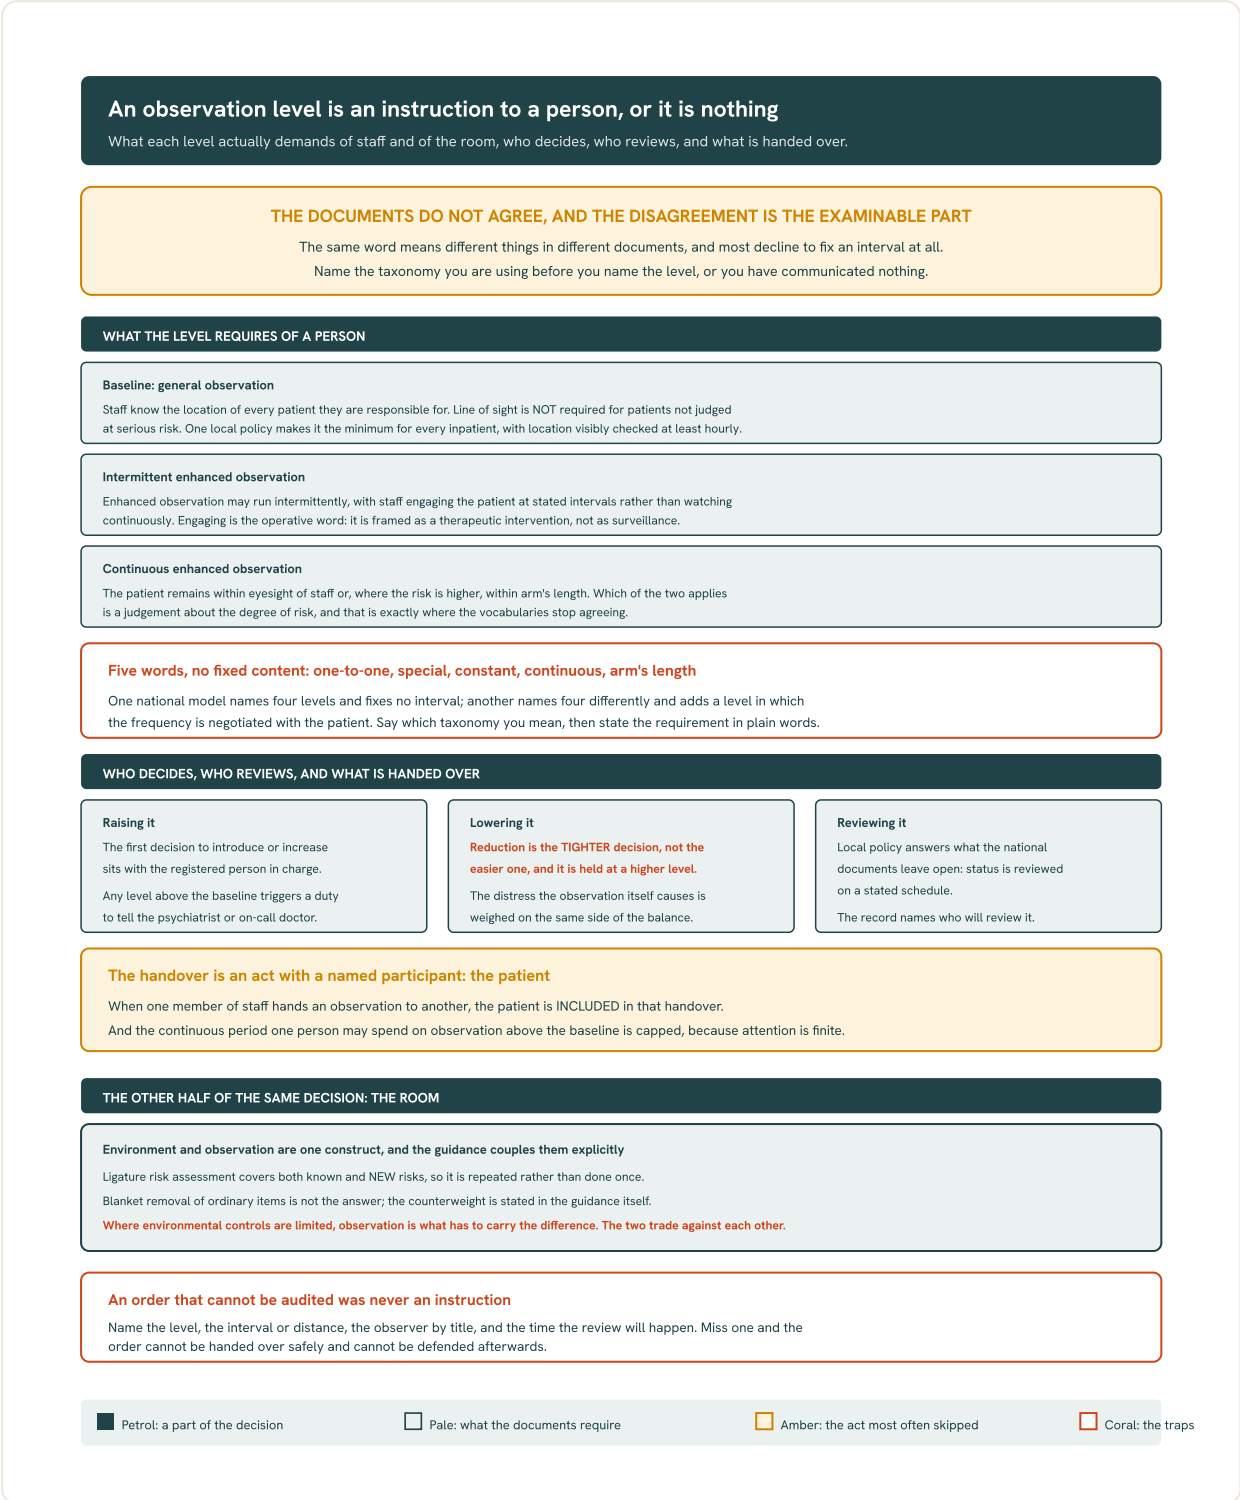

Fig 28.9. Observation as a decision rather than a label, with each level stated as what it requires of a person and of the room, the five interchangeable words that carry no fixed content across documents, the asymmetry by which raising a level is easier than lowering it, the review and the handover in which the patient is a named participant, and the environmental controls that observation has to compensate for when they are absent.

16.1 What an observation level is, and what it is for

Clinical observation is defined in the English self-harm guideline as a therapeutic intervention, used most commonly in hospital settings, that allows staff to monitor and assess the mental and physical health of people who might harm themselves or others, and to be seen as an opportunity for active engagement as well as sensitive supervision. Physical health sits inside that definition, which is where psychiatric observation and medical monitoring stop being separable: the observer is the person most likely to notice a falling conscious level, or developing aspiration in a sedated patient.

The statutory Code of Practice is more explicit about purpose. It calls **enhanced observation** a therapeutic intervention aimed at reducing the factors that contribute to increased risk and promoting recovery, describes its content in deliberately ordinary language as sitting with the person, talking, and supporting participation in activities, and names its indication as the short-term management of behavioural disturbance, or a period of distress, to prevent suicide or serious self-harm.

So a member of staff on a chair at the door, completing a form at intervals and not speaking to the patient, is not delivering the intervention these documents describe. An observation that generates no information is a rota cost with no clinical yield.

16.2 The baseline, and the named levels above it

Every taxonomy begins from a baseline, and the baseline is itself a decision. The Code sets it in one sentence: staff should know the location of all patients for whom they are responsible, and it is not necessary routinely to keep within sight those not considered to present a serious risk of harm to themselves or others. **General observation** is defined by knowledge of location, not by line of sight. One English trust operationalises it as the minimum level for every inpatient, with location and safety visibly checked **at least once an hour**, and rules out closed-circuit television as a substitute: a camera shows that a corridor is empty, not that a patient in a bay is breathing.

Above the baseline the English violence-and-aggression guideline names four levels. **Low-level intermittent observation** is its baseline for a specified psychiatric setting, once every **30 to 60 minutes**; **high-level intermittent observation**, for the patient at risk of becoming violent or aggressive but not presenting an immediate risk, runs once every **15 to 30 minutes**; above these sit continuous observation, built around a designated one-to-one nurse, and **multiprofessional continuous observation** for the highest risk. All four are defeasible: they apply unless a locally agreed policy states otherwise.

The statutory Code covers the same ground differently. Its intermittent enhanced observation is delivered at irregular and unpredictable intervals, and the irregularity is specification rather than accident, because a patient who can time the door knows how long they have. The Code adds that high use of intermittent observation has been shown to be associated with low levels of self-harm and to be tolerated by most patients. Its own **continuous observation**, and the trust's separately named **within arm's length observation**, sit alongside the national scheme rather than mapping onto it.

A second jurisdiction shows how much of this is convention. An Australian state guideline offers what it calls one possible model and fixes no interval anywhere in it: frequency and pattern follow the identified risk factors and the purpose of the observation. Its fourth level, **negotiated observation**, has nurses negotiate the frequency of engagement with people who have no identified risk factors requiring intermittent or constant observation, and is the only level in any of these documents whose frequency is set with the patient rather than for them.

DOCUMENT AND THE LEVEL AS IT NAMES IT	FREQUENCY OR PROXIMITY THAT DOCUMENT FIXES
Code of Practice: general observation	No interval; location known, those not a serious risk need not be in sight
English trust policy: general observation	Visible check of location and safety at least once an hour; cameras excluded
Violence-and-aggression guideline: low-level intermittent	Observation once every 30 to 60 minutes
Violence-and-aggression guideline: high-level intermittent	Observation once every 15 to 30 minutes
Code of Practice: intermittent enhanced observation	Intervals of between 15 and 30 minutes, deliberately irregular
Violence-and-aggression guideline: continuous	Within eyesight or arm's length of a designated one-to-one nurse
Code of Practice: continuous enhanced observation	Within eyesight, or arm's length for the most serious degrees of risk
Violence-and-aggression guideline: multiprofessional continuous	Within eyesight of 2 or 3 staff members and arm's length of at least 1
English trust policy: within arm's length	Close proximity, held during lavatory and bathroom use; care plan states staff numbers and distances
Australian state guideline: constant, arm's length and visual	Continuous one-to-one nursing observation by an experienced nurse
Australian state guideline: intermittent	No interval fixed; risk factors and purpose set frequency and pattern
Australian state guideline: negotiated	No interval fixed; frequency of engagement agreed with the patient

TRAP **Treating one-to-one, special, constant, continuous and arm's length as synonyms.** The confusion sits in the source documents, not in the reader. "Continuous" sometimes means eyesight and sometimes arm's length according to the degree of risk; "constant" is the Australian word for a similar idea and is itself split in two; "one-to-one" is a staffing ratio appearing inside several levels rather than a level of its own. Asked what one-to-one observation involves, say that the term has no fixed content, name the taxonomy you are using, then state the requirement. A level written in a vocabulary the receiving nurse does not use has communicated nothing.

Only four intervals are fixed anywhere in the English violence-and-aggression guideline; everything else is remitted to the provider's own policy. That division between what a national document fixes and what it delegates is the most useful single thing to carry into a question here.

30 to 60 min	15 to 30 min	2 hours	1 week
LOW-LEVEL INTERMITTENT OBSERVATION	HIGH-LEVEL INTERMITTENT OBSERVATION	LONGEST UNBROKEN SPELL ONE OBSERVER MAY HOLD	OBSERVATION THIS LONG TRIGGERS MULTIDISCIPLINARY REVIEW

16.3 Moving up: the trigger, the authority, and who must be told

The escalation rule in the Code is not a score: continuous observation should be carried out when intermittent observation is seen as insufficient to safely manage risks. That is a question about the sufficiency of the lower level rather than about how high the risk is, and it is the better question, because it forces the clinician to say what the lower level would fail to prevent and therefore what would have to change for the level to come down. No sourced document makes an instrument score the trigger, and no suicide-risk instrument's items, anchors or cut-offs appear here; the instruments belong to the Somatic-symptom, sexual, impulse-control disorders and suicide notes.

The first decision is a nursing one. The trust policy places the decision to introduce or increase observation, in the first instance, with the registered person in charge, where possible with medical staff and in response to an assessed risk, while holding that wherever possible it is made jointly by the multidisciplinary team and the patient. Medical involvement follows immediately rather than first: the violence-and-aggression guideline requires that the patient's psychiatrist or the on-call doctor be told as soon as possible whenever observation above the general level is carried out, and requires the record to carry the names and titles of the staff responsible for reviewing observation levels and when that review will happen. A reviewer who is a role rather than a person does not, in practice, review.

The level is never set on its own. The trust policy pairs it with an environmental decision, requiring consideration at the same time of searching the patient and their room or property and removing potentially harmful objects. How much of one is needed depends on how much of the other is already in place.

RULE **An observation level is a prescription, not a mood.** It has a named person who set it, a stated frequency or distance, a named reviewer recorded with their title, and a stated time at which the review will happen. A level entered without those four elements cannot be audited, cannot be handed over safely, and cannot be defended afterwards.

MNEMONIC

Level, interval, distance, observer, review

The five things an observation order must state before it is an instruction rather than an intention. **Level**: which named level, in the taxonomy this hospital's own policy uses. **Interval**: how often, if intermittent, and whether the spacing is deliberately irregular. **Distance**: eyesight or arm's length, and how many staff. **Observer**: who may hold it, and whether it may be delegated. **Review**: by whom, by name and title, and when.

16.4 Coming down, and the review that is supposed to bring it down

What the national guideline does not do is fix how often the routine review happens. Instead it requires every provider organisation to hold a policy on observation and positive engagement, and prescribes its contents:

- the definitions of the levels of observation the organisation will use;
- who can instigate, increase, decrease and review observation;
- when an observer should be male or female;
- how often reviews should take place;
- how patients' experience of being observed is taken into account;
- how observation is underpinned by continuous attempts to engage therapeutically;
- the levels of observation necessary during other restrictive interventions;
- the need for multidisciplinary review when observation continues for **1 week** or more.

The guideline fixes exactly one interval there and hands the routine interval to the local document. So the answer to "how often is an observation level reviewed" is not a number: the provider's own policy is required to state one. The trust policy supplies a worked example, requiring review a minimum of daily for any patient nursed above general observation level, with the care plan setting out in advance the conditions and observed behaviours that would allow a prompt reduction.

Reduction is deliberately the tighter decision. One registered person in charge may raise a level immediately; no one person may lower it. Because these patients are by definition those judged at highest risk, reduction follows a formal process producing a team decision founded on a current mental state and risk assessment and on the views of patient and carers, normally taken by registered nursing staff or a mental health practitioner with the team. One delegated route exists: where the responsible clinician and team have identified the circumstances in advance, 2 registered practitioners may implement the change in their absence.

Without a counterweight the level accumulates, rising on one clinician's judgement in seconds and falling only through a meeting. The Code supplies that counterweight as a duty: staff must weigh the distress that increased observation itself causes, particularly over many hours or days, against the identified risk of self-injury or behavioural disturbance, and must record every decision to increase or decrease.

GOOD TO REMEMBER

Write the exit criterion in the same entry that raises the level, in observable terms: what the patient would have to be doing, and over what period, before the level comes down. A team that has not pre-agreed this keeps patients at enhanced levels long after the clinical reason has gone, because at every review the safest decision for the individual reviewer is to change nothing.

16.5 The observer, the staffing cap and the handover

An enhanced level is a staffing decision before it is a clinical one, and the guideline concedes the point with a number. An individual staff member should not undertake a continuous period of observation above the general level for longer than **2 hours**, and where it is needed for longer, that staff member must be given regular breaks. The rationale is attentional rather than industrial: sustained vigilance directed at one person degrades with time on task. So every hour of enhanced observation must be filled by a named person on a rota, and the cap manufactures handovers inside every shift, which the documents specify:

- when one staff member hands an observation to another during a period of observation, the patient is included in the discussion where possible, so the handover is an event the patient is party to rather than a staff transaction about them;
- the staff member ending a period of additional observation gives a verbal handover, mindful of confidentiality, to the staff member taking over, involving the patient and their family or carer wherever possible;
- at the change of shift, the persons in charge of the outgoing and incoming shift are together responsible for reviewing and signing the observation record, confirming the documentation, and physically seeing the patients.

"Physically see the patients" is the load-bearing phrase. The characteristic serious incident involving an observed patient is not a level set too low; it is a level set correctly, recorded as delivered, and not delivered. A signature shows that a form was completed, and laying eyes on every patient is the only step here that checks the record against the world.

IN INDIA

None of the taxonomies above is Indian, and no Indian national standard for observation levels, intervals or observer-to-patient staffing is quoted here because none was available to quote. The operative document on any Indian unit is that hospital's own policy. The service reality bites hardest at the staffing cap: continuous observation, rotated as the guidance requires, consumes observer-blocks that a district unit with a thin night establishment cannot produce, and the gap is filled by a family attendant sitting with the patient. That is an understandable adaptation and it is not the intervention the guidance describes, because a relative has not been selected by profession and grade, cannot document, cannot be rotated off, and may be the person the patient least wants at the bedside. Where it is unavoidable, record the arrangement, state narrowly what it is relied on to prevent, and compensate through the environmental measures, which cost fixtures rather than nurses.

16.6 Privacy, dignity and the person being observed

The level that best protects life is the level that most intrudes on the body, and the documents handle this by requiring the intrusion to be planned rather than improvised. The Code makes the provider's policy on enhanced observation settle four things in advance: which profession and grade should hold the observation and when the duty may be delegated; how the observer is matched to the patient, with ethnicity, sexual identity, age and gender named; how the intervention is delivered so that it is least likely to be perceived as coercive; and how privacy is protected in states of undress, which the Code specifies as using the toilet, bathing, showering and dressing. The trust policy carries the same into the care plan for its closest level, requiring privacy, dignity and the gender of allocated staff to be written in, while stating plainly that observation is maintained when the patient uses lavatory or bathroom facilities.

The error this prevents is predictable. Faced with an undignified moment and no written plan, a nurse improvises, and the improvisation is almost always to relax the level informally for its duration: to step outside the bathroom door, or to turn away. That is the most predictable point of failure at an arm's length level, it is unrecorded by definition, and the next shift inherits a level that has quietly stopped meaning what it says.

16.7 Observation outside the psychiatric ward

Most patients who have just harmed themselves are not on a psychiatric ward. They are in an emergency department or on a medical ward, where the decision must be made by two teams sharing neither a policy nor a vocabulary nor a line of accountability. The English self-harm guideline makes close observation there a joint decision of mental health and acute ward staff, taken case by case with the person's views taken into account, and attaches three conditions: appropriately skilled and trained healthcare staff, the informed consent of the person or an appropriate legal framework, and regular review. Each fails in a recognisable way. Skilled and trained staff means a security guard posted at a bedside is not an observer, whatever the nursing note records. Regular review means an observation ordered on the night of admission does not silently persist through a long medical stay. And the consent clause is the medico-legal hinge of the subject.

The refusing patient. Observation, and continued presence in hospital, are either consented interventions or legally authorised ones, and no third category exists. Where the patient does not consent and the judgement is that they must be observed, or must remain, the decision moves from a clinical footing to a legal one, and that transition is made deliberately and documented before the observation starts rather than reconstructed afterwards. Which route exists, on what grounds, for how long and on whose signature is a matter for the governing mental health legislation and is set out in the Mental health legislation and forensic psychiatry notes; capacity and the standard of consent belong to the Forensic ethics, consent and legal procedure notes. No statutory ground, procedure, time limit or authorised signatory is asserted here, because none is sourced in this section, and a half-remembered provision is more dangerous than an honest referral to the statute.

The emergency department carries one obligation that is purely architectural: the waiting area for people who have self-harmed must be close to staff who can provide care, support and observation. This is the one place where the requirement is expressed as a floor plan rather than as a level, and a patient waiting where staff cannot see them is unobserved whatever the notes say.

16.8 The ward and the department as physical objects

Environmental safety inside the hospital is a distinct construct from counselling a patient and family about access to lethal means at home, and the difference is one of responsibility: this one belongs to the hospital. The English regulator's ligature guidance requires risk assessments to cover both known and new forms of **ligature anchor point**, treats environmental assessment as an active search for new points and for those manipulated or worn, and reverses earlier practice in terms: in all cases, and contrary to previous guidance, low-lying ligature points should not be judged as low risk and should be removed where possible.

On the fabric of the ward the same guidance names collapsible furniture, reduced ligature fixtures and fittings, and removal of fixed ligature points where possible. Two are not discretionary. Providers must use collapsible shower and curtain rails, and an incident involving a rail that does not conform is reportable as a **Never Event**, the strongest statement of obligation in this material. Services must also regularly assess ward areas to identify and remove ligatures and anchor points where possible.

The counterweight is stated with equal force and candidates consistently omit it. Clothing and other items commonly available on wards and in the home are the main materials used as ligatures, but most items are not dangerous in everyday use, so services should avoid a blanket approach to restricting them. What is removed from a particular patient follows individual risk assessment, regularly reviewed, and denying access to clothing is a last resort. A ward that strips every patient of every cord has converted a targeted intervention into a collective punishment.

The regulator then makes the relationship between environment and level explicit, and this is the reasoning that ties the section together. Where environmental controls are limited, or impinge on the patient's care, privacy and dignity, both individualised and system controls must reduce ligature risk, and the controls it names are an observation level set from individualised risk assessment together with the processes that support it: multidisciplinary working, and the sharing of risk information at handovers and huddles. That is a substitution rule and it runs both ways. An old ward with anchor points that cannot be removed needs a higher observation level than a new one for the same patient; conversely, capital spending on fixtures permanently reduces the nursing hours the ward must otherwise buy.

One part of the physical environment is deliberately left open here. The room a patient is actually assessed in, the cubicle or interview room where a first conversation happens before any ward is involved, has its own requirements: whether it can be spoken in without being overheard, what it contains, and whether it can be left safely by either person. No comparable standard is available

to quote for it, and none is invented here. Treat that as a gap to be closed by local policy rather than as a question this account has answered.

16.9 The admission decision at the door

Two questions get collapsed into one at the emergency department door. The first is whether this person needs to be in a hospital at all; the second is which hospital, and the answer is not always the psychiatric one.

The Indian Psychiatric Society's guideline on suicidal behaviour answers the first with two separate lists, and the separation is the teaching point. The standing-risk list sets out situations in which hospitalisation should be strongly considered, and it reads as four clusters: the act and its planning, being a prior attempt of high lethality, a well-thought-out plan and access to lethal means; the current state, being hopelessness and being uncommunicative; the social surround, being a recent major loss and social isolation; and what is untreated or destabilising, being a history of impulsive, high-risk behaviour, active substance abuse or dependence, and untreated mood, psychotic or personality disorder. Read as clusters, the list becomes a set of questions that can be asked in order.

The second list applies after a suicide attempt or an aborted attempt, and is more specific because there is now an act to interrogate. Hospitalisation is indicated where the patient is psychotic; where the attempt was violent, near-lethal or premeditated; where precautions were taken to avoid rescue or discovery; where a persistent plan or intent is present; where distress is increased or the patient regrets surviving; where the patient is male and older than age 45 years, especially with new onset of psychiatric illness or suicidal thinking; where family or social support is limited; where current impulsive behaviour, severe agitation, poor judgment or refusal of help is evident; or where there is a change in mental status with a metabolic, toxic, infectious or other aetiology requiring further workup in a structured setting.

That last item is where the psychiatric admission decision and the medical decision stop being two decisions, because a patient whose mental state has altered for a reason not yet established is admitted in order to establish it, and the correct destination may then not be a psychiatric bed. Which brings in the second question. The English self-harm guideline gives three indications for considering admission to a general hospital after an episode of self-harm: concerns about the person's safety, for example risk of violence, abuse or exploitation, where psychiatric admission is not indicated; safeguarding planning still to be completed, again where psychiatric admission is not indicated; and the person being unable to engage in a psychosocial assessment, for example because they are too distressed or intoxicated. Two of the three are framed explicitly against psychiatric admission not being indicated, which makes this a separate decision rather than a weaker version of the same one.

16.10 Discharge, and the patient who will not stay

Discharge after self-harm is governed by preconditions rather than an overall impression, and they are conjunctive: all must hold, not most. Before a person who has self-harmed leaves a general hospital, the English guideline requires that each of the following is in place:

- a psychosocial assessment has taken place;
- a plan for further management has been drawn up with all appropriate agencies and people;
- a discharge planning meeting with all appropriate agencies and people has taken place; and
- arrangements for aftercare have been specified, including clear written communication with the primary care team.

The last is the one that quietly fails. Where the receiving service is a private practitioner, a distant district hospital, or nobody at all, that written communication is the entire handover, and the working rule is to treat the discharge as incomplete until it has left the building.

The harder case is the patient who waits for none of this. The guideline treats discharge against advice as a service-design requirement rather than a judgement improvised at the door, requiring standing policies for the person who wishes to leave, and for the person who has already left, before physical and mental health assessment and care is complete. Both limbs matter and they are different problems. The person still in the department needs a procedure executable in minutes by whoever is standing there; the person already gone needs one naming who is contacted, by whom and within what period, and that second procedure is the one almost no department writes until after it has needed it.

One response is closed off explicitly. Mechanical restraint must not be used in emergency departments to prevent self-harm or to prevent a person from leaving the emergency department. Removing the reflex answer is the point of the prohibition: it forces the question back onto the only two legitimate footings, consent and the applicable legal framework, and obliges the department to decide which it is relying on before the patient is at the door. The statutory framework for detention, and for restraint itself, belongs to the Mental health legislation and forensic psychiatry notes and is named here rather than restated.

> An observation level is a prescription: a named person who set it, a stated frequency or distance, a named reviewer with their title, a stated review time, and a written condition that would bring it down.

17 · Management of acute psychotic and manic emergencies

Why the marks are here. The examinable question about psychotic emergencies and manic emergencies is almost never what the syndrome is. It is what is done with the man brought to casualty at two in the morning by his relatives, who has not slept for several nights, talks over everyone in the room, and has given away money the family does not have. The syndrome, its neurobiology and the agents that treat it belong to the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes and to the Mood disorders: pharmacotherapy notes. What is taught here is the decision sequence at the door: what is referred and how quickly, what is excluded before the psychiatric label settles, who may consent to what, which harms are already being done while the assessment proceeds, what is started before the diagnosis is settled, and where the patient goes next.

Two features separate this from every other behavioural emergency. The decision must usually be taken before the diagnosis is available, because a first episode arrives without a history and organic and substance-induced states sit in the same differential. And the harm is not principally violence: much of it is financial, sexual and relational, it is done by a patient who may be cheerful and cooperative, and it accrues by the hour. An answer built around sedation and restraint has addressed the smaller half of the problem, with material owned by other sections of this chapter.

17.1 The decision is triggered by suspicion, not by a settled diagnosis

The referral rule is unusually clean and unusually easy to misquote. The National Institute for Health and Care Excellence guideline on bipolar disorder, **CG185**, written for England and Wales, published in 2014 and last updated in **2025**, recommends referring people urgently for a **specialist mental health assessment** if mania or severe depression is **suspected**, or if they are a danger to themselves or others.

Read the limbs as separate doors into one pathway, because the source joins them disjunctively and either alone suffices. A dangerous patient is referred urgently even where mania is not suspected; a patient in whom mania is suspected is referred urgently even where nothing dangerous has happened. Candidates who remember only the danger limb convert an urgent referral rule into a violence rule, and then have no answer for the patient who is manifestly unwell and manifestly not aggressive.

The word carrying the weight is suspicion. Not confirmation, not a provisional diagnosis, not a specialist opinion. That choice is the point this section is built on, because the information that would settle the diagnosis is unavailable when the decision must be made: a first episode has no prior history to appeal to, the person who could describe the past fortnight is outside the room, and the organic alternatives are excluded by work that takes time the decision does not have. If the trigger were confirmation, every referral would be made after the harm rather than before it.

RULE **The threshold for acting is suspicion of the state or the presence of danger, never a confirmed diagnosis.** This inverts the order candidates are trained into everywhere else in medicine, and it is defensible because what is triggered is itself an assessment rather than a treatment. Nothing irreversible follows from referring urgently and finding no mania. A great deal follows from waiting for certainty in a condition whose defining features include impaired judgement about money, sex and personal safety, all of which keep operating during the wait.

17.2 What is excluded before the psychiatric label is allowed to settle

Before excitement, overactivity or florid psychotic phenomena are accepted as psychiatric, a physical exclusion runs. The most useful statement of it for this setting comes from the World Health Organization mhGAP Intervention Guide for mental, neurological and substance use disorders in non-specialized health settings, Version 2.0, issued in **2016**. Before settling a psychosis or mania label, the clinician evaluates by history, clinical examination or laboratory findings for signs and symptoms suggesting **delirium** due to an acute physical condition. The guide names what to look for:

- infection, and **cerebral malaria** specifically;

- dehydration;
- metabolic abnormalities, hypoglycaemia and hyponatraemia being the examples given;
- medication side effects, with some antimalarial medication and steroids named.

The choice of source matters. This is a guide written explicitly for non-specialised settings, and its list is populated by what actually presents in them: a high-income emergency guideline would not have named cerebral malaria or antimalarial medication at all, and an answer written for Indian practice needs the version that does. The delirium syndrome itself, its criteria, subtypes and assessment belong to the Stroke, TBI, delirium and focal brain syndromes notes and are named here rather than taught; the front-door triage of the undifferentiated confused patient is dealt with elsewhere in this chapter.

Three observations make the list usable rather than decorative. Steroids and antimalarials are prescribed medicines, so the exposure is documented somewhere and discoverable by asking one question of the person who brought the patient, before that person leaves. Hyponatraemia produces nothing visible at the bedside, so it is excluded by a sample or not at all. And dehydration sits here as a cause of delirium while also being a consequence of sustained mania: a patient who has not drunk anything for three nights can arrive with a confusional state layered on the excitement that produced it, and the two are then read as one.

None of this defers the act. The exclusion runs alongside the containment and the collateral history, and the sequence that opens every behavioural emergency is set out elsewhere in this chapter. What it buys is permission to let the label settle; until then the working formulation is an undifferentiated disturbance in a patient who may turn out to be manic.

17.3 Capacity in mania: the fluent examination that hides the failure

Capacity here separates good answers from adequate ones, because the examination that ought to detect the problem is the one that conceals it. A capacity assessment asks whether the patient can take in the information relevant to the decision, hold on to it, weigh it in arriving at a choice, and communicate that choice. The manic patient performs most of those beautifully: orientation is intact, speech is fluent, and information given a minute ago comes back verbatim. The failure is confined to the weighing, where elevated mood has altered not the reception of the facts but their appraisal, so the risk is understood, retained, restated accurately and then judged not to apply. An assessor who stops when the patient answers well has tested everything except the limb that fails.

The sourced counterpart is easy to skate past. Alongside its environmental advice, the bipolar guideline recommends advising people with mania or hypomania not to make **important decisions** until they have recovered. That is a substantial statement dressed as housekeeping. It concedes that decisional impairment is a feature of the whole episode rather than of its worst hour, and that it extends to the ordinary consequential decisions of a life: selling land, resigning a post, marrying, investing, standing surety. Those are decisions no consent form covers and no ward round asks about, and they do the lasting damage.

The same recommendation adds a third limb, that the person be encouraged to maintain their relationships with their carers where possible. It belongs in the same sentence because the people who will actually hold those decisions during the episode are the carers, and mania ruptures exactly those relationships at the moment their protection is most needed. Preserving the relationship is the mechanism by which the advice is enforced.

Two boundaries close this off. The authority question for the specific act of giving a drug to a patient who has not agreed to it is dealt with elsewhere in this chapter. The statutory basis on which a patient may be admitted or treated without consent in India, and the consent doctrine behind it, belong to the Mental health legislation and forensic psychiatry notes and the Forensic ethics, consent and legal procedure notes; no statutory provision is asserted here.

17.4 The risks specific to mania, and the act of assessing them

The risk assessment here has a stated form before it has content, and the form is itself an act. The bipolar guideline recommends carrying it out in conjunction with the person, and with their carer if possible, focusing on the areas likely to present possible danger or harm. Two things follow. It is done with the patient rather than about them, which in an irritable patient is also efficient de-escalation. And the carer is written into the method rather than consulted afterwards, because most of the domains below are invisible to anyone who has not seen the household.

DOMAIN NAMED IN THE GUIDELINE	WHAT IT LOOKS LIKE IN THE FIRST HOUR	WHAT ANSWERS IT NOW
Self-neglect	No sleep for several nights, no meals, no fluids, medicines for physical illness abandoned	Physical observations, hydration, and an explicit question about chronic medicines the family assumes are still being taken
Self-harm, and suicidal thoughts and intent	Irritable dysphoria inside an elevated state, the patient whose mood has begun to fall	Asked directly at this contact; the assessment framework belongs to the Somatic-symptom, sexual, impulse-control disorders and suicide notes
Risks to others, including family members	Irritability on being contradicted, an argument at home that preceded the attendance, children in the house	Who is at home tonight, who has already been hurt, and whether anybody is frightened to take the patient back
Driving	A patient who drove himself in and intends to drive home, at speed, on no sleep	Advice to patient and carer, keys accounted for, and the advice recorded rather than merely delivered
Spending money excessively	Purchases and gifts already made, loans taken, a business commitment entered into this week	What the patient can spend or transfer tonight: cash, cards, the banking application on the phone
Financial or sexual exploitation	New acquaintances of a few days' standing, generosity noticed outside the family	Who has access to the patient and to the patient's money, and who has recently acquired both
Disruption in family and love relationships	An engagement announced or ended this week, a resignation, an accusation made to relatives	Naming it as a feature of the episode in front of the carer, so it is not later read as settled intention
Disinhibited and sexualised behaviour, and risks of sexually transmitted diseases	Behaviour in the department itself, and contacts in the days before attendance	Sexual health follow-up arranged into the disposition, not deferred to a recovery nobody schedules

Two further risks belong to any honest account of the manic emergency and are not among the domains the guideline names: physical exhaustion from sustained sleeplessness and overactivity, and dehydration in a patient too preoccupied to drink. Both are stated as clinical observations with no figure attached, because none is available to quote. They matter because they are the limbs by which a behavioural emergency becomes a medical one.

17.5 Harm realised by the hour, and what can be done about it tonight

Why this is not the aggressive patient's emergency. In most behavioural emergencies the risk under discussion is a future event whose probability the clinician is estimating. In mania a substantial part of it is not prospective at all. Money is being moved now, contracts entered into now, contacts made now, and each hour of delay is an hour in which more of it happens rather than an hour of exposure to a possibility. That changes what the risk assessment is for: not only a prediction feeding a disposition, but a list of things to interrupt before the patient leaves the room. The interruptions available are modest, mostly non-clinical and almost never written down, and they are worth rehearsing because examiners ask what you would actually do and candidates answer with a drug.

- Establish what the patient can spend or transfer before morning, which means the phone as much as the wallet, and agree with patient and carer together who holds what tonight.
- Account for vehicle keys, and give driving advice to both rather than assuming the topic is covered by the admission.
- Identify who has newly acquired access to the patient or the patient's money, which is the practical form of the exploitation question.
- Name to the carer, in the patient's presence, which recent decisions are being treated as features of the episode, so a resignation is not later defended as a settled choice.
- Ask who is at home tonight and whether anybody there is frightened, because the answer changes the disposition more often than any symptom does.

Nothing here authorises confiscating property, and the boundary between what a clinician may do and what only a family or a court may do is not identical across jurisdictions. What is described is advice, negotiation and documentation, and the recorded fact that it was attempted is often the most useful thing in the notes a month later.

TRAP **Reading the absence of aggression as the absence of an emergency.** The manic patient who is euphoric, charming and grateful for the attention presents as the least urgent person in the department, and is given an outpatient appointment and sent home. The error is a category mistake: urgency has been tested against the danger limb of the referral rule while the state limb, which fires on suspicion alone, has been ignored. Candidates make it because emergency teaching is dominated by containment, so an emergency comes to mean a person who must be restrained. The correction is to ask what will have happened by the time that appointment arrives: what will have been spent, signed, promised, driven or contracted in the interval.

17.6 What is started before the diagnosis is settled

Something is done for this patient before anyone knows the diagnosis, and what the guideline asks for is not a drug. It recommends ensuring that people with mania or hypomania have access to **calming environments** and **reduced stimulation**. That is an environmental prescription, available immediately, requiring no consent and not waiting on the label. In an answer it is the cheapest mark on the page and the one most often left uncollected.

It is also mechanistically coherent rather than merely kind. The manic patient's difficulty is a failure to filter and prioritise incoming stimuli, so a crowded casualty with overhead lights, a television and six relatives all speaking is not a neutral background against which the illness is observed. It is an active driver of the presentation being assessed, and reducing it lowers the arousal generating the behaviour.

The physical acts running in parallel are unglamorous and belong here rather than in any pharmacology section: fluids offered and accepted, food offered, a place to lie down, and sleep protected rather than interrupted by the department's own routines. No target figure is attached to any of these, and none should be invented.

Deliberately absent is any drug. The staged escalation ladder, the agents and every first-dose figure belong to the Schizophrenia: management, antipsychotics and adverse effects notes; the choice of antimanic agent and everything about maintenance belongs to the Mood disorders: pharmacotherapy notes; and the rapid tranquillisation protocol considered as a protocol sits elsewhere in this chapter. The ordering taught here, environment before pharmacology, is lost the moment a drug appears in the same paragraph.

MNEMONIC

Suspect, Sweep, Settle, Secure, Site

Suspect: the referral is triggered by suspicion of the state or by danger, not by a diagnosis. **Sweep**: the evaluation for delirium from an acute physical condition runs before the label is allowed to settle. **Settle**: a calming environment with reduced stimulation is what is asked for first, before any drug decision. **Secure**: the risks being realised tonight, meaning money, driving, exploitation, sexual disinhibition and the safety of the household, are addressed as acts and not only as predictions. **Site**: where the patient is nursed tonight and where care sits once the episode has settled are two different decisions.

17.7 Where the manic emergency is routed, and what the routing tells you

There is no bipolar-specific emergency algorithm, and the bipolar guideline says so in the plainest possible way. Where people with bipolar disorder pose an **immediate risk to themselves or others** during an acute episode, it directs the reader out of itself: to the guideline on violence and aggression for advice on managing agitation, challenging behaviour and imminent violence and on rapid tranquillisation, or to the guideline on self-harm for advice on managing acts of self-harm and suicide risk.

That is worth more than its content: a major guideline devoted to a mood disorder, at the point where the disorder becomes an emergency, hands the reader to guidance organised around the behaviour rather than the diagnosis. The implication is direct. The label changes the risk profile and the disposition, but not the act performed in the first hour. The same de-escalation, the same parallel physical assessment, the same authority question and the same monitoring apply whether the excitement is manic, schizophrenic, substance-induced or organic.

WHAT IS IN FRONT OF YOU	WHERE THE BIPOLAR GUIDELINE SENDS IT	WHAT THAT MEANS FOR THE ACT
Suspected mania or severe depression, no immediate danger	Urgent referral for specialist mental health assessment	The referral is the act, and is not deferred pending diagnostic certainty
Immediate risk to self or others, with agitation or imminent violence	The guideline on violence and aggression, including its advice on rapid tranquillisation	Generic behavioural-emergency management, taught elsewhere in this chapter and in the Schizophrenia: management, antipsychotics and adverse effects notes; none of it is mania-specific
Acts of self-harm, or suicide risk within the episode	The guideline on self-harm	Risk assessment and the observation decision, both dealt with elsewhere in this chapter
Excitement or psychosis with a pointer to an acute physical cause	Evaluation for delirium due to an acute physical condition, before the label	The label is withheld, not the treatment; the syndrome belongs to the Stroke, TBI, delirium and focal brain syndromes notes
The episode settling, and where care continues	A supportive environment with family or community members outside the hospital setting	A principle for longer-term care, not an argument about tonight's bed

17.8 The admission decision, and the counterweight that is routinely misquoted

Admission here is not decided by the severity of the mental state, which is the reasoning candidates reach for and which produces both unnecessary admissions and dangerous discharges. It is decided by whether the risks identified above can be held where the patient would otherwise be. Framed that way the question becomes answerable at the door. Can somebody at home stay awake with a patient who will not sleep. Can the money, the phone and the vehicle be secured without a confrontation the household cannot survive. Is anybody in that house afraid. Is the physical exclusion complete, or does it need a setting where blood can be sent and repeated.

What admission buys is the substance of the answer. A place where sleep can be re-established and protected, which is the single change most likely to alter the trajectory. Separation from the instruments of financial and sexual risk for as long as the disinhibition lasts. The physical care a patient in sustained overactivity will not organise for himself. Observation at a level somebody has actually decided upon, that decision being taught elsewhere in this chapter. And completion of the medical exclusion a busy casualty rarely finishes. Where the presentation is life-threatening, manic exhaustion with refusal of fluids being the classic example, electroconvulsive therapy is among the interventions considered; its indications and technique belong to the ECT and neurostimulation notes and are named here and not taught.

Against that sits a principle quoted constantly and almost always out of position. The mhGAP guide states that in general it is better for the person to live with family or community members in a supportive environment outside of the hospital setting, and that **long-term hospitalisation**

should be avoided. It sits in general advice for people living with psychosis and those who care for them, and it speaks to where life is lived over months and years. It is not a statement about tonight and it does not discourage emergency admission. Quoted at the door it becomes an argument for sending home a patient whose risks nobody can hold. Quoted in its proper place it makes admission a bounded intervention with an exit, and puts the burden of justification on continued hospitalisation rather than on discharge.

IN INDIA

Every element of this pathway assumes a service that may not exist where the patient presents. Urgent referral for specialist assessment presupposes a specialist within reach of a district hospital at two in the morning; in much of the country it names a destination that is a bus journey away and open in the morning. Reduced stimulation presupposes a room, and a general casualty with one corridor and a queue offers none; the honest substitute is the quietest available corner with one relative rather than six. Observation presupposes staff, and where it cannot be staffed the family becomes the observation level by default, which should be acknowledged and instructed rather than left to happen silently. The financial acts above are entirely family-operated, because no service mechanism secures a patient's account. And the counterweight against prolonged hospitalisation reads differently where a private nursing home bed is the only one and its cost decides the length of stay. None of this changes the standard. It changes what has to be written down when the standard cannot be met.

17.9 What must be true before the decision is handed on

The handover is best stated as conditions rather than narrative. Before the acutely manic or floridly psychotic patient leaves the assessment area, whether to a ward, another hospital or home, the following should be true and recorded.

- The referral decision has been made against the stated trigger, and where urgent referral was not made in a patient in whom mania was suspected, the reason is written.
- The evaluation for an acute physical cause has been started and one named person owns finishing it, with existing medicines, steroids in particular, asked about while the family is present.
- A capacity assessment relevant to the decision being taken has been attempted and recorded, including what the patient could and could not do with the information.
- Each risk domain has been asked about with the patient and, where possible, the carer, and those being acted on tonight are distinguished from those being watched.
- The advice against important decisions has been given to patient and carer and written down.
- The disposition has been decided by a named person, with the level of care and the observation decision made rather than defaulted to.

GOOD TO REMEMBER

Two objects decide more of the outcome of a manic emergency than anything you will write in the mental state examination: the phone and the vehicle keys. The phone carries the banking application, the contacts, the messages sent at four in the morning and the purchases that clear before anyone wakes. The keys carry the collision. Both are missed because they feel administrative rather than clinical. Build them into the same breath as the advice against important decisions: ask who has the keys, ask what the patient can spend tonight, agree an answer in front of both parties, and record that you did.

In a manic emergency the trigger for urgent specialist assessment is suspicion and not diagnosis, the physical exclusion precedes the label, and the risks that decide disposition are financial, sexual and relational at least as often as they are violent.

18 · Deliberate self-harm and overdose triage

Why the marks are here. A patient who has taken an overdose arrives as a medical problem and is remembered as a psychiatric one, and the interval between those two descriptions is where the avoidable deaths sit. The question here is not whether you can estimate intent: that framework, and the intent-scale domains that go with it, belong to the Somatic-symptom, sexual, impulse-control disorders and suicide notes. What is asked here is narrower and harder to improvise. What is done in the first hour, what has to be true before the patient becomes yours, who is entitled to say that it is true, and where the patient goes next.

Three things make the medical triage of an overdose a psychiatric responsibility rather than a borrowed one. The psychiatrist is often the only clinician who knows what the patient was prescribed, and so what is plausibly inside them. The psychiatrist is who the emergency department is waiting to hand over to, so the handover criteria get set by whoever will state them. And the psychiatrist is the one asked afterwards why an assessment was recorded at an hour when the patient could not have participated.

18.1 Ordering the two assessments, and what medical priority does not buy

The version most of us were taught is a sequence: stabilise, clear, then assess. Two recent national guidelines do not.

The self-harm guideline of the National Institute for Health and Care Excellence, published in 2022, refuses the sequential model: physical healthcare and the psychosocial assessment are carried out concurrently. It then closes the two devices used to postpone the second, and closes them as prohibitions rather than preferences. The psychosocial assessment is not to be delayed until after medical treatment is completed, and breath or blood alcohol levels are not to be used to delay it. Where the person cannot participate, what follows is regular review and completion as soon as possible, not an open wait. Alcohol withdrawal scoring is the Substance use disorders notes'.

The Indian Psychiatric Society guideline on suicidal behaviour, issued in 2022, describes the same moment from inside an Indian casualty and reaches a priority rule instead. It tells the clinician to wait until conditions become conducive to assessment, and states that where the patient becomes drowsy from intoxication, medical management and stabilisation becomes a priority.

These are not contradictory once you see what each protects. A priority rule allocates the resource in the room at a given minute, and a falling conscious level takes it. A concurrency rule stops the assessment being deferred by a treatment with no natural end point.

RULE **Medical priority is a claim on resources, not a licence to postpone.** Stabilisation outranks assessment for the minutes in which it is actually happening and buys nothing beyond them. It is not permission to leave the psychiatric assessment until medical treatment is finished, nor to wait for a number before speaking to the patient. Where the patient truly cannot participate, what replaces the assessment is a stated review interval, not silence.

DOCUMENT, JURISDICTION AND YEAR	WHAT IT FIXES ABOUT THE ORDERING	WHAT IT FORBIDS OR SUBORDINATES
Self-harm guideline of the National Institute for Health and Care Excellence, England, 2022	Physical healthcare and the psychosocial assessment run concurrently, both as soon as possible after the self-harm episode	Delaying the psychosocial assessment until medical treatment is complete, and using a breath or blood alcohol level as the gate on it
Indian Psychiatric Society guideline on suicidal behaviour, India, 2022	The clinician waits until conditions in the emergency department become conducive to assessment	Assessment is subordinated where the patient becomes drowsy from intoxication and stabilisation becomes the priority
Task force of the American Association for Emergency Psychiatry, United States, 2017	Every patient is medically evaluated before transfer to a psychiatric setting, with the judgement recorded in writing	An unresolved question of delirium against psychiatric disorder resolves to medical observation or hospitalisation, never to psychiatric transfer

18.2 Refusing the phrase that used to end the argument, and stating what replaces it

Ask an emergency physician for **medical clearance** and you are asking for something the specialty has formally stopped offering. The American Association for Emergency Psychiatry task force on the medical clearance of adult psychiatric patients rejected the phrase on two grounds: it minimises the presence of chronic medical problems, and it is out of line with the terminology the rest of the emergency department now uses. Nobody is cleared of diabetes at transfer; they are transferred with it.

What replaces it is not a phrase but an assertion with two limbs. The note travelling with the patient states that the patient is **medically stable and appropriate for treatment in a psychiatric setting**: first that the behavioural disturbance is unlikely to be due to a medical condition or physical trauma, and second that medical or surgical treatment for any concomitant conditions falls within the capabilities of the receiving facility. Read the second limb again. It is a

statement about your service. The same patient is appropriate for a general hospital unit with a physician on site and inappropriate for a stand-alone facility an hour away, with nothing about the patient changed in between, and saying so is the mark.

The task force also states what the medical assessment hunts for, and it is two things. The first is **medical mimics**, the potential causative factors for the presenting complaint, with encephalopathy, substance intoxication or withdrawal, infections and central nervous system disease as the examples. The second, dropped under pressure, is medical problems needing ongoing care that contribute nothing to the psychiatric picture. Where the two cannot be separated, the recommendation supplies a decision rule: if there is a question whether the patient has delirium or a psychiatric disorder, that patient is medically observed or hospitalised. The delirium entity itself is the Stroke, TBI, delirium and focal brain syndromes notes' and is named here rather than restated. What belongs here is the direction the doubt resolves in: towards the medical bed, never the psychiatric one.

18.3 Screening every patient, and deciding who needs more than the screen

The same task force sets a deliberately unglamorous floor for universal screening: vital signs, history, physical examination and an assessment of mentation. It then does something more useful than listing them. It prefers a brief cognitive examination to a simple assessment of mentation, because the latter records nothing but alertness and orientation, and says it should ideally cover attention, executive function, orientation and recent memory. The gap between the two is the whole argument: a patient who is alert and oriented but cannot sustain attention or sequence a task has an abnormal **brief cognitive examination** and a normal assessment of mentation, and is precisely the patient the transfer note should not be written about.

Above the floor, the task force lists eight triggers for extending the medical evaluation:

- new-onset psychiatric symptoms after the age of **45 years**;
- advanced age, which the task force gives as 65 years of age and older;
- cognitive deficits or delirium;
- a positive review of systems indicating a physical aetiology, such as cough and fever;
- focal neurological findings, or evidence of head injury;
- substance intoxication, withdrawal, or exposure to toxins or drugs;
- a decreased level of awareness;
- other indications, such as abnormal vital signs that direct further assessment.

Notice how many of these an overdose carries automatically. Substance exposure is the presentation itself, a decreased level of awareness and abnormal vital signs are common, and in an older patient with no psychiatric history three of the eight are live before anyone has taken a history. Self-poisoning is therefore close to a standing indication for evaluation beyond the universal minimum.

The task force also reports an operationalised version of medical fitness that was actually tested. A retrospective review of 485 charts of psychiatric patients evaluated by attending emergency physicians used a five-item screen: stable vital signs, a prior psychiatric history, alert and oriented times four, no evidence of an acute medical problem, and no visual hallucinations. Patients answering yes to all five went to a psychiatric receiving facility without further testing, and only six, 1.2 per cent, came back for further workup, none needing medical or surgical admission. That is a screening algorithm reported inside a consensus statement rather than a validated instrument, reported here at second hand, and its last two items are judgements rather than observations. Its value is the shape of the argument: a short structured screen applied to everyone beats an unstructured impression applied to some.

18.4 Working out what was taken when nobody can tell you

Everything downstream, the decontamination decision, the observation period and the disposition, is a function of the substance and the amount. Yet identification is the part of overdose triage treated as clerical, and the part a psychiatrist is best placed to solve.

The Indian Psychiatric Society guideline on substance intoxication in the emergency setting specifies the task rather than leaving it to instinct. Details of the consumed substances are elicited from the patient if responsive and from attendants; medical records are consulted where available for substance use history and prescription details; past episodes of overdose or seizures are noted; and comorbid psychiatric illness and current psychotropic medication are identified in order to understand drug and substance interactions. That last item changes practice: the current prescription list is part of the toxicological history, not psychiatric background for later, because it names the tablets that were in the house.

Where the history fails, the same guideline turns the examination into the identification tool. Vital signs are monitored, specifically heart rate, blood pressure, respiratory rate, temperature and oxygen saturation, and consciousness is assessed serially; the complete physical examination looks for pupil size, peripheral cyanosis, characteristic odours from the nose or mouth, needle track marks and other tell-tale signs of what was consumed, with the systemic examination weighted towards the central nervous and cardio-pulmonary systems. Serially is the operative word: a single conscious-level entry describes a moment, and the triage decision needs a direction of travel.

For children and adolescents the guideline raises the standard explicitly. The nature of the substance ingested and its dosage per kilogram body weight are to be identified as accurately as possible, and where substance use is suspected but cannot be confirmed by clinical history, a detailed physical examination including a full neurological assessment becomes an important part of substance identification. A dose per kilogram is not a refinement here. It decides whether an ingestion is a reassurance or an admission, and it is unavailable unless somebody weighs the child and counts the strip.

GOOD TO REMEMBER

The prescription is a physical object, usually in somebody's bag in the corridor. Ask for the strips, the bottle and the last prescription while the attendants are still there: once the patient moves to a ward nobody goes back for them, and the tablets missing from a strip are often the only quantitative datum anyone will have. Recording that you asked and were told nothing distinguishes an unknown ingestion from an unexplored one.

18.5 Deciding whether to decontaminate, and how long that decision stays open

Most of us learned a single number for activated charcoal, and it is no longer the recommendation. The Clinical Toxicology Recommendations Collaborative, sponsored by the American Academy of Clinical Toxicology, the Asia Pacific Association of Medical Toxicology and the European Association of Poison Centres and Clinical Toxicologists, published recommendations in 2026 whose conclusions name the traditional **1 h** post-ingestion point as superseded. Single-dose charcoal is recommended beyond it in selected poisons, and a new category, **additional-dose activated charcoal**, is introduced for poison that may remain in the gastrointestinal tract for prolonged periods. Teaching that stops at the single-hour window is out of date.

What replaces it is a window belonging to the poison and its formulation. On an individualised risk assessment, charcoal is appropriate up to 6 h after ingestion for many poisons, and may be given beyond that where ongoing absorption is suspected, with **pharmacobezoar** formation, certain modified-release preparations and a drug burden exceeding the limits of solubility named as the mechanisms by which absorption keeps going.

The dose does not change between the single and the repeated use, and it is the same dose whatever the poisoning: 50 g of activated charcoal in an adult, or 1 g/kg in a child up to the adult dose. The recommendation as issued does not state a route in that passage and none is supplied here. Two repeat concepts sit on top of it and are routinely conflated. An additional dose is given at any point after the single dose where there is evidence or suspicion of ongoing absorption, so its timing follows the suspicion rather than the clock. **Multiple-dose activated charcoal** is a regimen: the same dose repeated every 4 h, or a half-dose every 2 h, to enhance elimination rather than to prevent absorption.

One question settles the matter for some patients entirely. The collaborative concluded that charcoal has no role at all in poisoning by arsenic, caesium, copper, ethanol, methanol, ethylene glycol, iron, lead, lithium and metformin. Three turn up at the psychiatric front door constantly: ethanol, methanol and lithium. For lithium the recommendation is against charcoal in every mode and both formulations, the cleanest example of a decontamination decision settled by the identity of the drug alone. The serum-level bands, precipitants and dialysis chain are the Mood disorders: pharmacotherapy notes'; the acute against chronic against acute-on-chronic typology sits with lithium toxicity and overdose management.

MNEMONIC

What, then when, then who

Taken in that order the decision holds. **What** was taken decides whether charcoal has any role at all, because for a defined list of poisons it has none, at any interval. **When** it was taken sets a window belonging to that poison and that formulation, not to a single remembered figure. **Who** is in front of you decides last, and can withdraw what the first two steps allowed: airway reflexes, peristalsis, perforation risk and the prospect of endoscopy all veto.

THE INGESTION	WHAT THE COLLABORATIVE RECOMMENDS FOR SINGLE-DOSE ACTIVATED CHARCOAL
Immediate-release paracetamol at or above 200 mg/kg	Charcoal recommended up to 2 h after an immediate-release paracetamol ingestion, suggested up to 3 h, suggested against beyond 6 h
Modified-release paracetamol at or above 200 mg/kg	Charcoal recommended up to 5 h after a modified-release paracetamol ingestion, the formulation moving the window outwards
Tricyclic antidepressants, at a dose threshold of 10 mg/kg	Charcoal recommended up to 2 h after a tricyclic antidepressant ingestion, suggested up to 3 h, suggested against beyond 6 h
Lithium, immediate-release or modified-release	Recommended against for lithium as single-dose, additional-dose and multiple-dose charcoal alike, for both formulations
Ethanol, methanol and ethylene glycol	No role for charcoal in poisoning by ethanol, methanol or ethylene glycol, alongside arsenic, caesium, copper, iron, lead and metformin
Many poisons, as a general position	Charcoal appropriate up to 6 h after ingestion for many poisons on an individualised risk assessment, and beyond 6 h where ongoing absorption is suspected

50 g
SINGLE DOSE OF ACTIVATED CHARCOAL IN AN ADULT

6 h
CHARCOAL APPROPRIATE UP TO THIS POINT FOR MANY POISONS

24 hours
MINIMUM OBSERVATION AFTER EXTENDED-RELEASE BUPROPION OVERDOSE

31.6%
SEIZED AFTER EXTENDED-RELEASE BUPROPION OVERDOSE IN HOSPITAL

18.6 Withholding charcoal, and refusing to secure an airway in order to give it

The contraindications are graded by strength of recommendation, and the grading is the teaching: it tells you which is a discussion and which is not. There are strong recommendations against giving activated charcoal where:

- airway protective reflexes are absent in a patient who is not endotracheally intubated;
- those reflexes are at risk, or are expected to become absent;
- the patient is at risk of gastrointestinal perforation.

There are weak recommendations against giving it where:

- administration may increase the risk of aspiration;
- peristalsis is absent;
- the patient is likely to require upper gastrointestinal endoscopy.

The second strong item is prospective, and that is the point. A patient whose reflexes are intact now but who has taken something that will remove them shortly is already in the strong-against group: the reflexes that matter are the ones that will exist when the charcoal is in the stomach.

The drowsy overdose patient generates the question every shift: should the airway be secured so that charcoal can be given? Endotracheal intubation should not be performed solely to administer activated charcoal in patients not anticipated to develop clinically significant complications of poisoning. Where intubation is already indicated on its own merits, the examples given being a compromised or unprotected airway, respiratory failure, a significantly diminished level of consciousness, refractory seizures or haemodynamic instability, a nasogastric or orogastric tube for decontamination is reasonable. A separate statement forbids passing a gastric tube without intubation purely to give charcoal. The logic generalises: an intervention carrying its own mortality is not justified by one of uncertain benefit downstream.

Gastric lavage has left the answer. The joint position paper update of the American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists, published in 2013, concluded that it should not be performed routinely, if at all, in poisoned patients, and that where it is indicated it should only be performed by individuals with proper training and expertise. The second clause is where the mark is lost: a rarely-indicated procedure done by whoever is on duty is worse than the same procedure done competently.

18.7 Refusing to be reassured by the patient who looks well

The trap this section exists to close. Triage rewards the sick-looking patient, and self-poisoning contains a class of agents whose early appearance is uninformative. Getting this wrong does not feel like an error at the time. It feels like prioritisation.

Paracetamol is the archetype and the regulator states it plainly. The approved product information tells prescribers that despite a lack of significant early symptoms, patients should be referred to hospital urgently for immediate medical attention, and that symptoms may be limited to nausea or vomiting and may not reflect the severity of the overdose or the risk of organ damage. The time course explains why. Symptoms in the first 24 hours after a paracetamol overdose are pallor, nausea, vomiting, anorexia and abdominal pain, while liver damage may become apparent only **12 to 48 hours** after ingestion, and acute renal failure with acute tubular necrosis may develop even without severe liver damage. Injury and presentation are separated in time, so the triage decision cannot be made on how the patient looks: an asymptomatic patient after a paracetamol overdose is not a reassured patient.

The psychotropic version of the same trap is the modified-release agent. A multi-poison-centre observational study of one hundred seventeen patients hospitalised after extended-release bupropion ingestion, published in the American Journal of Emergency Medicine in 2009, found

seizures in 37 of them, 31.6 per cent, with the first seizure anywhere from 0.5 to 24 hours after ingestion. Of those who seized, 12 patients, 32 per cent of the seizing group, had their first seizure later than **8 hours**, and further seizures followed in 49 per cent. The authors turned that into the disposition rule: the delayed onset suggests a minimum observation period of 24 hours after an extended-release bupropion overdose, and while agitation or tremor may mark greater risk, seizures can occur without preceding central nervous system toxicity. An untroubled early mental state is therefore not a discharge criterion here, which is exactly the criterion a busy department reaches for.

The teaching would be dangerous if it stopped there, because the opposite pole is also a psychotropic. The collaborative records, appraising tricyclic antidepressants, that they are associated with a rapid onset of symptoms and high lethality in overdose. Here the early picture does track the danger, which is why the decontamination window is short and why disposition cannot be deferred. So the discipline is not that appearances always deceive; it is that the relation between early appearance and outcome is a property of the drug, and therefore something you look up rather than judge. The toxidrome, the electrocardiographic picture and the antidotal management belong with anticholinergic toxicity and the other psychotropic overdose syndromes in these notes, where the antidote question is taken agent by agent and the serotonergic antidepressant and antipsychotic overdoses are set out as acts.

TRAP **Reading an asymptomatic overdose patient as a low-acuity one.** Candidates make it because every other part of emergency medicine trains them to triage on appearance, and because a reassuring examination usually is reassuring. The correction is not to distrust every well patient, which is unworkable, but to make disposition depend on the agent and the elapsed time rather than the mental state at the bedside. The question is never whether this patient looks unwell, but whether, for this drug at this interval, a patient who is going to deteriorate would look any different yet.

18.8 Deciding whether to reverse, and what reversal does not end

Antidotes are attractive at three in the morning because they promise to convert a monitoring problem into a completed task. In the undifferentiated overdose that promise is where the harm comes from.

The approved product information for flumazenil requires particular caution in mixed-drug overdose and supplies the mechanism rather than leaving it as a warning. Where benzodiazepines have been taken together with cyclic antidepressants, toxic effects such as convulsions and cardiac arrhythmias, which are caused by the antidepressants but emerge less readily while benzodiazepines are on board, are exacerbated by giving flumazenil. The benzodiazepine has been partly masking a second poisoning, and reversal removes the mask. That is why this antidote is not routine in the undifferentiated overdose, and why the identification work described earlier is a precondition for the antidote decision rather than a parallel activity.

The Indian Psychiatric Society guideline puts the same caution in more portable terms for the polysubstance presentation. Antidotes such as naloxone and flumazenil may be used with caution to avoid **unmasking** the effects of substances with opposing psychoactive effects; definitive

management depends on a confirmed report of the nature of the substances consumed; and sedatives are used judiciously to avoid worsening respiratory depression. In a polysubstance overdose almost every pharmacological act is provisional until you know what is in the patient.

Reversal also does not end the episode, the half of the decision forgotten once the patient opens their eyes. Patients who have received flumazenil are monitored for **resedation**, respiratory depression or other residual benzodiazepine effects for a period appropriate to the dose and duration of effect of the benzodiazepine involved, and with underlying hepatic impairment the effects may be delayed and an extended observation period required. No fixed interval is given and none is supplied here: the observation period follows the agent taken, not a standard number. No dose, route or rate for flumazenil is stated here either, and the full regimen must be read from the product information before the drug is drawn up.

PITFALL

Giving the benzodiazepine antidote to wake a patient so the psychiatric assessment can proceed. It inverts the logic of everything above: the assessment is not the emergency, and the drowsiness is information about the ingestion that the antidote deletes. In a mixed ingestion the same act can turn a sedated patient into a fitting one. Where the reason for reversal is diagnostic convenience rather than respiratory compromise, the answer is a documented review interval and a patient who is watched.

18.9 Setting the observation period, and handing the patient over

Disposition after an overdose has two components and only one is psychiatric. The first is how long this ingestion has to be watched, a property of the drug: the extended-release agent with a minimum observation period, the paracetamol whose injury declares itself long after the tablets, the tricyclic whose window closes fast. The second is the level of care the psychiatric risk requires, taken up where suicide risk assessment and emergency management are dealt with. They are decided together: a patient may need a medical bed for one reason and a particular kind of watching for the other.

What travels with the patient is a document, not a phrase. The task force specifies the contents of the **transfer note**: the details of the assessment performed, the results, and the medical decision-making that led to the judgement that the patient is appropriate for transfer, together with recommendations for the further assessment and care of any active medical problems. That last clause changes practice: active problems are handed over rather than closed. The task force adds a coda: documenting that a patient is stable for transfer to satisfy the American emergency-treatment statute should be treated as the minimum rather than the standard level of evaluation. A legal floor is not a clinical standard, and a note written to satisfy the first usually fails the second.

The psychiatric assessment then inherits three things, and in usable form only if the triage was done properly: a substance and an amount, an elapsed time with an observation period attached, and a list of medical problems that remain live, each with a named plan. An assessment beginning without those is not an earlier assessment. It is an assessment of a different patient.

IN INDIA

A structural gap explains why Indian answers here are assembled rather than looked up. The Indian Psychiatric Society guideline on substance intoxication in the emergency setting states its own scope exclusion: accidental ingestion, and ingestion of substances with intent for self-harm, are not catered to in it, referring the reader instead to the guideline on the management of suicidal behaviour, which carries nothing on decontamination, activated charcoal, gastric lavage, antidotes or toxidromes. The national stack routes deliberate self-poisoning away from its only toxicological chapter into one with no toxicology in it, so this triage must be taken from emergency-medicine and toxicology sources. The service consequence follows: a concurrency rule assumes a psychiatrist in the department at the same hour as the physician, and a minimum observation period assumes a monitored bed that stays free after the patient stops looking unwell. Where neither holds, name the assumption in the notes and record what was done instead.

An overdose is handed over with a document and not a phrase: what was assessed, what it showed, the reasoning that made the patient appropriate for a psychiatric setting, and a written plan for every medical problem that is still active.

19 · Restraint and seclusion (indications, ethics, monitoring)

What is left once the law and the ethics have been taught. When restraint may be used, on whose authority, and the principles constraining that choice belong to the Mental health legislation and forensic psychiatry notes and to the Forensic ethics, consent and legal procedure notes, and none of it is repeated here. Whether seclusion is lawfully available at all in India is likewise a question of statute for the first of those.

What is left over is the person on the floor with several pairs of hands on them, and that is where people die. A restraint correctly indicated, lawfully authorised and proportionate can still asphyxiate a patient, arrest them, or leave them with a clot. None of that follows from the decision; it follows from the execution.

19.1 What a hold does to a body

The clearest statement of mechanism is an emergency medicine one. The Royal College of Emergency Medicine best practice guideline on acute behavioural disturbance in emergency departments, in its 2023 version, holds that ongoing restraint be removed at the earliest opportunity, because continued exertion under restraint can contribute to poor outcomes through rising catecholamine levels, worsening hyperthermia and metabolic acidosis. It adds what candidates least expect: no high-quality data suggest any risk-free method of restraining an undifferentiated, potentially co-morbid patient.

Read those three as a loop. A person fighting a hold does maximal isometric work against a chest wall loaded from outside, so lactate accumulates while the ventilation that would clear the resulting **metabolic acidosis** is mechanically restricted, heat is made by someone who cannot move to lose it, and the catecholamine surge sustaining the struggle is arrhythmogenic.

RULE **There is no safe way to hold a person against their will, only less dangerous ways, and the difference is how much weight sits on the chest and how long it sits there.** The answer names the two modifiable quantities, load and duration, and who owns each.

19.2 Weight, arms and the chest wall

Two experimental studies carry the mechanical teaching. A controlled crossover study in Annals of Emergency Medicine in 1997 concluded that, in its study population of healthy subjects, the prone maximal restraint position produced a **restrictive pulmonary function pattern** without clinically relevant change in oxygenation or ventilation. Carry the scoping clause: those subjects were healthy young men with a negative urine toxicology screen and obesity excluded, not the population who die in restraint.

The second study moved the variable from position to limb placement. Comparing three recognised prone restraint positions in Medicine, Science and the Law in 2013, it found anterior chest pressure substantially lower in the **supported prone position**, where the upper limbs come underneath the shoulder joint rather than abducted from the torso. All three restricted respiratory function, and the reported risk falls as that pressure falls.

WHAT IS DONE TO THE BODY	WHAT WAS MEASURED OR STATED	WHAT IT CHANGES AT THE BEDSIDE
Prone hold, arms abducted from the torso	Mean anterior chest pressure of 102.6 mmHg and 101.4 mmHg across the two positions of this kind	Heaviest measured chest load, and the arms produce it
Supported prone, upper limbs under the shoulder joint	Mean anterior chest pressure of 72.7 mmHg in this position	Same patient, a third less load, adjustable mid-hold
Placement of staff weight in prone containment	Published Indian guidance bars sitting on any part of the patient, places staff weight to the side rather than on top, and prohibits significant body weight including knees, elbows and torso	The prohibited parts are the ones that load the thorax

19.3 Positional asphyxia, and the argument about its name

The term the syllabus uses is contested, and teaching it as settled mechanism teaches a disputed claim. The United States federal regulation on hospital patients' rights, issued by the Centers for Medicare and Medicaid Services and current as published in 2026, requires staff trained to recognise and respond to signs of physical and psychological distress in restraint or seclusion, and offers **positional asphyxia** as its worked example.

Against that, a comprehensive review in Medicine, Science and the Law in 2021 argued that deaths associated with prone physical restraint are not the direct result of asphyxia but of cardiac arrest secondary to metabolic acidosis compounded by inadequate ventilation and reduced cardiac output, proposing **prone restraint cardiac arrest** as the apter name. Weigh it as a single-author narrative review. Between the two sits the emergency medicine guideline, which states the

older prone theory is not supported by recent research and, in the same breath, that it remains prudent to ensure there is no obstruction to ventilation and to minimise the risk of asphyxiation.

The disagreement is about mechanism, not about the act. Whether the terminal event is asphyxial or arrhythmic, the instruction is identical: weight off the thorax, airway free, hold shortened, exertion stopped.

19.4 The positioning hierarchy, and where teaching loses it

The hierarchy comes from the National Institute for Health and Care Excellence guideline on violence and aggression in 2015, in three ordered limbs: avoid the floor at all; if that is unavoidable use the supine, face up, position if possible; and if prone, face down, is necessary, for as short a time as possible. Published Indian guidance in the Indian Journal of Psychiatry in 2019 arrives differently: prone restraint ideally not used; prone containment only where the immediate situation requires it to prevent imminent serious harm; the patient repositioned to sitting, standing or supine as quickly as possible with close attention to respiratory function.

Two features repay attention. Its escape route is a change of position, not release, so a team that cannot yet let go still has an act available. And the document is internally inconsistent: its narrative permits a conditional prone hold while its own precautions list says simply to avoid prone restraint. Follow the stricter limb, and say so.

TRAP **Answering "supine rather than prone" and stopping there.** Candidates make it because the supine against prone comparison is the memorable part, and examiners quote it. The flaw is that it is the second limb: the primary instruction is to avoid the floor at all, so a hold managed seated or standing has already satisfied a recommendation the supine answer is only a fallback within. Nor is supine a licence, since weight across the chest, or anything laid over the face, reproduces the hazard the position was chosen to avoid.

19.5 The airway, the face, and who is holding what

The prohibition defining a safe hold is stated as an absolute: do not use **manual restraint** in a way that interferes with airway, breathing or circulation, the examples being pressure to the rib cage, neck or abdomen, or obstruction of the mouth or nose. The Indian guidance adds what makes a supine hold survivable: the head is allowed to rotate freely, and the face is not covered with a towel, bag or similar. A restrained patient who vomits and cannot turn their head has no airway at all.

The same guideline bars restraint that obstructs the eyes, ears or mouth and so prevents communication, and the reason is clinical: breathlessness in restraint is reported before it is observed, so a patient who cannot be heard has lost the team's earliest warning. One staff member leads throughout the restraint, and that person's duty is not to hold but to ensure colleagues are supported and able to do three things:

- protect and support the head and neck if needed, which makes the head-and-neck hold a protective role and never a controlling one;

- check that airway and breathing are not compromised, a continuous task rather than a single observation;
- monitor vital signs, which needs somebody whose hands are free.

The allocation is to named people, not to the team in general: a hold in which everyone is holding has nobody watching, and that failure is silent.

19.6 The clock, and the rule that settles arguments inside a hold

Duration is the other modifiable quantity. The violence and aggression guideline sets a ceiling in one line: do not routinely use manual restraint for **more than 10 minutes**. The word routinely is part of the recommendation and must be carried: not an absolute prohibition, but a statement that a longer hold is an exception needing a recorded reason and a name against it. The alternatives that source offers include one whose lawful availability in India is a statutory question, left to the Mental health legislation and forensic psychiatry notes. Where sedation is chosen, its agents and first doses belong to the Schizophrenia: management, antipsychotics and adverse effects notes.

The most useful sentence here is Indian and it is a tie-breaker: during an episode of restraint, **medical priorities** supersede psychiatric ones. Every hard moment inside a hold is the same conflict, between containing the behaviour and protecting the body, and this resolves it the same way. The patient who says they cannot breathe is answered before the argument about whether they are exaggerating; the patient who suddenly stops resisting is a physiological event, not a success.

MNEMONIC

Airway, Weight, Clock, Eyes

What must be true at every moment of a hold. **Airway**: nothing pressing the rib cage, neck or abdomen, nothing over the mouth or nose, head free to rotate. **Weight**: to the side rather than on top, never the knees, elbows or torso. **Clock**: the hold not routinely prolonged, the position changed to sitting, standing or supine as soon as possible. **Eyes**: continuous visual observation, the condition written down at the stated interval.

19.7 Watched, assessed, written down: three separate duties

The commonest defect in a restraint policy is to collapse observation, assessment and documentation into one requirement. **Continuous visual observation** is a state holding for the whole restraint; documentation is a periodic act, signed and timed on a restraint form the facility itself has developed; nursing assessment is a clinical examination with its own cadence. A ward that writes an entry every quarter of an hour and never lays hands on the patient has satisfied one duty and failed another.

WHAT HAS TO HAPPEN	WHO DOES IT	HOW SOON, AND HOW OFTEN	WHOSE STANDARD
Visual observation of the restrained patient	Trained staff	Continuous throughout the restraint	Published Indian guidance, 2019
Documentation of behaviour, potential injury, circulation and respiration, with observer, date and time	Trained staff	**At least every 15 min**	Published Indian guidance, 2019
Assessment including respiration and other vital signs, circulation checked as containment begins	A nurse	**Within 15 min of the restraint, then at least every hour while it continues**	Published Indian guidance, 2019
Face-to-face evaluation of the situation, the reaction to it, the medical and behavioural condition, and whether to continue	A physician, another licensed practitioner, or a trained registered nurse	**Within 1 hour of the intervention starting**	United States federal hospital patients' rights regulation

Compare those frameworks; do not merge them. The Indian document puts a nurse at the bedside fast, then hourly; the American regulation, which has no force in India, buys one early medical review instead, and states more plainly than anything else here what monitoring must cover: respiratory status, circulatory status, **skin integrity** and vital signs.

15 min	10 minutes	1 hour	72.7 mmHg
FIRST NURSING ASSESSMENT AFTER A RESTRAINT BEGINS, PUBLISHED INDIAN RESTRAINT GUIDANCE	CEILING ON ROUTINE USE OF MANUAL RESTRAINT, VIOLENCE AND AGGRESSION GUIDELINE	FACE-TO-FACE EVALUATION AFTER RESTRAINT FOR VIOLENT BEHAVIOUR, UNITED STATES REGULATION	MEAN ANTERIOR CHEST PRESSURE WITH UPPER LIMBS UNDER THE SHOULDER JOINT

IN INDIA

Read that cadence as a staffing statement. Continuous visual observation means one person whose only task is to watch, and on most general hospital psychiatry units that person is a family attendant rather than a nurse. A quarter-hourly record needs a form, and the guidance leaves that to the facility, so where nobody has made one the cadence quietly stops existing. Two free acts convert this into practice: name the watcher aloud when the hold starts, so the role is not assumed by everybody and performed by nobody, and keep the printed form in the drawer beforehand.

19.8 The body under a long hold: drink, toilet, movement, skin and clot

Once a restraint outlasts the crisis that began it, the hazard changes character: the acute risk was mechanical, the later risk that of any immobilised patient who cannot get up to relieve it. The Indian guidance requires physical needs, comfort and safety to be addressed by staff competent to recognise signs of distress, and names three provisions:

- the opportunity to drink, offered rather than waited for;

- the opportunity to go to the toilet, as requested;
- a **range of motion** as needed for comfort, which is also what relieves pressure areas and venous stasis.

No frequency attaches to any of the three: as requested and as needed is the whole of the timing given. The acts are offered actively and the offers recorded; for how often, no comparable standard is available to quote, and none is invented here.

The clot risk is real and measured. A retrospective case-control study at one metropolitan psychiatric hospital in Japan, in the Journal of Psychiatric Research in 2025, identified 108 patients, or 0.9 per cent, with venous thromboembolism among 11,819 patients hospitalised. Adjusted for confounders, physical restraint was associated with higher risk at an **odds ratio of 6.7 with a 95 per cent confidence interval of 3.4 to 13.3**. One hospital, and the affected patients were elderly, so it establishes the association and its magnitude, not a figure that transfers to a young man held in an Indian casualty. It grounds no prophylaxis threshold, duration or regimen.

GOOD TO REMEMBER

A restrained patient will not ask for water or for the toilet, because asking is what they have just been overpowered for attempting. The offer is the clinical act, not the response to it, and a declined offer written down is what a later review reads as care. Build the round: offer a drink, offer the toilet, move each limb through its range, check the sacrum and heels, and record the four as one timed line with a name against it.

19.9 Release, and the hour after it

Release is a transition, not an ending, and the Indian guidance treats it as one: upon release from restraint a nurse observes, evaluates and documents the patient's physical and psychological condition. It states who and what, and neither for how long nor at what interval, so no post-release observation period is asserted; no comparable standard is available to quote, and none is invented here.

The principle survives the missing interval. Acidosis, hyperthermia and a catecholamine surge do not reverse when the hands come off, the clot risk has already been incurred, and injury sustained in the hold is easier to find on a patient no longer fighting. The examination impossible during a restraint becomes possible the second it ends, which makes these the best diagnostic minutes of the episode and the ones most reliably spent on paperwork. What the record owes the next team is narrow and usually missing: when the hold started and ended, the position used, who led it, what the first and last assessments found, and the state of skin and limbs seen once the patient was free.

No restraint position is safe: weight off the chest and to the side, head free and face uncovered, the hold as short as it can be, and one person watching who is not holding.

The rigid, hyperthermic and toxidromic emergencies

20 · Catatonia (types, Bush-Francis scale, lorazepam challenge, management)

Why an emergency chapter carries catatonia at all. The signs, their classification, the rating scale used to quantify them, the diagnostic threshold, and the benzodiazepine challenge with its dose, route and response criterion are set out in the Other psychotic disorders, delusional syndromes and catatonia notes, and none of that is repeated here. What is left over is the patient on the trolley: not moving, not drinking, not swallowing, not being turned. Almost everything that kills a catatonic patient in the first days kills through immobility rather than through catatonia, and almost none of it is treated by the drug that treats the syndrome.

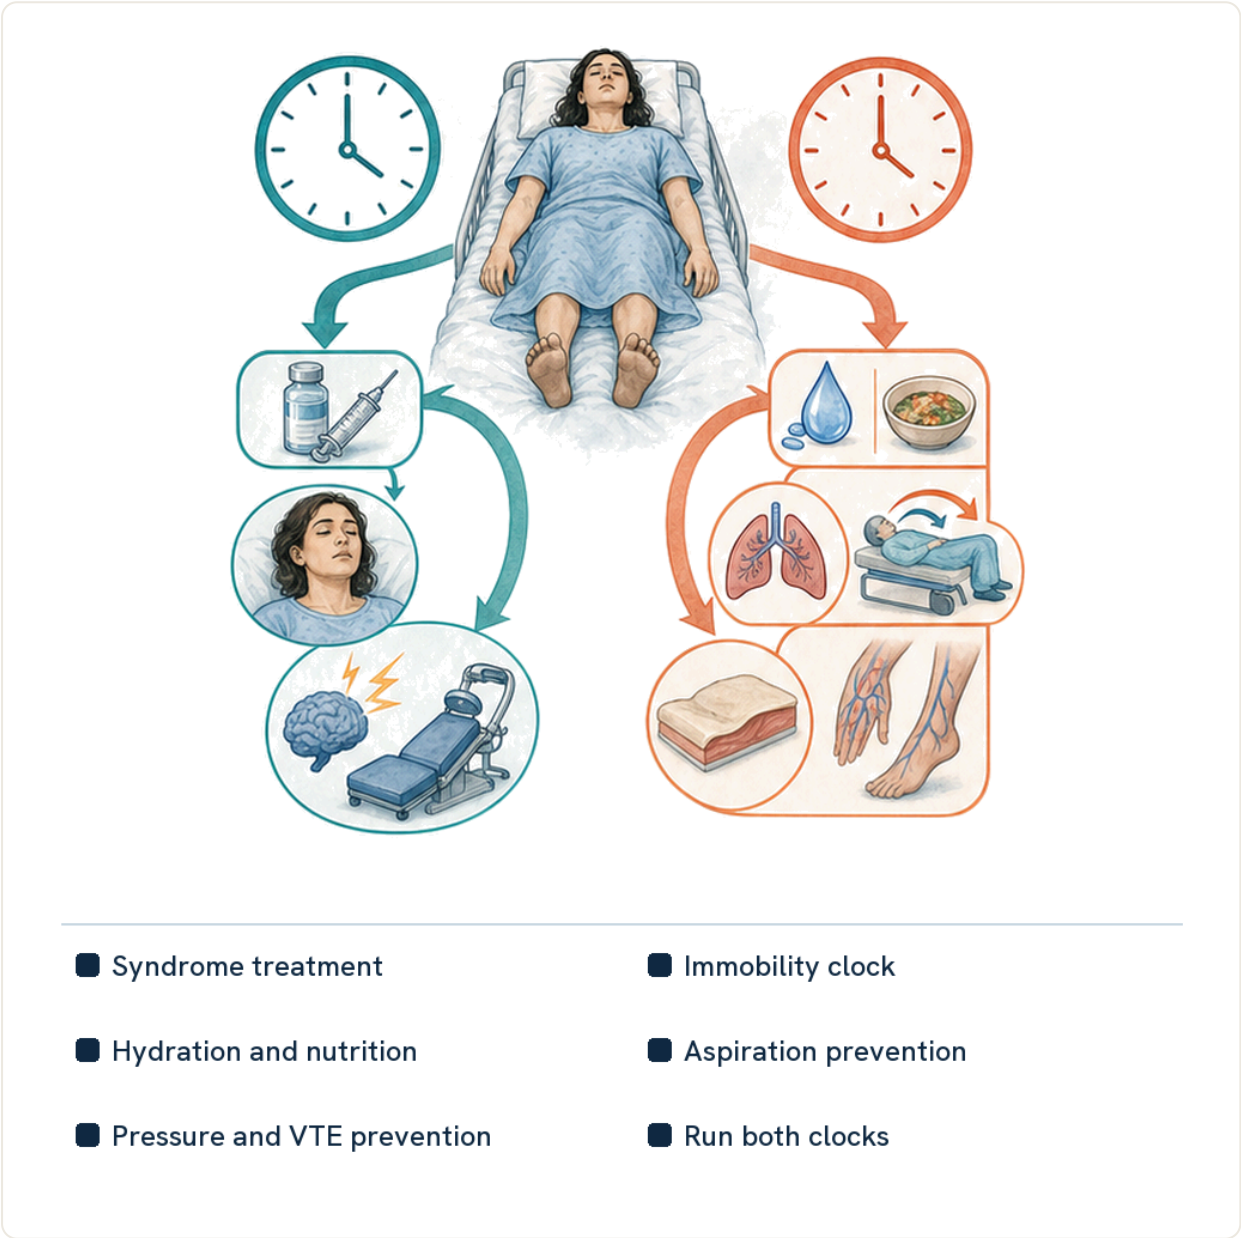

Fig 28.10 Emergency catatonia care runs on two clocks. Lorazepam and ECT treat the syndrome, while hydration, nutrition, aspiration prevention, pressure care and venous-thromboembolism prevention address complications already developing through immobility.

Hold two clocks apart. The therapeutic clock runs from the challenge through the response to the treatment ladder, and it belongs to the Other psychotic disorders, delusional syndromes and catatonia notes. The immobility clock started before the patient reached you and is already well advanced when someone first writes the word catatonia in the notes. Answer only the therapeutic clock and you produce a correct account of the syndrome with an unsafe plan, because the pneumonia, the clot, the ulcer and the electrolyte disaster all mature inside the interval during which the treatment is still being titrated.

20.1 Why the immobile patient is admitted as a medical case

The clearest quantification comes from a retrospective cohort that split **1719 schizophrenia inpatients** into those who exhibited **catatonic stupor** during the hospitalisation and those who never did. Among those inpatients, catatonic stupor carried an increased risk of death against no catatonic stupor, with an **odds ratio of 4.8 and a 95 per cent confidence interval of 2.0 to 10.6**. It is retrospective, single-country and confined to one diagnostic group, so treat it as a signal about magnitude rather than a rate to quote at a family.

The same cohort names what that excess is made of, and it reads as a work list. Increased risk was found for **pneumonia, urinary tract infection and sepsis**; for deep venous thrombosis, pulmonary embolism, arrhythmia and disseminated intravascular coagulation; for rhabdomyolysis, renal failure, dehydration and hypernatraemia; for urinary retention and decubitus ulcers; and for liver dysfunction and neuroleptic malignant syndrome. Fifteen entries that collapse, on the authors' own reading, into **sympathetic hyperactivity, dehydration and immobility**, with the conclusion that meticulous care of both the mental and the medical condition is what reduces them.

Read those three mechanisms as a division of labour. Dehydration is answered by a fluid chart and a route for fluid, immobility by turning, stretching, prophylaxis and a bladder plan, sympathetic overdrive by observations frequent enough to show a trend rather than an event. None of the three is answered by the drug that treats the syndrome, which is why all three get left undone on a ward waiting for a response promised within hours.

RULE **The catatonic patient is nursed as an immobile medical patient from the hour of recognition, not from the hour the treatment fails.** Prophylaxis, skin care, hydration and a feeding decision are not what you escalate to when the benzodiazepine does not work. They run in parallel with it, because a patient who responds beautifully on the third morning can still have thrown an embolus the night before.

4.8	1719	10 kcal/kg/day	5 days
MORTALITY ODDS RATIO, CATATONIC STUPOR AGAINST NO CATATONIC STUPOR, SCHIZOPHRENIA INPATIENTS	SCHIZOPHRENIA INPATIENTS IN THE COHORT BEHIND THAT ODDS RATIO	MAXIMUM STARTING RATE OF NUTRITION SUPPORT AT HIGH REFEEDING RISK	LITTLE OR NO INTAKE BEYOND WHICH FEEDING STARTS AT HALF OF REQUIREMENTS

20.2 The examination that opens the admission

The examination that matters now is not the one that establishes catatonia. The **British Association for Psychopharmacology catatonia guideline of 2023** sets out a physical

examination table with seven entries and no phenomenology anywhere in it. That omission is the teaching point: the specialist examination has done its work by now, and what changes the next hour is the examination any physician would perform.

EXAMINATION DOMAIN IN CATATONIA	THE ACT IT GENERATES
Volume and nutritional status	Establish when this patient last drank and last ate, and get a weight; this fixes the route for fluid and stratifies the feeding decision.
Temperature	Record it and repeat it, because one reading cannot show a trend and a rising temperature is an escalation trigger.
Cardiovascular examination	Emphasised where electroconvulsive therapy is being considered, so it is done early rather than at the treatment decision.
Respiratory status	Emphasised in a patient already on opioids, and before a benzodiazepine is given; a pre-treatment safety check, not a routine observation.
Neurological examination for localising signs	Triggers imaging and a neurology opinion ahead of psychiatric treatment where anything localises.
Evidence of deep vein thrombosis	Converts prophylaxis into investigation where the clot has already formed.
Pressure ulcers on all potential pressure points	Requires the patient undressed and the heels, sacrum, elbows and occiput looked at, giving a documented baseline.

Two entries carry a condition inside them that residents skip, and both are questions of sequence rather than content: the cardiovascular examination comes before the treatment decision it informs, and the respiratory assessment before the sedating drug rather than after it. A list of this kind is an ordering instruction disguised as a checklist.

20.3 The deterioration criteria, and the escalation they trigger

Catatonia sits on a continuum: milder presentations at one end, termed simple or benign, and at the other more severe forms involving hyperthermia and autonomic dysfunction, termed **malignant**. That sentence is all this chapter needs from the entity, and it is used for one purpose. Those two features are the deterioration criteria, the observations that convert a psychiatric admission into a life-threatening one, and they change the level of care before anybody has finished arguing about the label. What malignant catatonia is, how it stands against neuroleptic malignant syndrome and what treatment follows are taught in the Other psychotic disorders, delusional syndromes and catatonia notes; the hyperthermic differential is drawn in the Schizophrenia: management, antipsychotics and adverse effects notes. Neither is redrawn here.

Because the criteria are a temperature and an autonomic pattern, they exist only if somebody is measuring, and measuring often enough for a trend to appear. One admission set of observations cannot demonstrate autonomic instability, which is by definition a variability rather than a value. The practical consequence is a monitoring decision taken at the front door and written down

with a name against it. No temperature threshold and no autonomic parameter is asserted here, because none could be sourced for catatonia specifically.

20.4 Level of care: who is nursed where

The guideline answers this directly and narrowly: initial assessment and treatment of catatonia should be conducted within **secondary care**. Know the footing it stands on, because it is not a trial finding but a consensus position taken in the absence of systematic evidence, the weakest evidential class the guideline uses. That cuts both ways: it cannot be quoted as though outcome data established it, and equally nothing better exists, so a service treating catatonia in an unsupervised setting follows no evidence base at all rather than a weaker one. What secondary care buys can be named, and naming it is how an admission is justified: a bed where fluid can be given and charted, staff who can turn a patient and record it, laboratory access at short notice, and a physician who can be called to the bedside rather than referred to.

IN INDIA

That recommendation describes a United Kingdom service model and no Indian equivalent could be grounded, so the principle travels and the service architecture does not. The stuporous patient here often arrives at a district hospital or a small nursing home where the monitoring the guidance quietly assumes is uneven: continual cardiac rhythm monitoring may exist in one unit only, phosphate and magnesium assays may not run daily, pressure-relieving surfaces may be absent, and one-to-one nursing usually means a family attendant. State in the referral which of those capabilities the receiving setting actually has, and teach the attendant the turning schedule, the mouth care and the fluid chart explicitly, because they are the person who will do it. An unmeetable monitoring requirement is a transfer decision, not something to improvise around.

20.5 Airway, swallow and hydration before anything is given by mouth

Aspiration is what the sourced literature handles worst, and that should be said rather than papered over. The review that assembled the general guidance for this population searched on **4 medical complications: deep vein thrombosis and pulmonary embolism, pressure ulcers, muscle contractures, and nutritional deficiencies**. Airway protection is not among them. The grounding here is indirect: respiratory status is an examination domain, it is flagged before sedation, and pneumonia was among the commonest complications in the cohort. No aspiration protocol, swallow-screen instrument or nil-by-mouth rule specific to catatonia is asserted, because none was sourced.

The principle survives the missing protocol. A patient not swallowing saliva reliably will not swallow a tablet reliably, so assessment of swallow precedes the oral route rather than accompanying it. Sedation is subtractive: whatever lowers conscious level lowers airway protection in someone already immobile and often supine, which is exactly why the respiratory check sits before the benzodiazepine in the examination list. Positioning, suction and an explicit decision about the oral route are the acts; the fluid target that should accompany them is not sourced either.

20.6 Thromboprophylaxis in prolonged immobility

Of the four preventive limbs the guideline records for averting the medical complications of catatonia, **pharmacological thromboprophylaxis** has the clearest reasoning behind it and the least specific instruction attached. The synthesis review reached a decision rule rather than a prescription: prophylaxis guidelines support anticoagulant therapy for **patients with catatonia who are at lower risk of acute bleeding**. Bleeding risk is the variable that decides, and it is assessed and recorded before the first dose rather than after a complication. The underlying evidence is borrowed, and the borrowing must be declared: the **American Society of Hematology venous thromboembolism guidelines of 2018** made four strong recommendations in acutely and critically ill medical inpatients, not in catatonic patients.

- Give pharmacological prophylaxis to acutely or critically ill medical inpatients at acceptable bleeding risk.
- Use mechanical prophylaxis instead where the bleeding risk is unacceptable.
- Do not use direct oral anticoagulants for this purpose during the hospitalisation.
- Do not extend pharmacological prophylaxis after discharge from hospital.

The fourth is the one answered wrongly. A patient immobile for weeks feels like a patient who should go home on an anticoagulant, and the recommendation is explicitly against it: the risk being treated is that of the acute illness and its confinement, which falls when the confinement ends, while the bleeding risk does not. The population is medical inpatients, so applying any of this to a catatonic patient is an inference and should be stated as one. No agent, dose, route or duration specific to catatonia is grounded anywhere in this material, so none is printed; the choice follows local thromboprophylaxis policy, which is the honest answer in an examination as well as on a ward.

20.7 Skin, joints and bladder: the acts nobody writes down

The remaining preventive limbs are unglamorous and they are where the marks sit, because each has a nursing act and a documented interval attached. Pressure ulcer prevention rests on **frequent skin evaluation, support surfaces and repositioning**, with no interval, surface or frequency sourced beyond the word frequent. Contracture prevention is by **stretching**, and the evidence there is openly thin: it has to be extrapolated from studies of patients with neurological injuries, because catatonia-specific data do not exist. Say so when you quote it, because a resident who knows the evidence is borrowed involves physiotherapy early, while one who believes a protocol exists waits for it.

The bladder falls outside every review. Urinary retention carried increased risk in the cohort, and so did urinary tract infection, and that is the whole of the sourced case for attending to it. What follows is a decision rather than a protocol: retention is looked for actively, because a patient who is not speaking will not report it, and catheterisation is then a judgement between an undrained bladder and added infection risk in a patient who already carries one. No catheterisation criterion, residual-volume threshold or bladder-assessment interval is sourced, and inventing one would be worse than the silence.

MNEMONIC

Clot, Skin, Stretch, Feed

The four preventive limbs the catatonia guideline records, in roughly the order they are forgotten: **Clot**, pharmacological thromboprophylaxis; **Skin**, frequent assessment of pressure areas; **Stretch**, stretching to avoid muscle contractures; **Feed**, consideration of artificial feeding. Each carries a named person and a named interval in a good plan, and not one is a medication for catatonia.

20.8 The feeding decision, and the rate

Feeding is the limb where a wrong act does immediate harm, because a starved patient fed at full requirement is a patient in refeeding danger. No catatonia-specific feeding protocol exists, so the rules come from the National Institute for Health and Care Excellence nutrition support guideline, learned as a stratification followed by a rate. Somebody mute and immobile for a week has met an intake criterion by definition, and the only question is which one.

WHICH RULE APPLIES	WHAT HAS TO BE TRUE	HOW FEEDING STARTS
The general rule for anyone who has not been eating	Little or no intake for more than 5 days	**No more than 50 per cent of requirements for the first 2 days, then increase to full needs if monitoring shows no refeeding problems**
High refeeding risk on one criterion	Any one of: **body mass index below 16 kg per square metre; unintentional weight loss above 15 per cent in the last 3 to 6 months; little or no nutritional intake for more than 10 days; low potassium, phosphate or magnesium before feeding**	**A maximum of 10 kcal per kilogram per day, increased slowly to meet or exceed full needs by 4 to 7 days**
High refeeding risk on two criteria	Any two of: **body mass index below 18.5 kg per square metre; unintentional weight loss above 10 per cent in the last 3 to 6 months; little or no nutritional intake for more than 5 days; a history of alcohol misuse, or of insulin, chemotherapy, antacids or diuretics**	As for high risk above
Extreme starvation	**Body mass index below 14 kg per square metre, or negligible intake for more than 15 days**	Only 5 kcal per kilogram per day, with cardiac rhythm monitored continually in these patients and in any patient who has or develops an arrhythmia

Two things in that table are the examinable ones. The stratification is met on history rather than investigation: weight, weight change and the date of the last proper meal decide the starting rate, and all three come from a relative rather than a laboratory. And the monitoring clause

attached to the lowest rate is one of the few places in catatonia care where a guideline states what is watched and how often. Beside it sits the electrolyte cadence from the same source: **magnesium and phosphate at baseline, then daily where there is a risk of refeeding syndrome, then three times a week until stable, then weekly**, on the stated reasoning that depletion of both is common and under recognised. That laboratory table was written with parenteral nutrition principally in view and may be applied selectively to enteral or oral support, particularly in a patient who is metabolically unstable or at refeeding risk. The vitamin limb of the same recommendation is taught in the Substance use disorders notes.

GOOD TO REMEMBER

The date of the last proper meal is a prescribing datum, not social history, and it decays within a day as the family's account smooths into "he has not been eating properly". Take it at first contact in a form that can be counted, take a weight on arrival even if it must be estimated, and record who estimated it. Those two entries decide the starting calorie rate and neither can be reconstructed a week later.

20.9 The second episode, and what the handover carries

The most useful act-level rule here applies to the patient who has been in before. When a patient presents with a recurrent episode of catatonia, the assessing clinician should not presume that an adequate workup was completed previously; the **adequacy of prior medical evaluation** should be confirmed. It reads as an administrative courtesy and it is a safety rule, because the second and third presentations are where a medical cause hides: the first admission attracts a full investigation, the second attracts diagnosis by recognition, and "known catatonia" in a referral letter is an efficient way of stopping a physician from looking.

TRAP **Treating a recurrent presentation as a repeat of the first one, and inheriting its workup unread.** Clinicians and candidates both make this error because recurrence genuinely does raise the probability of an idiopathic or psychiatric cause, so the inference feels sound. The flaw is that it is an inference about the population while the question is about this patient, whose earlier evaluation may have been curtailed the moment the treatment worked. Confirming adequacy means reading what was done and finding the results. The correct answer to "was he worked up last time" is a list, never a yes.

What the emergency episode owes the team that inherits the patient is a record precise enough to make the next decision without repeating this one. Four entries belong in it and are routinely missing:

- the date and content of the last oral intake and the last drink, with the arrival weight and who measured it;
- the baseline observation set, the interval observations were then taken at, and who set it;
- whether thromboprophylaxis was started, when, on what bleeding-risk assessment, and if withheld, why;

- a pressure-area map from the admission examination, so a new ulcer can be told from an old one.

> Catatonia kills through dehydration, immobility and sympathetic overdrive, so the first hour buys the clot, the skin, the airway and the feed while the diagnosis is still being settled.

21 · Neuroleptic malignant syndrome (features, diagnosis, management)

Why this belongs in an emergency chapter at all. The syndrome itself is taught elsewhere. Its clinical picture, its tempo, the risk factors, the agents used to treat it and the rule for restarting an antipsychotic are set out in the Schizophrenia: management, antipsychotics and adverse effects notes, and none of it is repeated here. What is left over is where an emergency paper puts its marks, because the standard account of neuroleptic malignant syndrome describes the illness and then stops. It prints no formal criteria set, no scoring rule, no temperature functioning as a criterion rather than an observation, and no threshold at which a psychiatric inpatient becomes a critical-care one. Those four objects, with the laboratory limb the usual account leaves vague and the act performed while all of it is unsettled, are what is owned here.

Hold two decisions apart from the moment the patient arrives, because they run on different numbers at different speeds. The first is nosological: does this presentation satisfy a criteria set, and what must be excluded before that is said out loud. The second is dispositional: how deranged is this patient now, where can they safely be nursed, and who else needs to be at the bed. The second does not wait for the first, and it is the one that changes outcome. A candidate who fuses them describes the syndrome when asked what to do, and describes a ward round when asked how the diagnosis is made.

21.1 What kind of instrument the criteria set is

The criteria set to name in an answer came from a formal **Delphi** procedure over an international multispecialty panel in which psychiatrists were the largest group, alongside neurologists, anaesthesiologists and emergency physicians. That composition is not decoration. A syndrome recognised on the psychiatric ward, in theatre and at the front door accumulates three house styles of diagnosis, and the panel existed to force them into one statement. The instrument is a consensus product and not a trial-derived one: it encodes what experienced clinicians agreed they do, and inherits whatever they were collectively getting wrong.

The panel printed a caveat on its own work. The criteria were published with an explicit warning that they **required validation before clinical application**. That sentence is the difference between a criteria list and a decision rule, and it is the part most reproductions drop. A list says what a syndrome contains. A decision rule says what happens when it is applied to consecutive patients: how often it says yes when the answer is yes, and how often it says no when the answer is still yes. Until that is measured, a criteria set is a well-organised opinion.

RULE **Diagnosis and disposition are two decisions taken from two different sets of numbers.** The criteria and their critical values answer whether this is the syndrome. The temperature and the heart rate now answer where the patient is nursed and who is called. Fusing them produces the clinical failure in which a patient with a convincing story waits on an open ward for a creatine kinase result before anyone escalates, and the examination failure in which a candidate recites a presentation and never states a threshold.

21.2 The criteria themselves, and the values fixed to them

The consensus set runs to **eight** criteria, best held as four questions with an audit trail attached: was the dopaminergic system interfered with, is the patient hot and stiff, are the brain and the sympathetic outflow disturbed, and has anything else been ruled out. Four criteria carry a fixed quantitative value. For the rest, no critical value is recorded in the consensus statement of critical values available here, which is a limit of what can be quoted rather than evidence that the criteria set left them open. The table sets each against its value and against what it obliges the clinician to do, because a criterion that generates no act at the bedside is an examination artefact.

CONSENSUS CRITERION	CRITICAL VALUE FIXED WITH IT	WHAT THE CRITERION OBLIGES YOU TO DO
Recent dopamine antagonist exposure, or dopamine agonist withdrawal	No numerical value set	Reconstruct every dopamine-blocking exposure, including antiemetics prescribed by other teams and long-acting injectables given weeks earlier, and time the last dose. Stopping a dopamine agonist counts, and is missed because the chart records a subtraction.
Hyperthermia	**Temperature above 38.0 degrees Celsius, equivalently above 100.4 degrees Fahrenheit, recorded on at least two occasions**	Measure again, and write the second reading down. One elevated temperature does not satisfy this criterion, so the criterion is an instruction to re-observe rather than to conclude.
Rigidity	No numerical value set	Document tone now and again later, so a trajectory exists for whoever takes over.
Mental status alteration	No numerical value set	Record conscious level and orientation in enough detail that deterioration is visible to a clinician meeting the patient for the first time.
Creatine kinase elevation	**Creatine kinase at least four times the upper limit of normal**	Send it with renal function and potassium, and take the upper limit of normal from the laboratory running the assay, because the criterion is a multiple and not an absolute figure.
Sympathetic nervous system lability	**Blood pressure elevation at or above 25 per cent over the patient's own baseline, or blood pressure fluctuation of at or above 20 mm Hg diastolic or at or above 25 mm Hg systolic within 24 hours**	Find a baseline. The criterion is unusable where pre-morbid observations were never recorded, which is the argument for taking them on every admission that starts a dopamine antagonist.
Tachycardia with tachypnoea	**Heart rate at or above 25 per cent over baseline, together with respiratory rate at or above 50 per cent over baseline**	Count the respiratory rate yourself. It is the observation most often invented on a busy chart, and here it is half a criterion.
A negative work-up for other causes	No numerical value set	Do the work-up. This limb is satisfied not by considering alternatives but by investigations that come back and are recorded.

Read those values as a family rather than as separate numbers. Most of the quantitative criteria are referenced to the patient's own baseline rather than a population figure. A young man whose resting pulse normally sits low satisfies the tachycardia criterion at a rate that would not trouble a medical ward, and a chronically hypertensive patient satisfies the blood pressure criterion at a figure that looks routine. Such criteria are sensitive to the individual and wholly dependent on documentation, which is why the observation chart of the first hours of an admission is a diagnostic instrument here and not an administrative one.

Two further points are examinable. Creatine kinase enters as a multiple of the upper limit of normal, a different object from the absolute figure the Schizophrenia: management, antipsychotics and adverse effects notes already teach; the two must not be merged in an answer. And leukocytosis, which almost every textbook description lists, is not among the criteria at all.

21.3 The negative work-up limb, where the work hides

The eighth criterion looks like a formality and is the most laborious of the set. Its content comes from the regulator: the **United States prescribing information for haloperidol injection** states that the diagnostic evaluation is complicated, and directs the clinician first to identify presentations in which serious medical illness, pneumonia or systemic infection for instance, coexists with untreated or inadequately treated extrapyramidal signs. That pairing rewards attention, because it is how the diagnosis goes wrong in both directions at once: a febrile parkinsonian patient with a chest infection can look exactly like the syndrome, and a patient with the syndrome can be dismissed as a chest infection in someone who was always stiff.

The same source then names what else must be considered before this limb is satisfied: central anticholinergic toxicity, heat stroke, drug fever and primary central nervous system pathology. As a list of alternatives it is unremarkable, and that is not the point of it. As an instruction it is demanding, because every entry converts into an act with a time cost: an environment and exposure history, cultures, a lumbar puncture or imaging where the neurological picture warrants it, and a second reading of the drug chart for agents nobody thought of as psychotropic. Discriminating this syndrome from its hyperthermic mimics is taught in the Schizophrenia: management, antipsychotics and adverse effects notes and is not restated here; what belongs here is the obligation the criterion creates, that the exclusions are performed and written down rather than entertained.

> **GOOD TO REMEMBER**
>
> The exposure history is the one criterion nobody can reconstruct later. Which dopamine-blocking agent was given, when, by whom, and what was stopped lives in a drug chart, an emergency prescription and a relative's memory, and degrades within hours. Take it first, take it in writing, and take it before the patient moves to a department the chart travels to separately.

21.4 Scoring the criteria, and what a low score does not mean

The set is not applied by counting items met. Each criterion is weighted, so it is scored in priority points and a total is compared against a threshold. The threshold appeared only at validation, which was retrospective: it scored **archived reports of clinician-initiated calls to a national**

telephone consultation service against the set. Agreement was best where the threshold was set at **74 priority points, which gave a sensitivity of 69.6 per cent and a specificity of 90.7 per cent** against the modified research criteria used as the reference standard.

8	74	4x ULN	>40 C
CRITERIA IN THE CONSENSUS SET	PRIORITY-POINT CUT-OFF SCORE	CREATINE KINASE CRITERION	TEMPERATURE DEFINING THE SEVERE BAND

Read those two operating characteristics as clinical instructions. High specificity with modest sensitivity describes a rule-in instrument. Reaching the cut-off is strong evidence the syndrome is present. Failing to reach it means little, because a rule whose sensitivity sits below seventy per cent misses close to a third of true cases, and a third is not a rounding error when the missed diagnosis is this one. Use of the score is asymmetric: it can justify escalation to a sceptical colleague, and never justifies returning a patient to the ward.

State the limitation whenever you quote the cut-off. The criteria were scored against archived consultation records, not against patients examined prospectively at the front door, so the population in which the threshold performed as reported is one of cases already interesting enough to telephone about. That is not the undifferentiated patient in front of you, and the operating characteristics in that patient are unknown. This is not a reason to discard the cut-off, only to quote it as the best available calibration of a consensus instrument rather than a property of nature.

The same validation produced a second finding with direct bedside consequences. Experienced consultants' own diagnoses agreed considerably better with a modified reference standard, one that accepted less than **severe rigidity**, than with the original standard that demanded it, and the authors concluded that the severe rigidity requirement is more restrictive than what knowledgeable clinicians actually use. As an act: waiting for lead-pipe tone before treating a patient as having this syndrome is not what the criteria evidence supports, and the wait is paid for in hours during which the temperature and the muscle are still climbing.

TRAP **Treating a sub-threshold score, or an absence of severe rigidity, as evidence against the diagnosis.** Candidates make this error because a scored criteria set looks like a diagnostic test, and tests are taught as two-sided objects that confirm and exclude. This one is not. It was assembled by consensus to standardise agreement between specialties, calibrated against a selected population, and its sensitivity was never good enough to rule out. State the cut-off, then state in the same breath what a score below it does not entitle you to do.

21.5 The laboratory limb: what leukocytosis is worth

Leukocytosis is asserted in almost every description of this syndrome and almost never given a figure, leaving candidates repeating a finding they cannot quantify. Two things can honestly be said. The first is a frequency with a population attached: in a systematic review of published case reports of neuroleptic malignant syndrome in children and adolescents, creatine kinase elevation and leukocytosis were the commonest laboratory findings, each present in **42.1 per cent** of cases. That figure belongs to **children and adolescents described in published case reports**, a

population selected twice, first by being young and again by being interesting enough to publish. It is a proportion of cases and not a white cell count, and must never be transplanted into an adult sentence or quoted as a threshold. No adult numerical leukocyte cut-off is asserted here, because none could be sourced.

The second thing that can be said is that the standing of the leukocyte count as a criterion has been challenged directly. A single-centre retrospective case-control study of psychiatric admissions argued that the **neutrophil to lymphocyte ratio** and the lymphocyte percentage may serve as alternative minor criteria, more sensitive and more specific than the leukocyte level and creatine kinase. The direction of the finding is teachable. Its magnitude is not, because it rests on **a small single-centre sample of case and control hospitalisations drawn from the same patients**, and discrimination reported from a sample that size is almost certainly over-fitted. No ratio and no cut-off is printed here for that reason.

What survives at the bedside is short. A raised white cell count supports the picture and never establishes it, and a normal count is not reassurance. This syndrome's laboratory limb is dominated by muscle and kidney, and the tests that change the next hour are creatine kinase, potassium, renal function and a blood gas. Order the white cell count because sepsis sits on the exclusion list, not because it is a criterion, because it is not one.

21.6 The act in the department, stated without a single drug

The arrival sequence is common to every emergency in this chapter and is set out where that sequence is taught: recognise, stabilise, establish who holds the authority to act, act, monitor, decide the destination. What is specific here is that the first therapeutic move is a subtraction. The regulator states the management as three numbered steps, a structure worth keeping because it is the most authoritative statement available of what to do when the pharmacological evidence runs out. Per the **United States labelling for haloperidol injection revised in 2022**: immediate discontinuation of antipsychotic drugs and of other drugs not essential to concurrent therapy; intensive symptomatic treatment and medical monitoring; and treatment of any concomitant serious medical problem for which a specific treatment exists. The same source adds the sentence that keeps an answer honest: there is no general agreement about specific pharmacological treatment regimens for the uncomplicated form. Which agents are used, when, and at what dose is taught in the Schizophrenia: management, antipsychotics and adverse effects notes and is deliberately not carried here.

The supportive half of that middle step has been put in more operational terms by the **British Association for Psychopharmacology catatonia guideline of 2023**, on a consensus footing rather than a trial one, and it is the cleanest available statement of what intensive symptomatic treatment means:

- assessment and appropriate management of airway, ventilation, temperature and swallow;
- monitoring of fluid input and output, with aggressive fluid resuscitation where it is required;
- assessment for hyperkalaemia, renal failure and rhabdomyolysis;

- careful monitoring for cardiorespiratory failure, aspiration pneumonia, thromboembolism and renal failure, alongside early consideration of high-dependency care.

Notice what is absent. There is no drug in that list, and no interval either: the guideline says careful monitoring and does not say how often. No sourced observation cadence for this syndrome is asserted here, and an invented interval would read as universal when it would be nothing of the kind. The principle is defensible without a number: observation frequency is set by the rate at which the patient is changing, reviewed at every escalation, and recorded with the name of whoever set it. Note where "early" sits in that final clause: a higher level of care is considered alongside the surveillance, not after it fails.

> The criteria settle what to call it; the temperature and the heart rate settle where it is nursed, and the second decision never waits for the first.

21.7 Severity banding and the level-of-care decision

The same guideline bands severity by two observations available within a minute of arrival and needing no laboratory. The bands were written to structure a treatment choice; the treatment clause belongs to the chapter that owns the drugs, and what is used here is the half answering the question nobody else answers, which is where this patient should physically be. Two measurements needing no investigation are worth a great deal in an Indian emergency department, where the creatine kinase result may be hours away and the decision cannot wait.

BAND	PHYSIOLOGY THAT DEFINES IT	WHAT THE BAND DECIDES ABOUT LEVEL OF CARE
Mild, early	**Temperature below 38 degrees Celsius with heart rate below 100**, with mild rigidity, catatonia or confusion	The patient may remain in a psychiatric setting only if repeated observations are genuinely taken and read by somebody competent to act on a change. If that is not true of the ward, this band does not apply to it.
Moderate	**Temperature between 38 and 40 degrees Celsius with heart rate between 100 and 120**, with moderate rigidity, catatonia or confusion	Medical co-management from here: a named physician, secure intravenous access, fluid balance charting and laboratory surveillance for the complications listed above. This is the band in which transfer is arranged rather than contemplated.
Severe	**Temperature above 40 degrees Celsius with heart rate above 120**, with severe rigidity, catatonia or coma	The critical-care conversation, not a further period of observation. Airway protection becomes an active question, and high-dependency or intensive care is the destination being negotiated.

Two things about that table are this account's work rather than the guideline's. The third column is a level-of-care decision written here; the bands are the guideline's, but what each one buys in a district hospital is not, and no treatment recommendation is being lifted. And the bands are conjunctive, stating a temperature AND a heart rate, while real patients arrive discordant, hot with an unremarkable pulse or tachycardic and afebrile. No source consulted rules on that case, and none is invented. The working rule is that the higher band governs, because every consequence of over-calling is reversible and the consequence of under-calling is a patient watched on a ward that cannot watch.

A banding this crude is useful for a reason that is not biological. Temperature and pulse are continuous variables cut at round numbers, and their value here is procedural: they give two clinicians who disagree a common object to point at. A resident asking a physician at two in the morning to accept a patient is far stronger saying the temperature is above forty and the pulse above one hundred and twenty than saying the patient looks unwell. The bands convert an impression into a referral that is hard to refuse, and that is most of what a threshold is for. What they do not encode is speed: a patient climbing rapidly through the moderate band deserves the response of the band above.

IN INDIA

Each band assumes a service that may not be present. The mild band assumes observations are actually taken on an open psychiatric ward and that somebody reads them, where in practice the chart is often completed at the end of a shift. The moderate band assumes a physician will co-manage a patient who stays under psychiatry, usually achievable in a general hospital psychiatry unit and frequently not in a standalone mental hospital. The severe band assumes an intensive care bed exists and will accept a patient carrying a psychiatric diagnosis, which is where transfers stall. Plan for it before the patient arrives: know which medical unit takes your escalations, whether the laboratory runs creatine kinase after hours, where the nearest dialysis service is and whether it accepts referrals overnight, and record every refusal with its time. That is not defensive paperwork; it is the only thing that makes a delayed transfer visible afterwards.

21.8 Organ support and the renal replacement decision

The organ that fails first is the kidney, and the route is worth stating because it dictates early management. Sustained rigidity with hyperthermia produces rhabdomyolysis; myoglobin, with the volume depletion of a hot immobile patient who is not drinking, produces acute kidney injury; and that injury with the potassium released from the same muscle produces the hyperkalaemia that kills. The chain is why fluid resuscitation and potassium surveillance are early acts, and why the creatine kinase criterion has an operational meaning outliving its diagnostic one.

The threshold for replacing renal function is where candidates expect a number and there is not one to give. The **Kidney Disease: Improving Global Outcomes acute kidney injury guideline of 2012** states the emergent trigger as a clinical rule rather than as a value: renal replacement therapy is initiated emergently when life-threatening changes in fluid, electrolyte and acid-base balance exist. It then closes the door on the number explicitly, directing the clinician to the

broader clinical context, to conditions that replacement therapy can modify, and to the trend of laboratory tests, **rather than to single urea and creatinine thresholds alone**. An account promising a dialysis number promises something the guideline deliberately declines to supply, and a candidate who produces one has invented it.

What does have operational content is the set of situations widely accepted as emergent indications, which the guideline names while acknowledging that no randomised trial exists for dialysis on life-threatening indications:

- severe hyperkalaemia;
- severe acidosis;
- pulmonary oedema;
- uraemic complications.

Turn that into a psychiatric instruction. The psychiatrist does not start dialysis and is often the only person who knows the patient is heading towards needing it. The act owned here is anticipatory: recognise that a rigid hyperthermic patient is a rhabdomyolysis patient, repeat the potassium and renal function rather than sending them once, keep the fluid balance chart honest, and refer on the trend rather than a single value, because trend is what the guideline says the decision rests on. The equivalent statement for the airway is weaker and should be given as such: airway, ventilation and swallow are named as domains of supportive care, but no numerical threshold for intubation is asserted here, because none was sourced. The principle stands without a number. Swallow is assessed before anything is given by mouth, and a patient whose chest wall movement is limited by rigidity is an anaesthetic problem before a psychiatric one.

21.9 Disposition and handover

Disposition here is not one event but a series of transfers, and each loses information unless it is written to prevent that. The receiving team needs four things only the referring psychiatrist holds: the exposure history with times, which criteria were met and which explicitly were not, what the negative work-up covered and what is outstanding, and the observations establishing the trend rather than the single worst value. A referral saying the patient has the syndrome invites a debate about the diagnosis. One saying which criteria are satisfied, at what values, over what interval, and what has been excluded transfers the reasoning rather than the conclusion, and is much harder to send back.

The internal handover matters as much. Restarting an antipsychotic afterwards, including how long to wait and what to choose, belongs to the Schizophrenia: management, antipsychotics and adverse effects notes and is decided by the team carrying the psychiatric care, not at the front door. What the emergency episode owes that team is a record clean enough to make the later decision possible: the agent, the route, the cumulative exposure, the interval between exposure and onset, the peak physiology, and whether the diagnosis was made against a formal criteria set or on clinical impression. Two entries belong there that residents routinely omit:

- the score, where the criteria set was scored, together with the explicit note that a total below the threshold was not treated as exclusion;
- who decided the level of care, at what time and on what observations, since that is the decision reviewed first if the patient deteriorates afterwards.

One thing is worth carrying out of this section. Everything owned here is a discipline of writing things down while they are still measurable: a baseline observation set that makes a percentage criterion usable at all, a second temperature that turns the first into a criterion, an exposure history that decays within hours, a trend that justifies a referral, and a level-of-care decision with a name and a time on it. The syndrome is treated with drugs the Schizophrenia: management, antipsychotics and adverse effects notes teach. It is survived on organisation.

22 · Serotonin syndrome (Hunter criteria, differentiation from NMS, management)

Why the marks sit on the rule and not on the syndrome. What serotonin toxicity looks like, which agents produce it, and how it is told apart from the other hyperthermic emergencies is set out in the Schizophrenia: management, antipsychotics and adverse effects notes, and none of that is repeated here. What that account does, in common with almost every textbook account, is name the Hunter criteria and move on. A criteria set that is named but never set out is a dangerous object in a curriculum: every candidate can produce the name, very few can say what the rule actually asks, and a rule nobody can state is a rule nobody can apply or properly refuse to apply. Setting it out, with the patients it was built on and the accuracy that bought, is owned here. So is everything that follows once it has returned an answer: what is stopped first, what is cooled, what is sedated, whether an antidote has any place at all, how long the patient is watched before anyone uses the word discharge, and where that watching happens.

One structural point governs how much weight the rule can carry. It was derived in a poisoning service, on patients whose exposure was already known and whose remaining question was diagnostic: given this overdose, is this serotonin toxicity. The psychiatric emergency runs the other way. The physiology is in front of you and the exposure is not, because an agitated, sweating, tremulous patient arrives with a relative unsure what was taken and a prescription list months out of date. The rule is commonly used backwards from the direction it was built in, and the consequence is that a positive result is worth far more than a negative one. That asymmetry, rather than the list of features, is the examinable content of this topic.

22.1 The instrument: a decision rule, and what it displaced

The set to name in an answer is the **Hunter Serotonin Toxicity Criteria, published in QJM in 2003**. The object it is always contrasted with is **Sternbach**'s earlier criteria, and the contrast is not about which features appear on which list. Sternbach's set was a list: features associated with the condition, assembled from the literature, applied by recognition. The Hunter set is a different class of instrument. It was derived empirically from a consecutive admission series, measured against a stated reference standard, and its output is a decision rather than an impression.

The derivation both makes the criteria defensible and bounds them. Every patient admitted to a single regional toxicology service after overdose of a serotonergic drug across a long consecutive series was studied, and the outcome everything was measured against was the diagnosis of serotonin toxicity made by a **clinical toxicologist**. Predictive features were identified first in a learning dataset restricted to overdoses of a selective serotonin reuptake inhibitor taken alone, which strips out the confounding of mixed ingestions, and the rules were then built by **classification and regression tree analysis** and tested on all serotonergic overdose admissions.

2222	473	84%	97%
SEROTONERGIC OVERDOSE ADMISSIONS IN THE DERIVATION SERIES	SSRI-ALONE OVERDOSES FORMING THE LEARNING DATASET	SENSITIVITY OF THE HUNTER DECISION RULES	SPECIFICITY OF THE HUNTER DECISION RULES

Two properties of that design need stating, because the accuracy figures are usually quoted without them. The reference standard is expert clinical judgement: there is no assay and no imaging finding that settles this diagnosis, so the criteria were trained to agree with experienced toxicologists rather than with a biological truth, and that is the ceiling on the performance of every criteria set in this family. Second, a rule built by recursive partitioning is not a summary of what the condition contains. It is a sequence of questions chosen because they separate groups efficiently, so a feature can be entirely characteristic of the illness and still be absent from the rule, simply because another feature was already doing that work.

22.2 The features the rule uses, and the two that arrived by a different route

Counted as the criteria set enumerates them, the rule rests on **seven** features: **clonus** counted once, in any of its three forms, inducible, spontaneous or ocular, together with agitation, diaphoresis, tremor, hyperreflexia, hypertonicity and a maximum temperature above 38 degrees Celsius. Five of those were what was needed to predict the toxicologist's diagnosis and everything else associated with the condition fell out of the rule as redundant; the last two arrived by a different route, which is the next paragraph and is the examinable part.

Two further features were added afterwards, and the reason is itself examinable. The learning dataset contained no life-threatening cases, so features belonging to the sickest patients could not emerge from it statistically. Hypertonicity and a maximum temperature **above 38 degrees Celsius** were universal in such patients and were added on clinical grounds. The rule's coverage of severe toxicity therefore rests on expert consensus about what those patients look like, while the rest of it rests on the derivation that produced its accuracy figures. Two kinds of evidence sit inside one instrument, and an answer that notices the difference is better than one reciting the list.

The features are set out below as what they are, the inputs to a rule, and not as a portrait of the illness, which is taught elsewhere. The second and third columns earn the table its place: a feature never elicited cannot enter a decision rule at all, and the commonest way this rule fails is not disagreement about a finding but that nobody performed the examination which would have produced it.

FEATURE THE RULE USES	HOW IT IS ACTUALLY OBTAINED	WHAT IT OBLIGES AT THE BEDSIDE
Inducible clonus	Sustained brisk passive dorsiflexion of the ankle. It is elicited, never observed.	Examine both legs deliberately and record that clonus was sought and not found, rather than leaving the entry blank. A blank is read later as an absent finding when it was an absent examination.
Spontaneous clonus	Present without any manoeuvre, and visible only on uncovered limbs.	Look before you cover the patient and before you sedate. Sedation suppresses the finding, so the observation must precede the treatment or be lost.
Ocular clonus	Sought by watching the eyes at rest and on pursuit, which requires looking at the eyes on purpose.	Make the eye examination routine in any hot or agitated patient with a possible serotonergic exposure. It is the feature most often absent from the notes and present in the patient.
Agitation	Observed, then distinguished from the agitation of whatever brought the patient into contact with services.	Establish whether this agitation is new and time it against the last known dose. Agitation attributed to the primary illness is the commonest route to a missed diagnosis in a psychiatric setting.
Diaphoresis	Recorded by touching the patient.	Make the observation rather than infer it. This is the finding most often transcribed from an earlier entry without anyone reexamining the skin.
Tremor	Observed in the outstretched limbs.	Document it at first contact, so that a change later has something to be a change from.
Hyperreflexia	Requires a tendon hammer and a neurological examination.	Do the examination. Reflexes are the limb of this rule most often skipped in an emergency room, and skipping them removes a feature the rule depends on.
Hypertonicity, added for life-threatening presentations	Assessed by passive movement of the limbs, and reassessed rather than assessed once.	Treat its appearance as a change of category, not one more positive item. Rigid muscle is the tissue generating the heat, so this finding sets the tempo of what follows.

FEATURE THE RULE USES	HOW IT IS ACTUALLY OBTAINED	WHAT IT OBLIGES AT THE BEDSIDE
Maximum temperature above 38 degrees Celsius, added for life-threatening presentations	Measured, ideally centrally, and recorded as the maximum reached rather than the most recent reading.	Chart the trajectory, not a value. The criterion refers to a maximum, so a falling reading taken after cooling does not undo a peak that has already occurred.

TRAP **Treating the criteria as a checklist and counting how many features are present.** Candidates do this because the set being implicitly compared with was a list, and lists are counted, and because secondary reproductions lay the branch conditions out as bullet points that look countable. This set is a decision tree. Particular features in particular combinations are diagnostic and others are not, so two patients with the same number of positive items can fall on opposite sides of it. The verbatim branch structure is not reproduced here, because it could not be verified against the primary publication, and a branch condition recalled from a secondary source is the kind of detail that is wrong in a way nobody notices until it is applied to a patient.

22.3 What the accuracy figures actually bought

The rules were simpler than their predecessor and performed better on both axes: **84 per cent against 75 per cent for sensitivity, and 97 per cent against 96 per cent for specificity**. Read the two gains separately, because they are not of comparable size and do not carry the same meaning. The specificity gain is arithmetically trivial; both instruments were already highly specific, and what matters there is the level rather than the improvement, because within the population studied a positive result is close to conclusive, and that is what licenses acting on the rule instead of waiting for something else to confirm it. The sensitivity gain is the substantial one, and it is why the newer rule displaced the older, since it materially reduces the proportion of genuine cases missed while making the instrument simpler rather than more elaborate.

Turn both into instructions. A positive rule in the right setting is strong enough to justify stopping the drug, starting physical treatment and escalating the level of care over a colleague's scepticism. A negative rule is not strong enough to send anybody home, because an instrument that misses a meaningful minority of true cases is not an exclusion test, and because its sensitivity was measured against agreement with an expert rather than against a fact of nature. One further qualification changes the weight of both figures considerably, and it is the subject of the next section.

22.4 Where the rule was validated, and where you will be using it

The group that derived the criteria addressed this in the **Medical Journal of Australia clinical update of 2007**, and their statement is more restrictive than the way the criteria are usually quoted. The rules were validated in a **toxicology service** in which other drug-induced syndromes are frequent, and that setting is precisely why they are so much more specific than the older criteria for features belonging to serotonin toxicity alone. Because they are that specific, the authors say, they can be used for adverse drug reactions; but they have not been validated for that purpose.

Sit with what that excludes, because it describes most of the situations in which a psychiatrist reaches for the rule. A patient on therapeutic doses who becomes tremulous, sweaty and agitated after a prescription change is an adverse drug reaction, not an overdose. There is no time zero, no ingested quantity, and no toxicology service around the patient. Applying the criteria there is defensible and is what the authors themselves say the specificity permits, but the operating characteristics above were not measured in that population and are not properties of the rule in it.

What follows is a discipline of documentation rather than of treatment. Use a positive result to justify what you are about to do; do not use a negative result to justify not doing it, and write the reasoning in that form, because a note recording that the criteria were not met reads later as an exclusion when it was nothing of the kind. The honest entry names the setting, states which features were sought and which were found, and says explicitly that a negative rule was not treated as excluding the diagnosis.

22.5 The branch that changes the clock: severe toxicity

Severity, not the diagnostic label, determines the next hour, and the severe band has its own name and definition. Severe serotonin toxicity, or **serotonin crisis**, is characterised by a rapidly increasing temperature together with muscle rigidity, and it will progress to multiorgan failure if not treated within hours. It is a medical emergency, and it is almost exclusively associated with combinations of drugs acting at different sites rather than with any single agent. Three things follow, and each is an act.

The first concerns the word hours. Every other interval in this topic is counted in hours too, which is exactly why the distinction matters: the observation period and the expected recovery are periods during which you watch, while this is a period during which you must already have acted. It is the only clock here that finishes before a laboratory result does.

The second concerns the drug history. If the severe band is almost always a combination, the question asked of the patient and the relatives changes shape. It is not what was taken, it is what was taken together, over what period, and whether anything was started or stopped recently by a team other than yours. A single-agent answer, accepted and written down, closes the enquiry at the point where the severe band would have been identified.

The third concerns what is measured. The definition names a rapidly increasing temperature, not a high one, with rigidity beside it. A patient whose temperature has climbed steeply is in a different situation from one sitting at the same reading unchanged for some hours, and only one of those facts appears on an observation chart that records values without times. Insist on times.

> A rising temperature with rigidity is the branch that runs on hours, and it is answered by cooling, sedation and paralysis, never by an antidote.

22.6 What the differentiation from neuroleptic malignant syndrome actually changes

The grid is not the teaching here. How this syndrome is distinguished from neuroleptic malignant syndrome and the other hyperthermic emergencies is taught as a recognition exercise in the Schizophrenia: management, antipsychotics and adverse effects notes, and it is not redrawn on this page. What belongs here is the question a recognition exercise never answers: what the discrimination buys. A candidate who can separate the two syndromes on features but cannot say what changes when they do has learned the half that carries fewer marks.

- **Almost nothing changes in the opening minutes.** Both converge on the same physical act: airway, temperature, fluids, sedation, and a decision about where the patient is nursed. A resident who suspends cooling while the label is argued has the order of operations exactly backwards. The discrimination is made in parallel with resuscitation, never before it.
- **What is subtracted differs, so the history differs.** One picture asks what dopamine blockade was given or what agonist was withdrawn; this one asks what serotonergic agents were on board and, in the severe band, in what combination. That is a different conversation with the relative and a different reading of the drug chart, and it has to happen early because the information decays.
- **The expected trajectory after stopping differs, and only one of them can be stated with a source here.** Serotonin toxicity has a recovery window, set out below; no equivalent interval for the other syndrome is asserted on this page. That asymmetry is useful rather than awkward, because it means failure to improve inside the stated window is a reason to reopen your own diagnosis and is not by itself evidence that the other syndrome was the answer.
- **The antidote question exists on one side and is unsettled even there.** Getting the discrimination right does not hand you a drug, which is what most candidates expect it to do.
- **The disposition logic differs because the exposures differ in shape.** One typically follows an ingestion with an identifiable time zero, which is what makes a fixed observation period meaningful. The other may follow an exposure running for weeks, where a period counted from a moment has nothing to be counted from.

22.7 The order of operations, and why the antidote is a second-order decision

RULE **Supportive care takes precedence over any specific pharmacological treatment.** The clinical update of 2007 states it in those terms and gives the reason: hyperthermia and muscle rigidity are the effects that matter, and it is supportive care that prevents the secondary complications, rhabdomyolysis, renal failure and disseminated intravascular coagulation. Every question about which drug to give is therefore asked after the physical work is under way, not instead of it.

The arrival sequence itself is common to every emergency in this chapter and is set out where that sequence is taught: recognise, stabilise, establish who holds the authority to act, act, monitor, decide the destination. What is specific here is the content of the stabilise step, which the same source names as four physical interventions:

- passive cooling, and active cooling where passive measures are not keeping pace;

- sedation;
- intubation;
- muscle paralysis.

Those four are less an escalating menu than a single mechanical argument. Rigid, active muscle is the tissue producing the heat, so sedation reduces the drive to it, paralysis stops the production outright, and cooling removes what has already been made. Intubation is not a complication of that plan but a precondition for its last step, which is why it sits among supportive measures rather than among disasters. Once the chain is understood the sequence stops needing to be memorised, and the reason the antidote question sits downstream becomes obvious: no antiserotonergic agent removes heat from a patient, and heat is what causes the harm.

State the limits of that list honestly, because it stops short of several numbers a candidate will expect. No temperature at which active cooling should begin is asserted here, and no criterion for intubation, because neither could be sourced. The principle survives without them: the trigger for escalating physical treatment is the trajectory of the temperature and the presence of rigidity rather than any single reading, and the decision belongs to whoever will manage the airway. The sedative is named generically in the source and carries no dose there, so no dose, route or titration for sedation appears here either. A number invented at this point would be read as protocol, and there is no protocol behind it.

22.8 Stopping the agent, and the washout question

The first therapeutic act is a subtraction, and the same authors put cessation of the serotonergic medication alongside supportive care as the whole of what treatment should focus on. That is easy to say and routinely done incompletely, because stopping the drug that is charted is not the same as stopping the exposure. The relevant list is everything reaching the patient: what another department prescribed, what was bought without a prescription, what a relative supplied from home, and what was taken as a preparation the patient does not think of as medicine. Each entry needs a time against its last dose, because the times are what convert a list into a history.

GOOD TO REMEMBER

The exposure history is the one part of this presentation that cannot be reconstructed later. Names, doses and above all the timing of the last dose of each agent live in a relative's memory, a home strip of tablets and a chart that travels separately from the patient, and all three degrade within hours. Take it at first contact, take it in writing, and take it before the patient moves department. Record whether decontamination has been given, because it forecloses one of the treatment options discussed below.

The recovery window is the yardstick for everything afterwards: most patients improve within **24 hours** of ceasing the serotonergic medication. That figure earns its place by making an otherwise vague bedside question answerable. A patient not improving inside it has three explanations worth working through: the agent is still being absorbed or still present in quantity,

an exposure has been missed and is continuing, or the diagnosis is wrong. Each has a different next action, and none of them is to wait longer.

The reintroduction question is where this section stops. How long to wait before any serotonergic agent is restarted is not sourced here, and it plainly cannot be a single number, because it depends on the elimination of the agents involved and on which combination produced the episode. The principle is stateable and the number is not: the wait is governed by clearance of what was taken, the decision belongs to the team carrying the longer-term psychiatric care rather than to the emergency episode, and what that team is owed is a record precise enough to make the decision possible.

22.9 The cyproheptadine decision, stated honestly

This is where most accounts produce a dose, and the most authoritative statement available does the opposite. The group that derived the criteria write that although some **antiserotonergic agents** have been used in clinical practice, the preferred agent, the dose and the indications are not well defined. That sentence is the honest content of the decision. It is not a gap in this account; it is the state of the evidence, and an answer reporting it accurately is stronger than one reciting a regimen as though the question were settled.

One fact about the agent does more practical work than any regimen would, and it is a route constraint. Because **cyproheptadine** can only be given orally, it is unlikely to be effective in a patient who has been given activated charcoal, and it has limited use in severe toxicity. Follow that through and the antidote turns out to be least usable in exactly the patients who most invite the thought of using it: the patient in the severe band frequently has a compromised airway or is about to be paralysed, has often already been decontaminated, and may be vomiting, so the oral route either does not exist or cannot be trusted. The antidote is a second-order decision by construction rather than by preference, and that is a better answer than a dose.

No dose is printed here, and the reason should be given rather than left as an omission. The source most authoritative on this agent says its indications are unsettled, and printing a regimen beside that sentence would represent as protocol what is at best a practice habit. Where a dosing schedule is taught it belongs with the pharmacology of the antidepressants and not in an emergency pathway, and the division is the point: the pathway owns whether the agent has a place, the pharmacology owns what goes on the chart if it does.

22.10 Observation, disposition and what the receiving team is owed

The disposition rule has no counterpart anywhere else, and it rests on one physiological observation from the same clinical update: serotonin toxicity may increase progressively over a number of hours after ingestion. The patient assessed at the door and found well is therefore not a cleared patient but a snapshot taken early on a curve that may still be rising, and the whole logic of an observation period follows from that sentence.

Patients with moderate serotonin toxicity should be observed for **6 hours, extended to 12 hours where a slow-release formulation such as venlafaxine has been ingested**. The extension is not a safety margin added out of caution; it tracks the formulation, because a

preparation designed to release drug slowly moves the patient up that rising curve slowly as well, and a period long enough for an immediate-release ingestion simply ends before the peak.

What the period does not come with is a cadence. How often the patient is examined during it, what is measured and by whom, is not sourced here, and an interval invented at this point would read as standard when nothing establishes that it is. The principle is defensible without a number: the frequency of observation is set by how fast the patient is changing and reviewed whenever that rate changes; the examination repeated is the one that produced the finding, so if clonus was what was found, clonus is what is re-elicited rather than a set of vital signs alone; and whoever set the level of observation is named in the notes with the time, because that is the decision reviewed first if the patient deteriorates. Nor is there a sourced criterion here for fitness for discharge at the end of the period, beyond the period itself and the recovery window.

IN INDIA

An observation period is a service, not an instruction, and the two commonly come apart here. A stated period of several hours assumes somewhere with observations: a bed in an area where temperature and pulse are actually recorded at intervals, staff who read them, and someone competent to act on a change at three in the morning. A standalone psychiatric hospital often has none of that, so a patient needing the longer period after a slow-release ingestion needs it in a general hospital emergency department, which converts an observation decision into a transfer decision taken at the front door rather than six hours later. Physical treatment has the same problem, since active cooling and muscle paralysis require an anaesthetist and a monitored bed. Settle these before a patient arrives rather than during one: which medical unit accepts your escalations, whether an intensive care bed is negotiable for a patient carrying a psychiatric diagnosis, whether the pharmacy stocks an antiserotonergic agent at all, and whom you telephone when the answer is no. Record every refusal with its time, because a transfer that was sought and declined is invisible afterwards unless somebody wrote it down.

The handover is where this episode either survives or is lost, and the receiving team needs several things only the clinician who was present can supply:

- which features were sought, which were found and, explicitly, which were sought and absent, since a rule of this kind is unreadable later without the negatives;
- the exposure list with a time against the last dose of each agent, and whether a combination was involved;
- whether decontamination was given, because it removes the oral route for the antidote and changes what the next team can offer;
- the peak temperature with the time it was reached and the readings around it, so that the trajectory transfers and not just the worst value;
- the observation period chosen, the reason for the longer or shorter one, who chose it, and when it started.

Everything owned in this topic reduces to a single discipline. The rule is only as good as the examination that fed it, the severity branch is visible only to someone recording times as well as values, the recovery window is useful only to someone who knows when the drug was actually stopped, and the disposition is safe only if the place the patient is sent to does the thing the period assumes. The syndrome is named elsewhere and its pharmacology is taught elsewhere. What is decided here is whether anybody looked, when, and what they wrote down.

23 · Acute dystonia and other acute drug-induced emergencies

Why an emergency chapter carries this at all. What the reaction is, which agents provoke it, how it sits in relation to the other movement disorders of antipsychotic treatment, and the drugs that abolish it with their doses and routes are all set out in the Schizophrenia: management, antipsychotics and adverse effects notes, together with akathisia, drug-induced parkinsonism and tardive dyskinesia. None of that is repeated here. What is left over is the half that decides the outcome, and it is the half a ward improvises: whether anyone looked at the airway before the syringe was drawn, how long you are entitled to wait for the injection to work, what you do when it does not work, and why a patient whose spasm melted away in front of you can be back in casualty the same week on the same prescription. The Indian Psychiatric Society's guideline on medical emergencies associated with psychotropic medications settles the framing by classing **acute dystonia** as an emergency rather than as an adverse effect, and by attaching immediate intervention to it.

The second half of this topic is the wider class, and no chapter in these notes teaches it as a class: the acute emergencies that a psychotropic drug can produce in an organ system that is not the brain. Four of them are worth holding together, because they share one act-level spine and almost nothing else. Airway-threatening dystonia, the hypertensive crisis on a monoamine oxidase inhibitor, the severe cutaneous adverse reaction, and priapism all present to someone who is not a psychiatrist, all have a clock, and in all four the first act is not the antidote. It is stopping the drug and protecting the threatened organ while the antidote is being found.

23.1 The airway question, asked before the syringe is drawn

A dystonic reaction is usually described by where it is visible, which is why the neck and the eyes dominate the textbook picture and the throat does not. Read the same territories as an emergency map and the priority inverts. The Indian guideline maps each muscle group to the function it removes, and the **oromandibular territory** is where that mapping stops being cosmetic: most of those territories are swallow and airway problems wearing the label of a movement disorder. The guideline then singles one out from all the rest: **laryngeal dystonia** is the form that produces stridor and can be life-threatening.

United States approved labelling for a high-potency first-generation antipsychotic sets out the same escalation in the order it happens, which is more useful at the bedside than a list of sites: spasm of the neck muscles, then tightness of the throat, then difficulty swallowing, then difficulty breathing, with or without protrusion of the tongue. That ordering is what converts a dystonic reaction into an airway assessment. A patient with torticollis alone is at the first step of a

sequence a regulator has written down, and the question the first clinician answers is not whether the posture is dystonic but how far along that sequence the patient already is: can they speak in full sentences, can they swallow their own saliva, is there stridor.

The *oculogyric crisis* belongs in the same first look for a different reason. It threatens nothing anatomically, but a patient whose eyes are locked upward cannot see the person examining them, is frequently terrified, and is very often read by a busy department as behavioural disturbance or as psychosis worsening. The act does not change. What changes is who gets called, and how long the patient waits.

RULE **The first decision in an acute dystonic reaction is anatomical, not pharmacological: which territory is involved, because only some of them can obstruct.** The drug that is given is the same either way, which is exactly why the question gets skipped. What differs is the setting the injection is given in and who stays at the bedside for the next twenty minutes. A neck held to one side and a throat that is tightening are the same diagnosis and a different level of care, and the second one is not safely managed in a side room by a single nurse who has been told to call if there is a problem.

23.2 The drug that caused it is usually not on the psychiatric chart

Dopamine blockade is not confined to antipsychotics, and the drug histories that produce this emergency most often are not psychiatric ones. Current United States labelling for metoclopramide, an antiemetic, records that dystonic reactions have rarely presented as stridor and dyspnoea, attributed to **laryngospasm**. That single sentence carries two teaching points. The airway presentation is a property of dopamine antagonism rather than a property of antipsychotic drugs, so a patient who has never been prescribed a psychotropic can present with it. And the causative drug will usually not be volunteered, because the patient does not think of an anti-vomiting injection as a medicine that acts on the brain.

What this changes about the history. The useful question at the door is not what psychiatric medication the patient takes. It is what has been given or swallowed in the last few days, including in another department, including by a general practitioner, including over the counter, and specifically including anything given for vomiting or for gastric upset. In a general hospital the reaction is frequently iatrogenic within the same building and within the same shift, and the drug chart that explains it sits in a casualty file rather than in the psychiatric notes.

GOOD TO REMEMBER

When you are called to a young patient with an odd posture, an arched neck or eyes rolled upward, and the referral says the presentation is functional, hysterical or behavioural, ask one question before you examine anything: what injection or tablet was given, anywhere, in the last few days. The commonest answer that changes the diagnosis is an antiemetic. The referral being wrong is not the interesting part; the interesting part is that the reaction is still being produced by a drug that is still being prescribed on that ward for other patients.

23.3 The timed act, the repeat interval and the failure ladder

The agents used and their doses belong to the Schizophrenia: management, antipsychotics and adverse effects notes and are not printed here. What this section owns is the clock attached to them, and it is unusually well specified. The Indian guideline expects the symptoms to resolve within 15 to 20 min of the parenteral drug, and records that most patients respond to the first dose, with very few needing a second or third. That expectation is what makes the injection an assessment as well as a treatment: a reaction that has not settled inside that window is telling you something.

15 to 20 min	30 min	72 h	4 hours
EXPECTED RESOLUTION OF ACUTE DYSTONIA AFTER THE PARENTERAL DRUG, INDIAN PSYCHIATRIC SOCIETY 2022	INTERVAL AFTER THE INITIAL PARENTERAL DOSE BEFORE THE SAME DRUG IS REPEATED IN A PERSISTING EPISODE, INDIAN PSYCHIATRIC SOCIETY 2022	WINDOW WITHIN WHICH CORTICOSTEROIDS ARE PREFERABLY STARTED IN STEVENS-JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS, INDIAN DERMATOLOGY GUIDELINE 2016	ERECTION DURATION BEYOND WHICH ACUTE ISCHAEMIC PRIAPISM IS A MEDICAL EMERGENCY, AMERICAN UROLOGICAL ASSOCIATION AND SEXUAL MEDICINE SOCIETY OF NORTH AMERICA 2021

The **Indian Psychiatric Society guideline of 2022** then gives a repeat interval and a failure ladder, and the value of both is that neither contains a drug name. If the episode persists after the initial parenteral dose, the same drug may be repeated about 30 min later. If the patient has not responded to two doses, the medication is changed rather than repeated a third time. If the changed medication also fails, the instruction is to consider a diagnosis other than acute dystonia. That last rung is the one candidates omit and the one that protects the patient, because the differential at that point contains conditions that a further anticholinergic injection will not touch and may obscure.

The airway presentation is treated as a separate line in the same stepwise table, and the guideline names a different agent class as the treatment of choice for acute laryngospasm, stated to be equally efficacious with the first-line option used for dystonia generally. The agents and figures in that table cell are owned by the Schizophrenia: management, antipsychotics and adverse effects notes and are not reproduced here; what this section teaches is that the airway presentation has its own line rather than being the same treatment given more urgently. One thing the source does not give, and it should be said rather than filled in: no observation cadence is attached to that waiting period. How often the airway, the swallow and the saturation are rechecked between the first dose and the second is not specified anywhere retrieved for this section, so the interval is set locally and the principle is all that can be taught.

23.4 What runs after the spasm stops, and why discharge is a decision

The single most important thing about this emergency is that its resolution is not its end. Once the episode is managed, the Indian guideline recommends continuing anticholinergic cover for at least **24 to 48 h** specifically to avoid recurrence, and separately records that in routine Indian practice the cover is continued up to 4 to 7 days. Those are two different figures doing two different jobs, a recommended minimum and an observed habit, and they should be quoted as such rather than averaged into a single number.

Recurrence after an apparently complete response is not treatment failure. The injection that abolished the spasm is short-acting relative to the drug that caused it, so the cover falls away while the cause is still there.

The formal definition contains a limb that makes this concrete, and it is the limb most readers skip. Dystonia counts as antipsychotic-induced not only when it follows starting the drug or increasing its dose but also when it develops on reducing or removing the medication used to treat or prevent acute extrapyramidal symptoms. Stopping the cover is itself a recognised precipitant. That converts the taper from an afterthought into a planned act with a date, a person responsible for it and a warning given to the patient, which is exactly what a discharge prescription written as an open-ended supply fails to provide.

Prophylaxis is a separate decision and the guideline rules on it. Everyday prophylactic anticholinergic use is not recommended; where prophylaxis is used, three things are weighed:

- the patient's own risk factors for acute dystonia;
- the type of antipsychotic and the dose it is being used at;
- the other medications the patient is already taking.

Re-exposure is the last limb of the plan, and the hardest available anchor for it sits in regulatory text rather than in a guideline. For metoclopramide, a previous dystonic reaction to the drug is not a caution but a labelled contraindication to giving it again. That is drug-specific and must not be generalised: no equivalent labelled prohibition on antipsychotic rechallenge after a dystonic reaction was found for this section, and none is asserted. What survives generalisation is the discipline the contraindication models. A patient who has had an airway-threatening reaction to a named drug leaves with that drug named in the record as the cause, with the decision about ever giving it again recorded rather than left to whoever admits them next.

TRAP **Treating the response to the injection as the end of the episode.** The error is seductive because the response is genuinely dramatic and genuinely fast, and the patient is grateful and comfortable within the expected window. Candidates then write a management answer that finishes at resolution. What that answer omits is everything that determines whether the patient is back: the duration of continued cover, the fact that removing the cover is itself a precipitant, whether the causative drug is being continued, changed or reduced, and what the patient has been told to do if it happens again. An answer that stops at the injection has treated the spasm and not the patient.

23.5 The hypertensive crisis on a monoamine oxidase inhibitor

This crisis is the one psychiatric emergency in which the decision point sits before any measurement. The modern labelling for tranylcypromine instructs that therapy be interrupted on symptoms that may be prodromal, naming palpitations or headaches, and that the patient then be evaluated immediately. Read as an act, that means a patient who telephones with a bad headache is told to stop the drug first and be seen, not told to come in so that a blood pressure can decide the matter.

The same labelling supplies the threshold that turns a crisis into a **hypertensive emergency**: severe hypertension, given as a blood pressure of **more than 180/120 mm Hg**, together with evidence of organ dysfunction, requiring immediate attention. Having a criterion rather than an adjective matters, because it is what lets a psychiatrist hand over to a physician in terms that will be acted on. The same source requires immediate blood pressure reduction once that combination is present, and separates the temperature problem into two: fever is managed by external cooling, while hyperthermia driven by psychomotor agitation, increased neuromuscular activity or persistent seizures may need measures aimed at those causes instead. Cooling a patient whose temperature is being generated by muscle activity treats the reading and not the cause.

The act for a hypertensive crisis on a monoamine oxidase inhibitor is written out in the approved labelling for phenelzine and is unusually complete: discontinue the drug immediately, institute blood-pressure-lowering therapy immediately, give **phentolamine 5 mg** intravenously, administer it slowly so as not to produce an excessive hypotensive effect, and manage fever by external cooling. Two honest limitations belong on the page with it. The labelling requires the reduction to be immediate but names no target pressure and no ceiling on the rate of reduction, so neither is taught here. And phentolamine's own approved labelling confines its indication to the prevention or control of hypertensive episodes in phaeochromocytoma during preoperative preparation and surgical excision; crisis on a monoamine oxidase inhibitor is not among its labelled indications. The antidote recommended by one label is therefore used outside the indications of its own. A candidate who knows that is not less safe, but better prepared for the conversation with the physician who is asked to give it.

Disposition carries its own instruction, and it is the one most often lost. Patients are told to avoid high-tyramine foods and drinks while on tranylcypromine and for **2 weeks** after stopping it. This is a dietary rule that outlives the prescription, and it is a different question from the washout arithmetic used when switching antidepressants, which belongs to the Mood disorders: pharmacotherapy notes. Merging the two is how a patient gets discharged as safe on the day the tablets finish.

23.6 The severe cutaneous reaction: the three acts that are the psychiatrist's

Telling a benign drug rash from a dangerous one, and the stop-rules for the anticonvulsant mood stabilisers, belong to the Mood disorders: pharmacotherapy notes. What this section owns begins one step later, at the moment someone has decided the reaction is serious, and the psychiatrist's part in it is three acts rather than a spectator role.

The first is cessation, and the Indian dermatology guideline puts it above everything else it recommends. Instant cessation of the offending drug is of supreme importance; the earlier the causative drug is withdrawn the better the prognosis; and patients exposed to causative drugs with long half-lives have an increased risk of dying. That last clause is the one that bites in psychiatry, because several of the agents that most often cause **Stevens-Johnson syndrome and toxic epidermal necrolysis** in our patients are long-acting anticonvulsant mood stabilisers. Stopping them is not a neutral act either, which is precisely why the decision is a psychiatric one.

The second act follows from polypharmacy. Where the culprit cannot be identified, the guideline says it is generally logical to stop every drug the patient is taking, and then carves out the case that matters here: where a drug is absolutely essential, naming patients with epilepsy explicitly, it may be substituted with a structurally unrelated agent, and that decision is taken jointly with the treating clinician through an interdisciplinary approach. Choosing the structurally unrelated substitute for a patient on an anticonvulsant is work no dermatologist can do alone.

The third act is knowing what is being decided around you. For a severe cutaneous adverse reaction, meaning Stevens-Johnson syndrome and toxic epidermal necrolysis, the **Indian dermatology guideline of 2016** recommends prompt withdrawal of the culprit drug, meticulous supportive care and early systemic corticosteroids, given as prednisolone **1 to 2 mg/kg/day** or equivalent by the oral or parenteral route, preferably started within 72 h and tapered rapidly within 7 to 10 days. A psychiatrist does not prescribe that, but a psychiatrist whose patient is transferred and who does not know that the steroid decision has a window will not ask whether it was taken. The same guideline asks for an isolation room where possible, for infection and temperature control, and names the disciplines the treating team should contain: dermatologist, physician, ophthalmologist, plastic surgeon, chest physician, dietician, and others as required. One of those referrals has a cadence attached and it is the one a psychiatrist is most likely to forget: daily examination by an ophthalmologist, with vigorous treatment, reduces the risk of long-term ocular complications. A patient survives the reaction and lives with the eyes.

IN INDIA

The Indian guideline is unusual and useful in that it writes down what to do when the setting it recommends does not exist. Admission to an intensive care setting or a burns unit is preferred where such facilities are available. Where resources are limited, in a rural or district hospital, or where the patient is unfit for transfer, it accepts management in the general or dermatology ward, or in a high-dependency unit, with strict infection control and with nurses trained to deal with such cases. That is the honest architecture of this emergency in most of the country, and it converts the referral question from an ideal into a decision with two named branches. The practical consequence for a psychiatrist is that the transfer conversation is about capability rather than about category: whether the receiving ward can nurse an exposed skin surface, control infection and get an ophthalmologist to the bedside every day.

23.7 Priapism, which is a clock rather than a symptom

Priapism is the drug-induced emergency most likely to be delayed by embarrassment, on both sides of the consultation, and delay is the only variable that determines the outcome. The guideline of the American Urological Association and the Sexual Medicine Society of North America defines **acute ischaemic priapism** as prolonged, meaning more than 4 hours, with little or no cavernous blood flow and cavernous blood gases that are hypoxic, hypercarbic and acidotic, and states plainly that it is a medical emergency which may lead to cavernosal fibrosis and subsequent erectile dysfunction. The threshold and the consequence belong in the same sentence, because the consequence is what makes a four-hour threshold reasonable.

The act at the door is a test rather than a treatment. The **American Urological Association and Sexual Medicine Society of North America guideline of 2021** directs clinicians to obtain a **corporal blood gas** at the initial presentation, and records it as a clinical principle rather than as a graded recommendation. It separates the ischaemic emergency from the non-ischaemic form, which is not one, and it is what the urologist will ask for first. First-line management is then intracavernosal phenylephrine together with corporal aspiration, with or without irrigation, and the guideline places it before any operative intervention. The dose of intracavernosal phenylephrine is not stated here: the guideline places its dosing in an appendix and describes the use as off-label, and an incomplete dose is worse than a named referral.

The negative act is the one a psychiatric ward improvises when it does not recognise an emergency. In a patient with diagnosed acute ischaemic priapism the guideline states that conservative measures are unlikely to succeed and must not delay definitive therapy, naming four of them:

- observation, in the hope that it will settle;
- oral medication;
- cold compresses;
- exercise.

The act that belongs at the point of prescription. Current labelling for trazodone reports cases of priapism as painful erections greater than 6 hours in duration, warns that untreated priapism can cause irreversible damage to erectile tissue, and instructs that a man with an erection lasting greater than 4 hours, painful or not, should immediately discontinue the drug and seek emergency medical attention. Note the discrepancy inside the label itself: the reported cases are described at the longer duration, and the instruction to the patient triggers at the shorter one, which is also the guideline threshold. Teach the shorter one. The receptor pharmacology that explains why particular psychotropics do this belongs to the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; what belongs here is that the counselling sentence is part of the prescription, and that a man who has not been given it will wait until morning.

23.8 The spine the four have in common

PRESENTATION	WHAT MAKES IT AN EMERGENCY	THE FIRST ACT	WHAT FOLLOWS
Airway-threatening acute dystonia	Involvement of the laryngeal territory, which can produce stridor	Parenteral treatment, given where the airway can be watched while it works	Resolution expected within 15 to 20 min of the injection; a change of drug after two doses without response
Hypertensive crisis on a monoamine oxidase inhibitor	Blood pressure more than 180/120 mm Hg with evidence of organ dysfunction	Stop the drug and begin lowering the pressure immediately	External cooling for fever, with separate measures where agitation, neuromuscular activity or seizures are generating the heat
Stevens-Johnson syndrome and toxic epidermal necrolysis	A long half-life of the causative drug raises the risk of dying, so the interval to withdrawal is itself the emergency	Instant cessation, and all drugs stopped where the culprit is unclear	Intensive care or a burns unit where available; general or dermatology ward or a high-dependency unit where it is not
Acute ischaemic priapism	An erection lasting more than 4 hours, with the risk of cavernosal fibrosis behind it	A corporal blood gas at the initial presentation	Intracavernosal phenylephrine with corporal aspiration, before any operative intervention

Read down the columns rather than across the rows and the shape of the class appears. Every one of the four is defined as an emergency by an interval or a threshold rather than by severity of appearance; in every one the first act is available to a non-specialist; and in every one the specialist act that follows is time-bound in a way that makes the referral itself urgent. That is why these four are worth learning together even though they involve four different organ systems and four different specialties. They fail in the same place, which is the gap between recognising and acting.

MNEMONIC

Stop, Secure, Specific, Setting, Sign-off

The act-level spine of any acute drug-induced emergency. **Stop** the drug, which is the only act whose value falls with every minute of delay. **Secure** the threatened organ: the airway, the pressure, the skin and the eyes, the corpora. **Specific** intervention within its stated window, whether that is the injection, the antidote, the steroid or the aspiration. **Setting**: the level of care the next hour requires, and its named fallback where the ideal one does not exist. **Sign-off**: the causative drug named in the record and the decision about ever giving it again written down rather than left to whoever admits the patient next.

In every acute drug-induced emergency the first act is stopping the drug and protecting the threatened organ, and the episode ends not when the sign resolves but when the cover, the taper and the re-exposure decision have been written down.

24 · Lithium toxicity and overdose management

Why the marks sit on the history and not on the drug. What lithium toxicity looks like, the serum bands that grade it, the precipitants behind it and the chain ending in extracorporeal treatment are set out in the Mood disorders: pharmacotherapy notes and are not restated here. What that account does not carry is the question an emergency team settles first: not how toxic is this patient, but which of three poisonings this is. The answer is not in the assay but in a history assembled from a relative, an empty strip and an outpatient card nobody brought.

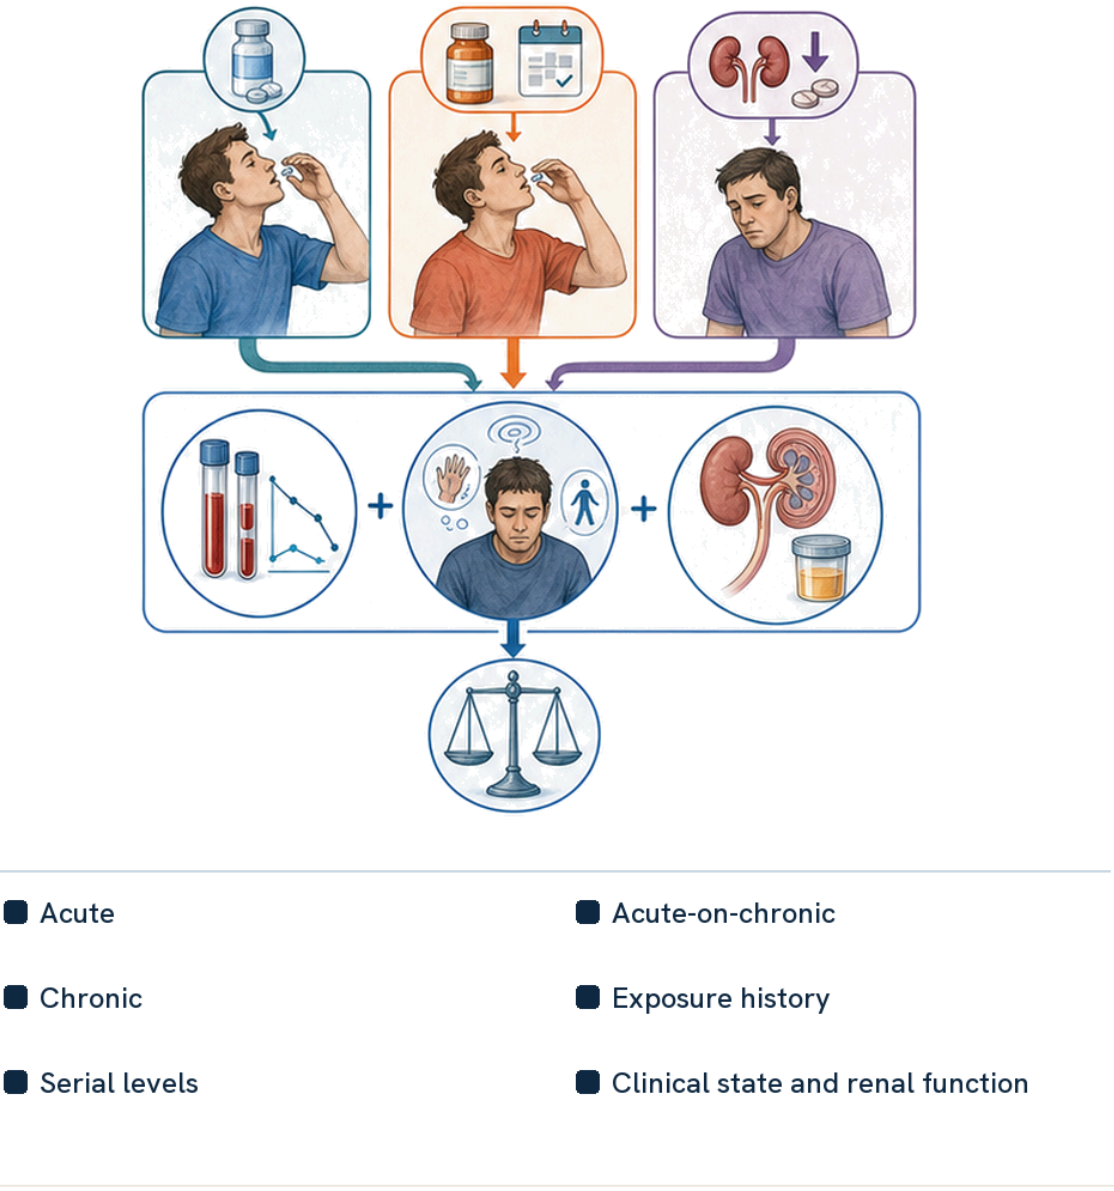

Fig 28.11 Lithium poisoning is classified from the exposure history as acute, acute-on-chronic or chronic. The pattern changes the kinetics and meaning of a measured concentration, so serial levels are interpreted with clinical state and renal function.

Three things move with it: the kinetics, the meaning of a measured concentration, and the decontamination decision, which exists in one arm and not at all in another. That last is the only point here where acting early still changes the ceiling of the illness. The ordered first-hour sequence is set out in this chapter's section on assessing and managing the acutely agitated and aggressive patient; intent after a deliberate ingestion belongs with the Somatic-symptom, sexual, impulse-control disorders and suicide notes.

24.1 Establish which of the three poisonings this is, and establish it from the history

The EXTRIP workgroup, in its 2015 systematic review of extracorporeal treatment for lithium poisoning, names **three** clinically recognised patterns and defines each by how it arose, not how it looks. **Acute lithium poisoning** occurs in a lithium-naive patient who overdoses. **Acute-on-chronic** poisoning occurs where an existing body burden from maintenance therapy meets an acute large exposure. **Chronic lithium poisoning** occurs on maintenance therapy where elimination has been compromised, by a recently increased dose, a decline in kidney function or an interacting drug; those precipitants belong to the Mood disorders: pharmacotherapy notes and appear here only because they are the definition.

The Indian Psychiatric Society's 2022 guideline on medical emergencies associated with psychotropic medications gives the same three types and controls Indian practice. It attaches a signature to each: acute manifests primarily with gastrointestinal symptoms and may progress to neuromuscular signs which usually appear after **2 to 3 days**; acute-on-chronic presents with both gastrointestinal and neurological symptoms; chronic presents primarily with neurological symptoms. It states the acute-on-chronic case separately, as long-term lithium plus an overdose taken either deliberately or accidentally. The second adverb catches teams out: an accidental overdose declares no intent, so nobody asks.

The bedside will not sort the arms out for you. EXTRIP is explicit that only the **gastrointestinal symptoms** tend to distinguish acute poisoning, where they are expected and prominent, from chronic toxicity, where they are almost invariably absent. One discriminating clause is all the examination offers, which is why this is a front-door history-taking task.

MNEMONIC

On it, on top of it, which tablet

On it: was there a maintenance body burden before today. **On top of it:** was something taken acutely as well, deliberately or accidentally. **Which tablet:** immediate-release or modified-release, because the formulation sets the absorption curve, the decontamination window and the risk after treatment.

PATTERN	HOW IT ARISES	WHAT THE HISTORY MUST ESTABLISH	WHAT A CONCENTRATION TELLS YOU	DECONTAMINATIO N
Acute	A lithium-naive patient overdoses.	No prior maintenance therapy, and when the tablets were swallowed.	Risk ahead, not harm done: the brain has not yet received what the plasma reports.	On the table. Drug may still be in the gut.
Acute-on-chronic	A patient already on long-term lithium overdoses, deliberately or accidentally.	Both halves; the second is missed when no intent is declared.	Two overlapping quantities, so the least interpretable of the three.	On the table, and the arm where timing has been studied.
Chronic	Maintenance therapy in which elimination has become compromised.	That no acute ingestion occurred, a negative that must be sought.	The population the severity grading was written for.	Not on the table. Nothing recent to remove.

24.2 Set the observation horizon from the kinetics, not from the first result

The typology changes the expected course because lithium is not a single-compartment drug. Its tissue distribution follows a **multiple compartment model** with delayed diffusion from the extracellular to the intracellular compartment; it is taken up rapidly by kidney, thyroid and bone, but its diffusion into the cerebrospinal fluid and the brain is delayed by approximately 24 hours compared with its appearance in plasma. In an acute ingestion, then, the sample in your hand reports the compartment that is not producing the illness you fear.

Clearance is equally uncooperative. The **terminal elimination half-life** is widely variable and depends on age, kidney function and duration of therapy, its upper end well beyond what a single overnight observation assumes. An identical swallowed amount in a naive young adult and in an older patient a decade into treatment is not the same exposure. The pattern therefore sets the observation horizon.

12 to 27 h	**up to 58 h**	**30 min to 2 h**
TYPICAL TERMINAL ELIMINATION HALF-LIFE OF LITHIUM	HALF-LIFE IN THE ELDERLY AND IN PATIENTS TAKING LITHIUM CHRONICALLY	PEAK CONCENTRATION AFTER THERAPEUTIC IMMEDIATE-RELEASE LITHIUM

24.3 Read the concentration as a guide to risk, never as a severity score

Candidates arrive carrying the severity grading. What is rarely taught with it is the population restriction the Indian Psychiatric Society attaches when introducing it: it is severity in patients with chronic intoxication, meaning those on long-term therapy, that the serum levels determine. The grading is a chronic-toxicity construct, never built for the acute ingestion in front of you, and the bands belong to the Mood disorders: pharmacotherapy notes.

EXTRIP supplies the mechanism that makes that restriction sensible rather than arbitrary: the delayed diffusion of lithium into the brain explains the absence or delay of symptoms in acute

poisoning despite highly elevated concentrations. Serum concentrations are therefore only a guide to potential risk of toxicity, always read against three things:

- **The history**, meaning which pattern this is and when the exposure occurred, since a rising figure and a falling one carry opposite implications.
- **The clinical findings**, meaning what the patient is doing now, and whether the neurological picture is worsening between examinations.
- **Kidney function**, which sets how fast the burden falls and whether it falls at all, and which in the chronic arm is often why the poisoning happened.

The error runs both ways, and the guideline closes the second: the toxic effects of lithium may also be seen in patients with therapeutic serum levels. A figure inside the therapeutic range is not a discharge criterion. A patient on maintenance lithium who is ataxic, coarsely tremulous and confused has a clinical problem whatever the laboratory returns, and the discrepancy is answered by disbelieving the reassurance.

RULE **The pattern comes from the history; the concentration estimates the risk ahead, not the severity in front of you.** The observation horizon, the decontamination call and the transfer threshold all follow from which arm the patient is in. The assay contributes to that decision and does not make it, and a team that waits for the result has spent the only interval in which decontamination was possible.

TRAP **Grading an acute ingestion against a scale built for chronic intoxication.** The candidate applies the grading to a lithium-naive patient who swallowed a bottle two hours ago, finds a striking figure in someone who looks well, and either panics or, worse, is reassured an hour later when that patient still looks well. Both readings ignore that the brain has not yet received the dose. The examiner is testing whether you know whose severity the grading grades.

Which of the three poisonings this is comes from the history, not the assay; the concentration then estimates the risk ahead, and grades severity only in the patient who was already taking lithium.

24.4 Reject the reflex decontaminant, and choose against the drug you are actually treating

Where the typology turns into an act. After therapeutic dosing, immediate-release lithium is almost completely absorbed and peaks early, whereas modified-release preparations peak generally at **4 to 5 hours**. Overdose does not simply scale that curve up: prolonged gastric absorption and clumping from insoluble aggregates may occur, especially with lithium carbonate, the least soluble of the lithium salts, providing a **reservoir for continued absorption**. That reservoir is why a decontamination decision exists in the two acute arms and not in the chronic one.

The first branch is the one a generic overdose protocol gets wrong, and it is the reason this topic mentions decontamination at all: **activated charcoal** is not favoured after an acute lithium overdose, for the plain reason that it does not bind lithium. That is a lithium fact and it survives

no matter what the general decontamination policy says; the current decontamination source carries the same position for lithium, and it is that source, not this one, which the overdose triage account in these notes holds. The general policy itself, including where gastric lavage now stands and what the current windows are, belongs with the medical triage of the overdose patient in these notes and is not restated here.

OPTION	WHERE THE GUIDANCE STANDS	WHOSE POSITION, AND WHEN
Activated charcoal	Not favoured after acute lithium overdose, because it does not bind lithium.	EXTRIP workgroup, 2015
Gastric lavage	May be performed if required, against a general position that it is not routine and belongs in trained hands.	EXTRIP workgroup, 2015; AACT and EAPCCT, 2013
Whole bowel irrigation with polyethylene glycol electrolyte lavage solution	May be performed if required, and separately named for substantial lithium ingestion because morbidity is high and other options are lacking.	EXTRIP workgroup, 2015; AACT and EAPCCT, 2015
Sodium polystyrene sulfonate	Suggested for this purpose, but yet to have a clearly demonstrable role.	EXTRIP workgroup, 2015

PITFALL

The commonest error is not a wrong drug but a reflex one. Charcoal given because the overdose protocol says so binds nothing here, the clock runs, and the notes record a decontamination that did not occur; with that box ticked nobody revisits the question while an option that might work is still open. Where a mixed ingestion makes charcoal right for a co-ingestant, give it for that and say so, leaving the lithium decision visibly open.

24.5 Rule whole bowel irrigation in, or rule it out before the patient rules it out for you

The joint position paper on **whole bowel irrigation**, updated in 2015, names lithium twice over. It can be considered for potentially toxic ingestions of sustained-release or enteric-coated drugs, particularly in patients presenting later than 2 h after ingestion when activated charcoal is less effective, which captures modified-release lithium by formulation; and separately for patients who have ingested substantial amounts of iron, lithium or potassium, because morbidity is high and other effective options are lacking, which captures it by name. The same paper records what makes it unavailable:

- **Bowel obstruction, perforation or ileus**, a mechanical bar to committing litres of solution to a gut that cannot move them.
- **Haemodynamic instability**, since the procedure is neither brief nor undemanding and an unstable patient needs the team elsewhere.

- **A compromised unprotected airway**, for lithium the contraindication with teeth, since the neurotoxicity itself is what produces it.

That last gives the decision its expiry date. A patient far enough into lithium neurotoxicity to be obtunded is by that fact no longer a candidate for the decontamination that could have helped an hour earlier. The option closes as the illness advances, which inverts the instinct to wait and see how bad this becomes: waiting removes the intervention. One thing is deliberately not asserted here. The volume and rate at which the polyethylene glycol solution is run, and the amount of sodium polystyrene sulfonate, come from the receiving unit's poisons protocol, and no figure for either is asserted.

IN INDIA

The typology gets settled at the door in most Indian emergency rooms whether the team intends it or not, because serum lithium is often a send-out assay returning after the decontamination window has closed. That is not a reason to defer the decision; it is why the history is the instrument. Whole bowel irrigation is also a staffing question before a clinical one: a nasogastric tube, a large volume of solution, a nurse to keep it running and an airway-capable clinician are rarely available together at night in a district hospital. Where they are not, what remains is early transfer, decided on the pattern and the clock.

24.6 Treat the decontamination decision as a timed one, and know how contested it is

The evidence is thin and divided, and presenting it as settled overstates it. EXTRIP records that gastric lavage or whole bowel irrigation may be performed if required, while stating in the same breath that there are no data to show improved outcome with any decontamination procedure. Against that sits the one cohort assembled inside this typology, a retrospective observational study from the Angers Poisons and Toxicovigilance Centre, published in 2013, which took acute-on-chronic overdoses and divided them into those undergoing **early decontamination**, by sodium polystyrene sulphonate or whole bowel irrigation or both, and those in whom decontamination was delayed beyond **12 h** or not performed.

On multivariate analysis, early digestive tract decontamination was significantly associated with a lower risk of severe poisoning, with an odds ratio of 0.21, a 95 per cent confidence interval of 0.04 to 0.99 and a p value of 0.049, and the association held regardless of the lithium dose ingested or the serum concentration. Read the caveats with the estimate: a retrospective design, so those decontaminated early may simply be those who arrived early; an interval that nearly crosses one; a single centre. What survives is the final clause: any benefit was independent of dose and of concentration, which describes the shape of the decision rather than its size.

GOOD TO REMEMBER

Establish the formulation before the evidence of it disappears. Ask the family to bring the strip, the bottle or the outpatient card, and ask whether the preparation was modified-release, because the answer changes the absorption curve, the case for irrigating rather than lavaging, and the risk in the hours after treatment. None of it can be reconstructed from a serum concentration.

24.7 Plan the period after treatment from the formulation that was swallowed

The typology has one more consequence, and it falls after the intervention rather than before it. EXTRIP distinguishes two kinds of rebound following extracorporeal treatment, and the one that concerns an emergency team is **rebound from ongoing absorption**. It occurs with extended-release formulations or decreased gastrointestinal motility, can be noticeably much greater in extent, and may be associated with recurrence of symptoms or clinical deterioration, because the absorbed drug will ultimately distribute into the central nervous system and other tissues. The indications for extracorporeal treatment are taught in the Mood disorders: pharmacotherapy notes; the corollary belongs here, that a good result at the end of a session does not close the episode.

This is where the arms separate for good. The chronic patient's burden is a distribution problem, and it descends predictably once the precipitant is corrected; the modified-release ingestion carries a second event in the gut whose timing nobody can specify, and the monitoring plan is written for that. Disposition is not answered by one improving result.

The handover carries the same content. A patient handed over as lithium toxicity with a number attached has been handed over with the least useful part of the assessment. Handed over as an acute-on-chronic ingestion of a modified-release preparation taken at a stated hour, decontaminated or explicitly not and why, tells the receiving team what to do next. The typology is not a classification appended to the case. It is the case.

25 · Anticholinergic toxicity and other psychotropic overdose syndromes

Why the marks sit on the act and not on the picture. What anticholinergic toxicity looks like, and how an antimuscarinic overdose is told from the other hyperthermic emergencies, belongs to the Schizophrenia: management, antipsychotics and adverse effects notes, and none of that is repeated here. Those accounts reduce the antidote to one clause: physostigmine, for specialist hands. What follows recognition is owned here: whether an antidote question has arisen, what is read before the drug is drawn up, who it must be refused to, and what is done instead.

The organising fact is an overlap: the commonest deliberate overdose presenting as antimuscarinic is a tricyclic antidepressant, which is also the overdose in which this antidote has killed people. So the first act is not pharmacological but an electrocardiogram.

25.1 Deciding whether an antidote question has arisen at all

The labelled indication is narrower than the drug's reputation. The United States prescribing information for **physostigmine salicylate injection**, in the label version updated in January 2023, indicates it to reverse the effect upon the central nervous system caused by clinical or toxic dosages of drugs capable of producing the anticholinergic syndrome. The operative word is central. A patient with peripheral effects alone, awake and oriented, is not what the indication describes.

Nor is the agent interchangeable with what a pharmacy is likelier to stock. Physostigmine contains a tertiary amine and penetrates the blood brain barrier easily, whereas **neostigmine**

carries a quaternary ammonium ion and cannot cross it.

RULE **The antidote decision in an antimuscarinic overdose is made on the agent, the electrocardiogram and the contraindication list, never on how antimuscarinic the patient looks.** Recognition names the family of poisons, not the member, and members diverge on whether this drug helps or kills. Where a tricyclic or other sodium-channel-blocking agent is known or suspected, physostigmine is refused whatever the current QRS, because a narrow complex early does not exclude progression.

25.2 Reading the electrocardiogram before anything is given

A prospective study of 49 patients with acute tricyclic antidepressant overdose, in the New England Journal of Medicine in 1985, set serum drug levels against **maximal limb-lead QRS duration** as predictors of seizures and ventricular arrhythmias. It concluded that QRS duration predicts the risk of seizures and ventricular arrhythmias while serum drug levels are not of predictive value. Where a level cannot be had in useful time, that is what makes it usable.

Among the 13 patients whose maximal limb-lead QRS duration was less than **0.10 second** there were no seizures and no ventricular arrhythmias; among the 36 whose duration was 0.10 second or longer, seizures occurred in 34 per cent and ventricular arrhythmias in 14 per cent. The consequences then part company: seizures occurred at any QRS duration of 0.10 second or longer, while ventricular arrhythmias were seen only from **0.16 second** or longer. Collapsing them into one figure loses the point: the bed is earned at the lower line, the arrhythmia arrives at the upper.

The American Heart Association focused update on poisoning of 2023 states that characteristic electrocardiogram changes usually precede ventricular dysrhythmias in sodium channel blocker poisoning, and names two: intraventricular conduction delay, meaning QRS prolongation, and a terminal rightward axis deviation best appreciated in lead aVR. Precede is what makes a tracing a triage instrument rather than a record.

TRAP **Giving physostigmine because the presentation is antimuscarinic, when what was taken was a tricyclic antidepressant.** The report that changed practice, in Annals of Emergency Medicine in 1980, described two patients with tricyclic antidepressant toxicity who developed asystole after physostigmine was given to treat seizures, when the drug was a commonly used therapy for the antimuscarinic manifestations of tricyclic overdose. The tracing separates them first.

25.3 Giving sodium bicarbonate, and knowing when to stop

Where the QRS is wide the act is **sodium bicarbonate**, which the same guideline names the intervention with the most evidence in sodium channel blocker poisoning, typically given as bolus intravenous administration of hypertonic solutions, 1000 mEq per litre in adults and 500 mEq per litre in children. Its antidote table completes the tuple: for sodium channel blockers and cocaine, an initial adult dose of 50 to 150 mEq and an initial paediatric dose of 1 to 3 mEq per kilogram, with a maintenance infusion prepared as a 150 mEq per litre solution and infused at 1

to 3 millilitres per kilogram per hour, by the intravenous or intraosseous route, watching for hypernatraemia, alkalaemia, hypokalaemia and hypochloraemia.

What makes it an act rather than a prescription is the endpoint. Boluses are titrated to resolution of hypotension and of QRS prolongation, so the monitor stops treatment, not a cumulative total, and whether to follow them with an infusion is unsettled. Two ceilings then make it a monitored infusion: serum sodium is not to exceed 150 to 155 mEq per litre and serum pH is not to exceed 7.50 to 7.55. Potassium is replaced during treatment, since hypertonic bicarbonate causes hypokalaemia.

The antidote table's footnote belongs in any answer printing a dose: the maximum paediatric dose should not exceed the adult dose, most antidotes should be repeated frequently and titrated to control of critical signs and symptoms, and the ideal dose of most antidotes is not known and is often controversial.

25.4 Reading the contraindication list before the syringe is filled

It is printed whole, because a partial contraindication list is more dangerous than none. Physostigmine salicylate injection should not be used in the presence of asthma, gangrene, diabetes, cardiovascular disease, mechanical obstruction of the intestine or urogenital tract, or any vagotonic state, and not in patients receiving choline esters or depolarising neuromuscular blocking agents, decamethonium and succinylcholine being named.

One clause carries almost all the mortality. **Cardiovascular disease** bars the drug in exactly the patient in whom the reflex to give it is strongest, because a poisoning that disturbs cardiac conduction presents as antimuscarinic at the same time.

The product record for this label also carries the marketing status of an unapproved drug, with a disclaimer that the drug has not been found by the regulator to be safe and effective and that the labelling has not been approved. It is the best primary statement of how to give the drug, and not an approval.

25.5 Pushing the drug slowly, and keeping its own antidote at hand

For overdose of drugs that cause anticholinergic effects the label gives physostigmine salicylate injection **2.0 mg** intramuscularly or intravenously at a slow controlled rate, repeatable if life-threatening signs such as arrhythmia, convulsions or coma occur. The repeat trigger is a sign, not a clock. The label's repeat interval of 10 to 30 minutes if the desired patient response is not obtained attaches to its post-anaesthesia indication, which carries a smaller amount; carrying it into a poisoning is a common transcription error.

The rate is the safety-critical figure and it governs the antimuscarinic-overdose dose too. In this poisoning as in every other indication the label carries, intravenous administration is to be at a slow controlled rate of **no more than 1 mg per minute**, and the reason belongs beside the syringe: rapid administration can cause bradycardia, hypersalivation leading to respiratory difficulty, and convulsions. Each converts a reversible delirium into an airway emergency.

Two preconditions remain. Because of the possibility of hypersensitivity in an occasional patient, atropine sulfate injection should always be at hand, since it is the antagonist and antidote for physostigmine, so the drug is not given anywhere its own antidote is not already drawn up. And overdose of physostigmine can cause a **cholinergic crisis**, for which the appropriate antidote is atropine sulfate, so one ampoule answers both.

> **GOOD TO REMEMBER**
>
> Write the clock time of the dose, the rate it was given over, and the time of the examination that follows. Without those three, bradycardia gets blamed on the poison rather than on the push, and recurrence reads as deterioration rather than as expected.

25.6 The airway question that gates decontamination in this poisoning

Whether gastric decontamination is worth attempting at all, which poisons are worth adsorbing, and for how long after ingestion each window stays open, is settled with the medical triage of the overdose patient elsewhere in these notes, and none of it is restated here: the windows are poison-specific, they have moved, and a chapter that fixes them in two places will eventually print them differently. What belongs to this topic is the question that gates the act whatever the window says. Charcoal is not given to a patient whose airway is unprotected, and in an antimuscarinic overdose the relevant limb is prospective as well as present: a patient whose protective reflexes are at risk, or can be expected to become absent as the toxidrome advances, is a patient in whom the decision has already been made against. The airway question here is answered by where the patient is heading rather than by where they are, so a decision deferred while the toxidrome advances is usually a decision made. For an agitated patient that usually settles it.

Three questions settle it at the door:

- is the airway intact or protected now, by somebody who can keep it so if the patient vomits;
- how long since ingestion, counted from a stated time not from arrival, and is that past the measured window;
- does charcoal now foreclose something better later, since the oral route is spent afterwards.

FINDING THAT FORCES A DECISION	ACT IT SELECTS	WHAT MUST BE TRUE FIRST	WHAT ENDS IT
Antimuscarinic exposure, consciousness disturbed, tracing clear, and no tricyclic or other sodium-channel-blocking agent known or suspected	Physostigmine considered	Contraindications read and clear, atropine drawn up, somewhere the patient is watched. A tracing is clear only if the QRS is inside the seizure line AND there is no terminal rightward axis in aVR, on a tracing repeated rather than taken once	Orientation returns, then a watch for recurrence
Peripheral effects only, patient oriented	No antidote, recorded as a decision	Conscious level assessed, not inferred	Nothing to end. Observe
QRS past the seizure line after a tricyclic ingestion	Bicarbonate bolus, physostigmine refused	Access, monitoring, and sodium, potassium and pH measurable on site	Hypotension and QRS prolongation resolve, inside the two ceilings
QRS past the arrhythmia line	The same act in a monitored bed, critical care in early	That the bed exists and was agreed beforehand	The same endpoint, and care not stepped down as the tracing narrows
A charcoal-adsorbable ingestion, inside the window that poison and formulation actually carry	Activated charcoal considered, per the overdose triage account	An intact or protected airway, and reflexes not expected to fail. If either is in doubt, the decision is made for you	Given per the regimen that account sets, never assumed to be a single dose

25.7 Holding the patient when the antidote is refused or unavailable

What the comparison against sedation showed. A blinded randomised trial in Clinical Toxicology in 2021 enrolled patients aged at least 10 and under 18 with at least one central and two peripheral antimuscarinic symptoms, together with delirium and moderate agitation, an adolescent population, not an adult one. Its physostigmine arm received a 0.02 mg per kilogram bolus followed by a four hour infusion at 0.02 mg per kilogram per hour, in adolescents. Physostigmine was superior to the benzodiazepine comparator in controlling delirium and agitation after bolus dosing and in controlling delirium at the fourth hour of infusion, with no serious adverse events in either arm, and the authors confined their recommendation to adolescent patients. The trial was small and its arm sizes are not asserted here.

Two things are deliberately absent. There is no sedative agent, dose, route or titration for the agitation: benzodiazepine dosing in the emergency belongs to the Schizophrenia: management, antipsychotics and adverse effects notes. Nor is there a temperature threshold at which cooling begins, a method or a target: no comparable standard is available to quote, and none is invented here. Heat here is generated by agitation in someone whose thermoregulation the poison has impaired, so sedation is a temperature intervention as well as a behavioural one, and what is charted is temperatures with times against them.

25.8 What changes at the door in the other psychotropic overdoses

The title of this topic promises more than one poison, and the promise is kept as acts rather than as a second toxidrome. Most psychotropic overdoses have no antidote of any kind, which makes what is examinable in each narrower and more useful than a picture: whether an antidote question arises at all, which single measurement selects the next act, and which reflexive act is refused.

For the serotonergic antidepressants the antidote limb closes at the first line. The approved product information for a **selective serotonin reuptake inhibitor** states that there are no specific antidotes to it, and directs instead an airway established and maintained, oxygenation and ventilation ensured where necessary, and general symptomatic and supportive measures; induction of emesis is not recommended. The measurement that does the work is the tracing. QTc prolongation and torsade de pointes have been reported following overdose, so electrocardiogram monitoring is recommended in all ingestions of it. In all ingestions is the phrase to hold: the tracing is not reserved for the patient who looks unwell, which is what makes it a triage instrument in a poisoning that has nothing else.

The negative act here is what separates this overdose from the one taught with the lithium toxicity account in these notes. Because the volume of distribution is large, forced diuresis, dialysis, haemoperfusion and exchange transfusion are unlikely to be of benefit. In the lithium overdose the decision at the door is precisely about elimination and level of care. Same word, opposite act, and the reason is pharmacokinetic and stated by the regulator rather than reasoned at the bedside. Where a second serotonergic agent is on board the question stops being overdose management altogether and becomes the serotonin toxicity decision rule, which the Hunter criteria account in these notes owns.

For the antipsychotics the shape repeats and the refusal is sharper. There is no specific antidote, and induction of emesis is not recommended. Cardiovascular monitoring is necessary to detect possible arrhythmias, and close medical supervision and monitoring continue until the patient recovers, so here too the stopping rule is the patient and not a clock.

RULE **In an antipsychotic overdose that becomes hypotensive, adrenaline, dopamine and the other beta-agonist sympathomimetics are refused.** The approved product information directs treatment of hypotension and circulatory collapse and support of respiratory function, then states the bar in terms: those agents are not to be used, since beta stimulation may worsen the hypotension. It is a refusal and not a caution, and it names what a team reaching for a pressor reaches for first. No alternative pressor is recommended by the source and none is asserted here.

Nor is an antipsychotic overdose finished when the patient wakes. Neuroleptic malignant syndrome is listed among the medically significant sequelae of overdose, alongside delirium, convulsion, coma, respiratory depression, aspiration, blood pressure disturbed in either direction, cardiac arrhythmia and cardiopulmonary arrest. The consequence is a disposition one: the criteria set taught elsewhere in these notes can become the relevant instrument hours after the overdose itself has been survived.

The remaining members of the class are held elsewhere on this chapter and are named here so that nobody is sent looking:

- the benzodiazepine overdose, its reversal agent, and why that agent is not routine in an undifferentiated ingestion, with the medical triage of the overdose patient;
- the mixed or unidentified ingestion, and the overdoses whose early appearance is deceptively benign, with the same account;
- lithium, with the lithium toxicity account, where the ingestion typology governs the kinetics and the elimination decision;
- serotonin toxicity, with the Hunter criteria account, which owns the decision rule and the antidote question that follows it;
- the tricyclic antidepressant, which is the rest of this topic and the one member of the class in which an antidote decision is both live and lethal.

25.9 Deciding where the patient goes, and for how long

Disposition follows from one pharmacological fact. Reversal can be expected within minutes of intravenous administration if the diagnosis is correct and the patient has not suffered anoxia or other insult, but the duration of action of physostigmine is relatively short, approximately **45 to 60 minutes**. The agents reversed outlast that, so recurrence is expected rather than a complication, and one dose is a diagnostic and temporary act. A failure to respond is informative: either the patient was not antimuscarinic, or something the antidote cannot touch has done harm.

The antidote therefore changes a disposition, and there is evidence on which one. A single-hospital retrospective chart review in Annals of Pharmacotherapy in 2019 found no difference between groups in age, sex or initial heart rate, and concluded that physostigmine use was associated with decreased resource utilisation, including intubation and intensive care placement, without increasing rates of bradycardia, vomiting or seizures. Retrospective, single-centre and unblinded, it gives a direction and not a cause.

141	46%	32%	20%
PATIENTS WITH AN ANTIMUSCARINIC TOXIDROME IN THE SINGLE-HOSPITAL REVIEW	PROPORTION OF THAT COHORT GIVEN PHYSOSTIGMINE	PROPORTION OF THAT COHORT ADMITTED TO INTENSIVE CARE	PROPORTION OF THAT COHORT INTUBATED

Whether the drug can be had is a separate question. A series in the American Journal of Emergency Medicine in 2025 records that supply of physostigmine has been limited because the United States manufacturer stopped production, and proposes **rivastigmine**, a long-acting acetylcholinesterase inhibitor approved for dementia, as a potential alternative. Read that as a signal about scarcity, not a substitution you may make: no dose or regimen is asserted here.

IN INDIA

Physostigmine does not appear in the antidote section of the National List of Essential Medicines 2022, whose specific antidote list begins with atropine, calcium gluconate, D-penicillamine, desferrioxamine and methylthioninium chloride and continues to N-acetylcysteine, naloxone, neostigmine, pralidoxime chloride, snake venom antiserum, sodium nitrite and sodium thiosulphate, while activated charcoal is the sole entry under non-specific measures. The local position is exact: the antidote's own antidote is on that list, the anticholinesterase that cannot reach the brain is on it, and the drug itself is not. So the antidote limb usually ends in a decision about a drug that is not in the building. What is scarce is not a molecule but a monitored bed with an anaesthetist attached. Settle in advance which medical unit accepts a wide-QRS poisoning and whom you telephone when the answer is no, and record each refusal with its time.

Three things belong in the handover, which only the clinician present can supply:

- the tracings in sequence with times, since direction of change matters more than any width;
- whether physostigmine was given, refused or unavailable and on which ground, so a cardiovascular refusal is not quietly reversed by a fresh team;
- whether decontamination was given and when, since it changes what can be offered by mouth.

Read the electrocardiogram and the contraindication list before physostigmine is drawn up, keep atropine beside it, give it no faster than the label allows, and treat one dose as an act that wears off before the poison does.

The medical emergency and the perinatal overlay

26 · Delirium triage and emergency management

Why the marks sit on the first ten minutes. What acute confusion is, how it is defined, separated from its mimics, investigated and prevented is set out in the Stroke, TBI, delirium and focal brain syndromes notes, and none of that is repeated here. That account, like almost every account in the literature, is written from the ward and the intensive care unit, and assumes a patient already recognised, admitted and labelled. This topic covers the window before any of that is true: an elderly man is brought in by relatives who say he has not been himself since morning, and nobody yet knows whether the answer is metabolic, a drug, a head injury, an infection or a psychiatric illness. What is done in that window, in what order, by whom, and where he goes at the end of it is a different object from the syndrome.

Two features make this a discipline of its own. Nothing is differentiated yet, so every act must be justifiable without a diagnosis; and the department is a throughput system with a queue, in which a quietly confused patient makes no demand at all. The general shape of the first hour, and the assessment of the patient who arrives agitated or aggressive, are taught where that assessment is set out in these notes. What follows takes the confused patient through it, built around acts rather than causes.

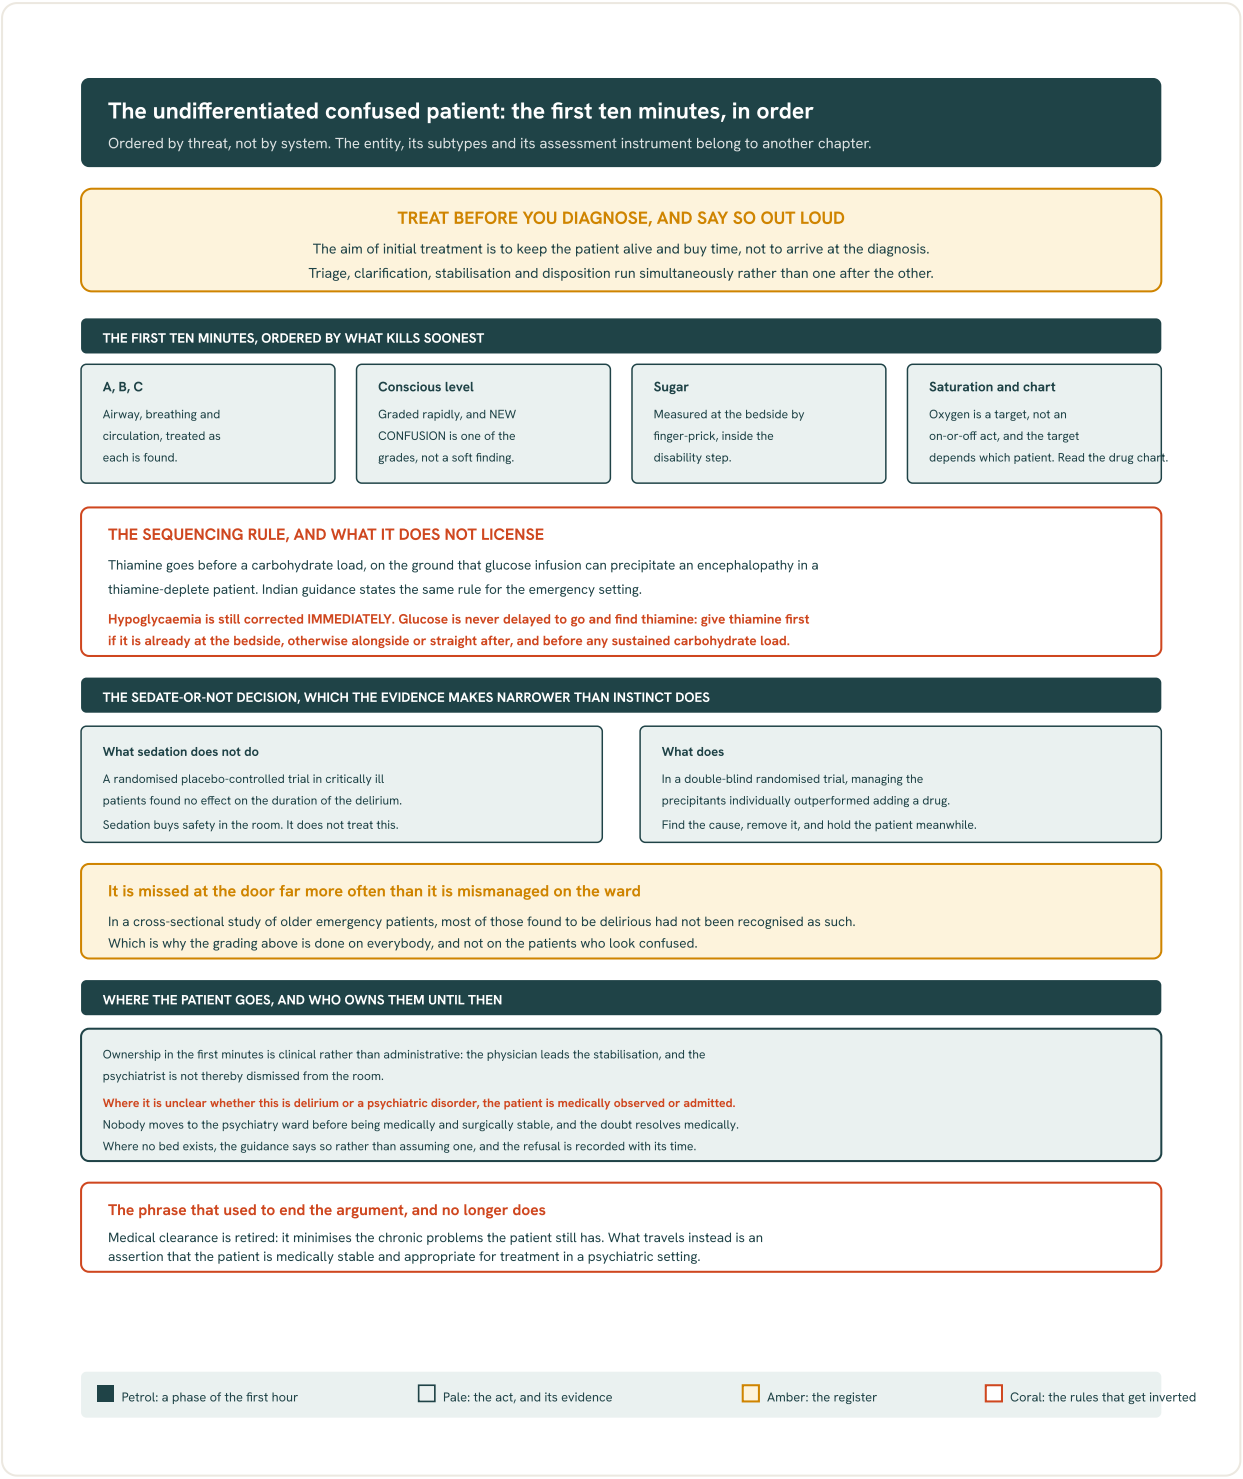

Fig 28.12. The undifferentiated confused patient at the front door drawn as a timed sequence ordered by threat, with conscious level, blood sugar, oxygen saturation and the drug chart taken in the first ten minutes, the thiamine and carbohydrate sequencing rule stated as a rule together with the correction that hypoglycaemia is never left waiting for it, the sedate-or-not decision set against the trial evidence on either side, and the disposition rule that doubt between delirium and a psychiatric disorder resolves towards the medical bed.

26.1 Recognising confusion at the door, and how often it is not recognised

The warrant for treating this as a separate skill is that the front door is where confusion is most reliably lost. In a cross-sectional study published in Academic Emergency Medicine in 2009 by Han and colleagues, a convenience sample of emergency department patients aged sixty-five and over in a single tertiary care academic centre in the United States was assessed formally, and the

result compared with the treating emergency physician's own conclusion. The great majority of those who were delirious had not been recognised as delirious by that physician.

19 of 25	76.0%	54.9 to 90.6%
DELIRIOUS OLDER EMERGENCY DEPARTMENT PATIENTS NOT RECOGNISED AS DELIRIOUS BY THE EMERGENCY PHYSICIAN	THAT UNRECOGNISED PROPORTION, IN A SINGLE TERTIARY CARE ACADEMIC EMERGENCY DEPARTMENT	95 PER CENT CONFIDENCE INTERVAL AROUND THE UNRECOGNISED PROPORTION

Read the estimate honestly: one department, one convenience sample, a small numerator and a wide interval. What is secure is a direction and an order of magnitude, not a precise failure rate, and the direction is the justification for the topic.

The reasons are structural rather than a matter of individual carelessness. Confusion without agitation makes no noise, and a system that allocates attention by noise allocates none to it; the history that would establish an acute change from baseline is not in the patient but in the relative sent to the registration counter; and the vital signs chart has no field into which a change in thinking can be written unless somebody creates one.

26.2 Treating what will kill the patient before naming what is wrong

Assessment of the undifferentiated patient is ordered by threat rather than by diagnosis. In **the ABCDE approach**, set out by the Resuscitation Council UK and last updated in 2024, the stated underlying principles carry the whole front-door lens. Each life-threatening problem is treated at the point in the assessment where it is found, before the assessment moves on. The effect of that treatment is then assessed rather than assumed. And the need for extra help is recognised and called for early, rather than once the assessment is complete.

RULE **Treat the life-threatening problem at the moment you find it and then reassess; do not carry it forward to the end of the assessment.** A candidate trained to take a history, examine, formulate and then act will complete the survey before intervening, because every clinical method they have been examined on is built that way. In an undifferentiated patient that is the wrong order: the problems which kill in the first minutes are the ones correctable in the first minutes, and each window closes while the survey goes on.

The same source states the aim of initial treatment explicitly, and it is worth quoting to yourself when a senior colleague asks what you think is going on: the aim is to keep the patient alive and achieve some clinical improvement, and doing so buys time for further treatment and for making a diagnosis. The diagnosis is not the first task and is not delayed by stabilisation; it is what stabilisation makes possible. And because every act here is justified by threat rather than by diagnosis, none of it is invalidated when the diagnosis turns out to be psychiatric; whereas deferring a correctable physiological problem because the presentation looked psychiatric is indefensible on any account of what happened.

26.3 Deciding who owns the patient, and running the first hour in parallel

Ownership in the first minutes is a clinical question, not an administrative one, because a patient who belongs to nobody is a patient in whom every act waits for a conversation. In the Indian Psychiatric Society's 2023 clinical practice guidelines on elderly patients presenting with

psychiatric emergencies, first importance in clinical stabilisation is given to airway, breathing and circulation, and the physician rather than the psychiatrist should primarily do this. The psychiatrist is not thereby dismissed from the room: the psychiatric contribution in that window is to manage the psychiatric manifestations that would otherwise obstruct physical stabilisation, since a patient pulling out a cannula or striking at the person taking blood is one in whom the physician cannot proceed.

The same guidance corrects a second misunderstanding: the measures of an emergency episode are carried out almost simultaneously rather than sequentially. A chapter that presents the first hour as a numbered list teaches it wrongly, because a numbered list implies each step waits for the one before it.

- **Triage and prioritisation**, beginning the moment the patient is inside the door and not when a bed is found.
- **Diagnostic clarification and clinical stabilisation**, each informing the other.
- **Patient safety and prescribing decisions**, taken while the physiology is still being corrected.
- **Briefing the family**, who in Indian practice are the history, the consent conversation and often the observation, and can supply none of it from the corridor.
- **Monitoring and the treatment-setting decision**, formed from the first minute and not announced at the end.

The work is therefore distributed rather than serialised, and the commonest reason a confused patient waits is that one clinician has taken all of it on and is doing it in sequence.

> **GOOD TO REMEMBER**
>
> When acts run in parallel, the record is the only thing that can reconstruct them afterwards. Write the clock time beside each act and the reassessment that followed it: the time the sugar was taken and its value, the time glucose was given and the conscious level afterwards. The instruction to assess the effects of treatment is unverifiable without it.

26.4 Triaging the confused patient: managing the environment as the first intervention

Triage is usually taught as a sorting decision made at a desk, determining how long somebody waits. For the confused older patient it is better understood as the first clinical intervention, because the environment the patient is placed in changes the presentation before any drug is given. Indian guidance is the one source here that describes the act concretely rather than merely naming it, and the five measures it names are worth learning as a set.

- **Reduce the waiting time.** Waiting is unstructured time in an unfamiliar place with nobody attached to the patient, and it worsens both the presentation and the assessment.
- **Ensure the patient's physical comfort.** Pain, a full bladder, cold, thirst and an uncomfortable trolley are all correctable, and all are commonly read as agitation belonging to the illness.
- **Reduce external stimuli.** The department is bright, loud and continuously in motion, which is the environment a disturbed sensorium handles worst.

- **Manage the patient in an isolation room where possible.** A single-patient space for the patient's benefit, not a segregation measure; the qualification is in the guidance itself.
- **Ensure there are no potentially dangerous objects in the treatment setting.** Done to the room before the patient arrives in it, not to the patient after something has happened.

These are interventions with an expected effect, not courtesies. A patient who settles once the lights are lowered and the bladder is emptied has told you something clinically useful, without a sedative and without confounding the neurological examination that follows. The environment is also the only intervention deliverable before the patient is assessed, which is why it belongs to triage rather than management.

26.5 Grading conscious level inside the primary survey

The single change that most improves recognition costs nothing and takes seconds: conscious level is graded during the primary survey, in the same pass as airway, breathing and circulation, and new confusion is one of the available grades. The Resuscitation Council UK approach makes a rapid initial assessment of conscious level by the **ACVPU** method, and offers the Glasgow Coma Scale as the alternative.

- **Alert.** Awake and engaged, with no qualifier attached.
- **Newly Confused.** A grade in its own right, and the one that matters here, because it gives the emergency chart a place to record disordered thinking at the moment it is noticed.
- **Responding to Vocal stimuli.** Not spontaneously awake, but rousable by voice.
- **Responding to Painful stimuli.** The stimulus the guidance names is supra-orbital pressure, applied at the supraorbital notch.
- **Unresponsive** to all stimuli.

For a psychiatric reader the placement matters more than the letters. New confusion is recorded inside the primary survey, alongside airway and circulation, not deferred to a mental state examination performed later by somebody else. That puts the observation in the hands of whoever meets the patient first; it timestamps the finding, so a later deterioration has an earlier grade to be a deterioration from; and it makes the observation part of the physiological record rather than the psychiatric one, which is what stops it being filed as somebody else's business.

The word new cannot be verified from the patient: establishing it requires somebody who knew the patient last week, which in an Indian department is the attendant in the corridor, so obtaining that comparison is part of grading the level, not a separate exercise afterwards.

26.6 Excluding reversible causes as a timed act rather than a list

Every textbook lists the reversible causes of an acute confusional state, and candidates reproduce the list well. What it does not carry is what makes it usable in an emergency: each item has a specific act, a specific moment at which that act must happen, and a specific result that looks reassuring and is not. Reorganised that way it becomes a sequence to be performed rather than a taxonomy to be recalled. The acts below are those the primary survey contains; the wider aetiological workup belongs to the Stroke, TBI, delirium and focal brain syndromes notes.

THE ACT AT THE DOOR	WHAT IT IS LOOKING FOR	WHY IT IS TIMED, NOT MERELY LISTED	THE RESULT THAT MUST NOT REASSURE YOU
Grade the conscious level	New confusion as a recorded grade rather than an impression	Taken inside the primary survey, so it exists before any history or label	An impression of alertness in a patient never actually graded
Measure the blood glucose at the bedside	Hypoglycaemia, correctable within a minute and lethal if left	The correction is given where the result appears, not after the survey	A normal finger-prick in a shut-down or peri-arrest patient, where the method is unreliable
Set the oxygen target, then give oxygen	Hypoxaemia, and the wrong target for this patient	The target is chosen when oxygen is started, and both errors follow that decision	A saturation inside the general target in a patient at risk of hypercapnic respiratory failure
Order thiamine and carbohydrate correctly	The patient in whom giving glucose is not a neutral act	Thiamine first if it is already at the bedside, otherwise with or straight after the glucose, and always before any sustained carbohydrate load	A low sugar treated as a self-contained problem with a self-contained answer
Read the drug chart and reverse what is reversible	Depressed consciousness that has a specific antagonist	An antagonist not given in this window is usually not given at all	A plausible psychiatric or social explanation that quietly ends the search

MNEMONIC

Conscious level, Sugar, Saturation, Chart

What is done at the bedside before anyone commits to a diagnosis: **Level** of consciousness graded inside the primary survey, blood **Sugar** measured and corrected where low, oxygen **Saturation** measured against a target chosen for this patient, and the drug **Chart** read for a reversible drug cause. The thiamine sequencing rule sits inside the sugar step.

26.7 Measuring the blood sugar, and knowing when not to believe it

Blood glucose is measured to exclude hypoglycaemia by a rapid finger-prick bedside method, inside the primary survey rather than in the batch of blood sent afterwards. The reason is arithmetic about time: hypoglycaemia is the fastest exclusion on the list, and a process that defers it to a laboratory result has spent an hour on it.

The correction follows local protocols, and the worked example the Resuscitation Council UK gives is a complete instruction rather than a bare number: in an unconscious patient whose blood sugar is **less than 4.0 mmol/L**, an initial dose of **50 mL** of 10 per cent glucose solution is given intravenously. Note what that threshold is and is not. It is a treatment threshold for hypoglycaemia in an unconscious patient at the front door, not a diagnostic band for any

psychiatric syndrome; it does not define a level below which confusion is explained, and a patient whose sugar sits above it has not acquired an alternative diagnosis.

The caveat attached to the method is the part most often dropped in reproduction, and it matters most in the sickest patients. In a **peri-arrest** patient a venous or arterial sample is used instead, because finger-prick glucose measurements can be unreliable in sick patients. The reason: a finger-prick samples capillary blood from a peripheral bed, and peripheral perfusion is exactly what fails in shock.

> **PITFALL**
>
> A normal finger-prick reading in a cold, shut-down, peripherally vasoconstricted patient is not a negative result. It is an unreliable result that happens to be reassuring, which is worse than no result, because it goes on the chart and is read thereafter as an exclusion. In any patient who is peri-arrest or profoundly shocked, take the glucose from a venous or arterial sample and record which you used, so a later reader can tell whether hypoglycaemia was excluded or merely tested for.

26.8 Giving thiamine before carbohydrate

Two acts each correct alone can be harmful in the wrong order, and this is the sequencing rule of the first minutes. Thiamine is given before any sustained carbohydrate load. Read that precisely, because the common misreading is dangerous in the other direction: a documented low sugar is corrected immediately and glucose is never held back while thiamine is looked for. Give thiamine first where it is already at the bedside, otherwise with the glucose or straight after it, and before any infusion, feed or oral intake that follows. The European Federation of Neurological Societies, in its guideline on Wernicke encephalopathy published in the European Journal of Neurology in 2010, states the rule and its ground together: it is important to give thiamine before any carbohydrate, because glucose infusion precipitates Wernicke encephalopathy in thiamine deficiency.

Indian guidance states the same rule for the emergency setting and supplies the mechanism, which is the version worth carrying into an examination because it explains rather than asserts. In the Indian Psychiatric Society's 2023 guidelines on patients with substance intoxication presenting to the emergency department, thiamine is administered before glucose replenishment so that the glucose is used in ATP generation, a process which itself uses thiamine as a co-factor. Giving carbohydrate first therefore sequesters an already limited store into metabolism, and that sequestration precipitates the encephalopathy. The glucose is not toxic; it is a demand placed on a supply that is not there.

The rule applies to the undifferentiated patient, because the population at risk is defined by nutritional state and alcohol history and neither is known at the door: the safe reading is that thiamine goes in first, or at latest with the glucose, in any confused patient in whom deficiency is even plausible. It requires no diagnosis, because the order is fixed before anyone has decided what is wrong. The thiamine dose, its route and duration, and the syndrome of Wernicke encephalopathy itself are taught in the Endocrine and metabolic psychiatry notes, and the withdrawal regimens carrying their own thiamine schedules belong to the Substance use

disorders notes. No dose is asserted here, deliberately, because a half-remembered regimen is more dangerous at this point than an explicit handover.

26.9 Setting an oxygen target rather than turning oxygen on

Oxygen is prescribed to a target, not delivered at maximum because the patient looks unwell, and the confused patient is where that distinction is most often lost. The Resuscitation Council UK gives two targets. In acute respiratory failure the aim is to maintain an oxygen saturation of **94 to 98 per cent**. In patients at risk of **hypercapnic respiratory failure** the aim is lower, at **88 to 92 per cent**.

The teaching lies in the existence of two targets rather than in either figure. A confused patient is not simply given the highest available flow, because the correct target depends on which failure is in front of you, and choosing wrongly is an error in both directions. Under-oxygenating a hypoxaemic brain prolongs exactly the state you are trying to reverse. Over-oxygenating a patient at risk of hypercapnic respiratory failure produces a rising carbon dioxide, and a rising carbon dioxide produces a drowsy, confused patient: the treatment reproduces the presenting complaint, and reads as deterioration of the original illness. The same saturation reading is therefore a success in one patient and a warning in another, and the chart cannot distinguish them unless somebody has written down which target was aimed at. Where the risk of hypercapnic failure is unknown, that uncertainty is handed over rather than resolved silently by turning the flow up.

26.10 Reading the drug chart, and giving an antagonist where one exists

Within the same step of the primary survey the drug chart is checked specifically for reversible drug-induced causes of depressed consciousness, and an **antagonist** is given where appropriate; the example the guidance names is naloxone for opioid toxicity. The important word is specifically: not the general medication review that happens later on the ward, but a targeted search, performed during the survey, for a cause with an immediate reversal.

Framed as a decision rule rather than as poisoning management, each part of it is a separate failure point. A reversible drug cause is actively looked for, which means somebody obtains the chart or the tablets the family brought, rather than recording that the history was unavailable. If one is found the antagonist is given, meaning now and not requested for later. And the effect is then assessed, because an antagonist given and not evaluated has produced a record rather than a result.

The opioid toxidrome, the naloxone dose, its titration and its re-dosing are taught in the Substance use disorders notes; what belongs to the front door is only the decision that a reversible drug cause is sought and reversed. In a psychiatric population the drug chart is two-sided: a list of possible causes, and a list of what the patient may have stopped taking. Neither reading is available unless somebody finds the chart, which in Indian practice usually means asking an attendant to bring the medicines from home, in the first minutes rather than at the end of the shift.

26.11 Deciding whether to sedate, and knowing what sedation does not buy

What the decision to sedate is actually for. A confused patient climbing off the trolley or pulling at lines obstructs the very stabilisation the preceding steps require, so there are legitimate reasons to sedate. What a candidate must be able to say is what sedation achieves and what it does not, because the commonest error is to treat a sedative as a treatment for the confusional state itself. Two trials settle it, and neither concerns dosing.

The first is the randomised, double-blind, placebo-controlled trial reported in the New England Journal of Medicine in 2018 by Girard and colleagues, in critically ill patients with acute respiratory failure or shock who were delirious in the intensive care unit. Haloperidol and ziprasidone, compared with placebo, did not significantly alter the duration of delirium. Whatever a sedative buys in that setting, it does not buy a shorter confusional state, and a plan built on the assumption that it does is a plan with no endpoint.

The second identifies the comparator that does work. In a double-blind, dose-titrated randomised trial in inpatient hospice and hospital palliative care services in Australia, reported in JAMA Internal Medicine in 2017 by Agar and colleagues, individualised management of the **delirium precipitants** together with supportive strategies produced lower scores and a shorter duration of the targeted distressing symptoms than the same care with risperidone or haloperidol added. What beat the drug was not nothing; it was doing the precipitant work properly. The caveat travels with the finding: these were palliative care patients with life-limiting illness, and the result is not transposed unqualified onto an undifferentiated emergency population.

TRAP **Recording the decision to sedate as the treatment of the confusional state.** Candidates make this error because sedation is the only act that visibly changes the patient in front of them, and because the notes have a space for what was given and none for what was corrected. Written as treatment it closes the episode: the patient is settled, the search for the precipitant stops, and the next clinician inherits a quiet patient with an unexamined cause. Written correctly it is an enabling act with a stated purpose, to let the physical assessment, the access and the imaging proceed, and it leaves the precipitant work still owing. The agent, its dose and the cardiac monitoring attached to it are taught in the Schizophrenia: management, antipsychotics and adverse effects notes.

26.12 Deciding where the patient goes, and writing the handover that says so

Disposition is where a wrong decision costs most, because the emergency department is the last point at which medical and psychiatric resources are both immediately present. Four questions arise, each answered in a named document from a named body.

THE QUESTION AT THE DOOR	WHAT THE GUIDANCE SAYS TO DO	WHOSE RULE, AND WHEN
It is not clear whether this patient has delirium or a psychiatric disorder	The patient is medically observed or hospitalised, after an appropriate medical screening examination and appropriate documentation for the presenting complaint	American Association for Emergency Psychiatry Task Force, 2017, by expert consensus
Can this patient be moved to the psychiatry ward	Not until the patient is medically and surgically stable	Indian Psychiatric Society, 2023, written for elderly patients
How long should the patient remain in the emergency setting	The shortest possible time; the emergency department is transit and not a destination	Indian Psychiatric Society, 2023, written for elderly patients
What does the transfer note actually say	That the patient has been evaluated medically and is medically stable and appropriate for treatment in a psychiatric setting, rather than that the patient is clear	American Association for Emergency Psychiatry Task Force, 2017

The first row is the most useful decision rule here. Uncertainty between a confusional state and a psychiatric disorder resolves towards medical observation, because the two errors are not symmetrical: a patient with a primary psychiatric illness observed medically for some hours loses very little, while a patient with an unrecognised medical cause admitted to a psychiatric ward loses the monitoring, the investigations and the medical team in one movement. Quote the grading with the rule, since the task force states its recommendations rest on expert consensus and should be treated as preliminary until further evidence is obtained. Note too what the requirement to be **medically and surgically stable** does to the sequence: it makes the physical stabilisation of the preceding steps a precondition for the psychiatric disposition rather than a parallel courtesy.

The fourth row is a point about language that turns out to be a point about safety, and it is made in full with the medical triage of the overdose patient in these notes rather than here: the same task force retires the term **medical clearance**, and what replaces it keeps the two claims a handover can actually support. What this topic needs from that argument is only its consequence for the confused patient, which is the row above: where it is unclear whether this is delirium or a psychiatric disorder, the doubt is resolved medically and not by transfer.

IN INDIA

Indian guidance addresses the case protocols elsewhere assume away. Where a patient requires inpatient care and cannot be moved to an inpatient ward or intensive care unit because no bed is available, the Indian Psychiatric Society's 2023 guidance states that the family should be allowed to shift the patient to another treatment setting. Disposition here is therefore partly a decision about where a bed exists, so the enquiry begins early rather than after the decision to admit. And the transfer that follows is a clinical act: the receiving setting must be told what has been done, what is still owed and what the patient was stable enough for, because a patient moved by a family without that handover arrives as an undifferentiated confused patient for a second time. The same reasoning covers the single room, the observation and the monitoring these pathways assume: where the department cannot provide them, that is recorded and factored into the disposition, not quietly assumed met.

In an undifferentiated confused patient, each life-threatening problem is treated the moment it is found and its effect reassessed; conscious level is graded inside the primary survey with new confusion as a grade of its own; glucose and oxygen are corrected to a target, thiamine before any carbohydrate; sedation is an enabling act, not a treatment for the confusional state; and where it is unclear whether this is delirium or a psychiatric disorder, the patient is medically observed or hospitalised rather than sent to a psychiatric bed.

27 · Acute alcohol withdrawal and delirium tremens (emergency aspect)

Why this is examined as an act. A man is brought in at night by relatives who say he drinks. He is drowsy, sweating, pulling at the trolley rails, and cannot account for himself. Nothing in that sentence is a diagnosis, and the one word everybody in the room has already supplied is the word that must be withheld longest. What the withdrawal syndrome is, when it declares itself, how its severity is scored and which regimens treat it belong to the Substance use disorders notes, which own that entity in full. What is owed here is the sequence that runs before any of it is known, and the decision about where this patient spends the night.

The examination question has the same shape: what is done first, what is excluded before anything is attributed, and which of three destinations the patient leaves for. The ordered sequence of arrival, safety, parallel differential, act and disposition is the spine every emergency presentation runs on, set out in the section of these notes on the assessment and management of the acutely agitated and aggressive patient, with the general front door of the confused patient in the section on delirium triage and emergency management. This section takes the version alcohol distorts.

27.1 The patient who arrives before the history does

The structural difficulty is that the diagnosis arrives ahead of the patient, and from somebody else. The escort supplies it, the smell appears to confirm it, and the patient cannot contest it, because the state being explained is the one that stops him explaining anything. Treat the

reported drinking history as collateral information with a source and a reliability, not as an established mechanism.

Before any of that is adjudicated, the same priority governs this arrival as every other. NICE guideline NG232 on head injury assessment and early management, published in 2023, sets it in one line: stabilise airway, breathing and circulation before attending to other injuries. In a patient who may be intoxicated this is not a formality. A depressed conscious level, a blunted gag, vomiting and the flat position he has been laid in make an aspiration set, and the restlessness that follows hypoxia is indistinguishable at the door from the restlessness of withdrawal. The airway is answered on the state in front of you, never on the mechanism you suspect.

27.2 Exclusion first, attribution second

The sentence this lens turns on is one recommendation from the same guideline, and its grammar teaches as much as its content. A depressed conscious level may be assumed to be due to intoxication only after an **important traumatic brain injury** has been excluded. The permission is genuine, but conditional, and it sits at the end of the sequence rather than the start. The injury itself and its imaging decision rules belong to the Stroke, TBI, delirium and focal brain syndromes notes; the order is what is owed here.

RULE **Intoxication is a conclusion, never a premise.** It is the label you arrive at once the exclusions have been performed, not the one you begin with and then defend. Written the other way round the assessment has no stopping rule: every abnormal finding is absorbed into the explanation already chosen, and the patient improves on paper by being observed rather than examined.

The order matters because the two states share almost every surface feature, diverge completely in what the next hour requires, and coexist in any drinker who has fallen. The wrong order also fails silently: a missed injury in a patient assumed to be drunk produces exactly the course everyone expects, and the deterioration reads as the alcohol taking its time.

TRAP **The smell closes the assessment.** The smell of alcohol is evidence of recent drinking, a different proposition from the cause of the conscious level, and compatible with every other diagnosis on the list. The examined version is the patient documented as sobering up while an extradural collection fills.

27.3 The parallel sweep, and what it is looking at

The 2023 Indian Psychiatric Society clinical practice guideline on substance intoxication presenting to the emergency department instructs that other causes of **altered sensorium** be ruled out, naming the metabolic set first with the investigations that answer it. The word carrying the teaching is parallel: the sweep does not wait for the alcohol assessment to finish, and is not a second opinion sought when the first explanation disappoints.

The same guidance adds a bedside step routinely skipped in a psychiatric assessment. Unresponsive patients may be harbouring an **occult head injury** identifiable from raised intracranial pressure, so direct ophthalmoscopy is advised, looking for papilloedema as a clinical sign of that pressure. It carries its own qualification: papilloedema without raised intracranial

pressure may also be seen in **methyl alcohol poisoning**, which matters greatly in Indian practice, so the sign narrows the field without settling it.

LIMB OF THE SWEEP	WHAT IS BEING EXCLUDED	THE ACT THAT ANSWERS IT
Metabolic	Hypoglycaemia, electrolyte imbalance, hyperosmolar hyperglycaemic state, diabetic ketoacidosis, metabolic acidosis	Blood glucose, renal function tests, arterial blood gases
Traumatic	An important traumatic brain injury, excluded before a depressed conscious level is attributed to drink	The head injury pathway, with imaging where it indicates
Raised pressure, at the bedside	Occult head injury in the unresponsive patient	Direct ophthalmoscopy, looking for papilloedema
Toxicological look-alike	Methyl alcohol poisoning, in which papilloedema appears without raised intracranial pressure	Raised whenever the fundal sign appears and the pressure story does not fit

MNEMONIC

Sugar, salts, gases, fundi

Blood glucose, renal function tests, arterial blood gases, then the fundi through a direct ophthalmoscope. The first three go with the first draw; the fourth costs nothing, needs no laboratory, and is available in every room where this patient is seen.

27.4 What converts a behavioural presentation into a medical one

The sweep answers what to exclude. When a patient presenting behaviourally should be pushed towards medical assessment at all is a separate question, and it is answered by a consensus TRIGGER LIST rather than by a battery. That list, its provenance and each of its items are taught with the medical triage of the overdose patient in these notes and are not restated here. What belongs to this topic is that intoxication and withdrawal sit ON that list: they are reasons to do MORE medicine rather than less, which is the exact inversion the drinking history invites.

Read where alcohol sits in that list. Substance intoxication and withdrawal appear as reasons to do more medicine, not as explanations permitting less, which is the exact inversion made at the door every night. Two other entries repay attention: age alone triggers the evaluation with no abnormal finding, and abnormal vital signs are a trigger rather than an expected accompaniment of agitation. The task force calls its own recommendations consensus and preliminary, so this is a prompt to think rather than a validated rule.

Airway, breathing, circulation
STABILISED FIRST IN EVERY EMERGENCY DEPARTMENT ARRIVAL, BEFORE OTHER INJURIES ARE ATTENDED TO

Never assumed
THAT A CONFUSED DRINKER IS CONFUSED BECAUSE OF THE DRINK, WHICH IS THE INVERSION THIS TOPIC EXISTS TO STOP

Papilloedema
BEDSIDE SIGN OF RAISED INTRACRANIAL PRESSURE SOUGHT ON DIRECT OPHTHALMOSCOPY IN THE UNRESPONSIVE PATIENT

Intoxication
LISTED FIRST AMONG THE FACTORS THAT WITHHOLD DISCHARGE AFTER A HEAD INJURY ASSESSMENT

27.5 Two diagnoses missed in the state that hides them

Where suspicion collapses. Some diagnoses are missed at random. Two here are missed systematically, because the feature that should raise suspicion is the feature that lowers it. NICE clinical guideline CG100 on the physical complications of alcohol use disorders, published in 2010 and last updated in 2017, meets this head on: maintain a high level of suspicion for the possibility of **Wernicke encephalopathy**, particularly if the person is intoxicated. That clause names the very situation in which the diagnosis is lost, since confusion and unsteadiness in a man who smells of drink are read as drunkenness. The clinical picture defining the syndrome belongs to the Endocrine and metabolic psychiatry notes, and the parenteral thiamine that follows suspicion, with its route and duration, to the Substance use disorders notes. What belongs here is the direction of travel: intoxication raises suspicion, it never lowers it.

The second runs the same way in a patient with liver disease. The 2014 joint American and European hepatology practice guideline on hepatic encephalopathy in chronic liver disease records that overt hepatic encephalopathy remains **a diagnosis of exclusion** in a population itself highly susceptible to mental state abnormalities from medications, alcohol misuse, drug use, the effects of hyponatraemia and psychiatric disease, so exclusion of other aetiologies by laboratory and radiological assessment is warranted, as clinically indicated, in such a patient with altered mental status. One sentence names three traps at once: the confused drinker with cirrhosis can be misattributed to the alcohol, to the liver, or to a psychiatric illness, each error made by a different team on grounds that look reasonable from where it stands. The safeguard is the head injury rule again: attribution after exclusions that were performed rather than assumed.

27.6 The level-of-care decision

Disposition is where this presentation is most often settled by habit. The Indian guidance draws the line at consciousness and medical involvement rather than at any score: mild and moderate cases, meaning those without impairment of consciousness or significant medical issues, can be managed in relatively simple surroundings without much medical intervention, while those who are **severely intoxicated** should be admitted and managed where high-dependency or intensive care can be provided. Two clinical variables carry the decision, and both are assessable without a laboratory.

Where the presentation is withdrawal rather than intoxication, NICE CG100 gives the admission rule a different logic. Admission for **medically assisted alcohol withdrawal** is offered to people in acute alcohol withdrawal who have, or are assessed as being at high risk of developing, alcohol withdrawal seizures or delirium tremens. The decision is driven by predicted complication and not by present distress, which inverts how emergency beds are usually allocated: a distressed,

tremulous, fully oriented patient may not need one, and a quieter patient with the risk profile does. The severity instrument, the withdrawal time course and the epidemiology of delirium tremens belong to the Substance use disorders notes, and none of them replaces this decision.

The line then moves with the person. For **certain vulnerable people** in acute alcohol withdrawal a lower threshold for admission is considered: those who are frail, have cognitive impairment or multiple comorbidities, lack social support, have learning difficulties, or are **16 or 17 years old**. Read as a group, those examples are not about severity. They describe who will be unobserved, unable to report deterioration, or unable to come back, none of which a severity score sees. Disposition is a clinical judgement with a score inside it, not a score with a clinician attached.

DESTINATION	WHAT SELECTS IT	WHAT MUST BE TRUE FIRST	WHAT FOLLOWS
Relatively simple surroundings, little medical intervention	Mild and moderate presentations: no impairment of consciousness, no significant medical issues	The sweep performed and negative, not waived	Observation by a named person, and a stated point of review
Admission for medically assisted alcohol withdrawal	Acute alcohol withdrawal with, or at high risk of, withdrawal seizures or delirium tremens	A threshold lowered where the person is vulnerable, isolated or very young	The regimen itself, owned by the Substance use disorders notes
A setting providing high-dependency or intensive care	Severe intoxication	Capability actually present, not a monitored bay nobody watches	Care led by the team the indication selects, psychiatry alongside

27.7 Admission, and who owns the bed

The Indian guidance is unusually concrete here. Inpatient admission of an intoxicated patient may be considered for:

- severe intoxication, or persistent disorientation;
- medical complications such as Wernicke encephalopathy or alcoholic hepatitis;
- dysrhythmias or convulsions, or continued abnormality of cardiopulmonary parameters;
- known chronic systemic illnesses requiring independent medical attention;
- prolonged aggressive behaviour, or perceptual abnormalities.

It then adds the clause psychiatrists most often skip, and it is the useful one: the speciality under which the patient is admitted is determined by the indication for admission. That settles the corridor argument. A patient admitted for dysrhythmias or a continued cardiopulmonary abnormality is a medical admission with psychiatric input, not a psychiatric admission with a medical consultation pending; one admitted for prolonged aggression or perceptual abnormality is the reverse. It also produces a defensible record, since the reason for the bed and the owner of the bed become one fact written once.

IN INDIA

The sweep assumes a working blood gas analyser, an urgent renal panel and a functioning ophthalmoscope at two in the morning. Many district emergency rooms have a glucometer, a slower overnight biochemistry and a borrowed fundoscope, so the honest local version is to do the bedside sugar and the fundi at once, send what the laboratory will process at night, and record which exclusions were performed and which deferred. The speciality rule assumes more than one speciality is admitting; where the bed goes to whoever has one free, that rule is the corrective, turning an availability decision back into a clinical one.

27.8 Discharge, and what this section hands on

The last decision is made quickest and defended worst. Returning to the head injury guideline: where imaging is not indicated and there is no suspicion of clinically important traumatic brain injury, discharge still requires that there be no other factors warranting hospital admission, and drug or alcohol intoxication is listed first among them, alongside other injuries, shock, suspected non-accidental injury, meningism and cerebrospinal fluid leak. Discharge additionally requires appropriate support structures for safe discharge and subsequent care, the example given being **competent supervision at home**.

Two consequences follow. Intoxication is not merely a confounder of the assessment; on its own it is a reason the patient does not go home yet, so a negative scan and a normal examination are not between them a discharge. The second requirement is about the destination rather than the patient: someone safe to leave has somewhere to be watched, which the department must ask about rather than infer from a relative in the waiting area.

What is not available here is the cadence. For the patient held because of intoxication, no comparable standard is available to quote, and none is invented here. Teach the principle instead: the reason for keeping the patient dictates what is watched for, that determines how often somebody must look, and the interval is agreed and recorded by name.

GOOD TO REMEMBER

Record which exclusions were performed and which were assumed. Notes on these patients carry the conclusion and not the work, so a later reader cannot tell whether the metabolic set was sent or the fundi seen. Three lines close it: what was excluded and by what test, why the patient is or is not going home, and who is watching him and where.

At handover the receiving team needs what cannot be reconstructed afterwards: which exclusions were completed, what was still pending when the patient moved, the indication that selected both bed and speciality, and who was told to look at him and how often.

In a drinker with a depressed conscious level, exclusion comes first and attribution second: an important traumatic brain injury is excluded, the metabolic sweep and the fundi run alongside, and intoxication is the label you arrive at, never the one you begin with.

28 · Psychiatric emergencies in pregnancy and the postpartum period

Why the marks are here. Psychiatric emergencies in pregnancy and after it are not different emergencies. An acutely agitated woman is still an acutely agitated woman, an overdose is still an overdose, a collapse is still a collapse. What changes is the act: where she is put, what may be used, what must not follow it, who is standing in the room while it happens, what is watched afterwards, and where she goes next. That is a short list, and it is examinable precisely because almost nobody rehearses it. Every one of the underlying conditions is taught in full elsewhere in these notes and none is restated here. What this section owns is the overlay: what is done differently, emergency by emergency, because the patient in front of you is pregnant or has recently delivered.

Two facts make this the highest-stakes intersection in emergency psychiatry. The first is that there are two patients and only one can be interviewed, examined or consented; the second is silent, is affected by every drug and every position, and is the one most often missing from the note. The second fact is where the mortality actually sits. On the confidential enquiry into maternal deaths for the United Kingdom and Ireland, reporting in 2025, suicide is the most common cause of maternal death in the period between six weeks and one year after the end of pregnancy, and mental health conditions together account for **over one third** of the deaths in that same late period. The dangerous window is not the pregnancy, where obstetric attention is concentrated, but the postnatal year, where nobody is looking.

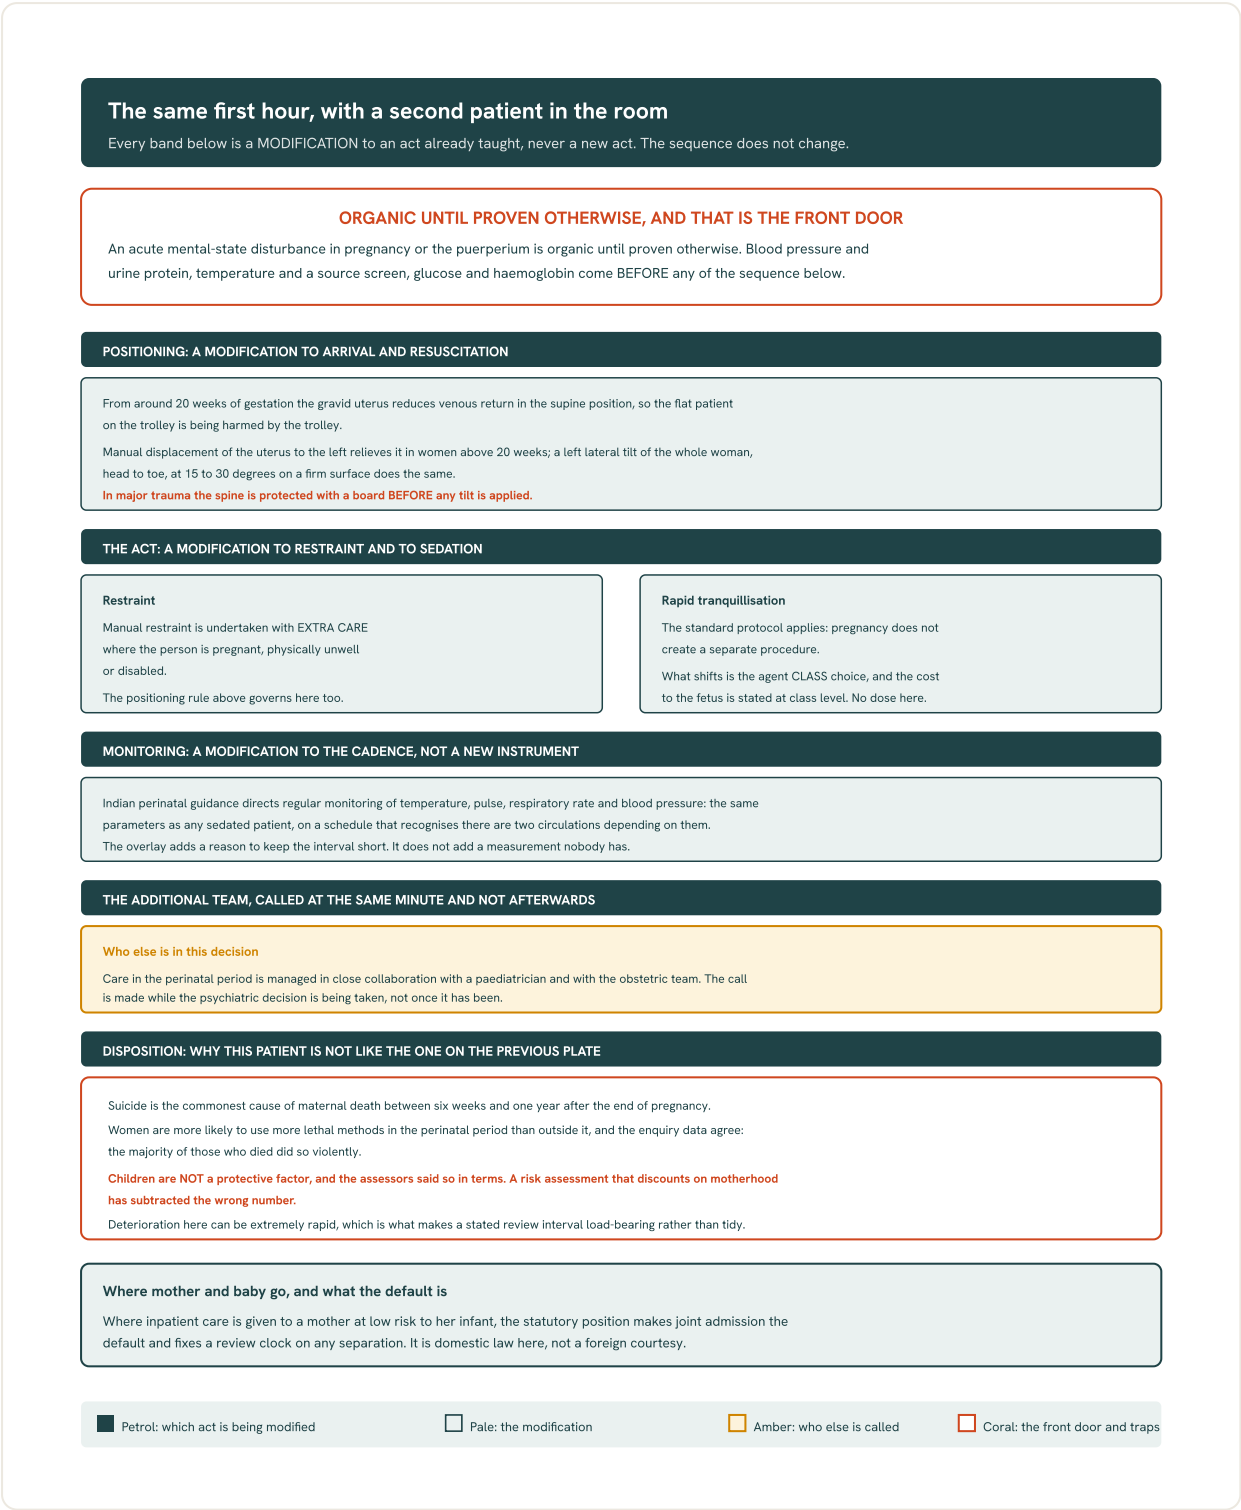

Fig 28.13. What changes when the emergency patient is pregnant or newly delivered, drawn as modifications overlaid on the first-hour sequence rather than as a separate algorithm: the organic exclusion that comes before everything, the positioning rules from around twenty weeks and the trauma exception to them, the extra care in restraint and the class-level agent shift in sedation, the monitoring cadence, the obstetric and paediatric team called at the same minute, and the disposition facts that make this patient's risk assessment different, including that children are not a protective factor.

28.1 Establish the second patient before you do anything to the first

The first act in a perinatal emergency is neither pharmacological nor physical. It is to establish, and to write down, that there are two patients and how far along the second one is. Everything downstream keys off that determination: the positioning rule, the resuscitation algorithm, the agent-class decision, the monitoring set and the destination.

The obvious problem is that the woman who most needs this determination is the one least able to give it. She may be agitated, mute, intoxicated, thought-disordered or brought in by neighbours who know nothing about her. Resuscitation guidance solves this with a physical criterion rather than a historical one: the manoeuvres that follow are indicated in women above 20 weeks of gestation, or wherever the uterus is palpable at or above the level of the umbilicus, on the Royal College of Obstetricians and Gynaecologists guidance on maternal collapse in pregnancy and the puerperium (2019). The second limb is the clinically useful one for us: an abdominal palpation takes seconds, needs no cooperation and no dates, and converts an unknown into a rule the whole team can follow. It also protects against the opposite error, since the positioning rules below answer a specific mechanical problem that does not exist early in pregnancy.

On the postnatal side the equivalent determination is the interval since delivery and whether an infant is physically present. The interval decides whether an obstetric team still has an active interest in her; the presence of an infant decides who is holding that infant while the emergency is managed, which has to be answered out loud in the first minutes. The wider framework for weighing a decision made for a mother and a fetus or infant at once, including the risk of the untreated illness as one of the risks being weighed rather than as the baseline, belongs to the topic on prescribing psychotropics in pregnancy in these notes and is not re-derived here.

28.2 Exclude the organic causes before you run any of what follows

This section comes first because everything after it assumes the answer. Acute disturbance of mental state in pregnancy or the puerperium is organic until proven otherwise, and the proving is done at the door rather than after admission. The reason is not caution in the abstract. The conditions that present this way are common, they are time-critical, and several of them are found by measurements a district casualty already has at the bedside.

Take the blood pressure and test the urine for protein, because hypertensive disease of pregnancy reaches well beyond delivery and can present as headache, visual disturbance, confusion or seizure in a woman whose pregnancy ended weeks earlier. Take the temperature and look for a source, because puerperal sepsis presents as agitation and confusion before it presents as anything a psychiatrist recognises. Take a capillary glucose. Look at the haemoglobin, because severe anaemia after obstetric haemorrhage produces exactly the picture that gets referred. None of these is a psychiatric act, and all of them precede one.

The trap is structural rather than clinical: a woman who arrives disturbed in the puerperium arrives with a psychiatric referral already attached to her, and the referral is itself a piece of anchoring. The general approach to the acutely confused patient, and what an organic screen contains, is taught with the emergency triage of the confused patient elsewhere in these notes. What belongs here is the order. No comparable perinatal standard is available to quote for which tests, at what threshold, in what sequence, and none is invented here; the acts above are named without figures for that reason.

RULE **A psychiatric diagnosis in the puerperium is a diagnosis of exclusion made at the door, not a diagnosis of first resort made in the referral.** The positioning, sedation and disposition decisions that follow are all correct, and all of them are wrong if the woman is eclamptic or septic.

28.3 Decide the position she is left in, and treat it as an intervention

This is the act most often omitted, and the omission is invisible because a woman lying flat looks like a woman lying down. From around 20 weeks of gestation the gravid uterus reduces venous return in the supine position, and cardiac output falls in consequence by **up to 30 to 40 per cent**. That is **aortocaval compression**, and it is the physiological fact that turns a positioning instruction into a clinical intervention rather than a comfort measure. A restrained or sedated pregnant woman left flat is not merely uncomfortable; she is being actively harmed by an omission no drug chart records.

20 weeks GESTATION FROM WHICH THE SUPINE POSITION REDUCES VENOUS RETURN	**15 to 30 degrees** ANGLE OF WHOLE-BODY LEFT LATERAL TILT, ON A FIRM SURFACE	**4 minutes** CORRECTLY PERFORMED CPR WITHOUT RESPONSE BEFORE PERIMORTEM CAESAREAN SECTION	**5 minutes** TARGET FROM MATERNAL COLLAPSE TO DELIVERY AT PERIMORTEM CAESAREAN SECTION

The corrective act has three checkable elements, and candidates lose the marks on the second and third rather than the first. A **left lateral tilt** of the woman from head to toe, at an angle of 15 to 30 degrees, on a firm surface, relieves the compression in the majority of pregnant women while still allowing effective chest compressions. Head to toe matters because tilting the trunk alone folds her at the waist and leaves the uterus where it was. The stated angle matters because a token lean achieves nothing and an extreme one rolls her off. The firm surface matters because a soft mattress absorbs the tilt and, if she arrests, makes compressions useless.

Where a tilt cannot be achieved, or where compressions are being given, the alternative is **manual displacement of the uterus to the left**, described in the same guidance as an up, off and over movement. Its value is that it relieves the compression while she stays supine, which is the only way to keep compressions effective during an arrest, and it needs no equipment.

One situation subordinates the whole positioning rule. In major trauma the spine is protected with a **spinal board** before any tilt is applied, and where no board is available manual displacement of the uterus is used instead. This is not an obstetric footnote for us. A pregnant woman who has jumped, fallen, been assaulted or been taken to the floor during a struggle on the ward is a trauma patient first, and tilting her may be the wrong act performed with the right intention.

SITUATION AT THE BEDSIDE	WHAT IS DONE	WHY IT IS THAT AND NOT SOMETHING ELSE
Uterus palpable at or above the umbilicus, and she is sedated, restrained or otherwise unable to move herself	Whole-body left lateral tilt, head to toe, at an angle of 15 to 30 degrees, on a firm surface	A tilt of the trunk alone bends her at the waist and does not lift the uterus off the great vessels
Chest compressions are needed	Keep her supine and displace the uterus manually to the left	Compressions are ineffective on a tilted or yielding surface; displacement relieves the compression without tilting her
Major trauma: a fall, a jump, an assault, or a struggle that ended on the floor	Protect the spine with a spinal board before any tilt is applied	Spinal protection outranks the positioning rule, and tilting an unprotected spine turns one injury into two
Major trauma, and no spinal board on the premises	Use manual displacement of the uterus instead of a tilt	It relieves the same compression without moving the spine, which is why it is the named fallback
An observation area with no tilting trolley and no firm wedge	Nurse her supine with the right hip elevated	Elevating the right hip is the same manoeuvre described from the other side, and it can be improvised

MNEMONIC

Board, then tilt, and displace when you cannot tilt

The precedence order for any pregnant woman who has to be laid down. The board comes first where there has been major trauma, because spinal protection outranks the positioning rule. Where there is no trauma, the whole-body left lateral tilt on a firm surface is the manoeuvre. Where a tilt cannot be achieved, where compressions are being given, or where no board is available, manual displacement of the uterus to the left does the same physiological work.

RULE **The position a sedated or restrained pregnant woman is left in is part of the prescription, not part of the nursing.** A woman who has just been given a sedating drug, or who is being physically held, cannot reposition herself. The position therefore stops being something she adopts and becomes something the team has chosen for her, and must keep choosing at every observation and handover. Written into the order alongside the drug, it survives the shift change; left to whoever last moved the trolley, it does not.

28.4 Adapt the restraint, and be honest about where the guidance stops

Pregnancy is named explicitly in general restraint guidance: manual restraint is to be undertaken with extra care if the service user is physically unwell, disabled, pregnant or obese, on the National Institute for Health and Care Excellence guideline on the short-term management of violence and aggression (2015). The perinatal guidance from the same body adds, inside its rapid tranquillisation recommendation, that restraint procedures should be adapted to avoid possible harm to the fetus.

Both statements stop at the level of principle. Neither specifies a hold, a position, a maximum duration, an observation interval or a gestational threshold at which the adaptation begins. That gap is load-bearing and should be stated rather than papered over: for how a hold is to be modified in pregnancy, no comparable standard is available to quote, and none is invented here. What can be said is what follows from sourced material, and a good answer says that and no more.

Three things follow. The positioning rule is the substance of extra care once the uterus is palpable at or above the umbilicus, so a hold that ends with her flat on her back and held there is the one configuration that must not become the resting state. Force applied over the gravid abdomen has no place in any hold, which is a statement about where hands go rather than about which technique is taught. And a woman taken to the floor has been through a mechanism of injury, so the trauma precedence above applies from the moment the hold ends. The general physical safety of any person in restraint, including the prone hazard, airway access and the risks of prolonged immobilisation, is the business of the topic on restraint and seclusion in these notes; the statutory authority for restraining anyone at all belongs to the Mental health legislation and forensic psychiatry notes, and the test of least restriction to the Forensic ethics, consent and legal procedure notes.

28.5 Choose the agent class, and refuse the seclusion that would normally follow

A pregnant woman who requires rapid tranquillisation is treated according to the standard guidance on violence and aggression, on psychosis and on bipolar disorder, with two named exceptions, on the perinatal guideline of the National Institute for Health and Care Excellence (published 2014, last updated 2020):

- she is not to be secluded after rapid tranquillisation;
- restraint procedures are to be adapted to avoid possible harm to the fetus.

Notice what those two have in common: neither is a dose. The protocol is not softened and the ladder is not rewritten. What changes is that two of the things normally available afterwards are withdrawn. The seclusion exception repays a moment's thought, because candidates reproduce it without being able to justify it. Seclusion is by construction a place where a patient is neither continuously observed nor physically accessible. A woman sedated in the second half of pregnancy needs the opposite: someone to keep her off her back, to take observations that include the fetus, and to reach her quickly if either patient deteriorates.

The agent decision is stated at the level of drug class and of the neonate, which is the level this section owns. When choosing an agent for a pregnant woman, an antipsychotic or a benzodiazepine with a short half-life should be considered; if an antipsychotic is used it should be at the minimum effective dose, because of **neonatal extrapyramidal symptoms**, and if a benzodiazepine is used the risks of **floppy baby syndrome** are taken into account. The short half-life preference and the minimum effective dose rule are one idea applied twice: what matters is the exposure still present in the neonate at delivery, so duration is being minimised alongside amount.

No dose appears in this section, deliberately. The rapid tranquillisation ladder and every first-dose figure belong to the Schizophrenia: management, antipsychotics and adverse effects notes, and a dose recalled from memory into a pregnancy answer is the error this material exists to prevent.

28.6 Monitor two patients afterwards, and give the cadence a name

Standard post-sedation monitoring watches one person. The Indian Psychiatric Society's guidance on the management of psychiatric disorders during the perinatal period (2022) extends the set: regular monitoring of temperature, pulse rate, respiratory rate, blood pressure and **fetal wellbeing measures** may be essential, and care is taken to ensure the patient is lying supine with **right hip elevation** to avoid compromising the blood supply to the fetus.

Two things there are worth separating. Right hip elevation and the left lateral tilt of the resuscitation guidance are the same manoeuvre described from opposite sides, and a resident who has memorised one phrasing will not always recognise the other. And the addition of a fetal parameter to a routine observation set is what makes this a two-patient protocol rather than an obstetrically flavoured version of the usual one.

What no sourced statement gives is a frequency. Neither the perinatal guidance nor the general restraint guidance sets an interval for observations after sedation or during restraint in pregnancy: for that cadence, no comparable standard is available to quote, and none is invented here. The principle is still teachable and is the operationally important part. An observation described only as regular belongs to nobody. Whoever writes the sedation order writes the interval and the parameters beside it, names the person who will take them, and states what change triggers a call. Observation levels as a construct are developed in the topic on suicide risk assessment and emergency management in these notes.

IN INDIA

The monitoring set above is national guidance, and its fifth item meets a wall. Fetal wellbeing measures need equipment and someone competent to interpret the trace, and in most district hospitals and general psychiatry units that person is in another building and off duty at night. The honest position is not to pretend the standard is met but to plan around it: for a woman beyond the middle of pregnancy who is likely to need sedation or restraint, the siting decision comes before the drug decision, and an observation area within reach of an obstetric response is worth more than a quieter one that is not. What is genuinely portable costs nothing, which is the positioning, the four maternal parameters and a named interval. Where guidance names a specialist perinatal mental health service as the destination, most of the country does not have one, and the referral that exists is to a general unit with an obstetric department attached.

28.7 Assess self-harm on the perinatal method profile, not the general one

What the lethality profile changes at the door. A general risk assessment weighs stated intent heavily and reads a low-lethality act as reassuring. That inference is unsafe here. On the same confidential enquiry, the majority of women who died by suicide died violently, and the commonest mode was hanging, accounting for **66 per cent** of those deaths, 58 women in the

reporting period. Indian perinatal guidance (2022) states the same clinical point from the other direction: women are more likely to use more lethal methods in the perinatal period.

Three consequences follow, and all three are acts rather than formulations. Method and access are asked about specifically and early, because the method distribution in this population is shifted towards those that leave little margin for rescue. An index act of apparently low lethality earns less reassurance than the same act would in a general presentation, so it raises rather than settles the question of admission. And the enquiry is not about one person: Indian guidance states that suicidal risk and infanticidal risk may occur together and require attention, so the infant's safety is asked about in the same conversation and recorded in the same note.

What this section does not do is re-teach the assessment itself. The framework, the disposition ladder, means restriction and the structured enquiry into intent are the property of the Somatic-symptom, sexual, impulse-control disorders and suicide notes. The classification of filicide and the forensic frame around it belong to the Mental health legislation and forensic psychiatry notes, and the assessment of the mother's relationship with her infant to the topic on mother-infant bonding and infanticide risk in these notes. What is owned here is narrower: the perinatal method profile changes what a given act means, and the risk assessment covers two people.

28.8 Refuse the two reassurances that discharge a woman who should be admitted

Most perinatal disasters are not diagnostic failures. The illness was recognised; the disposition was wrong. Two specific reassurances do that work, and both are addressed in the confidential enquiry material.

The first is the reassurance of the cross-sectional appearance. Deterioration of mental health in pregnancy or the postnatal period can be extremely rapid, so how she looks in the room now is a poor guide to where she will be tomorrow. The enquiry names the changes that must not be underestimated and that should prompt early review, urgent assessment and intervention, and two of the four appear in no general risk formulation:

- a significant change in mental state;
- the emergence of new symptoms;
- thoughts or acts of violent self-harm;
- expressions of incompetency as a mother, or estrangement from the infant.

Those are **red flags** in the strict sense: each is a trigger for an act, not an item to be scored and weighed against protective factors. The last is the one a general assessment reliably misses, because a woman saying she is not a good enough mother sounds like a depressive cognition and gets filed as one. Read as a red flag, it brings the review forward. The practical translation is that a perinatal presentation is triaged on its trajectory over recent weeks, so the collateral history covers direction of travel and not only the current picture.

TRAP **Counting her children as the reason she will not act.** The enquiry assessors concluded that the idea of children as a protective factor against suicide and substance use should be challenged and not taken as a matter of fact, even where the woman herself expresses it, because some women may be too unwell to keep themselves safe despite wanting to protect their children from harm. Candidates write "protective factors: young children at home" and then discharge, and the sentence does double duty it has not earned: it is treated as evidence about her intentions when it is only evidence about her values. Devotion is not capacity for self-protection, and in severe illness the two come apart.

28.9 Decide the mother and infant question as a decision with a clock on it

When an acutely unwell mother is admitted, somebody decides within the first hour whether her infant stays with her. In most Indian units that decision is made at night, by the duty team, on incomplete information, and is then never revisited because nobody was appointed to. Indian perinatal guidance (2022) restates the statutory position that stops this.

Where inpatient care is given to a mother at low risk of suicidal or infanticidal risk, **rooming-in** of mother and infant is the position Indian law takes, and the shape of that rule is what a candidate must be able to state. Rooming-in is the default up to a stated age of the child. A decision to separate is the deviation, it must be authored by the treating psychiatrist, it EXPIRES at a fixed statutory interval rather than running until somebody revisits it, and beyond a further fixed period it stops being the clinician's decision at all and passes to an external review body. The age, the two intervals, the body and the section they sit in are restated with the Mental health legislation and forensic psychiatry notes and are not reproduced here. What matters at the bedside is that in India the review clock is not the team's to set.

Read the structure rather than the numbers. Joint care is the default and separation the deviation, so the burden of justification sits on whoever proposes to separate. Separation is a decision and not a ward arrangement, which means it has an author, a reason and an expiry. The review interval is fixed in law rather than left to the team's convenience, so a separation that quietly persists is a lapse against a statutory duty. And beyond a defined period the decision leaves the clinician altogether and needs external permission, which is the statute's way of saying that indefinite separation is not a clinical decision at all. What a mother-baby unit is, and how the separation decision is worked up where there is a unit, are developed in the topic on lactation and mother-baby unit care in these notes; what is owned here is that decision taken in the emergency, before any of that assessment exists.

GOOD TO REMEMBER

Three lines that change what an admitting resident writes tonight. First, the gestational age or the interval since delivery, with how it was established, including by palpation where no history was available, because every rule below it depends on that entry. Second, the position she is to be nursed in, written in the same entry as the sedation or restraint order rather than left to the nursing note, with the observation interval and who takes it. Third, where mother and infant have been separated, the statutory review date entered as an actual date, since that interval is fixed in law and is not the team's to set.

28.10 Call the right team early, because the clock is shorter than the corridor

The same perinatal guideline of the National Institute for Health and Care Excellence attaches a team requirement to the rapid tranquillisation recommendation itself, which is deliberate placement: during the perinatal period the woman's care is to be managed in close collaboration with a paediatrician and an anaesthetist. Those two disciplines, named by title, are not the ones a psychiatrist instinctively calls. The anaesthetist is there for the airway of a sedated woman whose physiology has changed and who may need an operative delivery at short notice; the paediatrician for a neonate just exposed to whatever was given to the mother. Calling the obstetrician alone is the common half-answer. No timing threshold is attached to either involvement, so how early each is brought in is not sourced and no interval is invented here; the defensible position is to inform both when the decision to tranquillise is taken rather than after it.

The reason to build that habit is the arrest clock. In women over 20 weeks of gestation, if there is no response to correctly performed cardiopulmonary resuscitation within 4 minutes of maternal collapse, or if resuscitation continues beyond that point, **perimortem caesarean section** is undertaken to assist maternal resuscitation, ideally achieved within 5 minutes of the collapse, on the same Royal College of Obstetricians and Gynaecologists guidance (2019). The teaching point is arithmetical rather than surgical: both intervals are shorter than the time it takes to summon an obstetric and neonatal team from another building, so the call goes out at the moment of collapse and not at the four-minute mark. The procedure is performed to resuscitate the mother, which is the part most often misunderstood.

THE EMERGENCY AT THE DOOR	WHAT CHANGES BECAUSE SHE IS PREGNANT OR NEWLY DELIVERED	WHO IS BROUGHT IN, AND WHEN
Acute agitation requiring rapid tranquillisation	Short half-life agent class considered; an antipsychotic used at the minimum effective dose; no seclusion afterwards; she is not left supine and unattended	Paediatrician and anaesthetist, from the point the decision is taken
Manual restraint of a disturbed woman	The procedure is adapted to avoid harm to the fetus; the resting position is the tilt or the displacement, never flat and held	Ward team briefed on the position before the hold; obstetric advice once the uterus is palpable at or above the umbilicus
Collapse or cardiac arrest on the ward	Uterine displacement to the left so compressions remain effective; spinal protection takes precedence in trauma	Obstetric and neonatal teams summoned at the moment of collapse, not once the arrest is established
Self-harm or overdose presentation	Method and access asked about specifically; low apparent lethality earns less reassurance; the infant's safety is asked about in the same conversation	Medical or toxicology team in the usual order, with obstetric review to follow
Sudden disturbance in the postnatal weeks	Assessed against the perinatal red flags and on trajectory rather than cross-section; a timed referral standard applies	Secondary mental health service, preferably a specialist perinatal service where one exists
Admission of an acutely unwell mother with her infant	Rooming-in is the default where suicidal and infanticidal risk are low; any separation is authored, time-limited and statutorily reviewable	Paediatrician for the infant; the review board where separation runs long

One disposition interval deserves naming, because it is the only perinatal response time counted in hours. Where a woman has sudden onset of symptoms suggesting postpartum psychosis, she is referred for immediate assessment inside a response time that the same English perinatal guideline counts in hours and that the topic on postpartum psychosis prints; the presentation itself is developed in the topic on postpartum psychosis in these notes and in the Other psychotic disorders, delusional syndromes and catatonia notes. No equivalent Indian standard is available to quote, and none is invented here, so what transfers is the principle that a perinatal emergency referral is timed and audited rather than queued. Where the emergency is a woman who is not eating or drinking, or whose suicidality does not remit, electroconvulsive therapy remains a live option in pregnancy, and its indications, modifications and outcome data are the ECT and neurostimulation notes' in full and are not restated here.

Three acts in a perinatal emergency belong to the psychiatrist and to nobody else: the position she is left in once she has been sedated or held, the seclusion that must not follow rapid tranquillisation, and the call that brings obstetric, paediatric and anaesthetic colleagues into the room rather than after it.

Cross-cutting synthesis

29 · Cross-cutting synthesis

Every other account in this chapter teaches one presentation; this one is about what all of them have in common. What the two bands of this chapter share is an interlock rather than a boundary. The material looks like two bodies of knowledge sharing a cover, and that reading survives until the first patient who is both. What runs underneath is the same kind of object, and it is not a body of fact. Both halves are **sequences of decision**: ordered, timed, answerable in the order given rather than the order the information arrives. The entities are taught elsewhere, in full and with their numbers. What is left over, and what is examined, is the order.

Owned here and nowhere else: how the two seams sit against one another, where they repeat the same reasoning in different clothes, and what happens where they cross. Named in a clause and never re-derived: the front of the emergency sequence, the two-patient framework, and every entity, dose, level, interval and criterion belonging to either half. No figure appears on this page, because a number lifted out of the account that grounds it arrives without the conditions that made it true.

Sequence	Second patient	Written down
WHAT BOTH HALVES OF THIS CHAPTER TURN OUT TO BE, RATHER THAN BODIES OF FACT TO BE RECALLED	THE PERINATAL SEAM, ASKED OF EVERY STEP OF THE EMERGENCY ONE	WHAT SEPARATES AN ORDER FROM A DISPOSITION ON EITHER SEAM

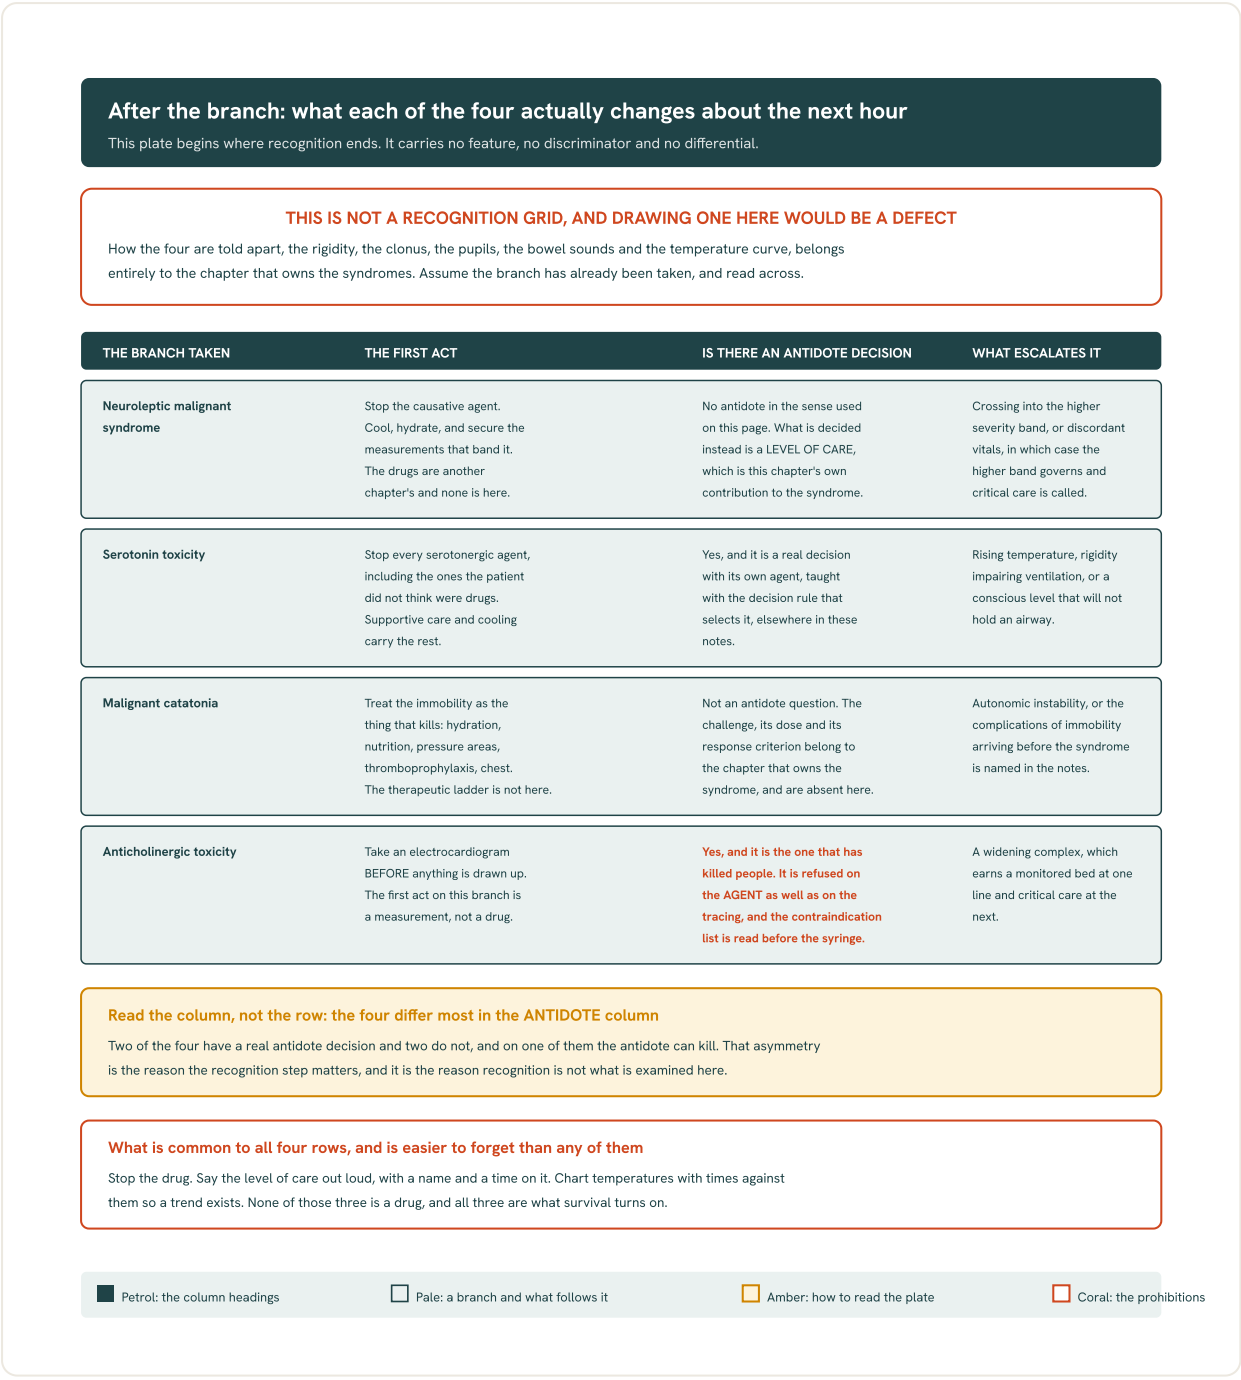

Fig 28.14. What follows each branch of the hyperthermic and toxidromic differential once the branch has already been taken, giving for neuroleptic malignant syndrome, serotonin toxicity, malignant catatonia and anticholinergic toxicity the first act, whether an antidote decision exists at all, and what escalates the level of care, with no discriminating feature anywhere on the plate because recognition belongs to the chapter that owns the syndromes.

29.1 Two seams, and the same kind of object underneath both

The emergency half turns on an ordered sequence every one of its presentations invokes: recognise, stabilise, establish who holds the authority to act, act, monitor, dispose. The order is the content. It is not a list of things that must all happen, but a statement about which question may not be answered until an earlier one has been. Its front end, from arrival to the treatment decision, is developed in this chapter's account of the acutely agitated and aggressive patient.

The perinatal half looks different and behaves the same. Every decision in it is made for a mother and a fetus or infant at once, only one of whom can be asked what she wants, and the risk of the

untreated illness is one of the risks being weighed rather than the baseline the others are measured against. That framework belongs to this chapter's account of prescribing psychotropics in pregnancy. What it shares with the emergency seam is its form: it too fixes an order of questions, and it too goes wrong when they are answered in the order the information arrives. The second seam is not a separate structure. It is the first one asked twice.

THE STEP	WHAT IT ASKS WHEN THERE IS ONE PATIENT	WHAT THE SAME STEP ASKS ONCE THERE ARE TWO
RECOGNISE	What is this, with the psychiatric answer reached last rather than assumed first, and the presumption of a physical cause carried until actively displaced.	Who else is here, established by examining her rather than by history, because the woman who most needs this is least able to supply it; and if an infant is present, who is holding it meanwhile.
STABILISE	Treat the life-threatening problem when it is found and reassess it, rather than carrying it to the end of an assessment that runs alongside the talking.	The same work, plus a position that is itself an intervention. A sedated or held patient cannot reposition herself, so the position is something the team chose and must keep choosing.
ESTABLISH AUTHORITY	Who may act for a patient who cannot agree, recorded as an assessment with a basis rather than inferred from how disturbed she looks.	Only one of the two can be asked, and she is not always the one at greater risk of being forgotten. Doing nothing is itself an exposure for both.
ACT	The intervention this presentation calls for, performed as a discrete act with a named reviewer rather than as a standing permission.	The same intervention, chosen additionally for the exposure still present in the second patient later, and stripped of whatever normally follows it that would put either out of reach.
MONITOR	A stated interval, a named person who takes it, an endpoint at which it stops, and a written change that triggers a call.	The observation set acquires a parameter belonging to the other patient. That single addition makes it a two-patient protocol rather than the usual one with an obstetric flavour.
DISPOSE	Where the patient goes, decided by somebody rather than defaulted to by nobody, and handed over as reasoning rather than as conclusion.	The destination must accept both, and any decision separating them is authored, timed and reviewable rather than a ward arrangement nobody remembers making.

29.2 The same error twice, in two different costumes

The commonest failure in each half is one failure. The emergency half states it repeatedly: a behaviour is a presentation and never a diagnosis; the smell of alcohol is evidence of drinking, not of the cause of a conscious level; intoxication is a label you arrive at, not one you begin with

and then defend. The perinatal half states it as often, and almost nobody sees it is the same sentence. A reproductive event is a **context** and not a diagnosis. A context tells you what else to ask and whom to involve, not what to treat.

Both guard against a ready-made explanation that closes a question before it is asked. In the emergency half that explanation is the psychiatric history, which is why the patient with an established diagnosis is the one in whom a physical cause is missed: the history explains why this person might become disturbed, a different question from why they are disturbed today. In the perinatal half it is the pregnancy or the puerperium. An episode is attributed to a transition and goes untreated; a distressing answer is attributed to mood, and the bond with the infant is never enquired about separately, so a negative mood enquiry is read as excluding something it never examined.

Only the costume differs, which gives the rule a usable form as a question about direction. Ask whether the account in your head was generated by this patient today or supplied by something you knew before meeting them. Explanations of the second kind are often correct; they are simply not entitled to close an enquiry, because they were equally available whatever the answer turned out to be. **Attribution** is the last act on both seams.

29.3 The option that looks careful is the one that has to be argued for

A second pattern crosses both halves and inverts an intuition. In each there is a choice presenting itself as the cautious one that is in fact the **deviation**, carrying the burden of argument and requiring a written reason.

The perinatal half says so explicitly. Stopping a drug is not a move into an unexposed condition, because no arm of that decision has nothing in it; the apparently careful option is a different exposure, usually the more poorly characterised. Separating a mother from her infant looks like safety and is the deviation from a default of joint care, which is why it needs an author, a reason and an expiry rather than a bed allocation. The emergency half runs the same inversion without naming it. Discharging the patient who looks well after an overdose feels like proportionate triage, and is the deviation in a presentation that may still be climbing. Routing a confused patient to a psychiatric bed while it is unclear whether the confusion is medical feels like appropriate referral, and is the deviation from continued medical observation. Recording that sedation was given feels like recording a treatment, and is the deviation from recording what was corrected. What makes one member of each pair the default is not that it is gentler. It is that it can be reviewed, reversed and undone while the other cannot, or cannot in time.

RULE **The default is the option that can still be changed, and the deviation is the one that has to be written down with a reason.** Intuition sorts these pairs by which act feels more careful, and here it sorts them wrongly about as often as rightly. Sorting them by reversibility is mechanical, works in both halves, and produces what an incident review actually looks for, which is never what was decided but what it rested on and who could still have changed it.

29.4 What converts an act into an order

Strip both halves of their entities and almost everything this chapter owns is one discipline: writing things down while they are still measurable. That is why the material is examinable, because the acts are often obvious and it is their conversion into an **order** that separates a plan from a mood. Four elements appear wherever this chapter makes a clinical instruction out of something ordinarily left to whoever is nearest.

- **An author.** A named person who decided it, recorded with their title, so the decision has somebody attached to it at handover.
- **A quantity.** An interval, a distance, a frequency, a position, a duration: stated rather than described, because an act described only as regular belongs to nobody and cannot be audited.
- **A time.** Against the measurement, so a single value becomes a trend; and against the review, so the instruction expires rather than persisting because nobody was appointed to end it.
- **A condition that would change it.** Stated in advance and behaviourally, so whoever takes the observations knows what to watch for and when to call, and a step down is a decision rather than a drift.

Read the chapter through that filter and its scattered instructions resolve into one. The level at which somebody is watched is a prescription with a setter, a stated frequency or distance, a named reviewer and a review time. A tranquillising drug given urgently is a procedure rather than a prescription, with an indication, one dose, a named reviewer and a cadence running until somebody decides it may stop. The position a sedated or restrained patient is left in belongs in the order beside the drug, where it survives a shift change, not in the nursing note, where it does not. A reassuring judgment about a settling postnatal state is permitted only if the threshold that would unmake it is stated aloud and handed to somebody who will still be there.

> **GOOD TO REMEMBER**
>
> Three sentences turn a defensible emergency entry into an indefensible one by their absence, and none is a diagnosis. Who decided the level of care, at what time, and on what observations. What was measured while somebody else was talking, with a time against each value rather than a value alone. And what has been handed on: the person who will resume the interrupted assessment, the interval until then, and the change that brings somebody back.

29.5 What taking a branch actually buys

The rigid and hyperthermic presentations are where candidates expect the marks to sit on telling them apart. Telling them apart is taught in full by the Schizophrenia: management, antipsychotics and adverse effects notes; nothing on this page compares those presentations by their features. The question a recognition exercise never answers is the one this chapter owns: once the branch has been taken, what changes. The plate accompanying this account carries the answer as acts.

Two findings emerge only from looking across the branches. How little changes at the front: whichever branch proves correct, the opening minutes converge on the same physical work, so a

clinician who suspends cooling, fluids or airway attention while the label is argued has the order reversed. And that the first therapeutic move on every branch is a subtraction.

THE BRANCH, ONCE TAKEN	WHAT IS SUBTRACTED, AND HOW FAR	WHAT THIS BRANCH ADDS TO THE SHARED PHYSICAL WORK	WHAT SETTLES WHERE THE PATIENT IS NURSED
NEUROLEPTIC MALIGNANT SYNDROME	The offending agent and every other drug not essential to concurrent treatment, discontinued immediately rather than tapered.	Surveillance of the chain running from sustained rigidity through muscle breakdown to kidney injury and the potassium that follows, which is why fluid balance is charted honestly and the relevant bloods repeated rather than sent once.	Two bedside observations available within a minute and needing no laboratory, which convert an impression into a referral hard to refuse; then the trend, since the emergent decision on replacing renal function is a clinical rule and not a threshold.
SEROTONIN TOXICITY	Every serotonergic exposure, which is wider than the chart: what another department prescribed, what was bought without a prescription, what a relative supplied from home, each with a time against its last dose.	Cooling, sedation and, where rigid active muscle is making heat faster than it can be removed, paralysis with the airway secured first, which is why intubation sits among the supportive measures and not among the disasters.	An observation period keyed to what was swallowed rather than to how she looks, because a presentation seen early may still be rising; the antidote question sits downstream and never substitutes for this.
THE CATATONIC PATIENT	Nothing pharmacological first. The opening acts are nursing acts, begun at the hour of recognition rather than the hour a treatment is found to have failed.	Airway and swallow settled before anything is given by mouth, hydration, prophylaxis against the clot prolonged immobility invites, attention to skin, joints and bladder, and a feeding decision that names a rate.	Deterioration criteria, and the honest question of who can nurse an immobile medical patient overnight, which makes this a level-of-care decision rather than a psychiatric one.
THE ANTIMUSCARINIC BRANCH	The agent, on the same principle, with the subtraction treated as the first therapeutic act rather than a preliminary to it.	The one branch on which a specific antidote question genuinely arises, and the one place the answer is read off objective evidence gathered before anything is drawn up rather than off how the patient appears. Its indications, exclusions and alternative belong to this chapter's account of anticholinergic toxicity and psychotropic overdose.	The duration of the poisoning rather than the patient's condition when the decision is taken, which is the logic the other branches reach by different routes.

That last cell deserves stating on its own, because three branches reach it independently and for unrelated reasons. Improvement is not clearance. A presentation may still be climbing when first assessed; a response to one intervention may outlast neither the poisoning nor the illness; a patient calmed and then left alone has received the half of the treatment given for the sake of the half then omitted.

29.6 Where the two seams cross

The patient who is both is not a special case; she is the general case with both seams running at once. Nothing about the emergency changes when the patient is pregnant or newly delivered. A disturbance is still a disturbance, an overdose still an overdose, a collapse still a collapse. What changes is every act performed on it, and that **overlay** is developed emergency by emergency in this chapter's account of psychiatric emergencies in pregnancy and the postpartum period.

The seams are ordered by different things. The emergency seam is ordered by time: a later question may not be answered before an earlier one. The perinatal seam is ordered by number: no question is finished when it has been answered once. Where they cross, both orderings apply at once, and the failure is not that a step is omitted but that it is completed for one patient and recorded as completed. The second patient is silent, is affected by every drug and every position, and is the one most often missing from the note.

The crossing is also where sourced guidance most reliably stops at principle. It says a procedure is adapted without saying how, that monitoring is regular without saying how often, that a specialist service is the destination without saying what to do where there is none. That is not a hole in the teaching; it is where the teaching is. State the principle, say plainly that no comparable standard is available to quote, then supply the quantity yourself under the discipline set out above: your interval, your name against it, your condition for calling somebody. A number you have authored is defensible; one you have recalled and cannot source is not.

29.7 The Indian seam, which has one shape in both halves

Read across both halves and the Indian difficulty is not a series of separate shortages. It is one shape repeating: the pathway exists on paper and the post does not exist on the roster. A de-escalation team of several trained people, a post-sedation cadence somebody takes and somebody else reads at three in the morning, an observation level that is a staffing decision wearing a clinical name, a fetal parameter needing equipment and a person competent with it, a joint mother-and-infant admission: each is a person on a duty roster before it is a line in a guideline. Neither easy answer earns marks. Claiming the specification is met collapses on the first follow-up question; abandoning it because it cannot be met locally throws away the standard the arrangement is judged against. What is defensible is the **substitution** stated in terms: name the standard, name what replaces it, name what that costs. Where staff are short, the parallel physical work is the first thing dropped and the last thing that should be, because the people who would have done it are the ones missing.

IN INDIA

Sort what this chapter asks for into what costs money and what does not, because the second list is longer than residents expect. Equipment and staffing decide the observation area, the trained team, the tracing somebody can interpret, the unit that admits a mother with her infant. Almost nothing else this chapter owns costs anything. The order of the sequence is free. Designating one person to hold verbal contact is free, and gets easier rather than harder when only two staff are on duty. Taking collateral from the people present before they leave is free and cannot be done later at any price. The position a sedated patient is left in is free, and so is a written interval with a name and a review time against it.

MNEMONIC

Recognise, stabilise, establish authority, act, monitor, dispose - and name the second patient first

Recognise: what this is, with the psychiatric attribution reached last. **Stabilise**: treated when found and reassessed, alongside the talking. **Establish authority**: who may act, recorded with its basis. **Act**: one act, with a reviewer. **Monitor**: an interval, a person, an endpoint, a trigger. **Dispose**: decided by somebody, handed over as reasoning. The perinatal half adds no further step and changes none of these. It moves the last clause to the front, and every step above is then asked twice.

Both halves of this chapter are sequences of decision rather than bodies of fact: the emergency seam runs recognise, stabilise, establish who may act, act, monitor, dispose, and the perinatal seam asks every one of those questions for two patients of whom only one can be asked anything. An act anywhere on either seam becomes safe in the same four ways: a named person who decided it, a stated quantity, a time against it, and a written condition that would change it.

TRAP **Answering the crossing point for one patient and recording it as complete.** The seams of this chapter meet at the moment a decision taken for the person in front of you is also a decision taken for someone who is not: an infant who is not yet the ward's patient, a fetus with no chart of its own, a family who will be doing the observing tonight. A candidate who has learnt both halves separately will answer the emergency correctly and the second patient not at all, and the answer reads as finished because nothing in it is wrong. The check is mechanical: for every act named, say who else it was a decision about, and where that was written down.

Apply and consolidate

30 · Applying the chapter

A vignette in this territory almost never asks what the illness is called. It asks what is done before the name is settled, on what ground it may be done to a person who has not agreed to it, who is watching afterwards, and where both patients are when the hour is over. Those are

separate findings reached by separate reasoning, and a candidate who prepared this material as a set of syndromes answers a question nobody asked.

These cases assert nothing of their own. Every threshold, interval, dose and statutory provision they touch is taught, and cited to its source, by the account that owns it, and is named here rather than restated. Cover the answer, decide what you would do at the bedside, then read on.

Act	Authority	Watch	Where
WHAT IS DONE IN THE FIRST HOUR, BEFORE THE LABEL IS ALLOWED TO SETTLE	THE GROUND FOR ACTING, ASSESSED AND WRITTEN DOWN RATHER THAN ASSUMED	WHAT IS MEASURED, HOW OFTEN, AND BY WHICH NAMED PERSON	THE DESTINATION DECIDED, NOT DEFAULTED TO BY WHICHEVER WARD HAS A BED

30.1 How to work a vignette in this chapter

Read the stem and ask which kind of question it is putting to you, because each has its own source of authority and none supplies another's answer.

- An **act question** asks what is done now, in what order, while the diagnosis is still open and may never turn out to be psychiatric.
- An **authority question** asks on what ground a person who has not agreed may be treated, held, observed or kept, and is answered from capacity and statute, never from how unwell the patient looks.
- An **observation question** asks what is measured, at what interval, by whom, until when, and on whose review.
- A **disposition question** asks where the patient goes, who is going with them, and what has to be true before either moves.

Every case below is more than one of these at once, and the marks go missing where a candidate discharges the easy one and treats the paper as finished. Deciding that a presentation is a psychiatric emergency settles the act question and none of the other three.

RULE **The name of the condition is not the answer to any question in this chapter.** What these disorders are, how they declare themselves and how they separate from their mimics are taught in full by the chapters that own them, and reproducing that material here scores nothing. What is examined is narrower and much harder to improvise: the act, the ground for it, the watch that follows it, and the destination. A case that ends at the name has stopped exactly where the patient in front of you begins.

30.2 Vignette: the stop request that is not the cautious option

Presentation. A woman in her late twenties has been well for over a year on an antidepressant, after two severe depressive episodes, the second needing admission. She has missed a period and tested positive at home. She brings a printed sheet from the internet grading her tablet on the old lettered risk scale, which her mother-in-law has read aloud in the waiting area. She wants to stop today, and the resident agrees and writes that the patient wishes to stop and the medication has been stopped.

Decision point. What is actually being compared here, and what leaves the room with her.

Reasoning to show. Refuse the comparison as offered. There is no unexposed arm: she will carry drug exposure or illness **exposure** and usually some of each, so counselling that quantifies one arm and leaves the other qualitative is not balanced, however carefully the drug figures are quoted. That frame belongs to the section of these notes on prescribing psychotropics in pregnancy. Deal with the sheet as history: the scale was read as an ordinal grade the data never supported, implied that agents sharing a rung carried the same risk, could not separate animal evidence from human, and saw only structural harm, which for psychotropics is the decisive objection. It was withdrawn from labelling and replaced by a **narrative labelling** structure, and the prescribing account dates it at both ends and names its replacement. Reciting a rung from it is a factual error, not a shortcut.

Then take the request apart, because stopping is two decisions wearing one word. Whether to stop is largely hers; how to stop is entirely yours, and the manner changes the outcome as much as the choice. Name every arm aloud and price each in her hearing, since continuing, switching, reducing and stopping are each a positive act with a bill, and reducing is the arm that can buy the exposure without buying the benefit. The figures pricing each belong to mood and anxiety disorders in pregnancy in these notes and to the Mood disorders: pharmacotherapy notes; quote neither from memory. And stopping today does not undo an exposure that has already happened, so it has to be justified forward rather than as a retrospective repair.

Answer. Do not stop the drug this afternoon on a printed sheet. Say what the sheet is and what replaced it, put both arms on the table, price each, and let her choose. If she still chooses to stop, the task becomes damage limitation and the **taper** is the instruction rather than the decision, with restarting, switching, a psychological intervention and increased monitoring all still on offer. Then the disposition, where this case is usually lost: she does not leave without a review date, a named person who owns the dose as gestation advances and its reversal after delivery, and an entry written where the antenatal team will read it. Record what she decided in her own words and what would change it, so a later clinician can tell a settled choice from an unresolved one.

PITFALL

The act that is recorded rather than done. A note reading that medication was stopped is half an instruction, and the missing half predicts the outcome. The same defect runs through every case here in different clothing: observation signed for at the right interval and not delivered, a decontaminant charted for a drug it does not bind, an evaluation abandoned because the patient was disturbed and never diarised again, a referral written into a plan that will arrive long after the problem has resolved itself one way or the other. Each reads correctly and delivered nothing. The only step in this chapter that checks the record against the world is the one the shift handover names, which is to go and physically see the patient.

30.3 Vignette: the mother, the infant, and the appointment for next week

Presentation. A woman delivered a fortnight ago is brought to casualty at night by her husband and mother-in-law. Over several days she has stopped sleeping, become perplexed and frightened, and said more than once that the baby in the house is not hers. Between episodes she is lucid and

apologetic. The infant is asleep in the mother-in-law's arms in the corridor. The duty resident, finding her settled and polite in the room, gives an outpatient appointment for the following week and records that she has good family support and would never harm her child.

Decision point. What happens tonight, and where do the two of them sleep.

Reasoning to show. Act before the diagnosis is available. The trigger is a sudden onset of symptoms suggesting the presentation rather than a confirmed one, and the response standard is a timed referral to a service that can admit; that standard and its interval belong to the postpartum psychosis account in these notes, and the disorder itself to the Other psychotic disorders, delusional syndromes and catatonia notes. It is classified as an obstetric and a psychiatric emergency at once, which is the operative part, because neither service may then hold her as a referral to the other. Begin the act, then call the other team. Two supervision rules bite from the moment the presentation is suspected, before the bed and before anyone agrees a name: she is not to be left alone, and she is not to be left unattended with the infant. The second is not a separation order but a statement about who else is in the room, compatible with feeding and holding. A **supervision plan** that names nobody is not a plan, so record which adult is with her, which adult is with the infant, who takes over at the next handover, and what would change the arrangement.

Then refuse both reassurances the resident relied on. How she looks now is a poor guide to tomorrow, because deterioration here can be extremely rapid and the triage is made on **trajectory** over recent weeks rather than on the cross-section, which is what the collateral history is for. And counting her children as the reason she will not act is to be challenged rather than accepted, even where she says it herself, because devotion is evidence about her values and not about her capacity to keep herself safe. The perinatal method profile is shifted toward acts leaving little margin for rescue, so an apparently minor act raises the admission question rather than settling it.

Answer. Assess her tonight, by somebody with the authority to admit. Put both supervision rules in force now and name the two adults who discharge them. Admit, and say what the admission buys, which is the physical evaluation that cannot be finished in a corridor and a place where sleep can be re-established; treat that evaluation and any sedation decision as one plan with one owner, or the workup is abandoned the moment she is disturbed again. On disposition, joint admission is the default and separation is the deviation that has to be argued in terms, authored, dated and reviewed, with the review interval and the point at which the decision leaves the clinician altogether fixed by statute rather than by the team's convenience. Where no mother and baby unit is within reach, which is the position of most Indian services, assemble what the ward permits: a side room rather than an open bay, a named female relative resident alongside with somewhere to sleep, infant care agreed with the family beforehand rather than assumed, and the separation reviewed out loud on a stated date. Hand over the clock, the risk assessment on both sides, the supervision instruction and the reason for the destination, because a handover carrying the diagnosis and not the supervision plan has passed on the label and dropped the safety.

30.4 Vignette: the injection, the authority for it, and the bed that does not exist

Presentation. A man in his thirties is brought to a district hospital casualty in the small hours by his brothers, who tied his wrists with a cloth for the journey. He has not slept for several nights, talks over everyone, has given away money the family does not have, and is certain nothing is wrong. His brothers say he was treated somewhere years ago. He is loud, has struck nobody, and refuses to sit. The resident is alone with one nursing officer and a security guard, wants to give an intramuscular injection, and plans to send him home afterwards because there is no bed.

Decision point. On what ground is the injection given, and where does he go when it has worn off.

Reasoning to show. Sedation is indicated by what the disturbance prevents, never by how disturbed the patient appears, so the clinician must be able to finish the sentence: this assessment cannot be made, this treatment cannot be given. Noise is not the indication, and a department that sedates noise will sedate distress and grief along with illness. Meanwhile the physical sweep runs alongside the talking rather than after it, because new agitation is presumed to arise from a general medical condition and a known psychiatric history is no exemption: the history explains why this man might become agitated, not why he is agitated tonight. Glucose, saturation and temperature cost minutes, and the brothers hold the only account of the past week and will be gone within the hour.

Then the authority, which is the half the resident has not begun. Incapacity is the likely finding in this population, and a likelihood is exactly what an assessment is for, so **capacity** is assessed and written down rather than inferred from the disturbance. Mania makes that harder, because the examination that ought to detect the problem conceals it: orientation intact, speech fluent, information returned verbatim, and the failure confined to the weighing, where the risk is understood, retained, restated accurately and then judged not to apply. The statutory ground for treating or holding a patient without consent in India belongs to the Mental health legislation and forensic psychiatry notes and the consent doctrine to the Forensic ethics, consent and legal procedure notes; name the ground and improvise no provision. The competence half is separate and no statute answers it, since whoever gives a drug that may stop him breathing must be able to manage a man who has stopped breathing: the decision may be delegable and the airway is not. Every agent and first dose belongs to the Schizophrenia: management, antipsychotics and adverse effects notes and appears nowhere in your answer.

Answer. State the indication as an inability and record it. Sweep while somebody else talks, and take the collateral before the brothers leave. Assess capacity, write the finding, name the ground. Decide early that sedation is likely, and stop the cup of tea otherwise brought to a man who may shortly be unable to protect his airway. Write the order as a single dose with a named reviewer and a review time, because an open order hands the next decision to whoever holds the chart at the worst hour, and set the monitoring by route and by state rather than by agent, a sleeping patient being an escalation and not a solved problem. Where the equipment is in another building, what replaces it is a different observation set taken from the end of the bed with one person's name written against it, never an absence of observation. If he is held, the load goes to

the side and never onto the thorax, the head stays free and the face uncovered, and one person watches who is not holding. Then refuse the disposition as proposed, because admission is decided by whether the identified risks can be held where he would otherwise be. Ask who can stay awake with a man who will not sleep, whether anybody in that house is frightened and whether there are children in it, what he can spend or transfer before morning, which means the phone as much as the wallet, and where the vehicle keys are. Where there is genuinely no bed, that is a thing to be escalated and recorded with the time of each refusal, never a clinical reason.

TRAP **Writing a plan with no person's name in it.** Monitor regularly, observe, family to watch, review, as per protocol: each reads as an instruction and none of them is one, because an interval assigned to a ward is assigned to nobody and a reviewer who is a role rather than a person does not in practice review. Candidates write this way because it is how the case sheets they have copied are written, and because naming somebody feels like an accusation waiting to happen. It is the opposite. Every duty in this chapter has an owner in the source material, and the mark is in supplying one: who set the level, who takes the observations, who reviews and when, who holds the infant, who finishes the evaluation that was interrupted.

30.5 Vignette: three antidotes offered, and which of them is read first

Presentation. A woman in her forties is brought some hours after being found drowsy at home beside empty strips. The family bring a cloth bag of tablets collected from three prescribers over several years and cannot say what she took or how much. She is flushed, dry, febrile, disoriented and has not passed urine. The intern proposes activated charcoal now, physostigmine to clear the delirium so that the psychiatric assessment can be completed, and asks whether flumazenil would speed matters up.

Decision point. Which of the three is given, in what order, and what is read before any syringe is filled.

Reasoning to show. Identification comes first, and it is a psychiatric job rather than a clerical one, because the psychiatrist is often the only person who knows what she was prescribed and therefore what is plausibly inside her. The prescription is a physical object in a bag in the corridor: ask for the strips, the bottle and the last outpatient card while the attendants are still here, count what is missing from a strip, and record that you asked and were told nothing, which distinguishes an unknown ingestion from an unexplored one. Then the antidote question, decided on the electrocardiogram and the contraindication list and never on how antimuscarinic she looks, because recognition names the family of poisons and not the member, and members diverge on whether this drug helps or kills. Where the width is past the line at which seizures become possible, the act is sodium bicarbonate and the antidote is refused; past the line at which ventricular arrhythmias appear, the same act happens in a monitored bed with anaesthesia and critical care in from the start. One clause of the contraindication list carries almost all the mortality, since cardiovascular disease bars the drug in exactly the patient in whom the reflex to give it is strongest. Given at all, it goes with the list read whole, atropine drawn up beside it because that is this antidote's own antidote, no faster than the label allows, and as one diagnostic dose that wears off long before the poison does.

The other two requests answer faster. **Decontamination** is settled by asking what, then when, then who. What was taken decides whether charcoal has any role at all, since for a defined list of poisons it has none at any interval; when it was taken sets a window belonging to that poison and that formulation rather than to a single remembered figure; and who is in front of you can withdraw what the first two allowed, because the airway reflexes that matter are those that will exist when the charcoal is in the stomach, and an airway is never secured in order to administer a decontaminant. The benzodiazepine antidote is refused on the right ground, which is not that it is unsafe in the abstract but that the reason offered is diagnostic convenience: the drowsiness is information about the ingestion that the antidote deletes, and in a mixed ingestion reversal removes a mask and can turn a sedated patient into a fitting one. Medical priority is in any case a claim on resources rather than a licence to postpone, so the psychosocial assessment is not deferred until treatment is finished, and where she genuinely cannot participate what replaces it is a stated review interval, not silence.

Answer. Electrocardiogram before anything is drawn up, and a second timed against the first, since direction of change matters more than any single width. Bicarbonate if the width demands it, and the antidote refused with the ground written down so that a fresh team does not quietly reverse a cardiovascular refusal. Charcoal only if the identified agent, the elapsed time and the airway all permit it. No flumazenil to make her interviewable. On disposition, refuse the phrase **medical clearance** and state the two limbs instead: that the disturbance is unlikely to be due to a medical condition or trauma, and that treatment of the concomitant problems falls within the capabilities of the receiving facility, the second being a statement about your service and not about her. The observation period belongs to the drug rather than to the mental state, and modified-release agents declare themselves late, so an untroubled early picture is not a discharge criterion. Where doubt between a confused state of medical origin and a psychiatric one is unresolved, she is medically observed and never transferred; the syndrome itself is the Stroke, TBI, delirium and focal brain syndromes notes'. Hand over the tracings in sequence with their times, whether the antidote was given, refused or unavailable and on which ground, and whether decontamination was given and when.

> **GOOD TO REMEMBER**
>
> Almost everything you will need in these cases is standing in the corridor and is about to leave. The relatives who saw the patient yesterday and can date the change, the strip with the missing tablets, the outpatient card, the ambulance crew, the person who could hold the infant tonight, the answer to what else is in the house: none of it can be reconstructed at the ward round, and all of it can be had while the patient is being stabilised by somebody else. Assign it to the team member who is not holding verbal contact, ask before anybody is released, and write down who said what, because a disagreement about when this started is usually the first sign that the story offered is not the story that happened.

30.6 The four cases on one grid, and the thread through them

Set side by side, the cases are one discipline in different clothes, and the right-hand column is a single family of mistakes.

VIGNETTE	THE QUESTION IT REALLY ASKS	WHERE THE ANSWER COMES FROM	THE CLASSIC WRONG ANSWER
THE STOP REQUEST	Which two exposures are being compared, and what leaves the room	The prescribing-in-pregnancy account, then the account that prices each arm	Stopping on a withdrawn scale, and recording a decision with no taper, no review and no owner
THE MOTHER AT NIGHT	What is done before the name is settled, and where the pair sleep	The postpartum psychosis account, and the perinatal emergency overlay	An appointment for next week, justified by how she looks and by the children at home
THE INJECTION IN CASUALTY	The ground for treating a man who has not agreed, and what holds the risk afterwards	The rapid tranquillisation account, the agitation assessment, and the statute named but not restated	An open order given on the disturbance itself, then discharge because the ward is full
THE UNKNOWN OVERDOSE	Which instrument selects the act, and what the receiving service can actually do	The overdose triage account, and the antidote and decontamination account	Charcoal by reflex, an antidote given on appearance, and reversal to make the patient interviewable

The thread, stated once. Every case turns on refusing to let one finding stand in for another. A clinical indication does not answer an authority question. A reassuring appearance does not answer a question about trajectory. A recognised toxidrome does not select an antidote, because a measurement does that. And a decision recorded is not a decision delivered, which is why every act here ends with a person's name, an interval and a place.

IN INDIA

Four service facts decide these cases more often than any clinical one. No funded pathway puts a psychiatrist inside the antenatal clinic, so nearly every contact a pregnant woman has belongs to somebody who was never asked to ask, and an arm of a decision that cannot be delivered locally should change which arm is chosen rather than be recorded as though it had been offered. Mother and baby units are very few across low- and middle-income settings, so the disposition question is usually which relative rather than which agency, and whether she can genuinely do it. The monitoring a sedation protocol assumes is often in another building at night, so what is owed is a different observation set, a named observer, and an honest record of what was unavailable. And the antidote is frequently not in the hospital at all, which leaves the tracing and the bicarbonate as the limb you actually use; what is scarce there is a monitored bed with an anaesthetist attached rather than a molecule, so settle in advance which unit accepts such a patient and whom you telephone when the answer is no.

MNEMONIC

Two patients, the inability, the name, the interval, the destination

Rebuild any case in this chapter from these when a vignette empties your head. **Two patients**: establish the second before doing anything to the first, whether that is a fetus, an infant in the corridor, or an untreated illness that is itself an exposure. **The inability**: the act is indicated by what the disturbance prevents, and if nobody can finish the sentence, nothing has been indicated. **The name**: an authority assessed and written down, and a person named against every duty, the reviewer, the observer, the adult with the infant, the owner of the evaluation that was interrupted. **The interval**: a cadence, a review time and an observation period belonging to the drug or the statute rather than to the ward's convenience. **The destination**: decided by whether the risks can be held where the patient would otherwise be, never by which bed happens to be free.

Every question in this chapter is answered in the imperative and ends with a destination: what is done now, on whose authority, watched by whom at what interval, and where both patients are when the hour is over.

31 · Consolidation

The last useful thing to do with this material is not to read it again but to produce it from memory, with nothing in front of you. Everything below is active recall against a risk category or a decision, and each is a question and nothing is answered, which is the design: **active recall** forces an answer out before it can be checked, whereas an answer printed beside its prompt converts the exercise back into reading, which feels identical from the inside and does far less.

Two things separate this list from a summary. It asks almost nothing about what a syndrome is, because throughout this material the marks sit in **the act** and **the setting**: what is done, in what order, on whose authority, watched how often, and where the patient goes next. And it prints no figure at all, partly because an answer beside its question destroys the exercise, and mostly because the numbers belong to the chapters owning the entities: sedation and the escalation ladder to the Schizophrenia: management, antipsychotics and adverse effects notes, suicidal intent to the Somatic-symptom, sexual, impulse-control disorders and suicide notes, the confusional syndrome to the Stroke, TBI, delirium and focal brain syndromes notes, and the catatonic signs and the benzodiazepine challenge to the Other psychotic disorders, delusional syndromes and catatonia notes.

Retrieve	Act	Authority	Destination
THE DEVICE THIS SECTION RUNS ON, NEVER REREAD	WHAT EVERY PROMPT ASKS FOR, NOT WHAT THE THING IS CALLED	NAMED BEFORE ANYTHING IS DONE TO A PATIENT WHO CANNOT AGREE	DECIDED BY SOMEBODY, NEVER DEFAULTED TO BY NOBODY

31.1 How to use this list

Six groups follow the order the material was built in, one prompt per topic. Answer aloud or on paper, in sequence, because sequence is most of what is examined: correct acts in the wrong order satisfy nothing. Two habits are worth imposing. Name who performs each act, because almost

every failure described here is an act nobody owned rather than an act nobody knew. And finish each answer where the patient leaves you, not where the patient settles.

RULE **Every question here is answered with an act, never with an entity.** Naming the syndrome earns very little, because it is taught in the chapter that owns it and the examiner knows that. What is asked is what happens in **the first hour**: what is excluded before anything is attributed, who has authority to act on a patient who cannot agree, what is done and by when, what is measured afterwards and how often, and which destination the patient leaves for. Answer the entity and you have written a correct paragraph from another chapter, scoring on none of it.

31.2 Group one: prescribing and treating in pregnancy and lactation

Every decision here is taken for **the second patient** as well, and no arm of any of them is unexposed.

1. A woman who may become pregnant needs a psychotropic. Which patients is the decision for, and why is doing nothing an exposure? Then: what replaced the withdrawn letter-based risk system, when did that take effect, why could one ordered label never carry the information, and what must a current label state instead?
2. She is breastfeeding. What does the standard exposure metric measure, and what does it silently omit? Why is a missing figure for an agent not a reassurance, which infants do the published figures not describe, and what is watched in the baby, by whom, and what would stop the drug?
3. She is already well on treatment and is pregnant or planning to be. Name the arms this decision actually has, price each against her illness rather than against nothing, and say which part is hers and which is entirely yours.

31.3 Group two: the postpartum period

Every prompt here has two subjects, and the second can report nothing at all.

1. Tearful and labile in the first days after delivery. What act does the front door owe her, into whose hands does the judgment then pass, and what must be said aloud and written down before that judgment is allowed to close?
2. Build the perinatal screening pathway as a service rather than an instrument: who is screened, at which contacts, by whom, and what actually happens to a woman who answers yes, and how soon? Then what does the Indian position supply, and what does it not?
3. A fortnight past delivery, behaving strangely, the family frightened. What does assessing her immediately oblige somebody to do, and by when? What does admission buy that no outpatient plan can, and which adults must be named before she or the baby is left alone?
4. Why is a mood enquiry not an enquiry about the relationship? How is the bond observed at the bedside rather than inferred from the mood, what does the formulation oblige you to arrange before she leaves your care, and when is the question asked again?
5. What is a mother-baby unit for, and which clause of its specification prevents which predictable failure? Where does the burden of proof sit when separation is considered, who

reviews it, and what does an Indian team assemble when no unit is within reach?

31.4 Group three: women's mental health across the lifespan

Three of these are routing problems before they are clinical ones; the fourth has a statute inside it.

1. A week of irritability and hopelessness each month, lifting as her period starts. Where does the classification file this, and what does that do to your pathway? What must be documented before anyone commits to a label, and in which direction across time does that record run?
2. Low mood and broken nights in midlife, with the explanation already agreed by everyone. Why is the transition a context and not a diagnosis, what must be established before anything is attributed to it, and how is the decision divided where there is nobody to divide it with?
3. What has to be true before you are entitled to ask a woman about violence at home? How is the question put, what is done in the minutes after the answer is yes, and what changes in an emergency department? Then name the Indian legal and service frame in words.
4. Reproductive medicine hands psychiatry separate tasks. Take each: what must be discussed in a fertility clinic and on whose statutory duty; which question a termination opinion actually answers and on what ground; and what must be in place before a contraceptive conversation is defensible when the drug complicating it is your own.

> **GOOD TO REMEMBER**
>
> Do not run this list once, the night before. Sweep the six groups now and mark two kinds of failure apart: prompts you could not answer, and prompts you answered by describing a syndrome. The second matters more, because it is the exact error this material exists to correct and it feels like knowledge while you produce it.

31.5 Group four: the behavioural emergency

The sequence itself, door to destination. Answer as an ordered account of who did what, and resist starting at the drug.

1. Before any escalation ladder begins: what is settled about the room and its exits, how many people are in it and which one may speak, where do you stand and why does the geometry matter, what is measured while somebody else talks, and which presumption do you carry about new agitation until it is displaced?
2. Take the drug chart away from rapid tranquillisation. What is left: the indication in the form the guidance uses, the authority when the patient cannot consent, who must be competent and within reach, what is checked before, what is measured afterwards and until when, and what happens when it fails?
3. What is an observation level as an object rather than as a feeling? What must be written for one to exist, who may raise it and who must review it, what may the observer not simultaneously be doing, and what must the ward be checked for as a physical space?

4. Brought in at night, elated, sleepless, certain nothing is wrong. What triggers urgent specialist assessment, what is excluded before the psychiatric label settles, why is the capacity assessment in this state most often got wrong, which harms accrue while you deliberate, and where is he routed?
5. An overdose arrives. How are the two assessments ordered, and what does medical priority not license? What replaces the phrase that used to end this argument, how do you establish what was taken when nobody can tell you, how long does decontamination stay available, why is the well-looking patient dangerous, and what must the handover contain?
6. Somebody is being physically held. Where may the weight go and where may it not, and why? What is done about the head and face, what governs how long the hold lasts, which duties are separate from watching, what does the body need if it is prolonged, and what happens in the hour after release?

31.6 Group five: the rigid, hyperthermic and toxidromic emergencies

Each entity here is taught elsewhere, so each prompt asks only what follows recognition. An answer listing features, or comparing one with a mimic, has answered the wrong question.

1. An immobile, mute patient is admitted. Setting the challenge and the rating scale aside: what is secured in the first hours while the diagnosis is unsettled, which complications of immobility are prevented rather than treated, what would convert this into a life-threatening emergency, and who nurses this patient where?
2. What kind of instrument is a formal criteria set, and what does its negative limb oblige you to do? What does a result below the threshold not mean, and which observations, quite separate from those criteria, decide where the patient is nursed and when organ support and renal replacement are called for?
3. The decision rule for serotonin toxicity: in what population was it derived, in which direction are you running it at a psychiatric front door, and why does that make a positive worth more than a negative? What does the distinction from the rigid hyperthermic alternative change about the next hour, and where does an antidote sit in the order of operations?
4. A patient's neck and eyes have deviated after a first injection. Which question precedes the syringe, why is the culprit drug often not on the psychiatric chart, how long may you wait and what follows when nothing happens, why is the episode not over when the spasm melts, and what do the drug-induced emergencies outside the brain share?
5. How do you establish which of the lithium poisonings is in front of you, and from what source? What does a measured concentration tell you about the patient you can see and what does it not, which decontamination decision exists in one pattern and not another, and what sets the length of observation?
6. An antimuscarinic picture follows an overdose. What is read before any antidote is drawn up, which overlap makes that antidote lethal, who must it be refused to, how is it given and what is kept beside it, and what is done instead for the patient who cannot have it?

31.7 Group six: the medical emergency and the perinatal overlay

The final prompt closes the loop, taking every emergency above and asking what changes when a second patient cannot be examined.

1. An elderly man, confused since morning. What is treated the moment it is found rather than carried to the end, how is conscious level graded inside the primary survey, which bedside measurements are taken and when is one not to be believed, what is given before any carbohydrate, what does sedation not buy, and where does he go when the answer is still unclear?
2. A man who drinks, drowsy and unable to account for himself. Which word has everyone already supplied, and why is it withheld longest? What is excluded before anything is attributed, what runs alongside it and what in that is routinely skipped, which diagnoses are missed in the state that conceals them, and where does he leave for?
3. The emergency patient is pregnant or newly delivered. What is established before anything is done to her? Why is the position she is left in after sedation or restraint part of the prescription rather than the nursing, how is a hold adapted and where does the guidance honestly stop, what must not follow sedation, what is monitored afterwards and how often, and who is called into the room rather than after it?

IN INDIA

Several prompts above have an honest Indian answer that is not the specification, and saying so earns more than reciting a standard the setting cannot meet. The de-escalation team the consensus describes is not what a district casualty holds at two in the morning. An observation level is a person, so a service that cannot supply the person cannot supply the level, whatever the chart says. The monitoring a sedation protocol assumes needs equipment and somebody free to use it. A mother-baby unit may be hundreds of kilometres away, and the referral a violence pathway names may have nobody at the far end. In each case the marks are in naming what is substituted, who does it instead, and what has been accepted by substituting.

31.8 The answers this material punishes

More marks are lost here to a small set of confident wrong answers than to genuine ignorance, because each is a compact sentence that sounds like clinical sense and each answers a question that was not asked. If anything you produced matches the middle column, reopen that section first.

AXIS	THE ANSWER THAT LOSES THE MARK	THE ANSWER THAT EARNS IT	WHERE TO REOPEN
THE AGITATED PATIENT	Starting at the escalation ladder, as though the question began at the decision to calm somebody	Room, team, one designated voice and the parallel sweep come first, and new agitation is presumed medical until displaced; the ladder is another chapter's	the acutely agitated and aggressive patient
SEDATING WITHOUT CONSENT	Answering with agents, sequence and doses, because the question looks like pharmacology	An indication stated as what the disturbance prevents, capacity written down, an airway-competent practitioner, one dose with a named reviewer, monitoring that outlives the drug	rapid tranquillisation protocols
HOLDING A PATIENT	Saying the patient is turned onto their back rather than their front, and stopping there	No position is safe: weight off the chest, head free and face uncovered, the hold as short as it can be made, one person watching who is not holding	restraint and seclusion
PRESCRIBING IN PREGNANCY	Reciting a letter from the withdrawn labelling system as though it were current practice	Name the system, date its withdrawal, name the narrative rule that replaced it, then reason from the evidence against a background rate that was never zero	prescribing psychotropics in pregnancy
THE WOMAN ALREADY ON TREATMENT	Stopping the drug the day the test comes back positive, and calling that cautious	The exposure has already happened, her untreated illness is the competing exposure rather than the baseline, and the manner of stopping matters as much as the decision	mood and anxiety disorders in pregnancy
THE CONFUSED PATIENT WHO DRINKS	Attributing the confusion to alcohol because there is a history of alcohol	Exclusion first, attribution second: injury and the metabolic causes are excluded alongside each other, and intoxication is a conclusion arrived at, never a premise begun from	acute alcohol withdrawal and delirium tremens

PITFALL

One error runs underneath all six, and it is why this list prints no figures. Every number that answers a prompt above belongs to a document and to a population, and stops being true when separated from either. A guideline's threshold is that guideline's. A rule derived in a poisoning service behaves differently at a psychiatric front door. An exposure figure calculated for a term, healthy, exclusively breastfed infant says nothing certain about a preterm one. Quote a figure with its source and its population, or quote the reasoning and say plainly that you assert no figure.

31.9 The frame to run on an unseen question

All of it collapses into one procedure, run in order on anything familiar or not, so that an unseen presentation becomes a sequence of decisions rather than a search for the nearest remembered rule. The word names the mistake: the patient who gets missed is the one nobody established was there, and the half of the answer that gets missed is the half that comes second.

MNEMONIC

SECOND

Second patient: before anything is done to the person in front of you, establish whether there is another, because every perinatal decision is taken for two at once and only one can be asked, examined or consented. **E**xclude before you attribute: the physical sweep runs alongside the talking rather than after it, and the psychiatric label is the last attribution made, not the first. **C**apacity and authority: written down before the act, never inferred from the disturbance, never confused with the judgment that the act is warranted. **O**n the clock: the act is timed and the window closes, so state how long you may wait and what follows when it does not work. **N**ame the cadence: what is measured, how often, by whom, until when, and the **level of care** that follows. **D**isposition: where the patient goes, who decided it, and a handover carrying what was assessed, what it showed, and what is still active.

TRAP **Ending the answer at the injection.** The commonest structural failure here is an answer that stops when the patient becomes calm, the spasm melts, the antidote is given or the diagnosis is finally named, as though the emergency were the problem and the calm were the solution. The avoidable deaths sit in the hour afterwards, which is why so much of this material is **monitoring cadence**, level of care and **disposition**. Whatever the question appears to be about, keep writing until you have said who watches this patient, how often, on whose authority, and where they are when the shift changes.

Establish whether there is a second patient before you touch the first, exclude before you attribute, settle whose authority the act runs on before it is performed, then name what is monitored, how often and until when, and where the patient goes: the marks here sit in the order of the acts and never in the name of the entity.

Previously asked

There is no indexed past-question bank for this chapter, so nothing in the table below is a catalogued past question and no board or year is claimed for any of them. Attributing a paper the index does not hold would be a fabrication, so each row is marked Representative and written in the register an examiner uses. Almost every question in this area is a mixed question, and only one of its halves belongs here. The naming half has been taught elsewhere and is expected rather than supplied: the rigid and hyperthermic drug reactions by the Schizophrenia: management, antipsychotics and adverse effects notes, catatonia by the Other psychotic disorders, delusional syndromes and catatonia notes, the confusional state by the Stroke, TBI, delirium and focal brain syndromes notes, the withdrawal syndrome by the Substance use disorders notes, and the authority to act on a patient who cannot agree by the Mental health legislation and forensic psychiatry notes with the Forensic ethics, consent and legal procedure notes. Bring those. What the table asks for is the doing.

QUESTION	FORM	ASKED
A woman established on a psychotropic is confirmed pregnant. How is continuing, switching, reducing or stopping decided, and what must the record show?	Long answer	Representative
Choosing an agent for a mother who is breastfeeding, and what the usual metric leaves out.	Long answer	Representative
Screening after delivery as a service question: who screens, at which contacts, and what happens to a positive answer.	Long answer	Representative
Postpartum psychosis at the point of contact: the act, what admission buys, and who holds the infant.	Long answer	Representative
Assessing the mother and infant relationship, and how risk to the infant becomes supervision and a discharge plan.	Long answer	Representative
Intimate partner violence: the decision to enquire, the preconditions for asking, and support in an emergency department.	Long answer	Representative
The mother and baby unit, and what is done where there is none.	Short note	Representative
The psychiatric opinion sought before a termination of pregnancy.	Short note	Representative
Premenstrual dysphoric disorder and the menopausal transition: which clinic each woman reaches psychiatry from.	Short note	Representative
The acutely agitated patient from the door to the handover: the room, the team, the parallel sweep, and what must be true before it ends.	Long answer	Representative
Rapid tranquillisation as a procedure: the indication, the authority, the check before the drug, the monitoring after it.	Long answer	Representative

QUESTION	FORM	ASKED
Observation levels written as a prescription: the named levels, who may move a patient up, and the review that brings it down.	Long answer	Representative
Physical restraint: what a hold does to a body, the positioning hierarchy, the clock, and who watches.	Long answer	Representative
The confused patient at the front door, including the drinker: exclusion before attribution, and which bed he occupies.	Long answer	Representative
Deliberate self-harm and overdose at triage: the order of the two assessments, and the decontamination clock.	Long answer	Representative
The rigid, hyperthermic patient in casualty: the criteria set as an instrument, the level of care, and organ support.	Long answer	Representative
Serotonin toxicity: the decision rule, where it was validated, and the branch that changes the clock.	Long answer	Representative
Acute dystonia and the other acute drug-induced emergencies.	Short note	Representative
Lithium overdose, and the antidote decision in psychotropic poisoning.	Short note	Representative
A psychiatric emergency in a pregnant woman: the position she is left in, the adapted hold, and monitoring two patients.	Long answer	Representative

Two things about the wording repay attention before the content does. The first is the verb. Manage and describe what you would do ask for an ordered act with a time in it, answered from the first minute forwards; discuss asks for a decision and its reasoning, with the alternatives named and priced rather than listed. The second is the setting, written into almost every stem and used in almost no answer. Casualty at night, the antenatal clinic and the postnatal ward are not scenery: each fixes who is in the building, what can be monitored, and where the patient can be moved to. An answer that would read the same in all three has not used its stem. Two habits then earn marks across the list. Answer in the order the marks sit in, what is done now, where, on

whose authority and where the patient goes next, rather than opening with what the thing is. And where an answer needs a figure this material does not hold, name the source instead of the number: the serum bands are in the Mood disorders: pharmacotherapy notes, the risk-assessment instruments in the Somatic-symptom, sexual, impulse-control disorders and suicide notes, and the infant-exposure metric in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes. A candidate who reproduces a dose he has not checked is doing the one thing this material is arranged to prevent.

The quick review

One table, read down the left column and cover the right. Every line is taught in full somewhere above and nothing here is new: each is that topic's single must-hold line, so a line you cannot recover is a topic to reread rather than a fact to memorise here. Five things are load-bearing across the chapter. Every section answers what is done now, where, on whose authority, and where the patient goes next, and none of them answers what the thing is, so a section that says little about a disorder you already know has been written on the assumption that you know it. In the perinatal half all four of those questions are answered twice over, because two patients are in front of you and only one of them can be asked, examined or consented. Exclusion runs before attribution everywhere: the psychiatric attribution is the last one made, and a known psychiatric history is the distractor rather than the answer. The default is the option that can still be changed and the deviation is the one that has to be written down with a reason, which sorts these decisions more reliably than asking which act feels more careful. And an act becomes an order the same way on both seams: a named person who decided it, a stated quantity, a time against it, and a written condition that would change it. The figures printed below are the ones this chapter itself owns, thresholds, intervals, cadences and denominators, each carried back from the section that grounded it; every treatment dose, and every figure that belongs to an entity rather than to an act, stays in the chapter that owns it, and those chapters are named here in words.

ASK	HOLD
PRESCRIBING AND TREATING IN PREGNANCY AND LACTATION	
THE ARM OF THE DECISION WITH NO DRUG IN IT	There is no unexposed arm, only two exposures: she will carry drug exposure or illness exposure and usually some of each, untreated illness being itself an exposure. The illness arm is measurable and belongs in the same sentence as the drug arm. Among women euthymic at conception, 68 per cent of those who discontinued an antidepressant relapsed across pregnancy against 26 per cent of those who maintained it, a hazard ratio of 5.0; in bipolar disorder the overall recurrence risk in pregnancy was 71 per cent. Counselling that quantifies the drug arm and leaves the illness arm qualitative is not balanced counselling.

ASK	HOLD
THE LETTER GRID, AND THE ONLY WAY IT MAY BE USED	A historical object, admissible only with both ends dated on the page and the instrument that replaced it named. The pregnancy categories A, B, C, D and X were adopted in 1979 and ceased to apply to new labelling from 30 June 2015, when the Pregnancy and Lactation Labeling Rule replaced them with a narrative labelling structure; older products had to strip the letter from their labelling within 3 years of that date, so the disappearance was staggered product by product. Two boundaries are routinely misstated: the letters never covered breastfeeding, so a lactation category is something that never existed, and the instrument reached prescription products only. A bare letter offered as current practice is a factual error, not a shortcut.
HOW A TERATOGENIC RISK FIGURE IS QUOTED	Every figure is an increase above a background that is not zero, on a clock you must name. The background major birth defect rate is 2 to 4 per cent and loss is reported in 15 to 20 per cent of clinically recognised pregnancies, and both are stated before any drug is mentioned. Absolute risk is then separated from relative: a tenfold rise in one rare defect, from 0.04 per cent to 0.4 per cent, can leave the total rate across a population unmeasurably changed. And the harm is placed against the window that could produce it, organogenesis at 3 to 8 weeks after conception for gross structural harm, the brain's most critical period running 3 to 16 weeks and past it. The comparator that makes these numbers mean something is the untreated ill woman.
WHAT HAPPENS TO THE DOSE AS THE PREGNANCY RUNS	The dose that was right at booking is frequently not right at term, and that is pharmacokinetics rather than the illness worsening: a woman whose symptoms creep back in the second half may be underdosed by her own physiology. The worked example is glucuronidation, where pregnancy upregulates UGT1A4 and lamotrigine clearance rises by up to 330 per cent, quoted purely as kinetics and never as a statement about that agent's safety. The direction of change is broadly predictable from the elimination route, which makes it teachable rather than merely cautionary. The reversal after delivery is the step this material names as owned by nobody.
WHAT A RELATIVE INFANT DOSE IS, AND IS NOT	An intake figure, not an exposure figure: calculated from what enters the infant and assuming he can clear it, with below 10 per cent of the maternal weight-adjusted dose treated as a notional line rather than as a test that settles anything. Every caveat in the topic, prematurity, the first postnatal days, dehydration, intercurrent illness and maternal genotype, is a statement about a clearance term the metric does not carry. Quote none of it without naming the metabolite it excludes and the infant it assumes, who is term, healthy and exclusively breastfed. What is acceptable in a thriving infant can be wrong in a jaundiced newborn on the same milk.

ASK	HOLD
THE BLANK CELL, AND THE METABOLITE	Where an agent has an active metabolite the drug name and the number in front of you describe different molecules: measured with its metabolite, fluoxetine averages about 7 per cent across a range of 3 to 12 per cent, the upper bound crossing a line the average sits below. The spread across the table is the teaching rather than any single entry, quetiapine at 0.09 per cent at one end and lithium at 12.2 per cent at the other, the latter from a series of 11 mothers and the only central estimate above the notional line. A blank in the percentage column is neither reassurance nor warning: the calculation was not made, and the reason differs by agent, being methodological for the anticonvulsant mood stabilisers. What is watched is watched in the infant, by a named person.
THE FOUR ARMS, AND WHERE THE BURDEN SITS	Continue, switch, reduce, stop, each priced aloud in her hearing so the conversation stops being a request for permission. The default is not neutrality: for most people and most medications the risk of the exposure is lower than the risk of exacerbation or relapse, so continuation stands unless a case is made against it, and the clinician who stops owes the argument. Whether to stop belongs largely to her; how to stop belongs entirely to you, and the manner is itself measurable, median recurrence latency running 11 times shorter after abrupt or rapid discontinuation than after a gradual one, with 47 per cent of recurrences falling in the first trimester. A progressive taper over 2 to 4 weeks is the other half of the instruction.
THE REFLEX STOP, AND THE WOMAN WHO HAS ALREADY DECIDED	Stopping the day the test comes back positive usually cannot reverse a first-trimester exposure that has already happened, and it adds a discontinuation in the very trimester in which recurrences cluster: a visible act substituted for a useful one. Where she has decided anyway the task becomes damage limitation, and the conversation carries restarting, switching and a psychological intervention. Antenatal anxiety and perinatal obsessive-compulsive symptoms are asked about in terms, because what you find depends on how you ask: obsessive-compulsive prevalence runs 1.08 per cent in the general population against 2.07 per cent in pregnancy and 2.43 per cent postpartum, while perinatal generalised anxiety reads 24.4 per cent by screening tool against 11.5 per cent by diagnostic interview, so roughly half the apparent prevalence is a property of the method.
THE POSTPARTUM PERIOD	

ASK	HOLD
BLUES AS A DISPOSITION RATHER THAN A DESCRIPTION	The front door chooses between reassure and review, treat now, and do not discharge, and the choice turns on what is safe to do next rather than on which picture fits best. The act is reassure, inform, return: awareness raised rather than experience dismissed, information about the depressive episode and the symptoms that announce it, and a return threshold held by a named person who will still be there. You may record blues only if you also state what would make you unmake it. This is the chapter's one topic carrying no figure here, and that is a property of the ledger rather than of the state: onset, course, duration and the three-way separation are owned by the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes, and nothing quantitative about blues was grounded here to restate.
WHY A SCREEN IS NOT A SERVICE	Who is screened, at which contacts, with what enquiry, and what happens next. The instrument is the second step of the pathway and never the first. A pathway is judged against its intervals, assessment for treatment within 2 weeks of referral and a psychological intervention within 1 month of that assessment, with the one guaranteed postnatal review at 6 to 8 weeks after the birth. Where a service cannot say who assesses the positives, within what interval, and who follows her if treatment starts, a questionnaire increases documented distress without increasing treated distress. India is where that bites: against a stated requirement of one psychiatrist per 100,000 population, the reported range runs from 0.05 in the lowest state to 1.2 in the highest.
THE SEQUENCING RULE INSIDE THE PATHWAY	Screening for bipolar disorder comes before pharmacotherapy for depression or anxiety is started, if it has not already been done. That is a rule about the order of the pathway rather than a fact about either illness, and it is the front door's most consequential ordering decision: a depression screen is cross-sectional and knows nothing of lifetime course, so a pathway beginning with a positive screen can end in a precipitated episode of a different kind. In India the contacts exist and the instruction does not.
POSTPARTUM PSYCHOSIS: ACTED ON BEFORE IT IS CONFIRMED	Immediate assessment within 4 hours of referral, by a secondary service that can admit, an admission that buys the medical evaluation, and a supervision plan naming an adult for the mother and an adult for the infant, written before either is left alone. It is the only perinatal presentation in the guidance given a response time in hours. Never alone, and never alone with the baby, the second being about who else is present rather than where the baby is. Both bite from the moment the presentation is suspected, which is the point of a rule that does not wait for confirmation.

ASK	HOLD
THE TWO TEAMS, AND WHERE THE BURDEN OF PROOF SITS	Each service assumes the other owns her: the obstetric team sees a psychiatric problem in an obstetric bed, the psychiatric team sees a recently delivered woman with a wound, a fundus and a feeding infant, the referral moves sideways while the clock runs. Begin the act, then call the other team. Joint admission is the default and separation is the deviation that must be stated in terms with its reason, because a written reason can be dated, reviewed and reversed.
BONDING: MOOD AND BOND ARE SEPARATE ENDPOINTS	Enquired about separately, recorded separately and recovered from separately: two passes at the same interview, first how she feels in herself and then how she feels towards this baby, in that order because the second is harder to disclose. Bonding disturbance is present in 29 per cent of mothers diagnosed with postnatal depression, so a negative mood enquiry has excluded a mood disorder and nothing else. Among over 200 mothers referred to specialist services, 10.6 per cent showed established rejection and 14.6 per cent threatened rejection, while 28.6 per cent had pathological anger, severe in 8.3 per cent. Ask her, watch them, ask them. The bond is re-examined after the mood recovers, and that second answer decides who is watching the baby at discharge.
THE INTRUSIVE-THOUGHT DISCRIMINATION	Distress about the thought is reassuring, conviction is not, and the enquiry continues either way. Reading a disclosed ego-dystonic thought as evidence that the baby is in danger costs both ways: the mother who described the most frightening thing in her head watches her infant removed and will not disclose again, while the presentation that genuinely warrants urgency, an idea held with conviction and without distress, is quieter, is not offered spontaneously, and is missed by a clinician whose alarm is already spent. The formulation becomes supervision, surrogate care and a discharge plan.
THE MOTHER AND BABY UNIT AS A SPECIFICATION	Read the definition as a specification and not as a description: an inpatient psychiatry service with at least four beds separate from other wards, a facility for joint admission of mother with baby, staffed 24 hours a day, 7 days a week by dedicated multidisciplinary staff. So is the reason there are so few of them, each network covering a population with between 25,000 and 50,000 live births a year. Joint admission is the default and separation the deviation that has to be justified, recorded and reviewed, and it happens: separations occurred in 23 per cent of consecutive joint admissions in one European series. The separation decision is made on safety and never on diagnosis; converting the diagnostic gradient into a decision rule fails both ways, separating manageable dyads and reassuring a team about a benign-sounding diagnosis attached to an unsafe home.

ASK	HOLD
THE TWO LACTATION QUESTIONS, ASKED SEPARATELY	How much drug reaches the baby, which decides whether the feed is safe, and what the drug does to the mother's prolactin axis, which decides whether there is a feed at all. Both are answered explicitly, and the second is answerable: in the Indian cohort of 237 admissions with a mean stay of 17.23 days, lactation was restored in 75 of the 87 mothers who had stopped, 86 per cent, by dispelling myths, correcting positioning, timing the feed and using expressed milk when she is too sedated. The familiar argument from the harms of separation is a chain its own source states as what the absence of a unit may produce: a mechanism argument, not a measured effect, and presenting it as measured is overclaiming. Where there is no unit, the family-caregiver model and its scaled-down variants are named.
WOMEN'S MENTAL HEALTH ACROSS THE LIFESPAN	
PREMENSTRUAL DYSPHORIC DISORDER: FILED UNDER GYNAECOLOGY	Coded GA34.41, in the genitourinary chapter rather than among the mental disorders, so psychiatry must go and collect it, since adjacency will never hand it to a psychiatrist. A premenstrual complaint is a routing decision before it is a diagnosis and a diagnosis before it is a prescription, and what decides the routing is information about time, which cannot be had in the consultation where the question is first asked. So the record is kept forward across cycles, with a named reviewer and a plan for the interval; compressing that into one sitting substitutes recall for observation.
THE PERIMENOPAUSE IS A CONTEXT, NOT A DIAGNOSIS	The transition has a nosological home of its own, GA30, and it is not in the mental disorders chapter. Most depressive episodes in the transition occur in women who have been depressed before, so the transition is where the episode happened rather than what it is. A context tells you what else to ask and whom to involve, never whether to treat. Collapse it into the diagnosis and two opposite errors open at once, an episode explained away and untreated, and a transition needing a gynaecological opinion absorbed into a psychiatric formulation. Waiting for the transition to finish is the comfortable error, and she often offers it herself. The endocrine material sits in the Endocrine and metabolic psychiatry notes.
READING A VIOLENCE OR DISPARITY FIGURE	The denominator is part of the number: who was counted, over what period, and under whose definition, and a figure quoted without them is not the same claim. The sex difference in depression has a shape that constrains which explanations survive it, an overall female-to-male odds ratio of 1.95 that is already present at age 12, peaks at 3.02 at ages 13 to 15 and then narrows. In India the female risk of a common mental disorder runs 1.53 times that of men, and the treatment gap for women is 81.5 per cent, which is why the gap belongs beside the prevalence rather than after it: the excess sits inside a population that is overwhelmingly untreated.

ASK	HOLD
ASKING ABOUT VIOLENCE IS A COMMITMENT, NOT A QUESTION	Alone, trained, and somewhere to send her. The size of the thing is not in doubt, 25.8 per cent of ever-partnered women worldwide reporting lifetime partner violence, 31 per cent in southern Asia, 22.3 per cent of ever-married Indian women and 2.7 per cent reporting physical violence during a pregnancy. Enquiry is targeted by presentation, unconditional inside those presentations, and routine in antenatal care alone; universal screening is the answer the guidance explicitly rejects where referral options are limited, because enquiry with nowhere to refer, no privacy and no trained response converts a disclosure into new risk she carries home. In an emergency department do everything at that contact, because there may not be another. The Indian civil statute is the Protection of Women from Domestic Violence Act, 2005, and the duties it places on medical facilities are named in words and never renumbered.
TERMINATION: WHICH STATUTORY QUESTION YOU ARE ANSWERING	The Medical Termination of Pregnancy Act, 1971, as amended in 2021, asks whether continuance of the pregnancy would involve grave injury to mental health, and grave injury to mental health is a statutory ground. It does not ask whether termination will damage mental health and does not ask you to predict outcome afterwards, so an opinion discussing later regret answers a question the statute does not pose and can defeat a lawful request while appearing thorough. Where she alleges the pregnancy was caused by rape, the anguish is presumed to constitute that injury; the extended window, beyond 20 weeks till 24 weeks on the opinion of two registered practitioners, turns on falling within a prescribed category of vulnerable women. Write about continuance.
INFERTILITY, AND READING THE ABORTION LITERATURE HONESTLY	The referral is mapped across the cycle, before, during and after treatment, on the psychosocial need domains, the burden being an outcome rather than a side issue: in a systematic review the commonest reason for discontinuing fertility treatment was postponement at 39.18 per cent, with psychological burden alone accounting for 14 per cent. Read the guidance's own caveat with it, only 45 of its 125 recommendations, 36.0 per cent, resting on strong evidence, and Indian law places a counselling duty on the fertility clinic. In the abortion literature the direction of a finding tracks methodological quality, the weakest designs generating the strongest claims of harm, and the comparison group is where most answers fail: comparing women who have an abortion with women never pregnant leaves the unwanted pregnancy itself, the exposure that predicts distress, uncontrolled. Calling the evidence conflicting and stopping there sounds balanced and is wrong.
THE BEHAVIOURAL EMERGENCY	

ASK	HOLD
AGITATION IS A PRESENTATION AND NEVER A DIAGNOSIS	The physical sweep runs alongside the talking rather than after it, and the psychiatric attribution is the last one made. Assessment and calming are interleaved, not sequential: the examination may be interrupted by treatment and then resumed, which makes somebody the owner of resuming it. The commonest real failure is not that the sweep is refused but that it is deferred to a moment nobody owns, and the patient is found hours later, calm, undiagnosed and still in the corridor.
ROOM, TEAM, VOICE, SWEEP	The space and its exits settled before the patient is in it, with attention to doors, stimulus and ligature points; enough people and the right ones present before the approach, a de-escalation team of 4 to 6 in a busy emergency service; one designated person who makes and keeps verbal contact; and what is measured while somebody else is talking. Keep at least 2 arm's lengths of distance on the approach. Where you stand is part of the plan, including your own way out. Collateral is taken now, during stabilisation. When de-escalation has not worked yet, and when it cannot be attempted at all, are different situations.
RAPID TRANQUILLISATION IS A PROCEDURE, NOT A PRESCRIPTION	Indicated by what the disturbance prevents, never by how disturbed the patient appears, and everything else follows: the indication states a purpose, the purpose sets the endpoint, the endpoint is what the post-dose review tests, and the monitoring keeps the patient alive until that review can be made. Monitor side effects, pulse, blood pressure, respiratory rate, temperature, hydration and consciousness at least every hour until there are no further concerns about physical health, and every 15 minutes where the maximum dose has been exceeded or the patient appears asleep or sedated. A protocol entered without a stated purpose has no endpoint, and sedation without an endpoint becomes sedation renewed by habit. Agents and first doses belong to the Schizophrenia: management, antipsychotics and adverse effects notes.
AUTHORITY, COMPETENCE, ONE DOSE, A CADENCE	Capacity is assessed and written down as a discrete step, before the drug rather than after it: severe disturbance makes incapacity likely, and likelihood is exactly what an assessment is for, so a correct conclusion reached without one is indistinguishable in the record from no conclusion at all. Somebody present who can manage the airway, and life-support-trained staff within reach. Who is less safe to sedate is checked first, the safety brief is run, and the order is written as a single dose with a named reviewer. Monitoring level is set by route and by state rather than by drug, stratified into four levels, and it runs until somebody decides the physical concern has ended. Name your parameters rather than assuming them: 97 per cent of 44 surveyed protocols specified monitoring parameters, and between them they listed 14 different ones.

ASK	HOLD
AN OBSERVATION LEVEL IS A PRESCRIPTION, NOT A MOOD	A named person who set it, a stated frequency or distance, a named reviewer recorded with their title, a stated review time, and a written condition that would bring it down. The frequencies are published: low-level intermittent observation once every 30 to 60 minutes, high-level intermittent once every 15 to 30 minutes, continuous within eyesight or at arm's length of a designated nurse, and multiprofessional continuous within eyesight of 2 or 3 staff members and at arm's length of at least 1. It is a rota problem before it is a clinical one, no staff member holding an above-general observation for more than 2 hours continuously. Going up and coming down carry different authority, somebody must be told when it rises, and the review that is supposed to bring it down is a duty rather than a courtesy. Privacy and dignity belong to the person being observed.
THE VOCABULARY PROBLEM, AND THE WARD AS A PHYSICAL OBJECT	One-to-one, special, constant, continuous and arm's length are not synonyms, and the confusion sits in the source documents rather than in the reader: name the taxonomy you are using, then state the requirement, because a level written in a vocabulary the receiving nurse does not use has communicated nothing. The department and the ward are physical objects, with ligature points, a waiting area and built-environment controls, and controls do not replace observation. The risk assessment itself is taught in the Somatic-symptom, sexual, impulse-control disorders and suicide notes.
MANIA: SUSPICION IS THE TRIGGER, NOT DIAGNOSIS	Urgent specialist assessment fires on suspicion of the state or the presence of danger to self or others, never on a settled diagnosis, and it is defensible because what is triggered is itself an assessment: nothing irreversible follows from referring urgently and finding no mania. The physical exclusion precedes the label. The risks that decide disposition are financial, sexual and relational at least as often as violent, so absence of aggression is not absence of an emergency: ask what will have been spent, signed, promised or contracted by the time an outpatient appointment arrives. Capacity here fails behind a fluent examination.
MEDICAL PRIORITY IS A CLAIM ON RESOURCES, NOT A LICENCE TO POSTPONE	Stabilisation outranks assessment for the minutes in which it is actually happening and buys nothing beyond them. It is not permission to leave the psychiatric assessment until medical treatment is finished, nor to wait for a number before speaking to the patient, and intoxication is not a gate on assessment either. Where the patient genuinely cannot participate, what replaces the assessment is a stated review interval, not silence, and the phrase that used to end this argument is refused rather than reinterpreted.

ASK	HOLD
WHAT, THEN WHEN, THEN WHO	What was taken decides whether charcoal has any role at all, because for a defined list of poisons it has none at any interval; when it was taken sets the window, appropriate up to 6 h after ingestion for many poisons on an individualised risk assessment; who is in front of you settles the rest. The window is formulation-specific, immediate-release paracetamol recommended up to 2 h and the modified-release form up to 5 h. Charcoal is withheld where the airway is unprotected rather than bought by securing an airway in order to give it. The asymptomatic patient is the trap: after extended-release bupropion overdose, seizures occurred in 31.6 per cent and first seizures ran 0.5 to 24 hours from ingestion, so the disposition is a minimum observation of 24 hours and not a mental state at the bedside. The patient is handed over with a document and not a phrase.
THERE IS NO SAFE WAY TO HOLD A PERSON	Only less dangerous ways, and the difference is how much weight sits on the chest and how long it sits there. The clock is written down: manual restraint is not used routinely for more than 10 minutes, a nurse assesses respiration and vital signs within 15 min of the restraint and at least every hour while it continues, and the medical face-to-face evaluation falls within 1 hour of initiation. Airway, weight, clock, eyes: nothing pressing the rib cage, neck or abdomen, nothing over the mouth or nose, the head free to rotate, weight to the side rather than on top, the hold as short as it can be, and one person watching who is not holding.
THE POSITIONING HIERARCHY, AND THE SEPARATE DUTIES	Supine rather than prone is the second limb of the answer, not the whole of it: the primary instruction is to avoid the floor at all, so a hold managed seated or standing has already satisfied a recommendation the supine answer is only a fallback within, and supine is not a licence either, since weight across the chest or anything laid over the face reproduces the hazard the position was chosen to avoid. Prone, arm position is measured and not a preference, mean anterior chest pressure falling from 102.6 mmHg with the arms abducted to 72.7 mmHg with the upper limbs brought under the shoulder. Watched, assessed and written down are three separate duties with different owners. Drink, toilet, movement, skin and clot belong to the body under a long hold, restraint carrying an odds ratio of 6.7 for venous thromboembolism in a hospitalised psychiatric cohort, and the hour after release is part of the episode.
THE RIGID, HYPERTHERMIC AND TOXIDROMIC EMERGENCIES	

ASK	HOLD
CATATONIA IS A MEDICAL ADMISSION FROM THE HOUR OF RECOGNITION	Not from the hour the treatment fails. It kills through dehydration, immobility and sympathetic overdrive, and the mortality is measured: catatonic stupor carried an odds ratio for death of 4.8, confidence interval 2.0 to 10.6, against inpatients without it. So the first hour buys the clot, the skin, the airway and the feed while the diagnosis is still being settled: clot, skin, stretch, feed, which is exactly the 4 medical complications the prophylaxis literature actually covers, venous thromboembolism, pressure ulcers, contractures and nutritional deficiency. Prophylaxis, skin care, hydration and the feeding decision run in parallel with the benzodiazepine rather than after it, because a patient who responds beautifully days later can still have thrown an embolus before he did.
AIRWAY AND SWALLOW FIRST, AND THE SECOND EPISODE	Airway, swallow and hydration are settled before anything is given by mouth, and the feeding decision carries a rate: at high risk of refeeding problems, nutrition support starts at a maximum of 10 kcal per kilogram per day and builds to full needs by 4 to 7 days; below that threshold, someone who has eaten little or nothing for more than 5 days starts at no more than 50 per cent of requirements for 2 days. A recurrent presentation is not a repeat of the first with its workup inherited unread: recurrence does raise the probability of an idiopathic cause, but that is an inference about the population while the question is about this patient, whose earlier evaluation may have been curtailed the moment treatment worked. The right answer to whether he was worked up last time is a list, never a yes. Entity, rating scale and benzodiazepine challenge sit in the Other psychotic disorders, delusional syndromes and catatonia notes.
NEUROLEPTIC MALIGNANT SYNDROME: TWO DECISIONS, TWO SETS OF NUMBERS	The criteria and their critical values answer whether this is the syndrome: hyperthermia above 38.0 degrees Celsius on at least 2 occasions, creatine kinase at least 4 times the upper limit of normal, and rises of 25 per cent over the patient's own baseline in blood pressure and heart rate. The temperature and the heart rate now answer where the patient is nursed and who is called, and the second decision never waits for the first: moderate is 38 to 40 degrees Celsius with a heart rate of 100 to 120 and severe is above 40 degrees Celsius with a heart rate above 120. Fusing them produces the patient waiting on an open ward for a creatine kinase result before anyone escalates. Severity is banded on two observations available within a minute of arrival and needing no laboratory.

ASK	HOLD
WHAT A LOW SCORE DOES NOT ENTITLE YOU TO DO	The criteria set was assembled by consensus to standardise agreement between specialties and calibrated against a selected population, and its sensitivity was never good enough to rule out: at the validated threshold of 74 priority points, sensitivity was 69.6 per cent against a specificity of 90.7 per cent. So a sub-threshold score, or the absence of severe rigidity, is not evidence against the diagnosis. State the cut-off, then state in the same breath what a score below it does not permit. The negative work-up limb is where the work hides. The act in the department is written without naming a drug, because the drugs belong to the Schizophrenia: management, antipsychotics and adverse effects notes.
SEROTONIN TOXICITY: A DECISION RULE, NOT A CHECKLIST	The named criteria are a decision tree derived empirically from 2222 consecutive serotonergic overdose admissions, with a learning dataset of 473, and measured against a stated reference standard; the older set they displaced was a list of associated features applied by recognition. Counting positive items is therefore the error: particular features in particular combinations are diagnostic and others are not, so patients with the same number of positive items can fall on opposite sides of the rule. The gain was real and modest, 84 per cent against 75 per cent for sensitivity and 97 per cent against 96 per cent for specificity. The reference standard was expert clinical judgement, since no assay settles this diagnosis, and that bounds what the accuracy figures mean.
WHERE THE RULE WAS VALIDATED, AND WHAT IT BUYS	Validated in a toxicology service in which other drug-induced syndromes are frequent, which is why it is so specific, and explicitly not validated for adverse drug reactions, which is most of the situations a psychiatrist reaches for it in. Use a positive result to justify what you are about to do; never a negative result to justify not doing it. Almost nothing changes in the opening minutes: supportive care takes precedence over any specific pharmacological treatment, because supportive care is what prevents rhabdomyolysis, renal failure and disseminated intravascular coagulation. A rising temperature with rigidity runs on hours and is answered by cooling, sedation and paralysis, never by an antidote. Most improve within 24 hours of stopping the drug, and moderate toxicity is observed for 6 hours, extended to 12 hours where a slow-release formulation was taken.

ASK	HOLD
ACUTE DYSTONIA: THE FIRST DECISION IS ANATOMICAL	Which territory is involved, because only some of them can obstruct. The drug given is the same either way, which is exactly why the question gets skipped; what differs is the setting the injection is given in and who stays at the bedside afterwards. A neck held to one side and a throat that is tightening are the same diagnosis and a different level of care, and the second is not safely managed in a side room by a single nurse told to call if there is a problem. Resolution is expected 15 to 20 min after the injection, a persisting episode is repeated at about 30 min, and failure to respond to two doses means changing the drug and then questioning the diagnosis. The causative drug is usually not on the psychiatric chart.
THE EPISODE DOES NOT END WHEN THE SIGN RESOLVES	It ends when the continued cover, the taper and the re-exposure decision have been written down: cover runs 24 to 48 h at minimum and in routine Indian practice up to 4 to 7 days, because the antidote wears off while the causative drug is still in the body. An answer that stops at the injection has treated the spasm and not the patient. The same spine carries the hypertensive emergency on a monoamine oxidase inhibitor, defined as a blood pressure more than 180/120 mm Hg with organ dysfunction and a tyramine restriction that outlives the drug by 2 weeks; the severe cutaneous reaction, where corticosteroids are started preferably within 72 h; and priapism, which is a clock rather than a symptom, an emergency beyond 4 hours. Every dose belongs to the Schizophrenia: management, antipsychotics and adverse effects notes.
LITHIUM: ON IT, ON TOP OF IT, WHICH TABLET	Which of the three poisonings this is comes from the history and not from the assay: whether there was a maintenance body burden before today, whether something was taken acutely as well, and whether the preparation was immediate-release, peaking at 30 minutes to 2 hours, or modified-release, peaking at 4 to 5 hours, because prolonged absorption and clumping provide a reservoir, and the reservoir is what creates a decontamination decision at all. The observation horizon is set from the kinetics rather than from the first result: the terminal half-life is typically 12 to 27 hours but reaches 58 hours in the elderly and the chronically treated, so the same ingested amount behaves differently in the two arms of the typology.

ASK	HOLD
WHAT THE CONCENTRATION IS ACTUALLY FOR	It estimates the risk ahead and grades severity only in the patient who was already taking the drug, and it is not reading the compartment that matters: diffusion into cerebrospinal fluid and brain lags appearance in plasma by about 24 hours. A grading built for chronic intoxication, applied to a naive patient who has just swallowed a bottle, gives a striking figure in somebody who looks well, and the team is either alarmed then or reassured later: both readings ignore that the brain has not yet received the dose. Charcoal does not bind this drug, and the alternative is ruled in or out before the patient rules it out for you; early decontamination was associated with less severe poisoning at an odds ratio of 0.21, confidence interval 0.04 to 0.99, regardless of the amount ingested or the level. Serum bands belong to the Mood disorders: pharmacotherapy notes.
THE ANTIMUSCARINIC ANTIDOTE DECISION IS MADE ON THE TRACING	Read the electrocardiogram and the contraindication list before the syringe is filled, never how antimuscarinic the patient looks: recognition names the family of poisons, not the member, and members diverge on whether this drug helps or kills. The tracing carries two thresholds and they are not the same threshold: at a limb-lead QRS of 0.10 second or longer, seizures ran at 34 per cent and ventricular arrhythmias at 14 per cent, while arrhythmias appeared only at 0.16 second or longer. The report that changed practice described asystole after the antidote was given in tricyclic toxicity, and the tracing separates them first. Sodium bicarbonate is given to a titration endpoint, which also means knowing when to stop.
ONE DOSE WEARS OFF BEFORE THE POISON DOES	The antidote's duration of action is approximately 45 to 60 minutes while the agents it reverses last far longer, so recurrence is the expected course and the disposition follows from that. Keep atropine beside it, push it no faster than the label allows, and treat a single dose as an act with a duration rather than a cure. When the antidote is refused or unavailable the patient is held instead, and that is not hypothetical: a 2025 series records supply failing after the manufacturer stopped production. Where the source gives no complete tuple of agent, amount, unit and route, the gap is declared rather than completed from memory. Decontamination is decided against a clock, and disposition names both the place and the period.
THE MEDICAL EMERGENCY AND THE PERINATAL OVERLAY	

ASK	HOLD
TREAT WHAT WILL KILL THE PATIENT BEFORE NAMING WHAT IS WRONG	Each life-threatening problem is treated the moment it is found and its effect reassessed, rather than carried to the end of the assessment: the problems that kill in the first minutes are the ones correctable in the first minutes, and each window closes while the survey goes on. Conscious level is graded inside the primary survey, with new confusion a grade of its own, because it is otherwise lost: of 25 older emergency patients found to be delirious, 19, or 76.0 per cent, were not recognised as delirious by the treating physician. Level, sugar, saturation, chart. Oxygen is corrected to a target rather than simply turned on, 94 to 98 per cent in acute respiratory failure and 88 to 92 per cent where hypercapnic failure is a risk. Glucose is corrected to a target too, thiamine goes before any carbohydrate, and an antagonist is given where a reversible drug cause exists.
SEDATION IS AN ENABLING ACT, NOT A TREATMENT	Written as treatment it closes the episode: the patient is settled, the search for the precipitant stops, and the next clinician inherits a quiet patient with an unexamined cause. Written correctly it has a stated purpose, to let the physical assessment, the access and the imaging proceed, and it leaves the precipitant work still owing. Where it is unclear whether this is delirium or a psychiatric disorder, the patient is medically observed or hospitalised rather than sent to a psychiatric bed, and the handover says which. The entity is taught in the Stroke, TBI, delirium and focal brain syndromes notes.
INTOXICATION IS A CONCLUSION, NEVER A PREMISE	It is the label you arrive at once the exclusions have been performed, not the one you begin with and then defend. Written the other way round the assessment has no stopping rule: every abnormal finding is absorbed into the explanation already chosen, and the patient improves on paper by being observed rather than examined. The triggers for further medical evaluation are worth holding as a list, because intoxication and withdrawal are on it rather than exempt from it, alongside new-onset psychiatric symptoms after 45 years, advanced age at 65 years and older, cognitive deficit or delirium, focal neurology or head injury, reduced awareness and abnormal vital signs. The smell of alcohol is evidence of recent drinking, a different proposition from the cause of the conscious level and compatible with everything else on the list.
SUGAR, SALTS, GASES, FUNDI	The first three go with the first draw; the fourth costs nothing, needs no laboratory and is available at the bedside. An important traumatic brain injury is excluded and the diagnoses that hide inside this state are looked for rather than waited for. Intoxication blocks discharge, the level-of-care decision turns on impaired consciousness with significant risk, and the threshold is lower in the vulnerable, the frail, the cognitively impaired, those with multiple comorbidities or no social support, and those who are 16 or 17 years old. The withdrawal regimen and its monitoring instrument are taught in the Substance use disorders notes.

ASK	HOLD
ESTABLISH THE SECOND PATIENT BEFORE YOU TOUCH THE FIRST	Three acts belong to the psychiatrist and to nobody else: the position she is left in once she has been sedated or held, the seclusion that must not follow rapid tranquillisation, and the call that brings obstetric, paediatric and anaesthetic colleagues into the room rather than after it. Position is part of the prescription and not part of the nursing, because a woman just sedated or being held cannot reposition herself, so it is chosen for her and re-chosen at every observation and handover. From about 20 weeks the gravid uterus reduces venous return when she is supine and cardiac output falls by up to 30 to 40 per cent. Board, then tilt whole-body from head to toe at 15 to 30 degrees on a firm surface, and displace the uterus manually when you cannot tilt.
THE CADENCE FOR TWO, AND THE REASSURANCES REFUSED	Monitoring afterwards is for both patients and is given a name, and self-harm is assessed on the perinatal method profile rather than the general one, since the majority of perinatal suicides are violent and hanging accounted for 66 per cent. Two reassurances discharge a woman who should be admitted, and both are refused: the cross-sectional appearance, because deterioration here can be extremely rapid and the red flags are triggers for an act rather than items scored against protective factors; and her children, since devotion is not capacity for self-protection. Where suspicion of postpartum psychosis is the presentation, assessment falls within 4 hours of referral, and where a treating psychiatrist separates mother from baby the decision is reviewed every 15 days, with the Review Board informed and permission sought beyond 30 days and rooming-in recommended for a child under 3 years of age; the statute itself is taught in the Mental health legislation and forensic psychiatry notes. Call the right team early, because the clock is shorter than the corridor.

References

Every specific in this chapter is bound to one of the sources below, and the count is the number of claim rows each carried. 11 of those rows are statutory and were read at the primary Act on India Code rather than from any textbook's summary of it, because a stale or paraphrased section changes what a clinician is legally obliged to do. Doses were read at current regulatory labelling, and each carries its own source receipt naming the regulator, the product, the label version and the retrieval date. 25 row(s) are recorded at partial confidence and 0 as a declared gap: a declared gap is a correct answer here, and no number has been supplied to fill one. The must-have-papers cross-check was NOT performed for this Paper III chapter, because the paper lists do not yet exist in the intel index; for Paper III the topic bank plus the syllabus scaffolding is the completeness authority. This table records provenance, not proof: it says where each specific came from, not that the chapter's prose uses it correctly, which the content pass and the ship review test.

PAPER III

Consultation-liaison, geriatric and transcultural psychiatry

Eleven bands . one complete notes document . the last chapter of Paper III

Orientation: four questions, one patient

1 · Orientation: two doors, one patient

One patient, and four different reasons somebody wants a psychiatrist. A woman of seventy-eight is on a surgical ward. The team has sent for you, though the slip carries a bed number and the word confused. Her son has already told the ward what he believes is wrong with her, and told you what he does not want said to her. Nobody has asked what she was like a month ago. The same encounter, compressed and performed aloud, is what examiners will mark. Four questions are being put to one bedside: who asked and in whose ward, what is different because she is seventy-eight, whose account of the cause reached the room before you did, and how all of it is said aloud under observation.

This opening is the chapter's **advance organizer**. It asserts no dose, interval, threshold or figure of its own, because each belongs to the section that owns it, and it describes no syndrome, because not describing syndromes is the design rather than an omission in it. What it owns is the shape: the decision the chapter is organised around, the four questions that run through it as seams, the bands and their order, the map of what it deliberately does not carry, and the reason its last band sits where it does.

Who asked	What age changed	Whose explanation	Said aloud
THE FIRST QUESTION, AND THE SEAM RUNNING THE LENGTH OF THE GENERAL-HOSPITAL BANDS	THE SECOND QUESTION, RUNNING THROUGH BOTH OF THE LATE-LIFE BANDS	THE THIRD QUESTION, AND THE ONE THE TRANSCULTURAL BAND IS BUILT AROUND	THE FOURTH QUESTION, AND THE WHOLE SUBJECT OF THE PRACTICAL EXAMINATION BAND

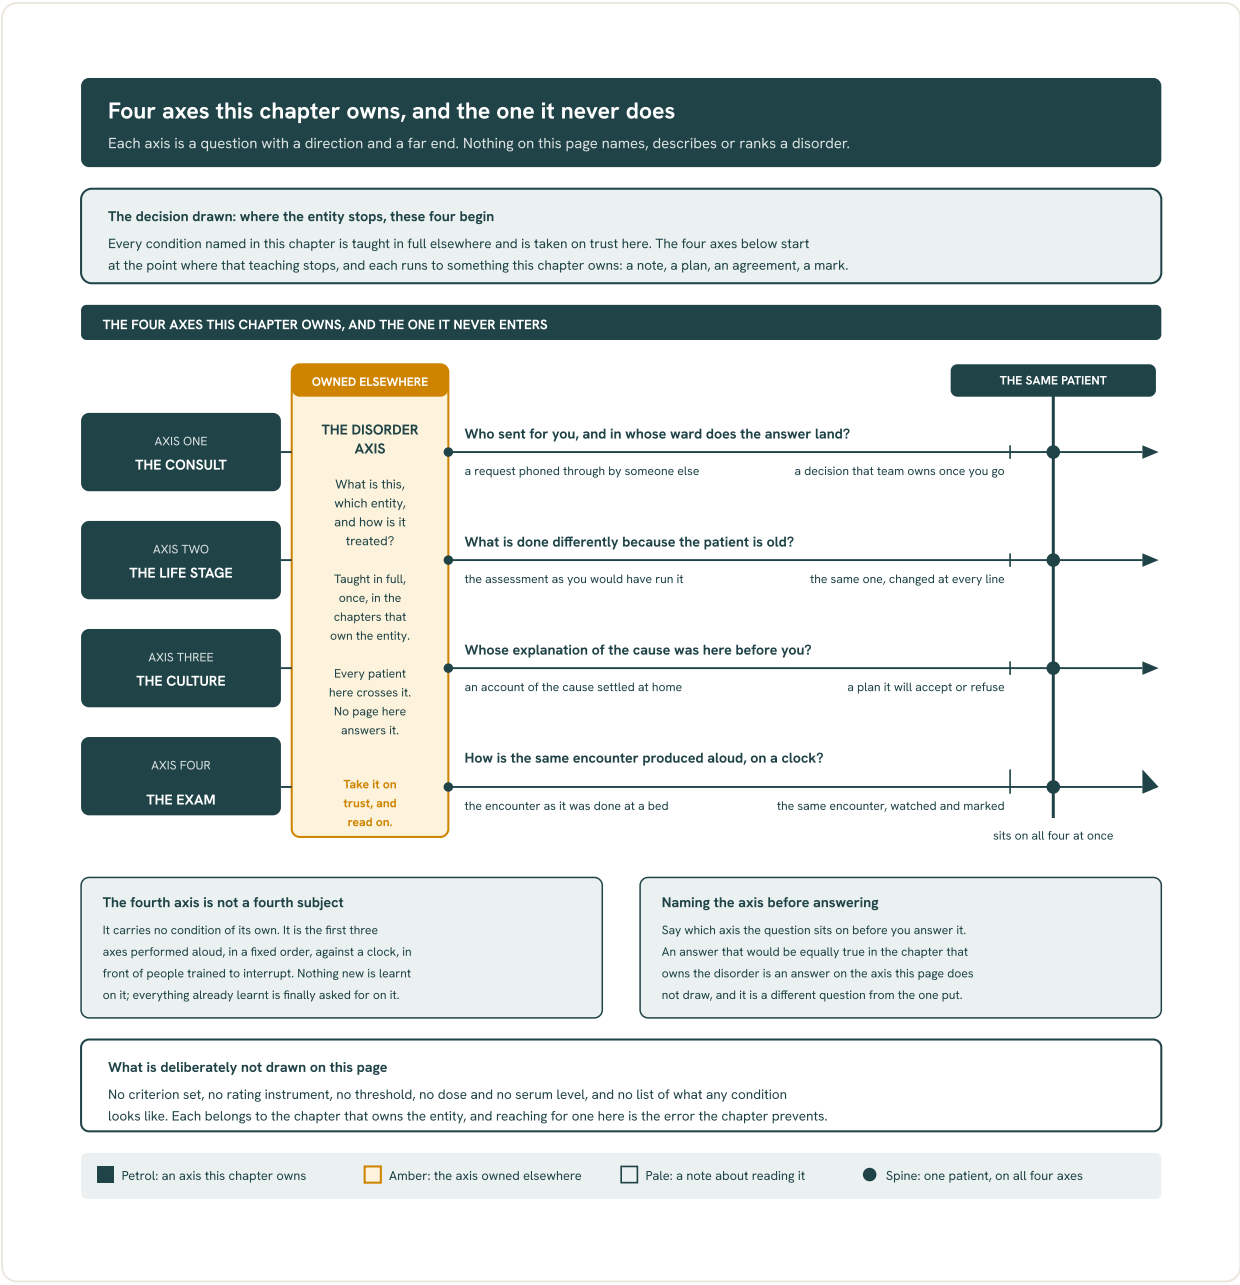

Fig 29.1. The chapter drawn as four axes rather than four topics, each one a question with a direction, running from the point at which the teaching of the condition stops to something these pages own, with the axis that asks what the condition is set alongside them as the one axis this chapter never enters, and the same patient marked as sitting on all four of the owned axes at a single bedside.

1.1 The decision this chapter is organised around

Almost every condition named in the pages ahead has already been taught properly elsewhere in these notes, with its clinical features, its differential, its investigation and its drug treatment. That body of work is the **entity**, and it is not repeated here in any form, at any length, in any box. The chapters that teach what the thing is sit largely in Paper II and Paper IV.

This chapter owns the other half, and nothing else in these notes carries it whole. That half is the **encounter**: who sent for a psychiatrist and what they actually wanted, in whose ward the patient is lying and therefore whose agreement any plan needs, what is different about the assessment because the patient is old, what the people around the bed had settled about the cause before anyone telephoned, and how all of it is produced aloud, in order, in front of somebody marking it.

The chapters that own the disorders answer *what is this*. This one answers *who asked, in whose ward, what changed because she is seventy-eight, whose explanation was already in the room, and how do I say it.*

That division is a decision and not a shortage of material. It is also the harder of the two, and the one practised badly and examined badly. A candidate who names a confusional state correctly but cannot say who to telephone first, what had to be established before walking to the bed, or which bed the patient should be in by morning has the entity right and the encounter wrong, and it is the second error the patient carries home. Every cross-reference in this chapter follows from the same division: it is a routing decision taken once, so that a subject is taught in full in one place rather than partly in three.

RULE **A section here is finished when it has said what was done, by whom and to what end. It is finished even if it has said almost nothing about the disorder.** Hold that while you read, because it settles what a complete section looks like here. A section that says little about a condition you already know is not thin: it is written on the assumption that you know it, and everything it does say is content the owning chapter does not carry. The corollary is where the marks sit. If you can describe a condition fluently but cannot say who called, what they wanted, what you would have established before the bedside, who owns the decision afterwards and when the patient is seen again, you have read the wrong half.

1.2 The four questions, and why each is a seam rather than a topic

The four questions are not four subjects placed side by side. Each is a **seam** running the length of a stretch of the chapter, so that the sections inside that stretch are variations on one question. Knowing which question your section varies is most of what makes this chapter quick to read.

The first is the **referral**. A consultation is asked for by somebody whose felt need is not the patient's, and the answer is owed to a team that will act on it with you absent. Everything in the general-hospital stretch follows from those two facts: what the request must be turned into before it can be answered, what is established before the bed rather than at it, what the written record has to settle, and who owns the next decision.

The second is what age changes. The question is not what conditions older people get, which is an entity question with owners elsewhere. It is what the clinician does differently: whose account the history now comes from and how well placed that person is to know, what must be made possible before an examination measures anything at all, what a drug decision costs in a body that handles drugs differently, and what a plan silently assumes about the household that will deliver it.

The third is the **explanatory model**. By the time most of these patients reach a psychiatrist, somebody has decided what is wrong and why, something has been tried on that basis, and a view has been taken about how much the patient should be told. Eliciting it is assessment and not courtesy, because it predicts what will be accepted and what happens next if your plan disappoints.

The fourth is the **examined performance**. An examination does not ask what you know; it asks for the encounter reproduced aloud, in a fixed order, against a clock, in front of people trained to

interrupt. The content is the same and the constraints are different, and the constraints are examinable in their own right.

MNEMONIC

Who asked. What age changed. Whose explanation. What is said aloud.

Four beats, and they are the whole chapter. **Who asked**: the request, the ward, the record, and the person who owns the decision after you leave. **What age changed**: not a new list of conditions but a changed meaning for every line you were already writing. **Whose explanation**: the account of the cause settled before the referral, in the words of the people who hold it. **What is said aloud**: the same encounter reproduced in front of examiners, which is how all of it is finally asked for.

1.3 The bands, in the order the chapter runs them

Between this opening and the close the chapter runs in nine **bands**. The order is a clinical progression rather than the syllabus taken flat, and eight of the nine carry the teaching while the ninth draws them together.

- **The consult as an act.** The consultation itself as the object rather than any setting or syndrome: what a liaison service is for, what a medical illness does to the psychiatric picture, and what a physical illness demands of the person carrying it.
- **What arrives on the ward.** The recurring short list of reasons a general-hospital team actually sends for psychiatry. Grouping them says what no single section says: the reasons are few and they repeat on every ward.
- **The high-stakes settings.** Transplantation, dialysis and intensive care, chronic infection, the organ-specific liaison work and the neurological interface: the settings in which the consult is hardest and the decision least reversible.
- **What changes at seventy-eight.** Normal ageing against pathology, the assessment that surrounds any cognitive testing, the prescribing decision, the sleep history, and the safeguarding question, which belongs inside an assessment and not in an appendix.
- **The late-life presentations that mislead.** The band's work is the differential between them, which no chapter can draw from inside a single entity it owns.
- **Culture and the explanatory model.** What changes when the account of the cause is not biomedical, run from the concept through the formulation to what a clinician does with it in an Indian clinic.
- **Cancer, dying and grief.** Recognition when the ordinary somatic signals have been taken over by advanced disease, and the conversations that carry most of the clinical work in that setting.
- **The practical examination bridge.** The observed station, the long and short case, the bedside demonstration, the difficult conversation, and the instruments a viva puts in front of you.
- **The cross-cutting synthesis.** The one place the four questions are shown converging on a single encounter and a single document.

After the ninth band come the chapter's own closers, and then one more that no earlier chapter has needed. This chapter closes Paper III, so its final section looks back across the whole paper rather than across these pages alone. The last thing you meet here is a map of ten chapters, not a summary of one.

1.4 What is deliberately not here, and where it is taught

An organizer is as much about the edge of the frame as about what sits inside it. Read the middle column of the map first: it is what this chapter does with each subject, and the reason the subject appears here at all. The right column is where the condition itself is taught, in full, once.

WHAT YOU MEET IN THESE PAGES	WHAT THIS CHAPTER TEACHES ABOUT IT	WHERE THE CONDITION ITSELF IS TAUGHT
Acute confusion, on a medical ward and in an older patient	Who calls and what the ward is actually asking for; and separately, what frailty, sensory loss and multiple drugs do to the same picture in later life	the Stroke, TBI, delirium and focal brain syndromes notes
Progressive cognitive decline in an older referral	The wider assessment it sits inside, and the behavioural picture as a reason a family or a ward asks for help	the Dementias and neurocognitive disorders notes
A first psychotic presentation late in life	What is different about assessing a first presentation at this age, and why its label has a contested history	the Other psychotic disorders, delusional syndromes and catatonia notes
Low mood late in life, and in advanced physical illness	How it is recognised when the somatic features belong to the disease or its treatment, and what age does to prescribing	the Mood disorders: pharmacotherapy notes
Fear and distress at a bedside, and after a diagnosis is disclosed	The reaction the setting itself produces, and when a reaction has become something to treat	the Anxiety, OCD and trauma-related disorders notes
Poor sleep in an older patient	The history to take before the complaint is attributed to age, and what that attribution costs when it is wrong	the Eating and sleep-wake disorders notes
Bodily symptoms without an explanation, fabricated illness, and self-harm on a medical ward	Why the team referred, what they are asking you to take off their hands, and what the note must settle before you leave	the Somatic-symptom, sexual, impulse-control disorders and suicide notes
The mental state examination, and the psychological work of a consultation	How it is performed at a busy bedside and presented aloud against a clock	the Psychotherapies, clinical assessment, MSE and nosology notes
Seizures, and the psychiatric picture around them	What a neurology team is asking psychiatry for, and where the consult enters that relationship	the Epilepsy and psychiatry notes

WHAT YOU MEET IN THESE PAGES	WHAT THIS CHAPTER TEACHES ABOUT IT	WHERE THE CONDITION ITSELF IS TAUGHT
Localisation and the bedside neurological examination	Which parts of it a general-hospital consultation requires, and when it cannot be deferred	the Neurology foundations for psychiatrists notes
Chronic infection, organ failure and the systemic disease behind a referral	The psychiatry of the setting: the unit, the team, the decision due this week, and who follows the patient afterwards	the Neuropsychiatry of systemic and neurological disease notes

Nothing in that table is an apology. A pointer here sends you to the full teaching and not to a second summary, and it expects to be followed once and then never again.

1.5 The band that is carried nowhere else

Read the last band even if you read nothing else twice. The practical examination bridge is the only band here with no clinical entity standing behind it, which is why it is placed last: from there it can look back across everything before it, and it hands directly to the close of the paper. It covers the observed station and what is being scored in it, the long and short case as they are actually presented, the demonstration of a scale or a bedside cognitive test with an examiner watching, the difficult conversation treated as an examined act, and the interpretation of investigations and instruments put in front of you without warning.

It is also the only body of material in this chapter that appears in no other chapter of any paper. Everything else here has an owner somewhere, so a reader who skips a section can pick the subject up at that owner and lose only time. This band has no owner. A candidate who skips it has read it nowhere, and meets the format for the first time in the room, where the cost is paid in marks rather than in preparation.

TRAP **Reading a short section as a low-yield section.** The length of a section here is a statement about ownership, not about yield. A section is short because the disorder it names is taught in full elsewhere, which means every line it does carry is a line no other chapter carries, and those are the lines examiners ask for. The failure has a recognisable shape across a table: asked what you would do about a patient, the candidate who skimmed produces the entity answer at speed, which is fluent, correct, and about a different question, and then has nothing left when the follow-up asks who they would telephone first and what they would write. The practical band is where this costs most, because there is no owner to fall back on.

1.6 How to read it

Three habits make the chapter read as one argument rather than as a heap of separate acquisitions, and each is a habit about what you do with a section rather than about how much of it you memorise.

- Read for what a section instructs you to do, and take the disorder it names on trust from the chapter that owns it. If you cannot recall that disorder, that is a signal to go and read it there, not a signal that this section is incomplete.

- When a section hands a point to another chapter, follow it before you answer on that point. Following a pointer here lands you on the full teaching, so it is done once and does not need repeating.
- Treat a stated absence as a finding. Where a section says that no figure is available to quote, that sentence is doing work: it stops a half-remembered number being written into an answer under pressure, which costs a candidate more than not knowing.

IN INDIA

Indian practice is the subject of this chapter, not a note appended to a Western one, and that has two consequences for reading it. Where the question is how a service is configured, who may lawfully decide, what a family expects to be told and when, or where a complaint about an older person's treatment at home is actually heard, an Indian source settles it and a familiar Western default does not substitute. And the route a patient took before reaching you, including any traditional or religious healing sought first, is a fact about access to care and a proper question to ask; it is never by itself a finding about pathology, and this chapter draws that boundary in prose, in the patient's own words and the family's own explanation, rather than in a list of features. The encounter you will be examined on is an Indian encounter, in an Indian hospital, with the relative in the room.

This chapter answers four questions about one encounter: who asked and in whose ward, what changed because the patient is old, whose account of the cause was already in the room, and how all of it is performed aloud under observation. It answers none of them by describing a disorder, because every disorder it touches is taught in full elsewhere and is named here without its features.

The consult as an act

2 · Principles and models of consultation-liaison psychiatry

Why the marks are here. Almost every other question in the syllabus asks what a condition is. This one asks what you did, in whose ward, at whose request, and what became of the decision afterwards. Liaison work is the only part of psychiatry in which the psychiatrist is a guest: the bed, the record and the plan of care belong to another team, and the patient did not ask for a psychiatrist. Procedure, unlike a syndrome, is examinable in fine detail. A candidate who lists service models without saying who telephoned, what they wanted, and who was left holding the clinical decision has answered a different question.

Two consequences follow from being a guest, and the rest of this topic works them out. First, the request is not the patient's: ordinarily the need to see a psychiatrist is a felt need of the patient or a relative, whereas here the need to appoint a psychiatrist is felt by the primary treating team, and the patient may be learning of it as you introduce yourself. Second, what you produce enters a decision that is settled with the primary team rather than announced to it. Both are set out in

the consultation-liaison chapters the Indian Journal of Psychiatry published in 2022, the fullest account of Indian general-hospital practice and the source used throughout.

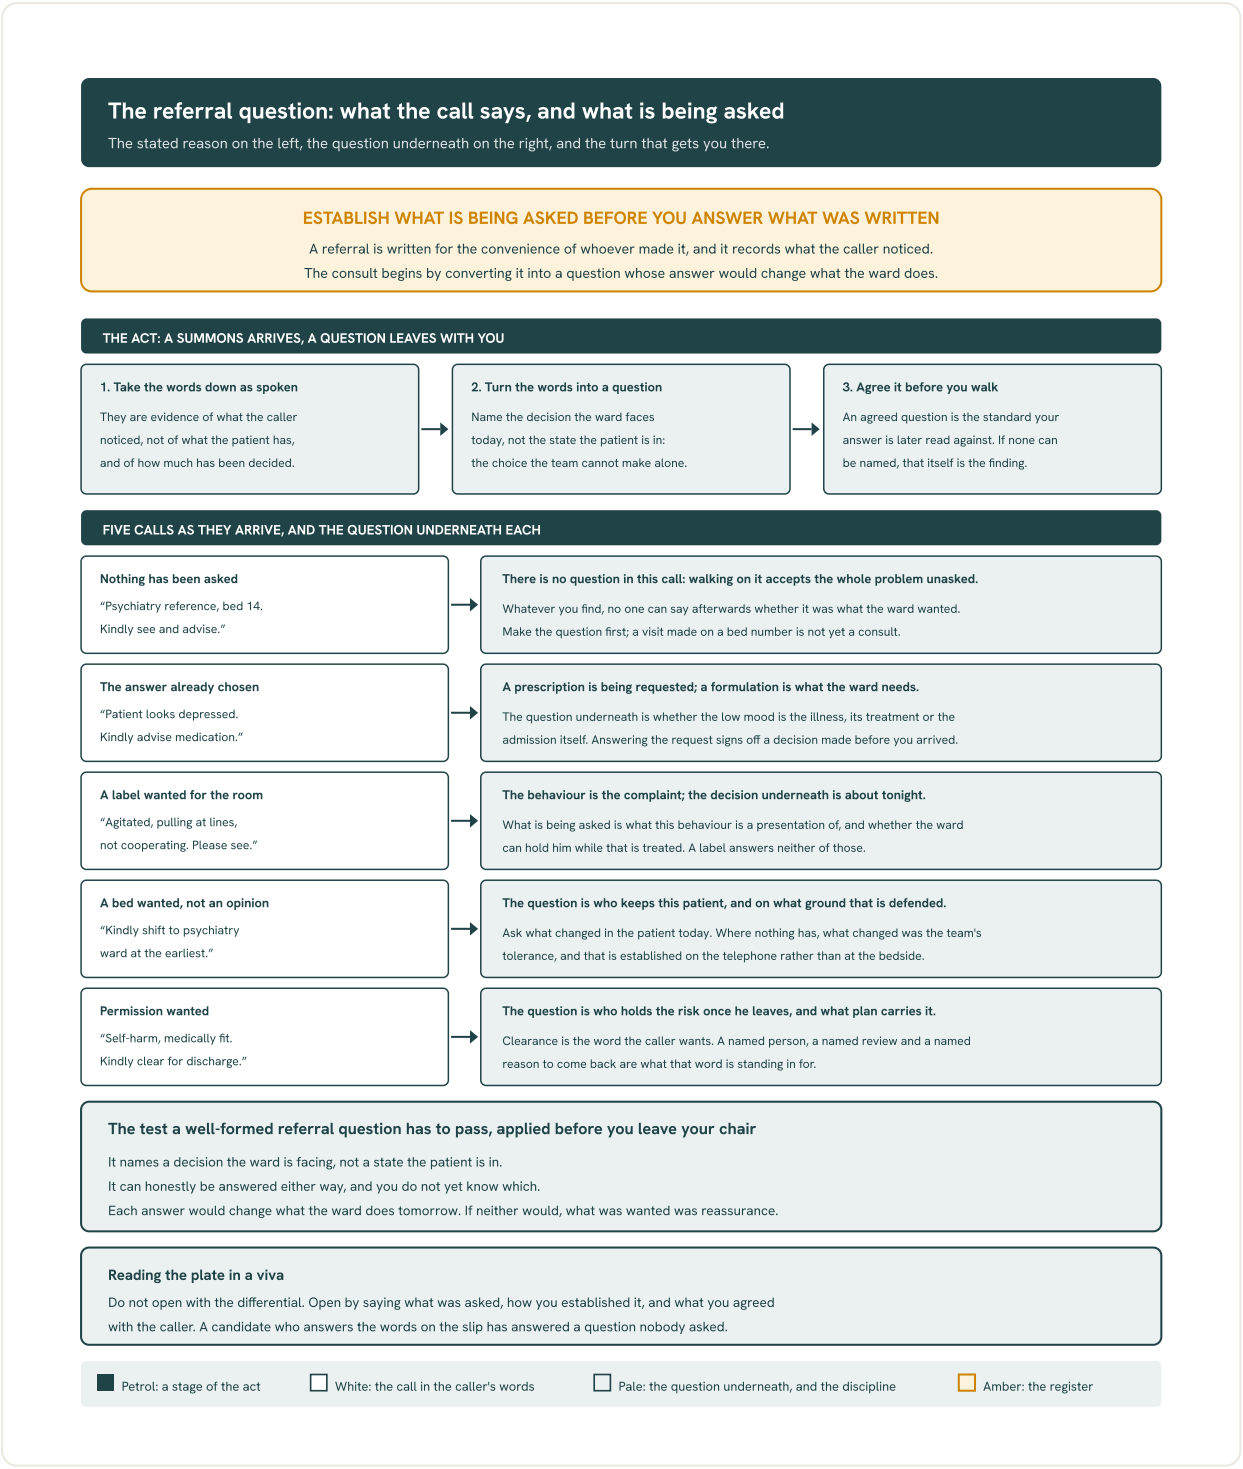

Fig 29.2. The referral question drawn as an act of extraction rather than as a list of reasons for referral, with the three stages by which a summons is turned into a question the consult can answer, five ordinary ward calls set beside what each is actually asking and what is lost by answering the words instead, and the test a well-formed referral question has to pass before the psychiatrist leaves the chair.

2.1 Whose need the consult answers, and what changes because of it

The person who telephones is the **consultee**, and naming them properly fixes three things candidates get wrong. Consent to be seen cannot be inferred from the referral, because the referral was not made by the person being seen. The referral question cannot be read off the

request, because the request was written for the convenience of whoever made it. And the output is a recommendation inside somebody else's treatment, so it must be written for a physician to implement rather than for a psychiatrist to admire.

RULE **The referral is the treating team's felt need, not the patient's request, and everything procedural in this topic follows from it.** It is why consent to be seen must be established rather than assumed, why the referral question must be extracted rather than received, why the psychiatrist speaks to the consultant and not only to the file, and why a patient may decline without anything having gone wrong. A consult conducted as though the patient had walked into a clinic is procedurally wrong even when the diagnosis is right.

2.2 Where general-hospital psychiatry began in India, and how the service is actually run

Indian psychiatric services were confined to mental hospital settings until the general hospital psychiatric unit appeared. The Indian account credits the first such unit, in the early 1930s, to **Girindra Shekhar** at R. G. Kar Medical College and Hospital, Calcutta, with rapid growth through the late 1960s and early 1970s; the source sentence dates it inconsistently within one clause, so the decade is given and no year asserted. The point is not historical. Most Indian postgraduate psychiatry training now happens inside general hospitals, and the same chapter observes that liaison work is still not emphasised within it. The trainee stands in the setting and is not taught it.

What the service looks like has been measured. A survey of ninety Indian training centres, as the 2022 overview reports it, found liaison work delivered as an on-call service in **three quarters** of institutes, with a junior resident as the initial respondent in **60 per cent** of teams. Only a handful included psychiatric nurses, psychiatric social workers or clinical psychologists. Most had no specific liaison posting for junior or senior residents, and fewer than half ran joint academic activity with other specialties. The respondents' own prescription was a dedicated liaison team.

That describes a failure mode, not simple under-resourcing. A service answered on call by its most junior member, with no protected posting and no shared teaching, can only respond: it accumulates no case-mix, no relationship with a ward, no reputation to generate the next referral. The commonest diagnostic categories across those centres were delirium, substance use disorders, self-harm and depression, the case-mix produced by whatever is loud enough for a busy team to notice.

2.3 The referral rate, and the gap it conceals

There is no single Indian referral rate, and quoting one is an error of construct rather than of arithmetic. Reviewing Indian data across institutes, Grover and Singh give it by setting: 0.01 to 3.6 per cent from the inpatient setting, 1.42 to 5.4 per cent from the emergency setting and 0.06 to 7.17 per cent from the outpatient setting, against a cross-institutional international range reported as low as under 1 per cent and as high as 13 per cent. Three settings, three denominators. An inpatient rate asks how often a ward that already holds the patient thinks of psychiatry; an outpatient rate measures a filter operating before admission.

The same discipline governs the morbidity figures the rate is compared against. Grover and Singh estimate psychiatric morbidity at about 30 per cent among medically ill inpatients and 50 per cent among primary care attenders. The overview chapter states that 20 to 46 per cent of patients with physical disorders admitted to medical or surgical wards have at least one diagnosable psychological comorbidity. The cardiology chapter puts prevalence in liaison populations at 48 to 87 per cent across cardiovascular, musculoskeletal and orthopaedic patients. These are not competing estimates of one quantity: unselected admissions, already-referred patients and single-specialty cohorts are three populations, and the population is part of the number. A percentage quoted without its denominator is not a fact.

Where the argument becomes clinical. Two Indian studies close the loop by measuring prevalence and referral in the same unit, which removes the denominator objection and makes them the most useful pair of figures in the topic.

68.5%	1.71%	65.5%	2.4%
DELIRIUM PREVALENCE MEASURED IN ONE INDIAN INTENSIVE CARE UNIT	PSYCHIATRIC REFERRAL RATE FROM THAT SAME INTENSIVE CARE UNIT	PSYCHIATRIC MORBIDITY AMONG ELDERLY ATTENDERS AT A MEDICAL EMERGENCY	PSYCHIATRIC REFERRAL RATE FROM THAT SAME EMERGENCY SETTING

TRAP **Reading a low referral rate as a low burden of psychiatric illness.** Candidates quote the Indian referral figures as though they measured the psychiatric morbidity a hospital contains. They measure how much of it is sent. The same-setting pairs settle it: the denominators are identical and the gap is not a rounding difference. A service with a very low referral rate is not a service with little to do; its case-finding has failed, and what needs interrogating is the referral pathway rather than the prevalence.

2.4 Who is referred, and what the caller owes you

The 2022 overview adopts a six-group classification of liaison patients, attributed to a consensus of the European Association of Consultation-Liaison Psychiatry and the Academy of Psychosomatic Medicine. It is the only compact answer to what a liaison service is for.

1. Comorbid physical and psychiatric disorder where managing one complicates the other.
2. **Medically unexplained symptoms** presenting in clinical services, taught as an entity in the Somatic-symptom, sexual, impulse-control disorders and suicide notes.
3. Mental and behavioural disorders attributed to general medical conditions or to their management.
4. Psychiatric patients attending a medical setting for a diagnostic or therapeutic procedure.
5. Suicidal or self-harming behaviour arriving in an emergency or medical unit.
6. Health behaviour, personality traits, cognitive function or social circumstances that influence management of the medical condition.

What arrives is narrower than that spread. Writing about the emergency setting, Ghosal and Ray name **confusion with behavioural abnormality** as the commonest cause of referral in Indian liaison settings, and note that in intensive care it is often called intensive-care psychosis. The first

discrimination the consult owes is therefore between a neurocognitive disorder and a primary psychiatric condition presenting with behavioural disorganisation. The entity, its criteria, its screens and its treatment belong to the Stroke, TBI, delirium and focal brain syndromes notes; what belongs here is that the commonest thing you are called for is the thing most easily misfiled as psychiatric.

The Indian account also sets out what the caller should convey: who is calling, the patient's demographic details including hospital number, any anticipated language difficulty, the location in the hospital, the primary diagnosis and reason for admission, the psychiatric concern for which the opinion is sought, and the urgency. Two parallel instructions written for referring physicians are sharper still: do not initiate a call without examining the patient, and do not initiate a consultation without informing the patient or the caregiver.

IN INDIA

The Indian chapters describe the referral call not as it ought to be but as it is. Grover and Singh record that in practice it is limited to informing the psychiatrist to come and see the patient on a given bed number. There is no referral question in it, and a psychiatrist who walks to the ward on it has accepted the whole diagnostic problem without knowing what was asked. Two questions turn it back into a consult before you leave your chair: what has changed in this patient today, and what do you want from me.

2.5 Receiving the call, and the patient's right to decline

The Indian account gives the psychiatrist a checklist for the call itself, and it is not a courtesy list. Respond politely and seek clarification of the issue. Establish when the patient will actually be available, and what will obstruct communication: language, a tracheostomy, other medical devices. Ask whether the referral was discussed with the patient and the caregiver and whether consent to be seen was obtained; whether the referral is an outcome of the treating team's frustration rather than of a change in the patient; and how urgent it is.

One clause outweighs the rest and is the most examinable sentence in the procedure: the patient has the right to refuse psychiatric assessment, and this should be respected if possible. It is easy to miss, because a medical admission has already normalised examination by strangers. A patient who declines has obstructed nothing: record the refusal, tell the consultee, and leave the door open rather than persisting on the team's authority. Capacity and treatment refusal proper are taught separately; this is an operational rule that applies before any capacity question arises.

GOOD TO REMEMBER

Before writing your own note, ask the person who telephoned to write theirs: the Indian account makes it an explicit step to ask the consultee to document the reason for the call in the file. It fixes the referral question in the record rather than in your recollection, so your answer can be read against what was asked; it commits the team to having wanted something, which is what makes a later review meaningful; and where the call arose from exasperation rather than from a change in the patient, this is usually where that becomes visible.

2.6 Urgency: how it is graded, and where the grading belongs

Ghosal and Ray present the **Mental Health Triage Scale** with five colour-coded urgency bands and explicit response windows. The scope is the examinable part: it is an emergency-room instrument, offered as something emergency and primary-care personnel may be trained to use, and it is not a standard for answering a ward call.

BAND	RESPONSE WINDOW	PRESENTATION THE BAND IS WRITTEN FOR
Immediate (red)	Immediate response, with referral to security or police	Violent aggression, possession of a weapon, an attempt at self-destruction
Emergency (orange)	Usually within **four hours**	Clear intent, plan and arrangement to harm self or others; very high-risk behaviour with confusion and disorganised behaviour
Urgent (yellow)	Within twenty-four hours	Suicidal intent without a clear plan, rapidly increasing confusion, psychotic behaviour
Semi-urgent (green)	Within seventy-two hours	Mood disorder or apparent psychosis without suicidal intent, uncooperative behaviour on the ward
Nonurgent (blue)	Within four weeks	Known stable psychiatric disorder requiring follow-up

The scale's own primary publication is not available to quote, so the windows are attributed to the chapter that prints them rather than to the instrument's authors. In a recent Indian tertiary-hospital study using the scale the yellow zone was the commonest zone of referral: the modal emergency referral is genuinely urgent without being immediate, and a service configured only for the red band mishandles most of its work.

For the ordinary inpatient call there is no equivalent figure. No comparable standard is available to quote, and none is invented here. What exists is a behavioural rule rather than an interval: respond in a timely way, and tell the team the time frame in which the referral will be attended. Naming your own time frame is what converts an open-ended promise into something a ward can plan around, and it is the honest answer to an examiner.

2.7 The preparatory phase, and the consult at the bedside

Ghosal and Ray draw the sharpest structural contrast in the topic: in individual practice there is no interval between the appointment and contact with the patient, whereas the liaison setting has a compulsory **preparatory phase** the psychiatrist must complete first. Skipping it is how a competent psychiatrist produces an incompetent consult.

- The current medical diagnosis and the treatment being given.
- A review of all available papers in the chart, not the summary handed to you.
- Any past or ongoing psychiatric illness, and how it was treated.

- Direct communication with the treating or referring consultant to understand their conceptualisation of the case, what they need, and where they want the focus.
- For an inpatient, the observations of the nursing staff or the duty doctor.
- For an inpatient, word sent to a family member to be present at the interview.

The bedside sequence is a psychiatric assessment with additions that only make sense in a hospital. Review the treatment record first, including the sleep chart and the nursing observation record. Introduce yourself and take verbal consent, with caregiver consent where the patient is not competent to give it. Find a private area or quiet side-room, which on an open ward takes effort. Take the history keyed to onset, symptom type, fluctuation, and relation to events in treatment. Examine physically, then perform a detailed mental status examination; the interview and the examination themselves are taught in the Psychotherapies, clinical assessment, MSE and nosology notes. Cover, without exception, cognitive functioning, catatonic features, substance use with quantity and time of last intake, overdose and withdrawal, suicidality, sexual behaviour, poisoning, trauma, nutrition and infection.

What distinguishes this from an outpatient interview is the step candidates omit: having established the phenomenology, look deliberately for links to medications, surgery, the fact of hospitalisation, the disclosure of the diagnosis, the behaviour of the team, a mismatch between what the patient expected and what is happening, and the physical environment: lights, sound, indwelling tubes and neighbouring patients. Each is a candidate cause absent from outpatient practice, each is potentially reversible, and several are reversible by the ward rather than by the psychiatrist.

2.8 The note, and the three-way aetiological question

The Indian account itemises the liaison note, and the list is the consult's intellectual content rather than its paperwork.

- The provisional or differential diagnoses, stated by current nosology.
- The probable aetiology of the psychiatric condition against the background of the medical illness: whether there is **mutual causation, comorbidity or coincidence**.
- The probable interaction of the psychiatric treatment proposed with the ongoing medical treatment and the treatment milieu.
- A comment on the biopsychosocial background relevant to management, including developmental issues, current personal stressors and personality.
- Any evidence of immediate risk to self or others, with the need for or the decision about transfer to a psychiatric ward.
- Any adjustment needed from the treating team itself to manage uncooperative behaviour.

Build the answer around the second of those. The question is not taxonomy: each answer sends the consult somewhere different. Mutual causation makes the psychiatric problem part of the medical plan, and it is the finding that most often changes what the ward does next. Comorbidity means two conditions treated concurrently, which puts the weight on interaction and sequencing.

Coincidence means the illness would be present in this patient anywhere, so the honest recommendation may be continuity of existing treatment. A candidate who writes a diagnosis and a drug has skipped the only question that required a psychiatrist to attend.

> The consult ends when the consultant who called has been spoken to, not when the note has been written.

2.9 Feeding back, and the etiquette that keeps you invited

Writing in the file is explicitly not sufficient. Ghosal and Ray say that beyond notes on paper certain further things are advisable: the psychiatrist should communicate directly with the treating consultant, at least by telephone, resolve the team's doubts from a mental health perspective, give the overall formulation, and suggest a comprehensive treatment plan. The verbs are advisable and should rather than must, and are worth quoting as written. A note transfers information; a conversation is what lets the team say your recommendation is impossible on their ward, which is how good psychiatric advice ends up never implemented.

The same chapter reproduces ten commandments for the liaison psychiatrist, attributed to Pasnau, and they should be attributed that way, as a framework reproduced inside the Indian account, because the original is not available to quote.

MNEMONIC

Be concrete; do not obfuscate, procrastinate, preach or steal

The commandments **Pasnau** sets for the consultant, in the order a consult uses them. **Concrete:** recommendations written clearly enough for the physician to implement without translation. **Obfuscate:** no jargon and no irrelevant psychiatric detail, in simple language any physician can understand. **Procrastinate:** do not leave a call unanswered. **Preach:** do not teach or offer unnecessary advice to the physicians. **Steal:** discuss with the consultee who will be the patient's primary physician in the long term.

The last reads as manners and is not. Settling openly who holds the patient prevents two failures: a patient followed by nobody because each side assumed the other, and a team that stops referring because referral feels like losing patients.

2.10 Who keeps the patient, and who owns the decision

The request to move the patient to the psychiatry ward is the standing point of friction in liaison work, and the Indian account answers it with criteria rather than with a rule.

PRESENTATION	WHERE IT IS MANAGED	WHEN TRANSFER BECOMES APPROPRIATE
Delirium	Continues in the medical ward, with regular psychiatric observation	Not on the ground of the behavioural disturbance itself
Substance use disorder	Medical ward while medical complications are stabilised	After initial stabilisation of the medical complications
Depression, suicidality or psychosis with serious medical morbidity, where a medical emergency may emerge	Medical ward, under regular psychiatric supervision	Only in stable medical conditions, such as a patient not on any ports and not requiring oxygen therapy, and then with regular observation by the medical team

The reasoning under the first row is what an examiner tests. The transfer is requested because the behaviour is unmanageable on a medical ward; the answer is that the behaviour is the presentation of an acute medical problem: physicians and surgeons need to understand that this is a medical emergency due to an underlying medical cause, with psychiatric manifestations. Moving the patient moves them away from the investigation and treatment that will resolve it. The entity belongs to the Stroke, TBI, delirium and focal brain syndromes notes. What this topic owns is the negotiation, and the fact that the psychiatrist's job here is to decline the transfer while accepting the work.

On formal responsibility, be careful. What is stated is operational: the primary team must be told what is required before a transfer, delirium stays where it is, the consultee records the reason for the call, and the long-term primary physician is settled by explicit discussion. Whether the recommendation is formally advisory, and where clinical and legal responsibility rests once it is made, is not stated in terms by any available Indian source. No comparable statement is available to quote, and none is invented here. Describe the decision as negotiated with the primary team, and do not convert the transfer criteria into a claim about liability.

2.11 What happens after the consult

Documentation is deliberately duplicated: the consultation is documented in the primary treating team's medical records and in separate treatment records kept by the psychiatrist. The reason is structural: the team's file is where a recommendation must live if it is to be acted on, and it travels with the patient to whoever is on duty tonight, while the psychiatrist's own record is the only place a longitudinal psychiatric account survives once the chart is closed.

Two obligations follow the note. The patient is reviewed from time to time during the admission and followed up even after discharge from the inpatient unit; no review frequency is specified and none should be inferred. One interval is: where a major psychiatric diagnosis is confirmed and pharmacological treatment started, follow-up should be **within a week** at the latest, with regular psychiatry outpatient follow-up after discharge stated as obligatory. Where no definitive diagnosis was reached, the recommendation is regular follow-up with psychometric evaluation and symptomatic management rather than a diagnosis asserted to close the episode. That

distinguishes a liaison service from an opinion service: the honest output of a single ward visit is often an unfinished formulation.

2.12 Models of the service, and the case for building one

The principles and models of consultation-liaison psychiatry are set out in the Indian overview along three axes rather than one list, by focus of consultation, by function and by focus of work, with fourteen named models distributed across them. The axes matter more than the names, because they say what a service has chosen: whether the unit of attention is the patient, the crisis, the consultee or the situation; whether the psychiatrist consults, liaises, bridges or works autonomously; and whether the work is organised around critical care, biological treatment, the ward milieu or an integrated model. Competing classifications exist and are not interchangeable, so name the axis and the source rather than merging two schemes into one table.

The distinction that does most clinical work cuts across all three axes. **Reactive** practice means the patient is seen only after the primary team refers. **Proactive** practice puts the mental health professional inside a **behavioural intervention team**, a multidisciplinary consultation service attached to the medical or surgical unit itself. Its stated benefits are easy access to mental health services, reduced length of stay, early detection and treatment, education of colleagues in behavioural problems and better relationships with other specialties; the same chapter notes that in patients with combined physical and mental disorders, earlier referral to liaison psychiatry is linked to a shorter length of stay.

A service answered on call cannot detect early, so the referral rate measures the model as much as the ward's awareness. One worked Indian example exists. For psychodermatological work the preferred set-up is a clinic comprising a psychiatrist, a dermatologist and a clinical psychologist, as followed at Kasturba Medical College, Manipal, with the source's hedge preserved: because of a dearth of specialists such a composite set-up may not be possible across the country.

The economic argument, used when a service has to be funded, must be quoted with its provenance intact. The Indian overview reports that psychiatric consultation brought the average stay at Denver General Hospital down from 28 days to 16 days, as Billings reported in 1937, and that strategies training primary-care physicians to manage outpatients with hypochondriasis, reported by Smith in 1986, decreased medical costs by 49 to 53 per cent without affecting patients' health or satisfaction. Both are historical United States findings reported at second hand, and neither is an Indian cost-effectiveness result; the chapter's own position is that Indian cost-effectiveness research is what is missing. Quote them as the classic economic argument, and say so.

3 · Psychiatric aspects of medical and surgical illness

Why the marks are here. Almost every other topic in the syllabus begins with a syndrome and works outward to its causes. This one begins with a body that is already ill and works inward. The psychiatric aspects of medical and surgical illness are set as one wide question, and the answer that scores is not a catalogue of organs with a syndrome hung on each. It is an account of what recurs on every ward whatever the specialty, of the several different routes by which an ill body

generates a psychiatric presentation, and of the reading habits that stop a psychiatrist mistaking one route for another. An examiner can usually tell within two sentences whether a candidate has stood on a medical ward or only read about one.

Four neighbouring subjects are named here and deliberately not taught. The patient's own psychological work of being ill, the adaptations and reactions a serious or chronic diagnosis sets going, is taken up separately in this chapter, as are the high-stakes settings of transplantation, dialysis and intensive care, the specific cross-links between psychiatry and cardiology, dermatology and nephrology, and the psychiatric care of people with cancer. What belongs here is the general case: the signature that does not change when the ward does, read in both directions, and what it obliges you to do about it.

3.1 What a psychiatric signature is, and the four routes that produce one

A **psychiatric signature** is the recurring pattern of psychiatric presentation that a class of physical illness produces, taken across many patients rather than in one. It is a probabilistic statement and not a diagnostic one: it tells you what to look for and how high your prior should be, never what this patient has. Candidates lose marks by treating a signature as a criterion set, and lose them again by treating it as though every organ owned a private syndrome.

Four different things are folded into that single phrase, and prising them apart is most of the clinical work.

- **What the disease does.** The illness acts on the brain directly, through metabolic, inflammatory, endocrine, vascular or hypoxic mechanisms, and the psychiatric presentation is a part of the disease rather than a response to it.
- **What you gave it.** The treatment rather than the illness produces the picture: a drug, a procedure, the ward environment, or a withdrawal state manufactured by stopping something the patient was taking at home.
- **What it means.** The patient's own reading of the diagnosis, the prognosis and the lost function, which is where a great deal of the distress on a general ward actually lives, and which is taken up separately in this chapter.
- **What it hides.** The reverse case, in which what presents as a primary psychiatric disorder is the first visible sign of an undiagnosed medical disease.

MNEMONIC

What it does, what you gave it, what it means, and what it hides

The four routes in the order a ward consult meets them. **What it does:** the disease acting on the brain. **What you gave it:** the drug chart, the procedure, the environment, the withdrawal state. **What it means:** the patient's reading of what has happened. **What it hides:** a medical disease presenting psychiatrically. The first two are the ones you can establish from documents before you reach the bedside, the third is the commonest, and the fourth is the one whose miss is least forgivable.

Deciding which route is operating in a particular patient, and committing that decision to the record, belongs to the consult itself and is taught with it. What this topic supplies is the material out of which that decision is made.

3.2 The constant across specialties

The most useful single fact in this topic is that the presentations vary far less than the syllabus implies. The consultation-liaison guidance published in the Indian Journal of Psychiatry in 2022 states it without qualification: across all medical specialties and all ages, the commonest psychiatric symptoms and morbidities are stress, anxiety, depression and **somatic distress**. Not an organ-specific list. The same handful, on the cardiology ward, in the burns unit, in the renal clinic and the surgical side-room.

Two consequences are worth building an answer around. The first is procedural. If the presentations are constant, the opening move on any referral is constant too, and a candidate who cannot state that move has no method, only a memory of organ lists. The second is that the specialty is informative about mechanism and not about presentation. Knowing which ward telephoned tells you which drugs are likely to be on the chart, which metabolic derangements are plausible, what the operation did, and what the illness probably means to this patient and this family. It does not tell you what you will see when you pull the curtain back.

RULE **The specialty predicts the mechanism, not the presentation.** Whichever unit calls, you will meet stress, anxiety, depression or distress expressed in the body. What changes across the corridor is why it is there and what you may safely do about it: the disease process available to act on the brain, the drugs on that unit's chart, the procedures it performs and the meanings its diagnoses carry. An answer opening with a per-organ catalogue has inverted the subject and will run out of time before it reaches what is actually examined.

Somatic distress deserves separate attention because it is the presentation most likely to be misread by everyone in the room, by the medical team as a failure to find the lesion and by the psychiatrist as an absence of psychiatric illness. The disorders themselves are taught in the Somatic-symptom, sexual, impulse-control disorders and suicide notes. What belongs here is simply that a medical ward will hand you this presentation as often as it hands you low mood, and that it arrives labelled as a diagnostic failure rather than as a referral question.

3.3 The step from the community to the ward

The second grounded fact is the size of the step between a general population and a hospital population. The same Indian guidance measures that step for depression and gives a band for anxiety, and both are worth carrying into the examination hall.

about 10%	up to 30%	20 to 30%
PREVALENCE OF DEPRESSION IN THE COMMUNITY, THE GUIDANCE'S BASELINE	PREVALENCE OF DEPRESSION REPORTED IN DIFFERENT MEDICAL UNITS	PATIENTS IN MEDICAL SETTINGS PRESENTING WITH ANXIETY DISORDERS

Read those as figures for depression and anxiety specifically, not for psychiatric morbidity in general, which is a wider quantity with its own literature. The step itself is a prevalence

observation and carries no causal claim on its own: more than one of the routes above is operating simultaneously in any medical unit, and none of them is measured by a prevalence figure. Illness acts on the brain, treatment acts on the brain, and being ill means something to the person; the count cannot say in what proportion. For stress and for somatic distress the same guidance gives no comparable figure. No comparable standard is available to quote, and none is invented here.

What the step does change is your threshold for asking. If the prior probability of depression on a medical ward is several times the community figure, a negative has to be earned rather than assumed, and screening only the patients who look sad will systematically miss those whose presentation has been absorbed into the medical picture. That, and not the arithmetic, is what the figure is for.

3.4 Which way the fraction runs

The current Indian clinical practice guideline for the assessment and management of depression, published in the Indian Journal of Psychiatry in 2026 by Tripathi and colleagues, tabulates how often other conditions accompany major depressive disorder. The table is headed as the prevalence of comorbidities in major depressive disorder, and that heading fixes the direction of every fraction in it: the denominator is the depressed population, not the medically ill one.

COMORBIDITY	SHARE OF PATIENTS WITH MAJOR DEPRESSIVE DISORDER	WHAT IT CHANGES FOR YOU
Anxiety disorder	**67 per cent**	The commonest travelling companion. A management answer for depression that never mentions anxiety has left out most of the patients it is about; the disorders themselves belong to the Anxiety, OCD and trauma-related disorders notes.
Obsessive-compulsive disorder	40 to 80 per cent	Quote it as the range it is. A band this wide is a statement about the spread of the underlying studies, not a point estimate waiting to be averaged.
Attention-deficit hyperactivity disorder	53 per cent	Inattention and restlessness in a depressed inpatient are not automatically depressive symptoms.
Substance use disorder	25 per cent	Withdrawal risk and interaction risk both change before a single dose is written up.
Irritable bowel syndrome	37 per cent	Abdominal symptoms in a depressed patient may be a comorbid disorder rather than distress expressed through the gut.
Parkinson's disease	40 to 50 per cent	The highest figure among the physical illnesses listed. The pairing is expected, not incidental, and it should never be explained to a family as a reaction to the diagnosis.
Metabolic syndrome	25 to 44 per cent	Weight and glycaemic consequences of the agent you choose are part of the treatment decision rather than an afterthought at review.
Hypertension	**27 per cent**	Blood pressure is a routine prescribing consideration in this population; the choice of agent belongs to the Mood disorders: pharmacotherapy notes.

Six further rows sit in the same table without a rate that can be quoted against them with confidence: autoimmune disease, eating disorders, epilepsy, multiple sclerosis, Alzheimer's disease and coronary artery disease. Their presence is itself the teaching point, because it tells you the pairing was thought worth tabulating. No dependable figure is available to quote for those rows, and none is invented here. Each of those conditions is taught elsewhere: epilepsy in

the Epilepsy and psychiatry notes, the degenerative dementias in the Dementias and neurocognitive disorders notes, eating disorders in the Eating and sleep-wake disorders notes.

TRAP **Quoting a comorbidity figure with the fraction inverted.** Because the table counts comorbidities within depression, its hypertension row states the share of depressed patients who also carry hypertension. It does not state the share of hypertensive patients who are depressed. Those are two quantities over two denominators, not interchangeable in either direction, and no arithmetic converts one into the other. An examiner who asks how common depression is in cardiac disease is asking for the reverse fraction, which this table does not contain; a candidate who supplies it from here has misread the title rather than the number.

3.5 The drug chart as a differential diagnosis

The most reversible cause of a psychiatric presentation on a medical ward is usually the one written on the chart at the foot of the bed. The same Indian depression guideline tabulates the drug classes reported to induce or exacerbate depression, and the practical value of that table is not that it should be memorised molecule by molecule but that it converts **medication-induced depression** from an afterthought into a standing item on the differential. The categories, as the guideline groups them, are these.

- Cardiovascular drugs and chemotherapeutics, the two classes most likely to be running when a specialty ward refers.
- Antiparkinsonian drugs, and antipsychotics, which is the row candidates forget because it names their own prescribing.
- Stimulants, where the guideline is explicit that the depressive picture usually belongs to **withdrawal** rather than to continued use, so the relevant date is the stop date and not the start date.
- Anti-microbial agents, antiretrovirals and central nervous system depressants.
- Hormonal agents, the row that names adrenocorticotropin, anabolic steroids, glucocorticoids and oral contraceptives, so that both an inflammatory prescription and a contraceptive one land in the same differential.
- A residual category holding agents that belong to no single specialty, among them cimetidine, disulfiram, phenytoin, tamoxifen and the non-steroidal anti-inflammatory drugs.

Note what the taxonomy is doing. It is organised by the ward that prescribes rather than by pharmacological mechanism, which is exactly right for a liaison psychiatrist: you are not asked to predict which receptor produced the low mood, but to read a chart written by somebody else and say which lines on it are candidate causes. The residual category matters most for that reason, since it collects the agent nobody thinks of as psychotropic, started for an unrelated indication by a team that will not connect it to the referral.

IN INDIA

The anti-microbial row is the one that changes most between a Western text and an Indian ward. It names chloroquine, cycloserine, dapsone, ethambutol, ethionamide, isoniazid and metronidazole. Those are not rarities on an Indian general ward; several are ordinary continuing treatment that arrives with the patient rather than being started in front of you, and the referring team may not list them when it telephones because it does not regard them as new. The antiretroviral row raises exactly the same issue. The obligation here is narrow and worth stating in exactly these terms: obtain the full treatment list, including what the family carries in a bag from home, before you accept that a low mood on this ward is primary.

3.6 Running the signature backwards

The fourth route turns a routine consult into a diagnostic emergency, and it is also the most reliably examinable content here, because it can be asked as a short list and marked without ambiguity. The Indian guidance sets out a small set of pairings that run from the psychiatric presentation towards an occult medical cause. Learn them as pairings and not as diseases: what earns the mark is the recognition that a particular combination of psychiatric picture and accompanying feature should send you back to the body.

PSYCHIATRIC PRESENTATION	THE FEATURE THAT SHOULD STOP YOU	CONSIDER, AND WHERE THE CONDITION ITSELF IS TAUGHT
Psychosis	Confusion, seizure, **subacute onset**	Autoimmune encephalitis, taught in the Neuropsychiatry of systemic and neurological disease notes
Depression	Weight loss with severe pain	Multiple myeloma. Not a psychiatric entity; the finding goes back to the treating team
Depression	Anorexia, nausea and abdominal pain	Gastric or pancreatic carcinoma
Depression or anxiety	Panic-like autonomic features with flushing	Paraneoplastic lung carcinoma in an older patient, phaeochromocytoma in a young one
Late-onset mood disorder	**Neuroleptic sensitivity** with a subtle movement disorder	Degenerative brain disease, taught in the Dementias and neurocognitive disorders notes
An apparently dissociative presentation	The label itself, when the psychiatric account behind it is thin	Localisation-related epilepsy, or non-motor vascular lesions including Balint, Gerstmann and Anton syndrome, taught in the Stroke, TBI, delirium and focal brain syndromes notes

Several of those rows share a structure worth naming. In each, the psychiatric diagnosis is entirely plausible on its own and the tell-tale is a feature that is out of proportion to it: weight loss too great for the mood state, pain too severe, autonomic arousal too paroxysmal, drug

sensitivity too marked for the dose given. Disproportion, rather than atypicality, is the signal. A patient whose depression is textbook except that the weight loss is extreme has a more suspicious presentation than one whose depression is merely odd.

The last two rows each carry a further lesson. Age itself narrows the differential, and the assessment of a first mood episode in later life has its own section here. An apparently dissociative presentation, meanwhile, is the psychiatric label most often applied without a positive account of why, and therefore the label under which a neurological diagnosis most easily survives untested.

GOOD TO REMEMBER

Run the reverse check at the end of the first assessment, not after the first treatment has failed. The common version of this failure is not a psychiatrist who cannot recognise an occult malignancy; it is a patient treated for depression for several weeks before anybody asks why the weight loss was out of proportion to the mood, by which time the case has acquired a history of non-response that is then read as treatment resistance. The check costs one question and belongs in the first note.

3.7 Where the per-system detail lives, and the table that is not here

A deliberate omission, and why. There is no single table in this chapter setting out the psychiatric signature organ system by organ system, and that is a decision rather than an oversight. No source consulted here carries such a table. The Indian consultation-liaison guidance distributes the material across **ten** separate organ-system chapters, each carrying its own prevalence figures, its own mechanisms and its own prescribing cautions. A single table assembled across those specialties from recollection would look authoritative and be unverifiable, so none is offered here.

What can usefully be given is the map. The organ systems treated separately in that guidance are cardiovascular, respiratory, hepatic and gastrointestinal, chronic kidney disease, endocrine, stroke and traumatic brain injury, Parkinson's disease, epilepsy, cancer, and human immunodeficiency virus infection with dermatology. The same body of guidance adds settings rather than systems: solid-organ transplantation, intensive care, bariatric surgery, the perinatal period, medication-induced psychiatric disorder and coronavirus disease. That last group is where the surgical half of this topic mostly lives, and it is the reason the subject is titled for medical and surgical illness rather than for medicine alone: an operation is an exposure in its own right, with its own environment, its own drugs and its own meanings.

Most of those are owned elsewhere and should be answered from there rather than from here. Epilepsy is taught in the Epilepsy and psychiatry notes. Stroke and traumatic brain injury are taught in the Stroke, TBI, delirium and focal brain syndromes notes, and the wider systemic and neurological diseases, endocrine disease among them, in the Neuropsychiatry of systemic and neurological disease notes. The localising and lesional groundwork behind all of those sits in the Neurology foundations for psychiatrists notes. Transplantation, dialysis and intensive care, the cardiological, dermatological and renal cross-links, infection with the human immunodeficiency virus, and cancer are each taken up separately in this chapter. What is genuinely owned at this

address is the cross-system pattern, the two directions of reading, the drug chart, and the referral habit that recurs whichever door the patient came through.

3.8 The habit that survives the specialty

Everything above collapses into a short sequence that holds whichever unit called, and it is what an examiner listens for when the question is set broadly. It is deliberately not a screening instrument; the instruments and their scoring belong to the assessment and bedside-testing material taught elsewhere. This is the order of thought.

- Establish the date on which the psychiatric change began, from somebody who saw it, and date every drug on the chart against that date rather than against the admission.
- Ask the treating team what changed in the medical illness itself inside the same window: a result, a complication, a procedure, an escalation of care.
- Ask what the patient has been told, and separately what the patient believes it means, because the two are routinely different and the second is what generates the distress.
- Before closing, run the presentation past the reverse list and satisfy yourself that nothing in front of you is out of proportion to the psychiatric diagnosis you are about to offer.

The first and second steps together are what distinguish a liaison assessment from an outpatient one. In a clinic the psychiatric history is the primary record; on a ward it competes with an obviously more urgent medical narrative, and the temporal relationship between the two is the single piece of information nobody else in the building is collecting. The clinical interview and mental state examination themselves are taught in the Psychotherapies, clinical assessment, MSE and nosology notes; what is added here is the discipline of laying two timelines side by side before interpreting either.

> Every specialty produces the same short list of presentations, so the ward tells you the mechanism and the prescribing, never the syndrome you are about to meet.

Answer the wide version of this question in that order and it holds together, and close it by conceding that the per-system detail is distributed across the specialties and should be answered from the relevant one. That concession is worth more marks than an invented table, because it is what a working liaison psychiatrist would actually say.

4 · Psychological reactions to physical illness and chronic disease

Why the marks are here. A question on the psychological reactions to physical illness is not a question about a disorder, and a candidate who answers it with a criterion set has answered something else. Almost every other topic in this area begins with a syndrome and works back to what produced it. This one begins with a person who has been told something about their body, and asks what they are now doing with that information: what the illness means to them, what it has cost them, and how much of that is visible on a ward round. The patient at the centre of it may carry no psychiatric diagnosis at the end of your assessment and still be the reason the referral was made.

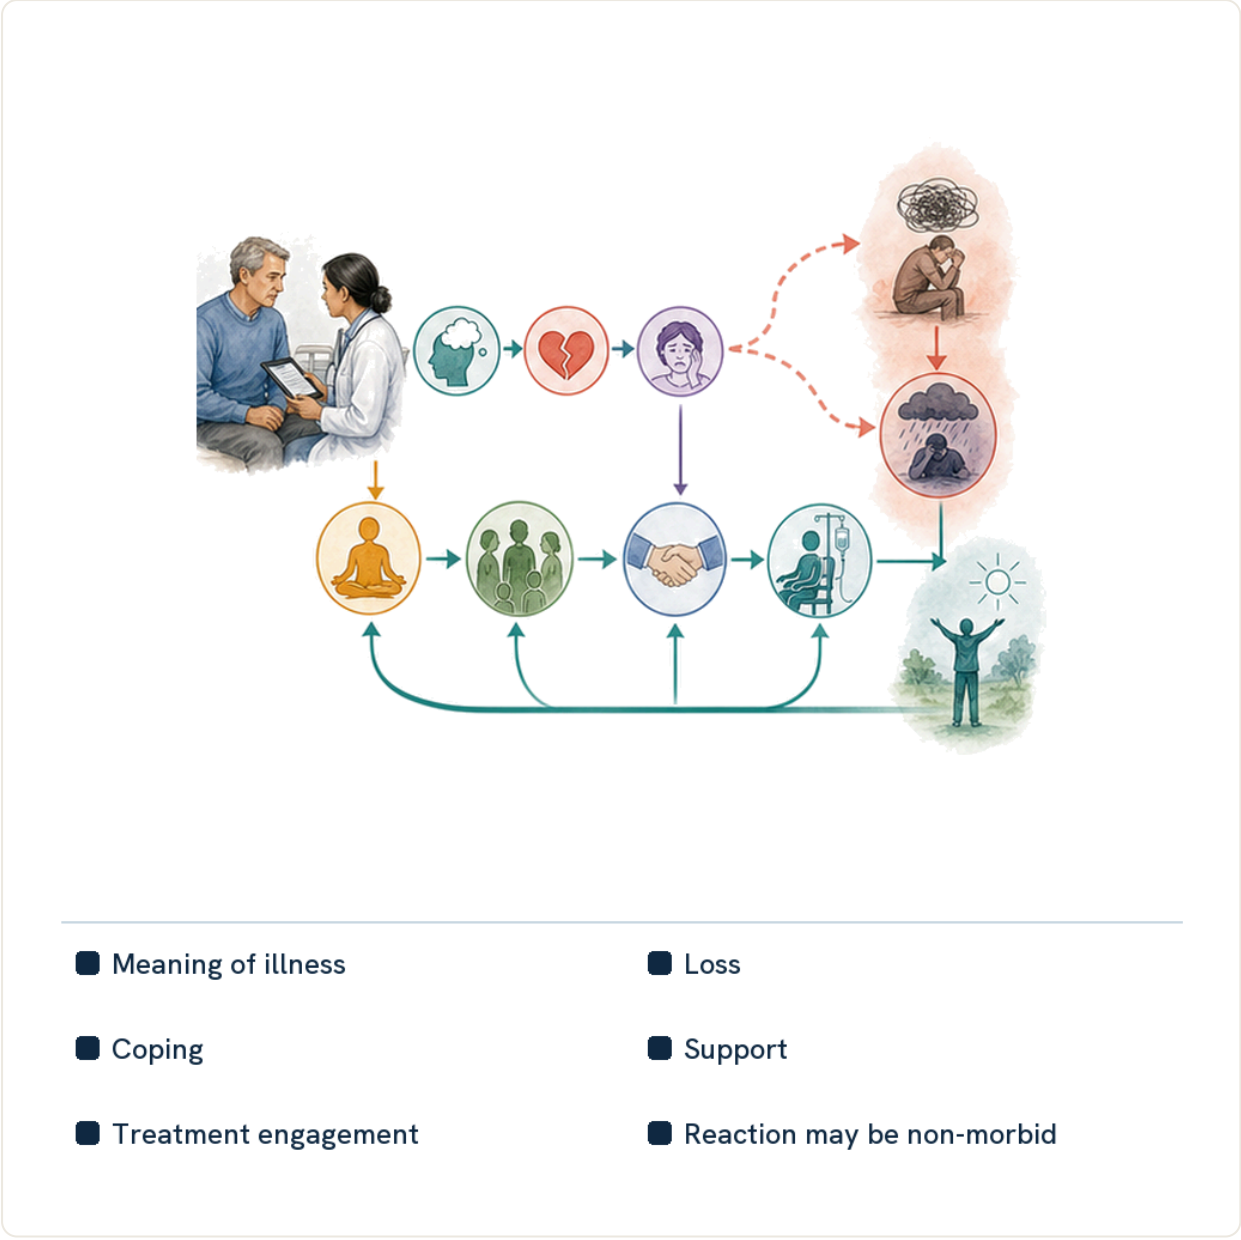

Fig 29.3 Every physical illness evokes a psychological reaction, but that reaction may or may not become morbid. Consultation explores the illness's meaning, losses, coping resources and effect on treatment engagement rather than assuming a psychiatric diagnosis.

Two boundaries keep the answer clean. Adjustment disorder as a diagnostic category, and the psychosomatic concept behind the two-way relation between mind and body, are taught in the Somatic-symptom, sexual, impulse-control disorders and suicide notes. The psychiatric presentations a physical illness generates through the disease, through its treatment, or by concealing itself behind a psychiatric label, are taken up separately in this chapter. What is owned here is the patient's own work: the reaction, its trajectory across a long illness, and what both of them do to treatment.

4.1 The reaction is universal, the morbidity is not

The consultation-liaison guidance published in the Indian Journal of Psychiatry in **2022** opens this subject with a sentence worth carrying into the hall intact: all physical illnesses and their management cause a psychological reaction, and that reaction may or may not reach **morbid level**. The second half does the clinical work. Because the reaction is universal, its presence is not

a finding, and a patient who appears to feel nothing has told you something about how they are managing the news rather than that no reaction occurred. What varies between patients is how far it goes, and that variation, not the reaction itself, decides whether anything needs to be done.

The same guidance runs the relation in both directions in one sentence: mental illness and stress in their turn predispose to a wide variety of physical illnesses. The consequence for a consult is that the patient's psychological state is never purely downstream of the medical one. It is also an input to the illness in front of you, which is why it is assessed rather than noted in passing.

That is why the same source lists the discrimination among the tasks of the consultation-liaison psychiatrist: the opportunity to assess the reaction to physical illness, and to differentiate it from psychiatric illness presenting in medical and surgical units. Recognising a depressive episode on a surgical ward is one skill. Recognising that the distressed man in the next bed does not have one, and saying so in terms the team can use, is another, and the guidance is explicit about where that leaves him: people referred in this setting may not fulfil the diagnostic criteria for any particular mental disorder, and may nonetheless need support for their psychological difficulties.

RULE **The reaction is universal, so the question is never whether the patient has one, but how far it has gone and what it is costing the treatment.** An assessment that concludes "no psychiatric illness" and stops has answered a question nobody asked. The referring team did not enquire whether criteria were met; it asked what to do about the patient in front of it. A reaction well below any diagnostic threshold can still be the reason a man will not sit up after his operation, and a consult that names it and says what would help has discharged its task.

4.2 Moving or stuck: the judgment the guideline actually asks for

If the threshold is not a criterion count, what is it? The current Indian clinical practice guideline for the assessment and management of depression, published in the same journal in **2026**, supplies the working rule for a response to loss, and it transfers directly to the losses a physical illness inflicts. Enquire whether the person is moving toward acceptance, or has been stuck in one place for a prolonged period. And because there are no universal ways of coping with or dealing with stress, the comparator is not other patients: it is the **premorbid history**, and the question is whether the current response is normal or out of character for this individual patient.

Three consequences follow. The judgment is about direction rather than content, so the intensity of what you see at the bedside settles little on its own: grief that looks severe but is moving is a different clinical object from a flatter picture that has not shifted in weeks. It needs two points in time, which makes a review appointment part of the assessment. And it makes the patient their own control, which is the only comparator the guideline leaves standing.

A second decision sits behind the first: whether pharmacological help is needed, or whether psychotherapy or a support group will suffice. Notice the order. The intensity decision comes after the normality decision and not instead of it, and a candidate who reaches for an antidepressant before establishing direction and character has skipped the step the question was set to test. The choice of agent belongs to the Mood disorders: pharmacotherapy notes.

TRAP **Judging the reaction against how people are supposed to cope, rather than against how this person has always coped.** Candidates make it because a sequence of named phases reads like a timetable, and a patient who is not where the timetable says they should be looks abnormal by arithmetic alone. The guideline forecloses that reading, and what it leaves standing is the premorbid account. The practical form of the error is a diagnosis made on a stranger: a lifelong undemonstrative man recorded as flat and withdrawn by a clinician who never asked anybody who knew him beforehand.

GOOD TO REMEMBER

The comparator has to be collected, and it is not in the medical file. Before recording a reaction as abnormal, get from a relative what this person was like the last time something went badly wrong: how they took bad news, whether they talked or went quiet, whom they told. Then ask the patient what they expected to hear before they were told, because the size of a reaction usually tracks the gap between what was expected and what was said.

4.3 What the reaction costs the treatment

Why it is a treatment variable. The case for assessing any of this rests on outcome, not on sympathy. The same consultation-liaison guidance states that psychiatric morbidity in people with medical illness is associated with a set of negative outcomes:

- higher utilisation of health-care services;
- prolonged hospital stay;
- frequent hospitalisations;
- poor **adherence** with medication;
- higher and earlier mortality.

Read that as a chain rather than as five separate associations. Adherence is the hinge in the middle: a patient not taking the treatment accumulates complications, complications generate admissions, and admissions generate cost and risk. The other entries are largely what adherence failure looks like once it has been running a while. That is what makes the psychological reaction a modifiable determinant of a medical outcome rather than a comment on the patient's mood.

The renal chapter of the same body of guidance states the mechanism in one disease with more precision. Comorbid depression adversely affects the attitude toward medication compliance and compromises sleep quality, and psychiatric comorbidity in chronic kidney disease worsens help-seeking, lifestyle and medication adherence, and so worsens the renal outcome itself. Note the phrasing: attitude toward compliance. What is affected first is not the ability to take a tablet but the reason for bothering, which is the ground the psychological reaction occupies. The direction is stated and the magnitude is not: no effect size, hazard ratio or adherence figure is attached to any of it in that guidance, and none is supplied here.

So the question you are answering is not really whether the patient is depressed. It is why this patient is not getting better, and the psychological reaction is one of the few answers to that question anybody in the building can act on.

4.4 The long illness: biographical disruption and biographical repair

A reaction to an acute illness resolves as the illness resolves. A chronic disease offers no such ending, and the reaction to it is better understood as a trajectory than as a state. The most useful frame treats chronic illness as **biographical disruption**: the illness interrupts the life a person was in the middle of living, and everything after is the work of assembling a life around it. Bury's model, as applied in a 2025 systematic review and thematic synthesis of the qualitative literature on people receiving maintenance dialysis, published in BMC Nephrology, gives that trajectory a usable shape.

59	30	2000-2024
QUALITATIVE STUDIES SYNTHESISED IN THE REVIEW THAT SUPPLIES THIS TRAJECTORY	COUNTRIES FROM WHICH THOSE INCLUDED STUDIES WERE DRAWN	PUBLICATION WINDOW OF THE STUDIES THE REVIEW INCLUDED

Two cautions. The review sits in one disease because that is where the qualitative literature is thickest, and its subject is the patient's experience rather than the psychiatry of the dialysis unit, which is taken up separately in this chapter. It is an international synthesis and not Indian guidance, so no statement about Indian practice rests on it. What travels is the sequence:

- the diagnosis itself, and the initiation of a treatment that cannot afterwards be stopped, as the point at which the biography breaks;
- disabling physical symptoms and functional limitations;
- impaired socio-occupational functioning, which is where the loss stops being private;
- uncertainty and psychological distress;
- changes in self-image and identity.

The order carries the teaching. The early losses are of function and the late one is of self, so two patients with identical results can sit at very different places on it. One still contending with symptoms and limitation is asking what can be done. One who has arrived at a changed sense of who they are is asking something else, and answering the first question when the second was asked is how a well-meant consultation lands badly.

What the review describes next is **biographical repair**, the half candidates leave out. Repair is carried by **coping styles**, meaning the characteristic stance a person takes toward the illness, and by **coping strategies**, meaning the particular things they do. Both are modifiable, which is why naming them matters, and the factors that help or obstruct them divide into what the person brings and what the setting supplies.

FACTOR	WHERE THE REVIEW PLACES IT	WHAT IT GIVES YOU TO WORK WITH
Age and gender	Internal	Fixed, but it predicts which losses matter most: earning, marriage, caring for others, independence.

FACTOR	WHERE THE REVIEW PLACES IT	WHAT IT GIVES YOU TO WORK WITH
Personal beliefs and misconceptions	Internal	Separate the misconception, which is correctable, before anything is called irrational.
Feelings of shame and guilt	Internal	Ask what the patient thinks caused the illness. Self-blame is rarely volunteered and drives concealment.
Financial constraints	Internal	Placed with what the person brings, and often the largest determinant of whether a plan is followed.
Religion and spirituality	Internal	A resource in this model, not a complication. Record what the patient draws on, not only what they suffer from.
Social support	External	Establish who is actually doing it. It is usually one exhausted person, whose state predicts the patient's.
Stigma	External	Governs disclosure at work and at home, and so how much help the patient can accept.
Role of the clinical team	External	The one external factor you control. How the illness was explained is either equipment or obstacle.
Health system factors and the wider context	External	Named as the type of dialysis, the availability and quality of services, and the provision of health insurance. Read generally: what the treatment demands, what is reachable, who pays.

The table puts two entries where a candidate does not expect them. Financial constraint sits among the internal factors rather than among external circumstances, and religion and spirituality sit there too, with what the person brings.

4.5 Coping and resilience as things you assess

The companion assessment chapter in that same Indian guidance states the loop plainly. Chronic and serious medical morbidity, together with hospitalisation, increases the stress on the individual, which in a vicious cycle further worsens the outcome of the illness. To cope with that stress a person needs **resilience**, which in turn predicts a good outcome. So **perceived stress** and resilience are themselves assessed, rather than inferred from whether a diagnosis was reached. The guidance names the settings where this matters most:

- oncology;
- trauma;
- burns;
- patients waiting for transplant.

What those four share is what lets the principle travel to a ward not on the list. In each the outcome is uncertain, the waiting is long, the treatment is itself an ordeal, and the patient has time to think about all three. Those are the conditions under which coping capacity, rather than disease severity, begins to account for how a patient does. Standardised measures exist for both constructs, and the instruments and their scoring are taught in the Psychotherapies, clinical assessment, MSE and nosology notes.

An assessment recording only the presence or absence of a disorder has not examined the thing that predicts the outcome. Asking what this patient has to cope with, and what they cope by, yields something to write down even when no diagnosis is made.

4.6 The classical frameworks, and the vocabulary this section will not invent

Indian guidance points to two classical sources for the psychological reaction to illness. In a 1956 paper titled "Psychiatry and Medical Practice in a General Hospital", Bibring and Kahana classified patients into personality categories, deliberately avoiding psychiatric jargon in favour of language that would help practitioners recognise these patients in their day-to-day work, and explained what disease meant to each patient type and how doctors might best handle their predictable behaviours. The second is Groves, in two essays: one on taking care of the hateful patient, and one on the management of the borderline patient on a medical or surgical ward.

The pairing tells you what the field found it needed. The first framework answers what the illness means to a particular kind of person. The second answers what to do when the reaction has become a problem for the staff rather than a complaint from the patient, and that referral is common and rarely phrased as a psychiatric question. The call reports that the patient is refusing, or demanding, or has upset the nursing staff, and the skill lies in hearing a reaction to illness inside a complaint about behaviour.

The categories themselves are not reproduced here. The guidance pointing to these works does not carry their content in a quotable form, and a personality typology written out from recollection would look authoritative and be unverifiable. Anyone wanting to use either framework should go to the primary work.

The same discipline applies to a vocabulary this topic is often expected to produce. Three words recur in ward teaching and in model answers: denial, regression and dependency. No sourced definition, list or clinical description of them as reactions to physical illness is available at this address. No comparable standard is available to quote, and none is invented here. The better answer is available anyway: describe what the patient is doing, in their own words and the family's. What they have been told, what they say about it, what they are and are not doing about

the treatment, and what has changed since the diagnosis. A behavioural description survives an examiner's follow-up question; a label attached without a source does not.

4.7 Coping in the patient's own frame

A patient's account of what has happened to them rarely arrives in the vocabulary of a textbook. It arrives as something about fate, or duty, or what the family will now have to do. A clinician who waits for it to be restated in clinical language will wait a long time, and will meanwhile record the patient as having no insight into the illness.

An Indian communication published in the Indian Journal of Endocrinology and Metabolism in 2018 demonstrates what working inside that frame looks like. It presents a curated and abridged selection of verses from the Bhagavad Gita, setting out the reactions of Arjuna to stress alongside the way Lord Krishna encourages him to develop and use positive coping skills. Diabetes is the exemplar, but the authors state that the selection is intended to be useful in any illness, and offer the verses to health-care professionals for encouraging healthy coping in people seeking medical care. It is a communication and a teaching resource; no claim about the frequency, classification or outcome of psychological reactions rests on it.

What it demonstrates is a move rather than a content. A patient's own tradition frequently contains a worked account of bearing what cannot be changed while acting where action is possible, and it will be more persuasive to them than anything constructed in a side room. The task is to find out what it is for this patient and work with it, rather than translate it into a mechanism and file it.

The clinical question about any such account is about consequence rather than content: is this belief carrying the patient toward continued treatment or away from it? The same sentence from two patients means two different things. That it is in God's hands can be what makes a decade of treatment bearable, and it can be why a man stops attending for review. Nothing in the sentence tells you which, so ask, and ask again at the next visit.

IN INDIA

Three questions belong in this assessment on an Indian ward, and none is about symptoms. Ask who is deciding about the treatment, because the answer is frequently a family group rather than the patient alone, and the reaction obstructing the plan may not be the patient's. Ask what the patient and the family are already doing that they feel is helping, and record it in the coping assessment: a practice the patient's community sanctions is not a finding, and treating it as one costs you the alliance. Ask what would make the next appointment difficult to keep, because where a chronic treatment is paid for from the family's own pocket, an interrupted course is often an economic event rather than a psychological one, and recording it as poor motivation puts the wrong problem in the notes.

4.8 What changes because of the answer

An assessment of this kind has to end in something the treating team can act on, and it resolves into three dispositions rather than a diagnosis.

Where the reaction is within character and moving, the output is a statement and not a prescription. Say plainly that this is a reaction within this person's range, name what it is a reaction to, and say what would help: information the team can supply, a change to what the patient is being asked to tolerate without explanation, contact with somebody at the same point in the same illness. Saying it clearly stops the team hunting for a disorder and starts them addressing what the patient is reacting to.

Where it is stuck, or out of character, the second decision becomes live and the intensity question is answered on its own terms. Where adherence has already been affected, name that outcome to the team in those words, because it converts an observation about mood into a statement about the medical result they are responsible for, and it is the sentence most likely to get your recommendation followed.

An examiner setting this question is testing whether you can hold two propositions in one answer: that this patient may have no psychiatric diagnosis, and that this patient needs psychiatric input. Assert only the first and you sound dismissive; assert only the second and every unhappy inpatient becomes a case. The space between them is why a general hospital keeps a liaison service.

> A psychological reaction to physical illness is universal and only sometimes morbid: judge it by whether the person is moving or stuck against their own premorbid character rather than against any norm, and report it in terms of what it is costing adherence and outcome.

What arrives on the ward

5 · Delirium in the medically ill (CL perspective)

Why the marks are here. Delirium in the medically ill is examined twice over, and the two questions are not one question asked differently. The first asks what the syndrome is: its definition, subtypes, screening instruments, causes, treatment and prevention are set out in the Stroke, TBI, delirium and focal brain syndromes notes. The second asks what a psychiatrist does when a medical team telephones about a patient who has become difficult overnight. That is the question taken up here, answered in acts rather than criteria: what the call is reporting, what can honestly be established in a single bedside visit, what the note must make happen after you leave, and who holds the decision when you go.

Two boundaries keep it honest. What ageing contributes is taken up where delirium in the elderly is dealt with in these notes; the referral pathway, the negotiation about moving a patient between wards and the models a service can be built on are taken up where the principles and models of consultation-liaison psychiatry are dealt with in these notes. What remains is narrow and heavily examined: consultation work on a condition medical in origin, psychiatric in presentation, and visible mainly to people who are not psychiatrists.

5.1 The call, and what its wording is actually reporting

A ward telephones about **disturbance**, and disturbance is not a diagnosis. The vocabulary of a referral is set by what can be seen from a nursing station across a bay: a patient who has climbed over the cot side, pulled at a cannula, refused a dressing, or simply cannot be settled. That reports an observed act and somebody's difficulty with it. Nothing in it commits the ward to a view about cause, and a candidate who reads the request as a diagnostic proposal has accepted the wrong problem before reaching the bed.

Three things are recoverable from the wording. What changed and when: a referral saying a patient has become uncooperative carries a hidden claim about a before and an after that the ward has usually not examined. Whose distress generated the call: a request from an exhausted night nurse and one from a consultant on a round differ even when the words match. And what is being asked for, which here is generally an act rather than an opinion: sedate, shift, certify, or take over. Answering the act without answering the question is how a consult becomes a prescription.

HOW THE CALL ARRIVES	WHAT THE WORDING IS REPORTING	WHAT THE CONSULT SETTLES FIRST
Not cooperating, pulling at the lines	An observed act and an interference with treatment, seen from the bedside	When it began, against what previous state, and who noticed first
Acute psychosis, please start something	A lay diagnostic label attached to disorganised behaviour by a team with no psychiatric training	That the label is the referrer's inference, and what was observed underneath it
Please sedate for the scan, or for the night	A request for an act, framed so that a refusal reads as unhelpfulness	Whether it is for the investigation, for the ward to cope, or for the patient's safety
Please shift to psychiatry, we cannot manage this	The team's judgement about its own capacity, not about the patient's diagnosis	What specifically cannot be managed, by whom, on which shift
Very quiet since yesterday, probably depressed	A change noticed only because somebody knew the patient before it	Whether the quietness is new, and what else changed the same day

RULE **The referral tells you what the ward can see from the corridor; the consult exists to convert that into something the ward can act on tonight.** Everything procedural here follows: why the wording is examined rather than obeyed, why the change over time is reconstructed from the people who were present rather than inferred from the patient before you, and why the output is instructions to a team rather than a formulation for a psychiatrist. A consult that reaches an accurate diagnosis and changes nothing the ward does overnight has failed at the one thing it was called for.

5.2 The patient who generates no call

Because a referral is generated by disturbance, the **referral filter** selects against the patient who causes no trouble. Someone withdrawn, slowed, staring at the ceiling and accepting every procedure without protest interferes with nothing, and a busy ward records that patient as tired,

low, or comfortable. The consequence is structural: a service that only answers calls sees the population its callers can notice, defined by nuisance rather than by severity.

This is the difference between responding to referrals and **case-finding**, and it costs little on an Indian ward round. While on the unit for one patient, ask the nurse in charge a general question rather than a specific one: has anyone else on this bay changed since yesterday. Treat an answer such as has been very quiet since the operation as a referral, because clinically it is one and administratively it is not, and record what prompted you to look.

5.3 A screen at a bedside you will visit once

You attend once, usually in working hours, for a few minutes of a patient's week. The **observation record** kept by the nursing staff, with whatever the family attendant noticed, covers the rest. Any screen worth leaving behind must therefore be usable by those people rather than by you, because the observations that matter will be made when you are not in the building.

A screen here has a different job from a diagnostic interview: detection, and fixing a time point in the record, rather than closing a question. Which instrument is used, how it is scored and what it is validated against belong to the Stroke, TBI, delirium and focal brain syndromes notes; administering one in front of an examiner is taken up where the demonstration of clinical scales and bedside tests is dealt with in these notes. What belongs here is the choice as a service decision: an instrument only a psychiatrist can administer solves nothing on a ward the psychiatrist visits once a day.

So what is handed to the ward matters more than what is performed at the bed. **Serial observation** means a small number of items, repeated by whoever is on duty, entered in the chart with a time against them. Three properties make such an instruction survive a handover:

- it can be completed by a nurse or duty doctor with no psychiatric training, inside a routine observation round;
- it is timed and written in the ward's own record rather than reported verbally, so a pattern across a day and a night becomes visible to someone who was present for neither;
- it names in advance what result should bring the psychiatrist back, so the ward is not left choosing between doing nothing and declaring an emergency.

TRAP **Reporting one lucid interview as an exclusion.** The candidate sees the patient at midday, finds them oriented and cooperative, and writes that there is no evidence of a cognitive disturbance. That reports one time point as a conclusion and overstates its own instrument: what was observed at a stated hour is a finding, while nothing is present is a claim about hours nobody sampled. It is compounded because a reassuring note stops the ward looking. Write what you saw, when you saw it, and what would change the answer.

5.4 The note as an allocation, not an opinion

What a consultation note must contain in general, and the aetiological reasoning it is built around, are set out where the principles and models of consultation-liaison psychiatry are dealt with in these notes. What is distinctive here is that almost nothing the note asks for will be done

by the psychiatrist. The search for the cause belongs to the admitting team, the ward environment to the nursing staff, the drug chart to whoever prescribes on it, the investigation to the specialty that ordered it. A note written as advice, in the register of a formulation, distributes none of that. A note written as an allocation does.

MNEMONIC

Owner, act, time, trigger

The test to apply to each line before closing the file. **Owner:** the person or role, named, not the team in the abstract. **Act:** what is to be done, in terms the owner can execute without translation. **Time:** when, or by when, since a recommendation with no time attaches to nobody's shift. **Trigger:** what change should bring the psychiatrist back, in observable terms rather than a judgement about severity. A line failing any of the four is an opinion wearing the clothes of a plan.

Two further entries earn their place specifically here:

- an explicit statement of what the psychiatrist is *not* doing, since the commonest misunderstanding here is that a psychiatric opinion transfers the problem. Recording that the cause is being sought by the admitting team, and that psychiatric input runs concurrently rather than in sequence, stops the investigation stalling while each service waits for the other;
- a record of what was not concluded, because a single visit often ends without a settled answer, and naming which possibilities remain open and what would separate them is safer than a label chosen to make the page look finished.

GOOD TO REMEMBER

Write for the person who will read this at three in the morning, not for the consultant who requested it. The reader who acts on it is the night duty doctor or nurse in charge, working alone, without the conversation you had on the round. Put the acts and their owners first, the formulation beneath, in plain language. A recommendation that must be interpreted before it can be carried out will not be carried out.

5.5 Who holds the decision, and what nothing here settles

The maxim is that the consultant advises and the treating team decides, repeated widely enough that candidates state it as a rule of law. Handle it carefully. Whether a liaison recommendation is formally **advisory**, and where responsibility for accepting or declining it rests, is not stated in terms by any source available for this section. No comparable standard is available to quote, and none is invented here. What can be reasoned from the structure of the situation is examinable, and it is most of what a candidate needs.

Begin from what the psychiatrist demonstrably does not control: not the bed, not the drug chart, not the investigation list, not the discharge. Every recommendation therefore needs an act by somebody else before it becomes treatment, which makes the practical task the reduction of friction between advice and execution. Three positions follow without depending on any contested rule about responsibility:

- put the recommendation where the acting team will find it, in the record they use, not in a document only psychiatry reads;
- make disagreement visible instead of repeating yourself, since a recorded exchange protects the patient and the discussion where a second note in identical terms protects nobody;
- where the disagreement concerns risk, state it in the currency of the specialty that must act on it, because a ward moves on what it recognises as danger.

Whether the patient moves to a psychiatric bed is a separate negotiation with its own criteria, settled where the consultation-liaison service and its models are dealt with in these notes; a patient refusing assessment or treatment raises a different question again, taken up where capacity assessment and refusal of treatment in the general hospital are dealt with in these notes. The referral settles neither.

5.6 The statutory floor under the ward consult

One thing is settled, and by statute rather than custom. The service you provide on somebody else's ward is not a favour between departments; it is local delivery of an obligation placed on the state.

IN INDIA

The Mental Healthcare Act, 2017 makes the availability of mental health services a duty of the appropriate Government rather than a matter for each institution to arrange. Under section **18(6)** that duty runs to all general hospitals the Government runs or funds, with basic and emergency mental healthcare available at all community health centres and upwards in the public health system it runs or funds. The ward consult is therefore a **statutory entitlement** of the patient in that bed rather than a courtesy between colleagues, and a general hospital without psychiatric cover is a shortfall against a duty, not a local misfortune. Quote it by number and duty-holder; the range of services required is specified elsewhere in the same section.

Read the provision for what it does and does not do, because an examiner will push on that edge. It establishes that a service must exist and how far down the system it must reach. It does not create a referral pathway, staff a rota, set a response time, or tell a physician when to telephone, and it is silent on the question the previous section left open: who owns the decision once the psychiatrist has attended. It answers availability completely and authority not at all, and a candidate who says precisely that has understood it better than one who recites it.

5.7 What this section hands on

The call reports behaviour	One visit is one sample	The note allocates
THE WORDING NAMES WHAT WAS SEEN AND WHOSE DIFFICULTY IT IS, NEVER A DIAGNOSIS	A SETTLED INTERVIEW AT MIDDAY RECORDS A TIME POINT AND EXCLUDES NOTHING OUTSIDE THAT HOUR	EVERY LINE NAMES WHO ACTS, WHAT THEY DO, BY WHEN, AND WHAT BRINGS THE PSYCHIATRIST BACK

What an examiner is testing. Given a medical inpatient disturbed overnight, the discriminating answer does not begin with a definition. It begins with the call: who telephoned, what they said,

what they wanted, what the wording concealed. It moves to the bedside as a sampled observation rather than a verdict, and to the instruction left for the people present when you are not. It ends with a note allocating acts to owners with times against them. Answer in that order and the entity looks after itself; answer with the entity and the question has not been addressed.

> You are called about behaviour, can sample only an hour of it, and leave holding none of the levers: so the output is not a diagnosis but a set of acts, each with a named owner, a time, and a trigger to call you back.

6 · Somatic symptom and related disorders in CL settings

Why the marks are here. The heading reads like a request for a taxonomy, and answered as one it loses almost everything on offer. What these conditions are, what each diagnosis requires, how the instruments are scored and what is prescribed all belong to the Somatic-symptom, sexual, impulse-control disorders and suicide notes, which open on this group because it carries the largest reclassification in this part of the syllabus. None of it is repeated here.

What is owed instead is the part no taxonomy answers. **Somatic symptom and related disorders** reach the psychiatrist through another doctor's exhausted enquiry rather than through anything the patient, the family or the ward has called psychiatric. That fact governs the consent, the timing, the first sentence of the interview and most of what one visit can achieve.

6.1 The referral nobody in the room asked for

Most consults on a medical ward begin with a change in the patient: new confusion, a refusal, a collapse of mood. This one begins with a change in the referring team, which has run out of investigations it can justify. The patient is usually no different that day, and often does not know the call is being made. That makes it an **unrequested referral**.

The referral is itself an event in the illness. Before you are called, somebody has told the patient something about his results, and whatever was said is the ground you will be standing on. **The handover sentence**, the actual words in which the physician explained the referral, decides whether you meet a man offered another opinion or one told his symptoms are not real. It is not in the file, and will not be volunteered.

RULE **Find out what the patient was told, and by whom, before you ask the patient anything.** The referral has already made a statement about his body and his credibility, and your interview begins as a reply to it. Treat the distance between the referring doctor's words and the patient's account of the same conversation as a clinical finding, not a misunderstanding to correct.

6.2 When the call comes, and what the timing tells you

Timing carries information the referral text does not. The point at which psychiatry is called indicates what it is being asked to absorb.

WHEN THE CALL IS MADE	WHAT THE REFERRING TEAM HAS CONCLUDED	WHAT THE CONSULT DOES FIRST
Early, with investigation still running	That a psychological contribution sits alongside an enquiry that remains open	Take the history without waiting for the work-up, and tell the team so
At the point results come back normal	That nothing has been found, and the absence is itself the answer	Establish what was said to the patient then, and in whose words
After repeated presentations across several departments	That the pattern belongs to the patient rather than any one organ	Assemble the sequence of contacts before going to the bedside
After an intervention has caused harm	That the enquiry must stop, and psychiatry will be the brake	Record by name who still holds the physical questions, so the brake is not read as closure

A referral in the last row is not a delayed version of one in the first. Each asks for a different opening act, and the wrong one spends the only visit many of these patients attend.

6.3 What the patient is being asked to accept

The referral asks two things at once and they are refused together: that the search for a physical cause is finished, and that another kind of doctor now takes it over. A patient described as unwilling to see psychiatry is more often unwilling to accept the first, so opening by explaining what psychiatrists do loses the consult in its first minute.

Two features of the setting make the position harder than in an outpatient clinic. **Investigative momentum** is the tendency of a work-up to continue because it has begun: each further negative raises the cost of stopping for the team that ordered it, so by the time psychiatry is called somebody has usually already lost an argument. And the **contact history**, the ordered account of who was seen, for what, with what result and what each said afterwards, is held by nobody; every department holds its own segment. Assembling it is the most useful thing this consult contributes.

Establish before you reach the bedside:

- whether the physical enquiry is being closed or held open, and who holds it;
- what the family was told separately, and whether the two accounts agree.

> **GOOD TO REMEMBER**
>
> Where the physician is willing, be introduced by him at the bedside instead of arriving alone. It presents the consult as something the medical team has added to its own care rather than the handover that ends it.

Where the team's difficulty is not that the enquiry is finished but that it doubts the patient's account, the question and the method have both changed. That situation is taken up where factitious presentations and malingering in the general hospital are dealt with here.

IN INDIA

Three features of the general hospital press on this referral. Much of the investigation is paid for from the family's own pocket, so a normal work-up is a financial loss as well as a clinical dead end. The contact history is usually long and crosses systems of medicine as well as departments, and is not offered unless asked for without disapproval. And the patient is frequently sent on without being told which speciality, so your arrival at the bedside is the disclosure, made by a stranger. No figure is attached to any of the three: no comparable standard is available to quote, and none is invented here.

6.4 How the heading is asked

Set as a short note it wants the route and the address: who refers, at what point in the medical career, why then, and where the diagnostic account belongs. Set as a long case or bedside station it arrives as a patient with a thick file and normal results, and what is watched is the opening: whether you found out what he had been told before you began, and whether your first question was about his symptoms or his tests.

TRAP **Answering the ward's question with the classification.** Candidates do it because the taxonomy is freshly learnt and feels safe. It fails structurally: the correct diagnostic label was never the thing the referring physician could not produce, so a candidate who supplies it has answered a question nobody asked and left the patient exactly where the referral put him.

Another doctor's exhausted enquiry
HOW THIS GROUP REACHES THE PSYCHIATRIST

Taught in full elsewhere
WHERE THE DIAGNOSES, THEIR CRITERIA AND THEIR INSTRUMENTS SIT

The words already spoken
WHAT MUST BE ESTABLISHED BEFORE THE INTERVIEW OPENS

This group reaches psychiatry when a physician runs out of investigations, not when anyone identifies a psychiatric symptom, so the consult begins by establishing what the patient was already told and by whom; the diagnoses themselves, their criteria and their instruments are read in the Somatic-symptom, sexual, impulse-control disorders and suicide notes.

7 · Capacity assessment and refusal of treatment in general hospital

Why the marks are here. The referral reads: patient refusing amputation, please assess capacity. It is one of the few consults in which a psychiatrist is asked not to describe a mental state but to underwrite or to block somebody else's surgical decision. It is also the consult on which Indian candidates most reliably reproduce a foreign answer, because the schema printed in most textbooks is not the test Indian law supplies. The marks are for knowing which law is in the room, what it actually asks, who else must be brought into the decision, what has to be written in the notes, and what follows when the patient may lawfully refuse.

Capacity assessment and refusal of treatment in the general hospital is two problems wearing one name. The first is a patient with mental illness whose treatment decision falls under a statute that states how capacity is to be judged and what may be done when it is absent. The second is a

physically ill adult with no mental illness who has heard the surgeon out and said no, and for whom Indian law is far less complete than examination answers pretend. Capacity, consent and confidentiality as general clinical doctrine are taught in the Psychotherapies, clinical assessment, MSE and nosology notes, and the admission pathways of the mental health legislation are not re-taught here.

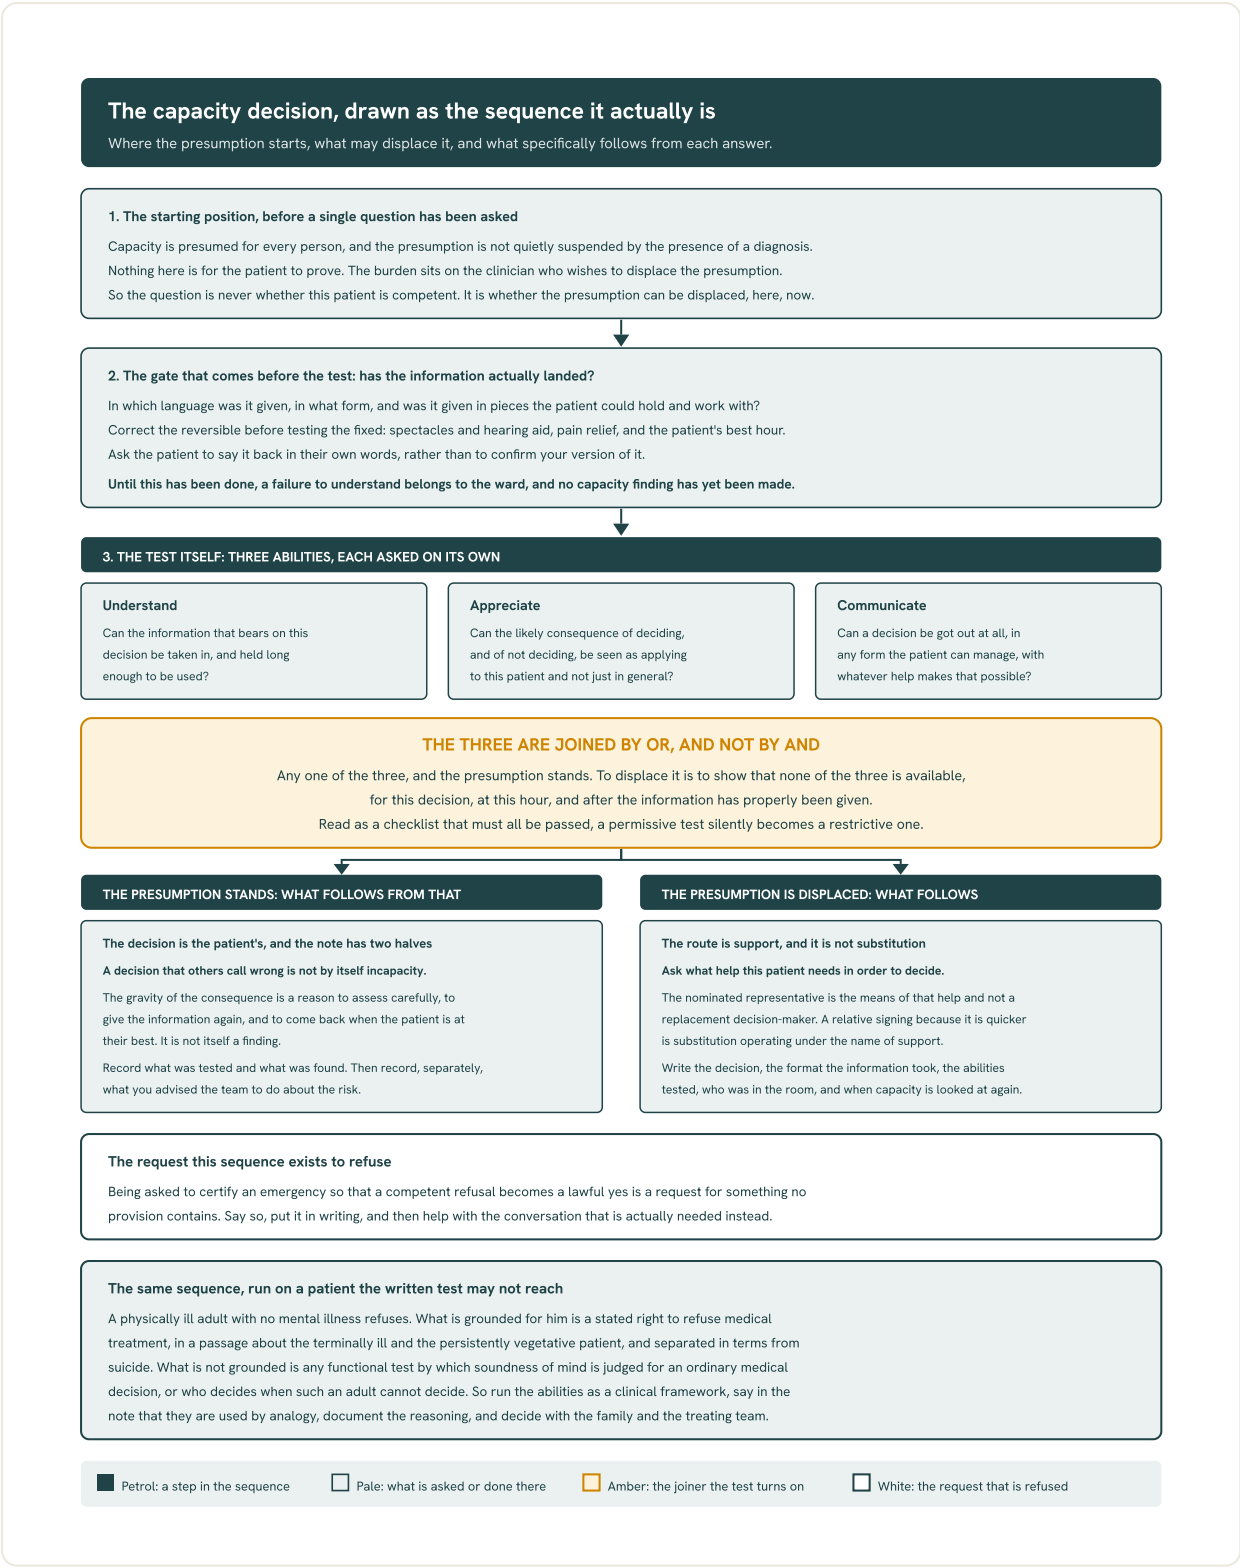

Fig 29.4. The capacity decision drawn as a sequence rather than as a checklist, opening at the presumption that puts nothing on the patient to prove, passing through the gate at which the information has to be given in a form that could land before any ability is tested at all, then the three abilities asked separately and joined at a disjunction that lets any one of them carry the case, and forking into what follows when the presumption stands, where a decision others call wrong is not by itself incapacity and the note has two separate halves, and what follows when it is displaced, where the route is supported decision-making and not a relative signing in the patient's place, with the request to certify an emergency so that a competent refusal becomes a lawful yes marked as the thing the sequence refuses, and the physically ill adult whom the written test may not reach given the same sequence by an analogy that is written down as an analogy.

7.1 Which law reaches the bedside, and how far

Two hinges decide whether the mental health legislation is in the room at all, and they point in opposite directions. The first is territorial and generous. The Mental Healthcare Act, 2017 defines a **mental health establishment** in words that expressly include any general hospital or general nursing home, whether established or maintained by government, a local authority, a trust, a corporation, a society or a private person, and expressly exclude the family residential place in which a person with mental illness lives with relatives or friends. A surgical ward in a district hospital is therefore inside the Act's reach. The ward assumption that the Act begins at the door of the psychiatry unit is simply wrong.

The second hinge is subject-matter and narrow. The statutory capacity test is written for decisions a person makes regarding his own mental healthcare or treatment, and the section names the decision domain three separate times as the treatment or admission or personal assistance. So the Act follows the psychiatrist onto the medical ward, but the test it carries there is scoped to a particular kind of decision. Whether it stretches over a decision about a laparotomy in a patient who also has schizophrenia is the question every real consult turns on, and the section does not answer it. A careful answer says only what is grounded: the establishment is covered, the test is written for mental healthcare decisions, and extending it to a purely medical decision is an argument rather than a citation.

7.2 The statutory test: a presumption, then three abilities

The section gives away the answer in most cases before it states the test. Capacity is **presumed** for every person, and the Act adds the words "including a person with mental illness" so that the presumption cannot be quietly suspended by a diagnosis. A person is deemed to have capacity to make decisions regarding mental healthcare or treatment if that person has the ability to:

- understand the information that is relevant to taking the decision;
- appreciate any reasonably foreseeable consequence of the decision, or of the absence of a decision; or
- communicate the decision, by speech, expression, gesture or any other means.

Now the point that carries the mark. The abilities are **disjunctive**: the section prints **three** abilities and joins them with "or", not with "and". Read as it is written, any one of them makes capacity out. That is a markedly lower threshold than the functional schemas taught in much of the international literature, in which understanding, appreciation, the ability to reason with the information and the expression of a choice are separate hurdles and a patient who fails one has failed the test. The Indian drafting is not careless; it is aimed. The same statute asserts that persons with mental illness have capacity to make treatment decisions and may require varying levels of support in order to exercise it, so a permissive test is consistent with the instrument it sits inside.

MNEMONIC

Understand, Appreciate, Communicate, and the joiner is OR

The three abilities in the order the section prints them, with the conjunction that decides the case. A candidate who memorises the abilities and forgets the conjunction converts a permissive Indian test into a restrictive foreign one, and loses the answer where the difference mattered.

RULE **The Indian statutory test is a presumption plus three abilities joined by "or", not a checklist that has to be passed in full.** The burden sits not on the patient to demonstrate competence but on the clinician who wishes to displace the presumption, and it is discharged only by showing that none of the three abilities is available to this patient, for this decision, at this time, after the information has properly been given.

7.3 The assessment is not finished until the information has landed

A capacity assessment tests what a patient can do with information, so it is only as good as the information given. The Act makes that a duty rather than a courtesy. The information referred to in the capacity test must be given in **simple language which the person understands**, or in sign language, or through visual aids, or by any other means that enables understanding. On a medical ward this is the step most often skipped before a team records that a patient lacks capacity. The surgeon explains the operation in English at the foot of the bed, the patient nods at everything, the nurse writes that the patient seems confused, and a consult is raised. Nothing in that sequence has yet tested capacity, because the first ability was never given a fair chance to operate.

The practical translation is a short sequence the psychiatrist controls. Establish which language the patient is comfortable in, and use it or find somebody who can. Correct the reversible before testing the fixed: spectacles and hearing aids left at home, an assessment timed for the patient's best hours rather than the team's convenience, analgesia before the conversation rather than after it. Give the information in pieces, and ask the patient to say back what has been understood rather than to confirm your version. Only then does a failure to understand belong to the patient rather than to the ward.

The Act also intends the procedure to be standardised rather than left to individual style. It requires the central authority to appoint an expert committee to prepare a guidance document for medical practitioners and mental health professionals containing procedures for assessing capacity, and it obliges every medical practitioner and every mental health professional, when assessing capacity, to comply with that document and to follow the procedure specified in it. Note the reach: it binds the physician and the surgeon who assess capacity, not only the psychiatrist called to confirm it. Whether the guidance document has in fact been prepared and published is a separate question, and it is one this account does not answer in either direction: no comparable standard is available to quote, and none is invented here. State the duty, then say plainly that its implementation is unresolved: the distance between an Act and its machinery is itself an examinable point.

7.4 Refusal is not the evidence of incapacity

Almost no capacity consult is generated by a patient who cannot decide. Almost all of them are generated by a patient who has decided something the team disagrees with. The Act closes that door explicitly. Where a person makes a decision about mental healthcare or treatment that others perceive as inappropriate or wrong, that **unwise decision** does not by itself mean the person lacks capacity, so long as the abilities in the test are present. That is not a legal nicety. A test that treated disagreement as evidence would be circular, and would make capacity a function of how strongly the team feels about the recommended treatment. That is precisely how capacity assessments are misused.

What legitimately raises the question is a change in the machinery of deciding rather than in the content of the decision:

- a fluctuating level of consciousness, or an acute confusional state that waxes across the afternoon;
- an inability to hold the information long enough to do anything with it, or to communicate any decision at all;
- a psychotic belief that bears directly on this decision, such as a conviction that the operating team intends harm.

Delirium is much the commonest of these on a medical ward, and it is taught with the ward delirium material in this chapter, and in older patients with the late-life delirium material.

TRAP **Answering that the patient lacks capacity because the refusal is dangerous.** The gravity of the consequence is a reason to assess carefully, to give the information again, and to come back when the patient is at their best. It is not itself a finding. Candidates slide into it because the alternative feels like abandoning the patient, and because the team asked the question in a form that presupposes the answer. Record the finding about the abilities you tested, then record separately what you advised the team to do about the risk.

7.5 The physically ill adult who says no, and the hole in the law

Now the harder half. A man of sixty with a gangrenous foot and no psychiatric history refuses amputation. He is not a person with mental illness, so the statute discussed above is not obviously his. The highest Indian authority on his position comes from a five-judge Constitution Bench of the Supreme Court of India, whose 2018 judgment states that a person who has come of age and is of sound mind has a **right to refuse medical treatment**, and separates that right in terms from suicide, from physician-assisted suicide and from euthanasia.

Quote it with its context or you will over-claim it. The passage sits inside the Court's discussion of the terminally ill patient and the patient in a persistent vegetative state, so it is not, on its face, a rule for every refusal on every ward. It is nonetheless the sentence to cite, and the separation it draws is clinically load-bearing: a competent refusal that ends in death is not a suicide, so a patient who declines dialysis is not thereby a psychiatric emergency, and does not become one because the physician finds the decision intolerable.

Where the law runs out. The phrase "of sound mind" describes a status, not a functional test: it names the condition the person must be in without saying how to establish it for this decision on this afternoon. That is the gap at the centre of this topic, and it is a gap in the law rather than in the reading. No Indian statute or binding authority is set out here that supplies a functional capacity test for an ordinary physical-treatment decision by a patient who has no mental illness, and none that settles who decides for an adult who lacks capacity and is not a person with mental illness. No comparable standard is available to quote, and none is invented here. The examinable discipline is to say so, and not to import a foreign capacity statute or schema and present it as Indian law, or to assert an Indian best-interests doctrine you cannot cite. What a good answer does instead is reason by analogy and admit it: apply the abilities the Indian statute names as a clinical framework, record in the note that they are used by analogy because this is not a mental healthcare decision, document the reasoning and not only the conclusion, and involve the family and the treating team in a determination no single clinician has been authorised to make alone.

THE SITUATION ON THE WARD	WHAT IS REALLY BEING ASKED	WHAT INDIAN LAW SUPPLIES	WHAT IT LEAVES UNSETTLED
A patient with mental illness refusing psychiatric treatment or admission	Is the statutory test made out for this decision?	A presumption of capacity, and three abilities joined by "or"	How long a finding holds outside a supported admission
A patient with mental illness whose medical treatment cannot wait	May treatment be given now, and on whose consent?	An emergency route open to any registered medical practitioner, on three defined triggers	What happens if the ceiling expires before any establishment has assessed the person
A physically ill adult of sound mind refusing medical treatment	Must the refusal be respected?	A stated right to refuse medical treatment, in a passage about the terminally ill or persistently vegetative patient	The functional test by which soundness of mind is to be judged for an ordinary medical decision
A physically ill adult who cannot decide and has no mental illness	Who decides, and against what standard?	Nothing that can be grounded here	Who the lawful decision-maker is, and the standard the decision must satisfy

7.6 Who else is in the decision

The Indian model is not the solitary competent patient of the Western textbook, and the Act is explicit. The **nominated representative** is a person the patient may appoint, and where none has been appointed the Act supplies a default order of precedence, which is worth reading in the bare Act itself. Two rules about the appointment carry the marks. Appointing a representative, or being unable to appoint one, is expressly not to be construed as a lack of capacity. And persons with mental illness are asserted to have capacity to make mental healthcare or treatment decisions, while requiring varying levels of support from their representative.

Read together, those provisions install **supported decision-making** in place of the substituted decision-making that Indian wards mostly practise, and the distinction is the thing to show an

examiner. Substituted decision-making asks the relative what should be done. Supported decision-making asks what help this patient needs in order to decide, and treats the relative as the means of providing that help. A son who signs the consent form because it is quicker is the substituted model operating under the name of the supported one, and the Act does not authorise it merely because obtaining the patient's own decision would be laborious.

IN INDIA

Before recording that a patient lacks capacity, ask three questions and write the answers into the note: in which language was the information actually given, who was in the room when it was given, and whom has the ward been treating as the decision-maker up to now. Where an accompanying relative countersigns consent as a matter of routine, the format duty is the step that gets skipped, and the capacity opinion then rests on a conversation the patient was never properly part of. Asking the patient to explain the operation back, in their own language, is a bedside test and a legal safeguard in one act.

7.7 What must be written down, and when capacity is looked at again

Capacity is specific to a decision and to a moment, so a finding has a shelf life. The Act fixes that shelf life in one place only, and knowing where is the discrimination. Where a patient needs nearly total support and the nominated representative therefore consents on the patient's behalf during a supported admission, the officer in charge must record that consent in the medical records and review the patient's capacity to consent every **seven days**. Where the admission has run beyond thirty days, the counterpart provision requires the same recording and a review of capacity on the expiry of every fortnight. Two intervals, two admission provisions, and a question that asks which is which.

Then the absence, which is the more useful half. Both duties sit inside supported admission. The Act imposes no equivalent express recording interval on a one-off capacity opinion given as a liaison consult on a medical ward, which is the situation this topic is actually about. That silence is not permission to write once and walk away. It means the review interval is a matter of clinical judgement rather than of statute, and that the judgement has to be justified in the note. A patient found to lack capacity during an acute confusional state and never reassessed has lost a decision to an administrative accident rather than to an illness.

GOOD TO REMEMBER

A capacity note that will survive scrutiny records the specific decision it is about, the information that was given and in what language and format, what the patient could do with that information tested against each of the abilities the statute names, the conclusion for that decision at that time, who else was involved and on what footing, and when capacity will be looked at again and by whom. A note reading only "not competent, family to decide" records none of them, and it is the note that actually gets written.

7.8 When treatment cannot wait

The emergency provision is what makes the Act usable in a general hospital. Its scope is wider than most candidates expect and narrower than most wards assume. Notwithstanding anything else in the Act, any medical treatment, including treatment for mental illness, may be provided by any registered medical practitioner to a person with mental illness, either at a health establishment or in the community, subject to the informed consent of the nominated representative where one is available, and only where it is immediately necessary to prevent death or irreversible harm to the person's health, or the person inflicting serious harm on himself or on others, or the person causing serious damage to property where that behaviour is believed to flow directly from the mental illness. The Act's own explanation extends **emergency treatment** to transporting the person to the nearest mental health establishment for assessment, which is what makes a lawful transfer out of a medical ward possible.

Three limits follow immediately, and they are what a question on this section usually turns on. Nothing in the provision allows treatment that is not directly related to the emergency itself. Nothing in it allows electro-convulsive therapy to be used as a form of treatment under this power. And the authority is limited to **seventy-two hours**, or until the person has been assessed at a mental health establishment, whichever is earlier, extending to a maximum of seven days only during a disaster or emergency declared by the appropriate government.

3	Seventy-two hours	Seven days	Seven days
STATUTORY ABILITIES IN THE CAPACITY TEST, JOINED BY "OR", ANY ONE OF THEM SUFFICING	CEILING ON EMERGENCY TREATMENT, OR UNTIL ASSESSMENT AT A MENTAL HEALTH ESTABLISHMENT, WHICHEVER IS EARLIER	EXTENDED EMERGENCY CEILING DURING A DISASTER OR EMERGENCY DECLARED BY THE APPROPRIATE GOVERNMENT	INTERVAL FOR REVIEWING CAPACITY WHERE THE REPRESENTATIVE CONSENTS IN A SUPPORTED ADMISSION OF UP TO THIRTY DAYS

Now the scope limit on which a whole answer can founder. The emergency provision operates on a person with mental illness. It is not authority to treat a physically ill patient who has no mental illness and refuses, however grave the consequence of that refusal, and it is not a mechanism for converting a competent no into a lawful yes. A surgical team asking the psychiatrist to certify an emergency so that a competent refusal can be overridden is asking for something the section does not contain. The correct reply is to say so, to put it in writing, and then to help the team with the conversation that is actually needed: what the patient believes will happen to them, and who they want in the room when the decision is made.

> Capacity is presumed, the statutory abilities are joined by "or", and a decision that others regard as wrong is not by itself incapacity.

The examiner is testing whether a candidate can hold two situations apart: a statute deliberately generous to the patient and a ward that is not, and a second situation the statute does not reach, where the honest answer names the limit rather than filling it with borrowed law. Both halves are marked, and the second more often than candidates expect.

8 · Factitious disorder and malingering in the general hospital

Why the marks are here. Factitious disorder and malingering in the general hospital are examined as a sequence of acts, not as a pair of definitions. What the two conditions are, how each is separated from the other and from the unconsciously produced somatic disorders, and what the criteria require, are set out in the Somatic-symptom, sexual, impulse-control disorders and suicide notes. The question here is narrower and much harder to answer well. A medical or surgical team has begun to believe that its own patient is producing the illness, has said so aloud on the ward, and has telephoned psychiatry. Everything that follows happens on a ward the psychiatrist does not run, inside a record several services write in, in front of a family, and almost always before anything has been established.

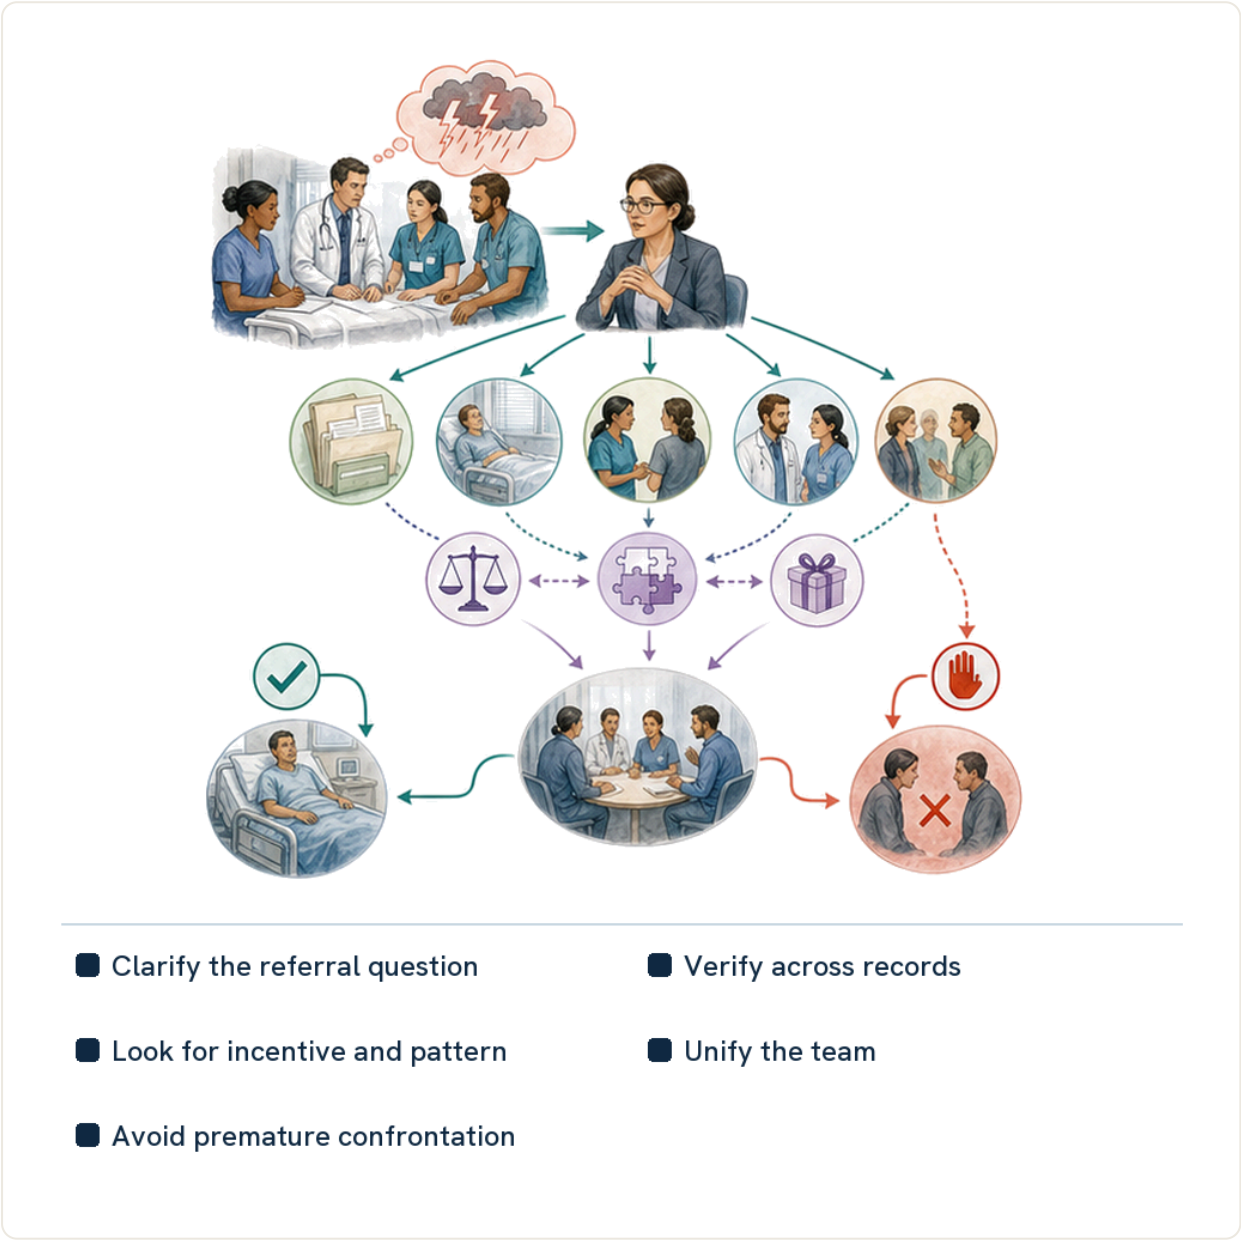

Fig 29.5 When factitious disorder or malingering is suspected in a general hospital, the liaison task begins by clarifying the referral, verifying observations across records and teams, and assessing pattern and incentive. Premature confrontation can harden error and fracture care.

The hinge is a fact of geography. These presentations do not begin in a psychiatric clinic. They arrive carrying a physical complaint, first to the general physician, so the psychiatric question is raised late, by a team that has already committed a long run of investigation to a different explanation, at the point where withdrawing it costs somebody something. Where the same suspicion arises in a medico-legal assessment there is an instructing party, a documented incentive, a defined report and an established method of assessing feigning. On a ward there is none of that: only a round tomorrow morning, a bed that is needed, and a team that has already used the word.

8.1 The request, and the three different things it can mean

Wards do not refer this question in clinical language. What arrives is that the patient is putting it on, that the story keeps changing, that nothing fits, or, from the more careful units, a request to rule out malingering. Read as a clinical question, that request cannot be answered at a bedside. Read as a report of where the team has arrived, it is highly informative: something has changed on that ward, and finding out what is the first act of the consult.

Three quite different requests hide inside the same sentence, each needing a different answer.

- **A request for certainty.** The team holds an inconsistency it cannot resolve and wants it converted into a finding by a speciality thought to deal in motives. No such conversion exists at a single visit, and supplying one is where the harm begins.
- **A request for permission.** The team wants to stop investigating, stop escalating, or discharge, and is asking psychiatry to authorise that so it does not have to own it. This is the commonest of the three and the best disguised.
- **A request for relief.** The ward is angry, exhausted, or feels it has been made a fool of, and the referral puts that somewhere. It tends to arrive out of hours and in strong language.

Deciding which is actually in front of you, early and out loud, reorganises the consult, because the second and third are addressed to the team and cannot be answered by anything found at the bedside. Left unnamed, what forms instead is a **corridor diagnosis**: a word that passes between staff, hardens with each retelling, acquires the authority of repetition, and is in the notes before anybody has decided whether it is true.

8.2 What a general ward can and cannot establish about its own patient

The working method of a medical ward is **exclusion**: candidate explanations are removed one at a time until one survives. When the last has gone and none survives, the ward reads the empty result as though it were a positive finding, because every previous negative in that sequence functioned as one. Here it does not. A work-up that has explained nothing licenses the statement that the illness is not yet explained, and nothing further. The distance between not explained and deliberately produced is the entire subject, and it is crossed by evidence about production, never by exhausting the medical list.

Two further limits belong to this setting. First, inconsistency is not deception. An account that differs between the admitting doctor at night and the unit round next morning has differed;

whether it differed because it was invented, because the two sets of questions were not the same, because the patient was frightened, sedated, in pain or delirious, or because the second version came from a relative, is not settled by the change itself. Second, once the suspicion exists the ward's observation stops being neutral. Behaviour that passed without comment last week is now offered to you as evidence, and observations that do not fit quietly stop being reported. You are given a filtered account by people who do not know they are filtering it.

The honest position at the end of a first visit is nearly always that the question is not settled, and that is not a failure of the consult. Managing an **unresolved suspicion** is the clinical task; producing a verdict is not, and cannot be done from a bedside chair.

RULE **A suspicion of fabrication changes what the team must do long before it changes what the patient may be called.** Everything worth doing is justified by the suspicion being unresolved and none of it by its being confirmed: slowing an invasive work-up the suspicion has itself made hard to justify, keeping the medical differential formally open under a named clinician, dating and attributing every observation so that a pattern rather than an impression survives, and bringing the disagreement out of the corridor into a meeting. A candidate who spends the answer on how to prove the deception has taken up a question the bedside cannot settle and left undone every act that protects the patient.

8.3 The record, and what a single entry can carry

This is where the consult is most exposed. A record made while a suspicion is unresolved is read later by people who were not present, for purposes nobody in the room intended: the next admitting team, the discharge summary, a certification request, an insurer, occasionally a court. The writer controls the sentence and none of its readers.

What may lawfully and ethically be entered when deception is suspected but not established, whether anything may be sought about the patient from another institution and on whose authority, and how such a conclusion is or is not communicated to the referring team, are not settled by any source available for this section. No comparable standard is available to quote, and none is invented here. What can be reasoned, and what an examiner will accept, is that entries differ in kind, and that the kinds carry very different weight once they leave your hands.

KIND OF ENTRY	WHAT IT ACTUALLY ASSERTS	WHAT IT CAN SUPPORT LATER
Timed observation of something you saw yourself	That one thing was seen, by you, at a stated hour	A pattern, if enough accumulate with times against them; alone, almost nothing
Attributed observation, naming who reported it	That a named person stated something, and that you are not the witness	Provenance: a later reader can return to the source instead of inheriting your confidence
A discrepancy between two documents, both named	A finding about the records, not yet about the patient	A reason to look further, and a trail somebody else can check
An inference about intention	Your reasoning, only as far as its steps are written out	Little; an unreasoned inference is read downstream as a conclusion
A diagnostic label entered in a summary	A settled conclusion, to every reader who was not there	Everything, including consequences outside the hospital, so it is the entry to weigh hardest

The discipline that follows is small and entirely learnable:

- write what was seen, and when, and name who saw it;
- keep reasoning visible as reasoning, with its steps shown;
- let the **permanent record** carry a conclusion only once one has been reached.

A note built this way stays useful if the suspicion proves right and harmless if it proves wrong, which is the only test a record made under uncertainty can be asked to pass.

TRAP **Letting the suspicion enter the permanent record as a diagnosis.** Asked what would be written, the candidate puts the label into the discharge summary, and it is wrong for reasons that are examinable rather than merely cautious. The label is short and the observations are laborious, so the label is what gets copied forward; it then travels further than the evidence that produced it, to readers who cannot see how thin that evidence was, and it closes the medical differential behind it. Write the observations, name their sources, state what remains open, and record who is continuing to look.

IN INDIA

Three features of the general ward press directly on this. A family attendant is at the bedside for much of the admission and is usually the only continuous observer the team has, so the account that would most change the picture is already in the room and is rarely taken systematically. Much of the admission is paid from the family's own pocket, so a request for a certificate, a fitness statement or an early discharge is not administrative; it has money attached, and that pressure reaches the note. And the questions raised here about records, and about what may be sought from anywhere else, have answers a candidate must find in the institution's own governance rather than in anything quotable. The examinable move is to say so, and to name who in your hospital answers it, rather than to invent a national rule that does not exist.

8.4 What the suspicion does to the team

The most reliable clinical sign in this situation is not on the patient. It is that the ward has divided, and it divides along concrete lines rather than temperamental ones: the clinician who admitted the patient and argued for the diagnosis against those never persuaded, the night nursing staff who carry the behaviour against the day team who see a settled patient on the round, the junior now being told, with varying kindness, that they were taken in. Each group has staked something, and the split holds because conceding costs face.

What makes it worse than ordinary clinical disagreement is the shift of **moral register**. The question stops being what is wrong with this person and becomes whether this person is honest, and once it has moved there the two available positions are naive and cruel. Nobody wants either, so the argument leaves the open forum and continues in the corridor, in handovers and in the tone of the notes, where it cannot be corrected. The **ward split** is therefore not a curiosity to observe; it determines whether the patient is investigated, and it is the liaison psychiatrist's work.

MNEMONIC

Stop, hold, name, date

The four acts an unresolved suspicion requires, in order. **Stop:** pause the escalating invasive work-up, whose justification the suspicion has itself removed. **Hold:** keep the medical differential open under one named clinician, so nobody assumes somebody else is still looking. **Name:** put the split into a meeting with both positions stated. **Date:** attribute and time every observation entered from here on. Not one of the four requires the suspicion to be true.

GOOD TO REMEMBER

Ask the ward two questions before the consult ends, and ask the group rather than the referrer alone. What would change your mind, and who is still responsible for the medical differential. The first makes the belief testable and shows the team it currently has no answer; the second stops the most dangerous thing that happens here, every service quietly assuming some other service is still investigating.

8.5 What the suspicion does to the patient's care

Once a ward believes it is being deceived, the risk to that patient rises in two opposite directions at once and a good answer names both. In one direction the admission simply stops: investigation ceases the moment the suspicion is voiced, each new symptom is attributed to the old belief before it is examined, and concurrent disease is missed because it is now expected to be absent. Suspicion and organic illness are not alternatives, and a patient may be doing both at once. In the other direction sits **iatrogenic escalation**: a team that cannot let the question go, ordering the next scan and the next procedure to settle an argument rather than to answer a clinical question. Both flow from the same unresolved belief, and the same acts make both less likely.

The third outcome is that the admission ends before the question does. A patient who senses the change in how a ward speaks to them often leaves, and a consult called to settle a suspicion has instead ended the only relationship through which anything could have been settled. Hence one

more reason for the consult to stay in a clinical register: a bedside interview conducted as an interrogation reliably closes the admission and answers nothing.

8.6 How the question is asked, and the order to answer it in

The ward is reporting itself	Exclusion proves nothing	Kind before content
THE REFERRAL DESCRIBES WHAT THE TEAM HAS COME TO BELIEVE, NOT A PROPERTY OF THE PATIENT	A WORK-UP THAT HAS EXPLAINED NOTHING LICENSES ONLY NOT YET EXPLAINED, NEVER DELIBERATELY PRODUCED	WHAT AN ENTRY CAN SUPPORT LATER IS SET BY ITS KIND, BEFORE ANYTHING IT SAYS

What an examiner is testing. Given a medical inpatient whose team suspects fabrication, the discriminating answer does not open with definitions or with how feigning is detected: both belong elsewhere and are available to anyone who has read the taxonomy. It opens with the referral, with who called, what they said and which of the three requests they were making. It moves to what can honestly be established at that bedside and says plainly that the usual answer is not yet. It then gives the acts, each standing without the suspicion being confirmed, and states what will be written and what will not. Where it reaches a standard that does not exist, it says so rather than inventing one, which reads as maturity and not as ignorance.

> The ward asks you to settle whether it is being deceived; what you can actually settle is what it must do while that stays open, and every act of the consult is justified by the suspicion being unresolved, not by its being confirmed.

The high-stakes settings

9 · Transplant, dialysis and ICU psychiatry

Why the marks are here. Transplant, dialysis and ICU psychiatry reads like three settings and is really one problem stated three times. In each, the treatment keeping the patient alive is also what generates the psychiatric presentation, and the psychiatrist works inside another team's decision, on their premises and against their timetable. And in each, the referral is rarely a request for a diagnosis: it asks that a decision be underwritten, or that a patient be made easier to treat. A candidate who answers with a differential has answered a question nobody asked.

Clear the ground first, because most of what these wards generate belongs elsewhere. The acute confusional state that dominates critical care, the decisional-ability question behind a refusal, and the standing link between an organ system and psychiatric morbidity each have an owner of their own, named below at the point where each arrives; the neurological substrate of confusion sits in the Stroke, TBI, delirium and focal brain syndromes notes. What survives those subtractions is small, specific and almost unwritten elsewhere: the evaluation before an organ is allocated, the psychiatry of a treatment room a patient returns to for life, and the state a survivor of critical illness is discharged into.

9.1 The structure the three settings share

Side by side, these settings differ less in psychopathology than in who holds the decision and what psychiatry can genuinely add. Learn the row rather than the disease: an examiner can move you between settings and expect the reasoning to transfer.

THE SETTING	WHAT IS ACTUALLY BEING ASKED	WHO HOLDS THE DECISION	WHAT PSYCHIATRY ADDS THAT NOBODY ELSE CAN
Before a transplant	Whether this person should receive a scarce organ, or whether something about them can be changed first	The transplant team and its selection process, never the psychiatrist	A statement of what is modifiable and over what interval, in place of a verdict
After a transplant	Why a patient given exactly what they wanted is not well	The treating unit, indefinitely	Separating adjustment from drug effect from acute brain syndrome, and dating each against the operation
The dialysis unit	Usually nothing, because the referral is never made	The nephrology unit, and in practice its nursing and technical staff	A detection routine the unit runs itself, since this morbidity is invisible to a service that waits to be called
The intensive care unit	Behaviour that is obstructing treatment now	The intensivist, minute by minute	A formulation that survives sedation and restraint, and a plan that does not need cooperation to begin
After intensive care	Also nothing, because nobody is looking	Nobody, and that is the finding	The question about the admission that no later clinician will otherwise ask

RULE **In each of these settings the treatment is the stressor, and the treatment cannot be withdrawn to test the hypothesis.** The usual experiment of removing the exposure and watching symptoms resolve is unavailable, so attribution rests on timeline, previous function and informant report rather than on response. The aim is not relief from the stressor, which is not on offer, but the ability to keep receiving it. And because the treatment outlasts your consult, an opinion filed once is worth far less than an arrangement the unit is still running next month.

9.2 The pre-transplant evaluation: whose question, and what kind of answer

One thing about this evaluation is settled: it happens. Psychiatric and psychosocial assessment is treated as imperative in judging whether a candidate is **suitable** as a recipient, and evaluating that suitability is described as a defined part of the psychiatrist's role in solid-organ transplantation.

Its contents are another matter, and an honest answer beats a confident one. The domains such an evaluation should cover, any structured instrument for conducting it, what separates an absolute from a relative psychiatric contraindication, and whether Indian transplantation law

imposes any requirement of psychiatric or psychological evaluation on a recipient or a living donor: no comparable standard is available to quote, and none is invented here. Two consequences are examinable. Do not import a Western programme's eligibility rule and present it as an Indian legal duty, because a condition written into one country's transplant programme is not thereby a statutory obligation in another. And establish what your own institution's process requires and who signs it, because that is what you will be asked across a table.

Dual agency changes the interview, and candidates handle it worst. You are not this patient's treating psychiatrist here; you are producing an opinion for someone else, and the patient knows what they say may cost them an organ. Under-reporting of alcohol use, low mood or a difficult household is not deception but a rational response to an incentive you created by walking in. Two moves reduce it. Say at the outset what the assessment is for, who reads it and what it cannot decide alone. And take collateral history as routine rather than as a challenge, so that corroboration is procedure and not accusation.

The output should do work rather than close a door. An opinion reading "unsuitable" gives the team nothing to act on and nothing to argue with. A useful pre-transplant opinion instead specifies:

- the decision it is addressed to, since an opinion written to no question answers none;
- what is currently a problem and whether it is changeable, stated as a condition rather than a label;
- over what interval a change could be shown and by what observable sign, because a team allocating an organ needs a date more than a diagnosis;
- what would make you revise the opinion in either direction, which turns a verdict into an assessment that can be repeated.

Where the donor is living, a second person is being evaluated for an operation that will not benefit their own health, inside a family in which the pressure to agree may never be spoken aloud. That interview belongs away from the recipient's relatives and clinician, and the question is not only whether the donor consents but whether refusal is a real option. Consent given in front of those who would be disappointed by it has not been tested.

9.3 After the graft: the work that begins when the operation succeeds

A successful transplant is not the end of a chronic illness but the exchange of one for another: lifelong immunosuppression, indefinite surveillance, and a new class of fear in which any ordinary symptom may be the start of rejection. Function returns faster than identity does, and someone whose family, work and routine were organised around being ill must renegotiate all of it while everyone celebrates. Low mood after a technically perfect operation is therefore not paradoxical, and reading it as ingratitude is the commonest failure of the ward's response.

Where the organ came from a living relative, the donor stays in the psychological field permanently. The patient carries part of someone they will meet at every family gathering, sometimes someone they had conflict with, and a sense of unpayable debt can push adherence

either way: fierce compliance as repayment, or avoidance of a relationship impossible to be ordinary in. Ask about the donor by name, and ask what the patient believes they owe.

Two things arriving now are routed rather than guessed. The acute brain syndrome after major surgery belongs where delirium in the medically ill is dealt with in these notes. The neuropsychiatric effects of the immunosuppressive regimen, and the interactions constraining what may be added to it, are prescribing matters: the antidepressant agents are set out in the Mood disorders: pharmacotherapy notes, and nothing is started without the current regimen in front of you and the transplant team told what you added.

9.4 The dialysis unit, which nothing else in these notes owns

Maintenance haemodialysis is the only treatment in this chapter that is also a place. The patient returns on a fixed recurring schedule to a shared room, is connected through a **vascular access** that is itself a source of anxiety and of repeated medical incident, sits immobile for hours beside other patients whose deterioration they watch, and lives in between under restrictions on food and fluid that reorganise a household's cooking. But nobody is admitted, so nobody is referred, and psychiatric morbidity accumulates in a population that is technically outpatient and permanently supervised. The organ-system link itself is taken up where the psycho-cardiology, psycho-dermatology and psycho-nephrology cross-links are dealt with in these notes; what is owned here is the treatment room as a place.

IN INDIA

The firmest Indian anchor is a study of 282 patients on maintenance haemodialysis across four Mumbai centres, two public charitable and two private fee-for-service, reported in the Indian Journal of Nephrology in 2025. Some degree of depression was present in **76 per cent**, and **21.28 per cent** reached the moderate-or-above band on the screening instrument. Carry the population with the number: these are prevalent patients already established on dialysis at four urban centres, of median age 55, with more men than women in the sample. It is not an all-India prevalence and must never be quoted as one.

The associations matter more at the bedside than the headline proportion. Female sex, a catheter as the vascular access and the stress of dietary restriction were each positively associated with significant depression, while being employed was protective; public charitable and private fee-for-service centres did not differ. Two repay thought. Access type is a technical variable visible on the chart and sometimes changeable by the unit, so a psychiatric risk marker here can be read off a nephrology note and acted on by a surgeon rather than by you. And employment being protective turns a medical schedule into an economic one, since the hours the treatment consumes are hours of wages; whether work protects, or better health permits work, is not separable in a cross-sectional design. Women were depressed roughly twice as often as men, 29.13 per cent against 16.76 per cent, and the study cannot tell you why.

Depression is substantially commoner in dialysis populations than in the general population, and under-recognised in both. That much is safe to say, and it is why a screening routine is justified at all. No pooled prevalence from the international meta-analytic literature is quoted here and none

is invented in its place: carry the Mumbai figures with their population attached rather than promoting them into a world number.

9.5 Why the unit does not see it, and what to examine instead

The reason offered for that invisibility is diagnostic rather than attitudinal. On its authors' account, depression here remains under-evaluated and under-addressed because the symptoms of **uraemia** mimic depressive symptoms and can mask a true depressive illness. That is a mechanism they propose, not an effect they measured. Recognising depression when advanced physical disease confounds the somatic criteria is taken up where depression, anxiety and delirium in cancer and palliative care are dealt with in these notes; what is specific here is that the confounder is not the disease alone but the treatment and its timetable.

WHAT IS OBSERVED	WHAT THE URAEMIC STATE AND THE UNIT GENERATE ON THEIR OWN	WHAT STILL DISCRIMINATES
Fatigue and loss of energy	Anaemia, the metabolic state, and the hours the treatment consumes	Whether energy recovers after a good session or stays flat across the interval
Poor appetite and weight change	Prescribed dietary and fluid restriction, altered taste, and shifts that make weight uninterpretable	Whether food the patient is permitted and used to enjoy still gives pleasure
Disturbed sleep	Restless legs, itch, cramps, and a schedule that fragments the week	Early waking with dread, and what the patient does with the waking hour
Slowed thinking and poor concentration	The metabolic state, and fluctuation around each session	A stable deficit that does not track the session, which raises a different question
Withdrawal from family and social life	Immobility, transport cost, and a timetable nobody else's life is built around	Whether the patient wants contact they cannot get, or no longer wants it

What survives the correction is interpersonal and evaluative rather than bodily: guilt, self-blame framed as being a burden, hopelessness that is absolute rather than realistically bleak, loss of pleasure in what the illness does not prevent, and whether any of it fluctuates with the treatment cycle. That last is the practical discriminator this setting hands you, since the schedule supplies a repeated natural measurement.

TRAP **Subtracting the somatic features, then treating what is left as too little to diagnose.** The candidate who has learned that uraemia mimics depression applies the correction and stops: fatigue, appetite change and sleep disturbance are discounted because the treatment explains them, and the conclusion becomes that only low mood remains, falling short of a threshold. Subtraction is half a method and useless alone. The second half is substitution: having set aside what the setting can generate, examine what it cannot and weight it more heavily than in a physically well patient. Examiners watch for the substitution, because the subtraction is the part everybody remembers.

How detection is actually done. Not by referral, which is the whole point. That study used the **PHQ-9**, and the operationally important detail is not the instrument but the administration: it was read aloud to every patient in their native language regardless of literacy. A self-report form handed out in an Indian dialysis unit measures literacy, language and eyesight at least as much as mood, and those it silently excludes are least able to complain of it. A screen that runs is one unit staff administer aloud, at a fixed point in the session, to everybody rather than to whoever looks unwell.

9.6 The referrals from the unit that are not what they say

When a dialysis unit does telephone, the request has usually been generated by an act rather than a symptom: a patient leaving sessions early, abandoning the fluid restriction, missing appointments, or saying outright that they want to stop. All arrive labelled as depression or poor motivation, and all need the same first move: establish what stopping would actually solve for this person before deciding what it means.

The pressures the answer names are often not psychiatric. The same Indian source describes the burden on these patients as physical, financial, occupational, social and dietary, and any of those can produce the behaviour with no psychiatric illness present. A man whose sessions are consuming a household's income, whose employer will not hold his job, may be making an intelligible economic decision that presents as a wish to die. Medicalising that misses a problem with a different remedy; missing depression in the same presentation is equally serious. The discriminating question is whether the wish is to stop treatment or to stop existing, and it is asked in those terms rather than inferred.

Where the refusal stands and the team wants it overridden, the question has become one about decisional ability, settled where capacity assessment and refusal of treatment in the general hospital are dealt with in these notes. What belongs here is the step before: refusing to let a capacity assessment become a device for producing compliance, since establishing that a refusal is informed and stable is a different task from establishing that it is wrong.

> **GOOD TO REMEMBER**
>
> Before leaving the unit, put four things in the note that the next person to open it can act on. What was asked of you, in the referrer's own terms. What you established about the timeline, including what changed and against what previous state. What you have asked the unit to do, named to a role rather than to the team in general, and by when. And what brings you back, stated as an observable event, so the nurse seeing the patient next knows the threshold.

9.7 Intensive care, and the state the survivor is discharged into

Inside the unit, most psychiatric work is delirium, dealt with elsewhere in these notes, and most of the rest is a request to make a sedated or restrained patient tractable. Two things there are genuinely psychiatry's: a formulation built without a usable interview, from the pre-admission history taken off relatives, the substance history that explains withdrawal states and the timeline of what was given when; and documentation of what the patient appears to be experiencing while unable to report it, which becomes the only record of that period.

More clearly this chapter's, and what candidates rarely have, is the aftermath. **Post-intensive care syndrome** is the agreed term for the residue of critical illness, settled at a multidisciplinary stakeholders conference convened by the Society of Critical Care Medicine. It denotes impairment across three domains, physical, cognitive and mental health status, the physical typically exemplified by weakness acquired in the unit and the cognitive by thinking and judgment. The qualifier does the real work: the impairment must be **new or worsening**, so a deficit present before admission does not count, and the construct rests on a baseline somebody must have recorded or reconstructed.

MNEMONIC

Body, mind, mood, and new or worse

The three domains and the qualifier, in the order that keeps them straight. **Body:** the physical domain, weakness acquired during the admission. **Mind:** the cognitive domain, thinking and judgment. **Mood:** mental health status. **New or worse:** the qualifier, because impairment carried into the unit is not this construct, and an answer without it describes any survivor of any severe illness.

How common it is, how long it lasts, how it is best detected, whether it looks the same in Indian survivors, and whether any follow-up clinic model operates in Indian tertiary practice: on all of these, no comparable standard is available to quote, and none is invented here. Resist supplying a figure: this is exactly the construct where a confidently quoted percentage is likeliest to be wrong and likeliest to be repeated.

Missing data does not remove the clinical duty, and the duty is specific. Whoever sees this patient next is usually a physician who did not treat them in the unit, working from a discharge summary that records organ support and antibiotics and nothing about the mind. The patient will not raise it, partly because the memory of the admission is fragmentary and partly because they have been told repeatedly how lucky they are. So ask, at every later contact:

- what they remember of the admission, accepting that what is remembered may not match what happened;
- what they have not got back, in function rather than in symptoms;
- what frightens them now, which is where stress symptoms surface if they are going to.

Record the answer where the next clinician will find it. Where the psychiatrist has influence over the unit's own practice, the higher-value intervention is upstream: a discharge document stating what this person was like beforehand, so the word new can later mean something.

9.8 What this section hands on

The treatment cannot stop	Detection, not referral	Subtract, then substitute	New or worsening
ATTRIBUTION RESTS ON TIMELINE, BASELINE AND INFORMANT, NEVER ON REMOVING THE EXPOSURE AND WATCHING FOR RECOVERY	THE DIALYSIS UNIT GENERATES CASES THAT NEVER BECOME REFERRALS, SO THE DELIVERABLE IS A SCREENING ROUTINE THE UNIT ITSELF ADMINISTERS	SET ASIDE THE FEATURES THE SETTING GENERATES, THEN EXAMINE AND UP-WEIGHT THE ONES IT CANNOT	A SURVIVOR'S DEFICITS ARE INTERPRETABLE ONLY AGAINST A BASELINE RECORDED BEFORE THE ADMISSION

An examiner is testing whether a candidate stays on the axis of the act. Given a transplant candidate, the discriminating answer opens not with a checklist of what to assess but with whose question it is, what the opinion is for, and how dual agency distorts what is disclosed. Given a dialysis patient, it explains why the setting hides the features rather than reciting them, which observations survive the correction, and how a unit that never refers can be made to detect. Given a survivor of critical illness, it names what is new or worsening against a baseline, and who is going to ask.

> In these settings the treatment that sustains the patient is also what generates the presentation, so the psychiatric task is not to remove the stressor but to keep the person able to receive it: an opinion naming what can change before an organ is allocated, a detection routine the dialysis unit runs without being asked, and a question about the critical-care admission at every contact that follows it.

10 · Psychiatric aspects of HIV and chronic infection

Why the marks are here. Two questions travel under the heading psychiatric aspects of HIV and chronic infection, and the answer is lost if they are not separated. One is about the brain: what a neurotropic infection does to cognition, how it is staged and what imitates it, and which antiretroviral agents carry psychiatric effects or constrain psychotropic prescribing. All of it is set out in the Neuropsychiatry of systemic and neurological disease notes. The other is the consult: a person with a lifelong transmissible diagnosis has been referred, and that question is answered in acts, not features.

They are examinable because a psychiatric interview's ordinary assumptions fail at the door. The diagnosis may not be usable in the room you are in. The treatment cannot be left to the medical team, because the psychiatric state often decides whether it continues to be taken. And the consult cannot be closed: illness and treatment outlast every relationship in the building.

10.1 Four properties, not one organism

The lens comes from the shape of the illness and of its delivery, not from virology, which is why the topic pairs one named infection with chronic infection in general. Four properties do the work, and any condition carrying all four produces the same consult:

- treatment that is lifelong, so the outcome rests on a repeated daily behaviour and never on a completed course;

- transmissibility, which makes the diagnosis partly another person's information and brings law into a clinical conversation;
- social meaning strong enough that hiding the condition is a reasonable strategy rather than a symptom;
- care delivered through a **vertical programme** with its own clinic, counsellor, register and drug supply rather than through general services.

The fourth is the property candidates omit, and it most changes practice because it settles where the patient physically is and whose cooperation any plan needs. Little of this work happens on a ward: the medical home is an outpatient clinic attended for review and supply, so a service built on inpatient referrals meets these patients only after something has gone wrong.

MNEMONIC

Lifelong, catching, shaming, separately run

The four properties, in the order they change what you do. **Lifelong:** the target is a daily act sustained for decades. **Catching:** the information is not the patient's alone, so speech and documentation are constrained. **Shaming:** hiding is rational, so it is not evidence of illness. **Separately run:** the patient belongs to a programme clinic, where any durable arrangement is made.

Where a condition carries only some of the four the lens shortens predictably: a long treatment nobody can catch generates the adherence work without the disclosure work. Taking on a chronic diagnosis is dealt with where psychological reactions to physical illness and chronic disease are taken up in these notes; added here is what changes when the diagnosis is also a secret.

10.2 The disclosure map is drawn before the interview, not during it

Disclosure is not one event that has either happened or not. It is a set of separate permissions, each granted or withheld before you were called, each governing a different part of what you may say and write. Neither the referral nor the file records them reliably, because a file holds what was written down rather than what was understood.

WHO MAY HOLD IT	WHAT THEIR KNOWING DECIDES	THE ASSUMPTION THAT COSTS MARKS
The patient	Whether they can name their condition, and in which words, which fixes the interview's vocabulary	That an explanation recorded as given was understood
The accompanying relative	Whether a supervised dose or collected supply is possible, the attendant being the working unit of care on an Indian ward	That whoever brought the patient in knows why
The sexual partner	The one relationship where the patient's interest and another's can diverge, and the only one with a separate answer in law	That the clinical and the legal question are one
The employer and neighbourhood	Where loss of work, housing and standing is generated, and so what is protected	That secrecy outside the hospital signals shame rather than calculation
The record you are about to write	A note in a shared chart discloses to every later reader, many with no clinical role	That documentation is neutral because it is routine

RULE **Nothing in this consult is information about the patient alone, and nothing in it ends when you leave.** The first half governs speech and documentation: what may be said, in front of whom, and what may safely appear in a chart other people read. The second governs the output: an opinion filed once is worth little against a treatment measured in decades, so the deliverable is an arrangement somebody else runs.

10.3 Where the law enters, and the consult it generates

Candidates treat the serological test as an investigation like any other and are caught by the question that follows. The commonest consult on this axis is a consent question: a patient too unwell or too frightened to agree, and a team asking whether the agreement it holds is worth anything.

IN INDIA

Consent for this test and this treatment has a place of its own in central legislation. The HIV and AIDS (Prevention and Control) Act of **2017**, as recorded in the India Code maintained by the Legislative Department of the Ministry of Law and Justice, gives section **5** the heading informed consent for undertaking HIV test or treatment. What that section requires in operative terms, what conditions it attaches, and what national counselling guidance in turn requires of a clinic: on all of these, no comparable standard is available to quote, and none is invented here. The structural fact is the examinable one. A legislature that gives consent for one test a section to itself has taken it out of ordinary medical custom, so arranging that test for a patient who cannot presently agree is a governed act and not a courtesy.

The psychiatric half is **capacity**, and the bedside assessment is dealt with where capacity assessment and refusal of treatment in the general hospital are taken up in these notes. Two additions are specific here. A result, once it exists, must be given to somebody, somewhere its consequences can be absorbed, so an opinion answering only whether the patient can consent has answered half the referral. And whether anyone may be told without the patient's agreement is a separate statutory question, settled in Indian law and not at the bedside.

What belongs to psychiatry is the preparation preceding any disclosure, and it is concrete. Establish what the patient believes will follow, separating a realistic fear of violence or destitution from a catastrophic one. Rehearse the actual sentence, in their own language. Offer to be in the room. Let them fix the timing, because a disclosure made to a clinician's deadline is one they live beside afterwards without you.

10.4 Stigma predicts behaviour, it does not decorate the answer

Handled as sociology, stigma ornaments an answer and changes nothing at the bedside. Handled as a clinical variable, it predicts what this patient will do. Three forms do different work:

- what the patient has met: the refused tenancy, the relative who stopped visiting, the staff member whose manner changed, which is history and can usually be dated;
- **anticipated stigma**, a prediction rather than an experience, which governs behaviour whether or not events confirm it;
- **internalised stigma**, where the community's judgement has been accepted as accurate and turned inward.

The second reaches the medical outcome, because it produces **concealment**: where tablets are kept, whether they travel, whether a clinic visit can be explained at home. Concealment answers a real hazard, and recording it as denial costs you the next problem the patient would have brought.

The third is most often mistaken for a mood disorder, and the distinction changes what you do: one calls for treatment of an illness, the other for work on a belief taken from other people. Where advanced disease confounds the somatic features, recognising depressive illness is dealt with where depression, anxiety and delirium in cancer and palliative care are taken up in these notes.

10.5 Adherence has links, and the repair follows from which one broke

Asking whether a patient is adherent yields a proportion and no plan. **Adherence** to a lifelong regimen is a chain of separable behaviours: knowing why, obtaining the supply, remembering the hour, having somewhere unobserved, and doing it again tomorrow. Each psychiatric problem attacks a particular link, so the useful question is which link.

WHAT THE ASSESSMENT FINDS	THE LINK IT DISABLES	WHAT THE CONSULT ASKS FOR
Depressive illness	Valuing the future the treatment is taken for, so the tablet is remembered but stops feeling worth it	Treatment of the mood disorder itself, and a named person who asks about tablets next visit
Alcohol or other substance use	The regularity of the day, so the dose is not to hand at the same hour	Quantification without a moral frame, and a plan that works during continued use
Cognitive impairment	Remembering, sequencing and self-monitoring, so the failure is of machinery rather than will	External structure: a supervised dose, a box filled by someone else, a shorter review interval
Psychotic illness	The meaning of the tablet, absorbed into the patient's account of what is being done to them	Work on the meaning before any argument about compliance, and a supply not conditional on agreement
Concealment	Doing it where it could be seen, the link no motivation repairs	A dosing hour and place kept unobserved, and collection that does not announce itself

Two constraints govern prescribing. Cognitive impairment here may or may not be attributable to the infection: its classification, staging and detection are set out in the Neuropsychiatry of systemic and neurological disease notes, while the consult contributes the timeline and the functional consequence, taken from an informant against a stated previous level of function. And no psychotropic is started without the current antiretroviral regimen in front of you, since safe combination and those drugs' own psychiatric effects sit in the same place. **Attribution** settled before the history is taken is the error this topic punishes.

TRAP **Answering the referral as written instead of the referral as meant.** The note says assess for depression; the unstated request is usually make him take his tablets, or get her to tell her husband. Answer the written words and you produce a diagnosis nobody needed. Deliver the unstated request and you have accepted a job psychiatry cannot honestly do, because an outcome cannot be extracted from a patient on another team's behalf. The discriminating answer names the real question aloud, says which part is psychiatry's, and hands the remainder back with a reason.

10.6 The durable output is an arrangement with the treating clinic

Because these patients are mostly not inpatients, this is service design rather than bedside technique, and the unit of work is a standing arrangement that is renewed and audited. The clinic already holds a counsellor known to the patient and present at every visit, so supervision, shared triage and joint review of the difficult few use a psychiatrist far better than a parallel clinic nobody attends.

That role is governed centrally, and knowing so changes how you approach the clinic. The National AIDS Control Organisation, within the Ministry of Health and Family Welfare, is the source of the national reference set for this work: a handbook for HIV and STI counsellors, a handbook on the prevention and management of stigma and discrimination, and a guideline for

HIV counselling and testing services. Their contents are neither reproduced nor characterised here. What follows is practical: establish what the clinic is already mandated to do before proposing anything, because a plan duplicating a programme requirement is dropped and one cutting across it is ignored.

Four things a workable arrangement specifies, in order:

- who screens, with what, and at which point in the visit, since a screen offered after the drugs are collected is never completed;
- what result escalates, how fast and by which route, so whoever screens never chooses between doing nothing and declaring a crisis;
- where the psychiatric record will live, given what a shared chart discloses;
- who notices and who acts when a patient stops attending, since disengagement is invisible to a service that sees only attenders.

Where these arrangements fail. On geography and timing far more often than on clinical disagreement. A referral requiring a second journey, to another building on another date, is one a patient paid by the day will not make, and the non-attendance is then recorded as poor motivation. **Same-visit access** decides whether the arrangement functions, and it costs a room and a fixed hour rather than a new post.

GOOD TO REMEMBER

Settle the documentation before the note is written. Decide which facts must sit in the shared record for the team to treat safely, which belong somewhere with narrower access, and what the patient has been told about who reads each. Then write, and tell them what you wrote. Put the follow-up arrangement in the same note, named to a role and carrying a date.

10.7 What this section hands on

Map before you speak	Name the broken link	Stigma is a predictor	Contract, do not visit
WHO HOLDS THE DIAGNOSIS IS ESTABLISHED PERSON BY PERSON, BECAUSE NO RECORD CARRIES IT	EACH PROBLEM DISABLES A DIFFERENT STEP OF THE DAILY ACT, AND THE REPAIR FOLLOWS	ANTICIPATED STIGMA PRODUCES CONCEALMENT, WHICH IS WHAT REACHES THE MEDICAL OUTCOME	THE DELIVERABLE IS AN ARRANGEMENT THE CLINIC RUNS AND AUDITS AFTER YOU HAVE GONE

An examiner is watching whether the candidate keeps the consult and the entity apart. The answer does not open with the neurocognitive syndrome. It opens with who knows and who is in the room, moves to consent and to what the referral is really asking, treats stigma as a predictor rather than as sympathy, identifies which link in the daily act has broken, checks the medical prescription before writing a psychiatric one, and closes with an arrangement rather than an opinion.

Psychiatry is not called here for the infection but for what the infection generates: a disclosure map governing every word said and written, a daily act that must survive decades of psychiatric weather, and a working contract with the clinic that outlasts the consult.

11 · Psycho-cardiology, psycho-dermatology and psycho-nephrology cross-links

Why the marks are here. Three medical specialties send psychiatry a steady stream of referrals, and each sends them for a different reason. Cardiology refers because a mood state is altering a cardiac outcome. Dermatology refers because a substantial share of its clinic is carrying a psychiatric problem dressed as a skin complaint. Nephrology refers because a treatment that will not end has become intolerable to the person receiving it. A candidate who answers all three with one generic account of depression in the medically ill has not answered any of them, because what is examined here is the specific traffic between psychiatry and each organ: who refers and at what point in the illness, what the psychiatric finding does to the physical prognosis, and what the psychiatrist's own prescription does back to the organ.

Three boundaries first, because this topic sits between several others in this chapter. The general psychological work of adjusting to physical illness, including denial, adherence and the shifts in identity a chronic disease brings, belongs to the companion topic on psychological reactions to physical illness and chronic disease. How a consult is requested, negotiated, answered and recorded belongs to the companion topic on principles and models of consultation-liaison psychiatry. The dialysis unit, the transplant work-up and the intensive care bed considered as settings belong to the companion topic on transplant, dialysis and ICU psychiatry. What is taught here is the organ-specific link itself: the size of each interface, its prognostic weight, the classification the referring specialty actually uses, and the drug traffic running in both directions.

1.6 to 2.7 fold	Under 15%	30% to 40%	21.4%
INCREASE IN MORTALITY RISK REPORTED WHEN DEPRESSION FOLLOWS MYOCARDIAL INFARCTION	DEPRESSION IN CORONARY ARTERY DISEASE THAT IS ACTUALLY DIAGNOSED	DERMATOLOGY OUTPATIENTS WITH AN UNDERLYING PSYCHIATRIC ISSUE	DEPRESSION REPORTED ACROSS CHRONIC KIDNEY DISEASE STAGES ONE TO FIVE

11.1 What a cross-link is, and what to call it

An organ cross-link is not a disorder and not a service. It is a relationship between two specialties around one organ system, and it has four parts worth separating before any of the three is discussed: how much psychiatric morbidity that clinic carries, how much of it is recognised, what the psychiatric state does to the physical outcome, and what each specialty's drugs do to the other's territory. Every examinable point in this topic is one of those four.

The names themselves need a word of caution, because they are used with different degrees of authority. Of the three head terms psycho-cardiology, psycho-dermatology and psycho-nephrology, only the dermatological one is securely attested in Indian guidance: **psychodermatology**, with its cognates psychocutaneous and psychodermatological, is the language the Indian guideline uses for that field, including in the heading under which it teaches the subject. The corresponding cardiac and renal terms did not appear in the body text of the two

Indian chapters read for this account. That is a statement about two documents and not about the literature: the cardiac and renal chapters title themselves as the management of psychiatric disorders in patients with cardiovascular diseases and in patients with chronic kidney diseases respectively, which is descriptive rather than terminological. Use psycho-cardiology and psycho-nephrology as convenient labels for a field of work, keep confident terminological claims for the dermatological one, and do not assert in a viva that the other two are established technical terms.

RULE **The clinically important number at every one of these interfaces is not the prevalence but the gap between the prevalence and the proportion diagnosed.** A physician who is told that a fifth of their clinic is depressed will reasonably reply that they have not seen it, and they are usually right, because they have not. That is the argument for a proactive arrangement rather than a referral-only one: a service that waits to be asked is measuring the referring team's recognition, not the ward's morbidity, and on these three interfaces those two quantities are known to be far apart.

11.2 Psycho-cardiology: how much depression, and in which cardiac patient

The cardiac interface is the best quantified of the three, and the Indian guideline published in 2022 gives figures at each stage of coronary disease rather than a single global rate. Depression is present in fifteen to twenty per cent of patients with coronary artery disease, in fifteen per cent of patients after coronary artery bypass grafting, and in twenty per cent of patients with congestive heart failure. After myocardial infarction the figure depends entirely on what is being counted: at least sixty-five per cent report depressive symptoms while twenty per cent fulfil criteria for a major depressive episode. Those are not two estimates of one quantity but two different quantities, and the distinction is the most examinable thing here.

Two modifiers are worth carrying. Risk is roughly two-fold in women compared with men, and particularly so under the age of sixty, which matters because the younger woman with cardiac disease is precisely the patient a busy unit is least likely to think of as depressed. And device recipients carry an anxiety burden of their own: around thirty per cent of patients with an implanted cardioverter defibrillator have clinically relevant anxiety, which is intelligible once you consider what the device does when it fires and how little warning the patient has.

Course is the part candidates omit. Depression at a cardiac index event is not a transient reaction that resolves as the patient recovers. At follow-up, the illness was chronic or relapsing in almost half of those who had a major depression at the index episode, and forty per cent of those with only minor depressive symptoms had progressed to a major episode within one year. The second half of that sentence is the reason a cardiac unit cannot safely apply a watch-and-wait rule to subthreshold mood symptoms, and it is the justification for a follow-up appointment rather than a single consult note.

TRAP **Quoting a symptom prevalence as though it were a disorder prevalence.** The commonest version of this error is the flat assertion that most patients after myocardial infarction are depressed, which takes a symptom-report figure and reads it as a diagnosis rate that is more than three times the true one. Candidates make it because the larger number is more striking and because the source sentence carries both figures and only the first is remembered. Always state the denominator with the number: symptoms reported, or criteria met. An examiner who hears a bare percentage for post-infarction depression will ask which one it is, and that follow-up is the whole point of the question.

11.3 Psycho-cardiology: why it is a prognostic problem, and the one procedural constraint

What makes cardiology different from the other two interfaces is that the psychiatric finding is a prognostic variable in its own right. Depression is described as an independent risk factor for coronary artery disease carrying a **bidirectional** relationship with it, meaning that the association runs in both directions and cannot be dismissed as understandable distress in a sick population. The mortality multiplier reported for depression following myocardial infarction is set out above; it should be quoted as the guideline reports it, because no confidence interval, no source study and no follow-up period accompanies it, so it is a reported range and not a pooled estimate you can defend as such.

The prognostic weight is not confined to depression. Stress, anxiety, panic and post-traumatic states are reported to increase mortality in cardiovascular disorder with a relative risk of 2.0 to 4.0, and post-traumatic stress disorder following an acute coronary syndrome carries a relative risk of 2.0 for relapse of that syndrome over one to three years. Severe mental illness belongs in the same frame: cardiovascular mortality in bipolar disorder is described as roughly doubled, with a relative risk of 1.5 to 2. That last figure is the one to have ready when a viva turns from the general hospital to the psychiatric outpatient, because it converts routine cardiovascular monitoring in a long-term patient from good practice into a mortality intervention.

One procedural constraint belongs here and only here, because it is a cardiac fact rather than a technique question. There are no absolute contraindications to electroconvulsive therapy, and recent unstable angina or myocardial infarction within **30 days** is a relative contraindication, with procedural precautions specified alongside it. The reasoning to show is why a relative contraindication with a time window is the right form for this rule: the haemodynamic surge is brief and manageable, the vulnerable myocardium is not, and the window closes.

11.4 Psycho-dermatology: the size of the interface and the Indian evidence

The dermatological interface is the largest of the three by proportion of the clinic and the least served by psychiatry. The headline proportion of dermatology attenders with an underlying psychiatric issue is given above, and what turns that figure into teaching is the Indian evidence sitting behind it, which is unusually good for a subject this neglected. Psychiatric morbidity is reported in thirty-five per cent of patients with acne and in **fifty-two per cent** of patients with chronic dermatoses, and depression in around thirty per cent of those with alopecia areata. The chronicity gradient in those three figures is the finding: the longer the skin disease has been visible, the larger the psychiatric fraction.

Stress as a trigger is measured separately and the two measurements should not be merged. Stressful life events in the year before onset or exacerbation were recorded in twenty-six per cent of patients with psoriasis vulgaris and sixteen per cent of those with chronic urticaria. Patient-reported emotional triggers run far higher, at fifty per cent in acne and almost all patients with hyperhidrosis. The hedge on that last one is part of the claim and should be reproduced with it. The gap between a documented life event and a reported trigger is not evidence that patients are wrong: it reflects two different questions, one asked of a record and one of a person.

IN INDIA

These dermatological figures are Indian studies quoted in an Indian guideline, and that is what makes them usable in an Indian viva without an apology. The decision they support is a service decision. A dermatology outpatient in a general hospital sees very large numbers in a short clinic and has no time to open a psychiatric enquiry, so a psychiatric problem in that clinic is found only if someone has arranged for it to be looked for. The renal chapter states the same requirement in plainer words, closing with the statement that collaborative work between the nephrologist and the psychiatrist is required; it was itself co-authored with a nephrologist. Asked how you would set this up, describe an arrangement in which psychiatry attends the other specialty's clinic, because the alternative depends on a referral that the figures above show is mostly not made.

11.5 Classifying the psychocutaneous disorders

Dermatology is the one interface where the classification itself is examinable, because the referring question changes completely depending on which class the patient falls into. Indian guidance adopts the classification attributed to Koo and Lee, which sorts psychocutaneous disorders into **three** types and adds a separate group of sensory presentations.

CLASS	WHAT DEFINES IT	NAMED EXAMPLES
Psychophysiologic (type 1)	Dermatological disorders that flare during stress	Alopecia areata, atopic dermatitis, acne, psoriasis, psychogenic purpura, rosacea, seborrhoeic dermatitis, urticaria
Primary psychocutaneous (type 2)	A psychiatric disorder is the root of the dermatological condition	Skin picking disorder, trichotillomania, delusional parasitosis, body dysmorphic disorder, factitious dermatitis
Secondary psychocutaneous (type 3)	Psychological problems arising from chronic skin disease or disfigurement	Alopecia areata, cystic acne, haemangioma, psoriasis, vitiligo, ichthyosis, Kaposi's sarcoma
Cutaneous sensory disorders	Unpleasant skin sensations with no known dermatological cause	Commonest on the face, scalp and perineum; includes glossodynia and vulvodynia

MNEMONIC

Flares, Drives, Scars

The three types in order and in the direction each runs. Type 1 is the skin disease that **flares** under stress. Type 2 is the psychiatric disorder that **drives** the skin lesion, so the lesion is produced by behaviour or by belief. Type 3 is the skin disease that **scars** the person, the psychological problem arising from chronic disease or disfigurement.

Two features of the table are worth arguing rather than memorising. First, alopecia areata and psoriasis appear in two classes each, and that is in the source's own table rather than an error to be tidied away. It is the most useful thing in the classification, because it says that one disease can both flare with stress and disfigure the person who has it, and that the two mechanisms need separate management in the same patient. Second, the type 2 examples are entities other chapters own: delusional parasitosis is taught in the Other psychotic disorders, delusional syndromes and catatonia notes, and skin picking, trichotillomania and body dysmorphic disorder in the Anxiety, OCD and trauma-related disorders notes, while factitious presentations are taken up in the companion topic on factitious disorder and malingering. What belongs here is the referral logic: a type 2 patient reaches psychiatry through a dermatologist who has usually already been consulted several times. The **matchbox sign**, the patient bringing collected specimens of the supposed organism to the appointment, is named in that guidance and is a cross-link observation rather than a psychopathological one: the dermatologist sees it first.

11.6 The arm that runs back: drugs, skin and the psychiatrist's duty

The dermatological interface is the clearest illustration of traffic in both directions, and both directions carry drugs. Running from dermatology into psychiatry, the same Indian guidance sets out a further and more recent classification of psychodermatological disorders, cut differently from the one above and to be named separately rather than merged with it. That newer scheme includes a category the first does not: psychiatric complications of the drugs dermatologists prescribe.

- **Depersonalisation** is named with minocycline.
- **Mood disorders** are named with isotretinoin, methotrexate and systemic steroids.
- **Psychoses** are named with dapsone and hydroxychloroquine.

The use of that list is a habit rather than a fact. In any patient referred from a skin clinic with a new psychiatric presentation, the drug chart is part of the mental state examination, and the temporal relation between starting a dermatological agent and the onset of the symptom is the first thing to establish, because it is the one that will not be recoverable later.

Running the other way, psychotropics can produce **severe cutaneous adverse reactions**, which the Indian guidance describes as potentially lethal, rare and sudden in onset. This account deliberately prints no rates, no onset windows and no per-syndrome mortality figures for them, because the tabulated values available here disagree with the same document's own prose and one of the cells is corrupted, so no comparable standard is available to quote, and none is invented

here. What survives that caution is the part that changes behaviour, and the guidance states it explicitly: the prescriber must warn the patient and the attendants, so that a rash is brought back rather than watched. That instruction is the examinable content. A psychiatrist who has started a psychotropic on a medical ward is responsible for recognising a serious skin reaction to it and acting on it, and cannot make a rash the dermatologist's problem because it is on the skin.

11.7 Psycho-nephrology: the burden along the disease course

The renal interface differs from the other two in that the psychiatric burden is described stage by stage along a trajectory that ends in either lifelong dialysis or transplantation, and it does not fall after transplantation.

- **Depression** is reported in 22.8 per cent of patients with advanced chronic kidney disease and 25.7 per cent of kidney transplant recipients, the stage-wide figure being given above.
- **Anxiety** is reported in 24.8 to 34.3 per cent of patients in stages three to five, and 26.6 per cent of transplant patients.
- **Cognitive impairment** reaches **up to 60 per cent** in advanced disease and in patients on haemodialysis, with deficits described in attention, concentration, orientation and executive function, and low serum albumin associated with decline in delayed memory, visuospatial skills, language and general cognition.

Two points follow. That transplantation does not return these rates to the population baseline is the finding most often assumed away, and it is the argument for continuing psychiatric follow-up after a successful graft rather than discharging at that point. And the cognitive figure is large enough to change how the rest of the assessment is conducted: a patient with that degree of impairment cannot reliably give a history of mood over months, cannot be assumed to have understood a consent discussion about modality, and may be misread as depressed on the basis of psychomotor slowing that is cognitive in origin. Where that impairment needs to be worked up as a neurocognitive presentation in its own right, the substrate belongs to the Neuropsychiatry of systemic and neurological disease notes.

The distress in end-stage disease has named sources rather than a general miserableness, and the guideline lists them: compromised health, dependence on others, regular frequent dialysis, the continued cost of treatment, and uncertainty about transplant. Two of those five are structural rather than psychological, and in Indian practice they are the two that dominate, because a family financing dialysis indefinitely and waiting on an uncertain transplant is not experiencing a distorted cognition that can be restructured. Naming them accurately is what separates a formulation from a diagnosis here.

Treatment at this interface has one grounded drug signal and one grounded psychological one, and the rest is deliberately not given. Citalopram increases the risk of sudden cardiac arrest in patients undergoing haemodialysis, significantly more than other selective serotonin reuptake inhibitors, with no effect size stated and none supplied here. On the psychological side, a meta-analysis supports the efficacy of cognitive behavioural therapy for depression in patients with renal disease on dialysis, which is worth quoting because it is a positive treatment claim in a

population where most trials are small. What is not printed here is any dose, any clearance threshold and any drug-by-drug schedule for prescribing in renal impairment; that material has its own owner and no fragment of it is reproduced here, while the general principles of antidepressant selection belong to the Mood disorders: pharmacotherapy notes.

11.8 Reading the three together

The comparison an examiner is actually testing. Asked to compare these interfaces, most answers list three sets of prevalences and stop. The better answer compares them on what the referring team wants, which differs in each case, and on what the psychiatrist's own decisions do to the organ.

INTERFACE	WHAT THE REFERRING TEAM IS ACTUALLY ASKING	THE PSYCHIATRIC ARM	THE ARM RUNNING BACK INTO THE ORGAN
Cardiology	Will this mood state change the cardiac outcome, and can it be treated safely here	Depression at every stage of coronary disease, mostly undiagnosed, often chronic or relapsing	An independent risk factor with a bidirectional relationship, plus the time-limited constraint on electroconvulsive therapy after an acute coronary event
Dermatology	Is the skin disease the problem here, or is the patient	A large minority of the clinic carries psychiatric morbidity, and the class decides the pathway	Dermatological drugs producing psychiatric syndromes, and psychotropics producing severe cutaneous reactions the prescriber must warn about
Nephrology	Why is this patient not tolerating a treatment they cannot stop	Depression, anxiety and substantial cognitive impairment across stages, persisting after transplantation	One drug-specific arrhythmia signal on haemodialysis, and clearance questions belonging to prescribing in renal impairment

GOOD TO REMEMBER

Two lines that candidates routinely omit should be in the consult note before it is closed on any of these three wards. The first states what the finding means for the physical illness, not only its psychiatric label, because that is the sentence the referring team can act on. The second states what has been done about the drug traffic in both directions: what the existing physical medication may be contributing to the mental state, and what warning the patient and the attendants have been given about the psychotropic just started.

Every organ cross-link has two arms: what the physical illness and its drugs do to psychiatric morbidity, and what the psychiatric disorder and its drugs do back to the heart, the skin or the kidney, and an answer that travels in only one direction has answered half the question.

12 · Psychiatric aspects of epilepsy and neurological disorders

Why the referral arrives at all. The neurology team has finished its investigations, reached its own view, and written one line at the foot of the chart: please see, query psychiatric. Nothing in that request is a question, and a psychiatrist who treats it as one ratifies a decision somebody else has already made. The psychiatric aspects of epilepsy and neurological disorders are taught in full elsewhere: what epilepsy is, how seizures are classified, which psychiatric presentations cluster around them and how the drugs behave belong to the Epilepsy and psychiatry notes; the rest of the neurological interface is listed below. What is owed here is the neurological instance: how the request is generated, what must be established before it can honestly be answered, and who holds which decision afterwards.

The examination question has the same shape. It is rarely a request to list the psychiatric complications of a neurological disease; it is a station in which a neurological patient has a behavioural problem and a team that wants an answer today. A candidate who reaches for the syndrome list has answered a question about the disease. The question was about the consultation.

Observed	Attributed	Owned
WHAT THE CONSULTATION ADDS THAT THE CHART DOES NOT	THE DECISION MADE INSIDE THE REFERRAL BEFORE THE PSYCHIATRIST ARRIVES	WHICH TEAM CARRIES WHICH DECISION AFTERWARDS

12.1 The referral question is not the question in the referral

The written reason for referral is a compressed account of the referring team's reasoning, and it almost always carries an **attribution** already made: this behaviour belongs to the brain disease, or it does not, and therefore it is yours. The **referral question** is the clinical decision actually pending on the ward, and the two are frequently different. The gap widens where the presentation is **paroxysmal behavioural disturbance**, because a paroxysm invites several competing explanations at once and the referring team has usually settled on one. The psychiatrist's value is not a better guess at the mechanism; it is the obligation to return to what was seen before deciding what it was.

WHAT THE REFERRAL SAYS	WHAT IS ACTUALLY BEING ASKED	WHAT HAS TO BE SETTLED FIRST
Please see, query psychiatric, investigations normal	Confirm a negative the team has already reached	Whether anyone has yet described an episode to a psychiatrist
Please see, low mood since the diagnosis	Is this the illness, the treatment, or a disorder in its own right	The sequence in time and the drug record, from a source that watched rather than inferred
Please see before discharge	Share a risk the team will not carry alone	What decision is pending, who may make it, and what the family has been told

12.2 What has to be established before an opinion is worth having

None of it is a mental state finding. A **witness account** is worth more than the ward's account of the same episodes, because a team's summary is where the attribution gets smuggled in, and the sequence in time must be recorded as observation, not as a label, since that labelling is taught with the entity. The **drug record** earns its place because a recent change nobody has connected to the presentation is a common explanation on a neurology ward, and because that record is seldom complete.

MNEMONIC

Witness, timing, list, owner

Witness: who watched an episode, quoted in their own words. **Timing**: where the disturbance sat in relation to the episodes, as sequence and not category. **List**: the drug record with dates, including what was stopped. **Owner**: whoever makes the next decision on each problem, named. An opinion with no named decision-maker is a paragraph, not a consultation.

IN INDIA

Outside the medical colleges and the metropolitan private sector neurology is thinly distributed, and the patient with paroxysmal episodes often reaches a psychiatrist first. The drug history often arrives with no prescription and no record of who started it or when, so it has to be reconstructed rather than assumed. And referrals go unanswered in both directions, so the working relationship with the neurology or medical team is built, not inherited. A national standard would settle how quickly and in what form these consultations happen; no comparable standard is available to quote, and none is invented here.

12.3 Shared care, and the decisions the psychiatrist declines

This patient is the standing example of **shared care**, which fails in a specific way: both teams assume the other is holding a decision, and nobody is. By convention rather than by rule, the seizure diagnosis, the anticonvulsant regimen and the advice about driving and occupation that follows from the seizures stay with **the primary team**. The psychiatric diagnosis, the psychotropic decision, the risk formulation and the psychological plan are the psychiatrist's. Where the two collide, chiefly in prescribing, the decision is joint and is recorded as joint, with a named person on each side.

Declining is an active clinical act, not a retreat. A psychiatrist asked to adjudicate whether the episodes are seizures at all should record that the question belongs to the referring team, state what they observed that bears on it, and set a **review point**. Silence is read as agreement, and an undeclined question tends to be answered by default in whichever direction the ward was leaning.

RULE **Answer the psychiatric question, decline the neurological one, and write both down.** The consultation's authority comes from a visible boundary. An opinion that quietly extends into the seizure diagnosis invites the referring team to stop thinking about it; one that withholds the psychiatric decision leaves the patient with two clinicians and no plan. Neither is visible unless the note says which question was taken and which returned.

12.4 What the examiner tests, and where the rest is taught

How the marks are allocated. A neurological patient is set before a psychiatry candidate to see whether two illnesses and two teams can be held in mind without collapsing either into the other. What is scored is the sequence, the sourcing of the history, the explicit attribution and the handover. Entity knowledge is assumed and examined elsewhere, which is why fluent recitation earns less than a candidate expects.

- Seizure classification, the psychiatric presentations related to seizures, and the anticonvulsants: the Epilepsy and psychiatry notes.
- Examination, investigation and localisation: the Neurology foundations for psychiatrists notes.
- Stroke, head injury and focal brain syndromes: the Stroke, TBI, delirium and focal brain syndromes notes.
- The neurocognitive disorders: the Dementias and neurocognitive disorders notes.
- Systemic disease with neuropsychiatric presentations: the Neuropsychiatry of systemic and neurological disease notes.

TRAP **Answering the referral's attribution instead of testing it.** Candidates make it because the attribution is usually reasonable, comes from a specialist team, and is the only framing the request supplies. It is also the check a psychiatrist is well placed to make, having no stake in the conclusion already drawn. The correction is not scepticism about neurology; it is separating, in the note, what was observed from what was concluded.

A consultation on a neurological ward is discharged by naming what was observed and by whom, what is and is not attributed to the neurological illness, and who carries which decision from here.

What changes at seventy-eight

13 · Normal ageing and psychiatric assessment of the elderly

Why the marks are here. The examiner who turns to the older patient is rarely asking what dementia is, or what late-life depression looks like; those have their own questions and their own answers. This one asks something harder to prepare for. Here is a person of eighty: show me how you assess them, and then tell me which of your findings is the illness and which is simply the age. The second half is where answers collapse, because a candidate with no defensible account of what ageing normally does has nothing to measure abnormality against, and every finding in the

interview becomes uninterpretable in both directions at once. Slowness gets called depression. Forgetting a name gets called dementia. A genuine early deficit gets waved through as expected for age.

The topic has an awkward shape for a reader. Almost everything written about older people concerns their diseases, so the normal baseline is the least rehearsed part of the subject and simultaneously the part every diagnosis silently rests on. That is why normal ageing and psychiatric assessment of an older person belong in one answer rather than two: a procedure is only as good as the norms it is read against.

13.1 The instrument does not change; the weights inside it do

Begin where the guidance begins, because it is unusually blunt. A clinical practice guideline on older people presenting with psychiatric emergencies, published in the Indian Journal of Psychiatry in 2023, states that the basic principles of psychiatric assessment remain the same in old age, and then names them: thorough history taking, physical examination, mental state examination, and carrying out the investigations required. **Four** parts, in the order every candidate already knows. Nothing is deleted because the patient is old, nothing exotic is inserted, and there is no separate geriatric interview to name.

What changes sits inside the first part. The same guideline directs that in taking the history the clinician should not confine attention to the psychiatric history but must also cover **comorbid physical illness**. Read that as a statement about weight and not about coverage. An adult history asks about physical illness too, but handles it as background against which the psychiatric story is told. In later life it stops being background and becomes a second history of equal standing, taken with the same care, the same chronology and the same insistence on detail as the psychiatric one.

Four reasons make that shift defensible rather than merely dutiful, and a good answer gives at least two. The physical illness is more often the cause of the presentation than a context for it. It frequently dictates what treatment is available, so a plan written before the physical history is complete may have to be abandoned. It changes the reading of the mental state, since fatigue, poor appetite, disturbed sleep and slowing all have honest medical explanations in a patient with several active diagnoses. And it is the part the patient is least likely to volunteer, having normalised it over years and having come to see a psychiatrist.

RULE **The skeleton of the assessment is age-invariant; the weight distributed across it is not.** Anyone who answers this question by describing a special geriatric interview has misread it. The examinable content is which parts of a familiar structure grow, what gets added to the history because of the patient's age, and against what baseline the mental state findings are then read. Say the structure is unchanged in your first sentence, and spend the rest of the answer on the redistribution.

One qualification belongs in the answer. The document stating the principle most crisply is written for the emergency presentation, so its setting is the acutely disturbed older patient rather than the routine outpatient. That sentence about the structure is itself general and travels, but a candidate who names the source should name its scope too.

PART OF THE ASSESSMENT	WHAT IS UNCHANGED	WHAT THE PATIENT'S AGE ADDS
History	The same sequence, the same headings, the same discipline about chronology	Physical comorbidity taken as a full second history; three added domains an adult clerking omits; an informant account that is rarely optional
Physical examination	The examination itself	It cannot be deferred to another team, because its findings now enter the psychiatric formulation rather than sitting beside it
Mental state examination	The same structure, the same terminology, the same descriptive discipline	Every finding is read against a normal-ageing baseline before it is called abnormal, and correctable sensory deficit is dealt with before cognition is tested at all
Investigations	Those the assessment has shown to be required	The physical differential raised by the history is longer, so the list is driven by that differential rather than by a fixed panel

13.2 The premise underneath all of it: reduced reserve

A single line in the same guideline carries the physiology for the entire subject. Older people have a lower level of **physiological reserve**, and the consequence drawn from it is that any tiny change should be given due importance. The guideline says this while instructing the reader how to evaluate drug intoxication and withdrawal, which is where a small change is most easily dismissed, but the premise is not specific to drugs and the reasoning generalises across the assessment.

Reserve is the distance between what a system does at rest and the most it can produce under load. Ageing narrows that distance across several systems at once, and the corollary is worth memorising: a perturbation absorbed silently in a younger patient produces a disproportionate effect here. Two things follow for the assessment.

- The size of the trigger stops predicting the size of the effect, so a search that stops because nothing impressive has been found has stopped too early, and a small complaint is pursued rather than filed.
- A change in mental state becomes a system-level signal rather than a psychiatric one, and it earns a physical review before it earns a psychiatric label.

What is deliberately not supplied here is the arithmetic. How far renal clearance falls per decade, and what happens to hepatic metabolism, lean body mass, total body water, albumin and receptor sensitivity, are exactly the figures a candidate reaches for at this point. For each of them no comparable standard is available to quote, and none is invented here. Those numbers belong to prescribing rather than to assessment, and are taken up where the principles of

psychopharmacology in later life are dealt with in these notes. In an assessment answer the qualitative statement is what earns the mark.

13.3 Normal cognitive ageing is a pattern, not a slope

The most useful correction to make early is that normal ageing is not global decline. A review of normal cognitive ageing published in Clinics in Geriatric Medicine in 2013 frames it as a split. Some abilities are resilient to brain ageing and may even improve with age, vocabulary being the standing example. Others decline gradually across time, and the three the review names are conceptual reasoning, memory and processing speed. The rate at which any of this happens varies widely between individuals, which is the reason chronological age predicts a given person's performance so poorly and the reason a normative table can never replace a premorbid baseline.

The same review puts numbers on the two trajectories, and they are the only quantified ones offered here. The abilities it groups as fluid, naming executive function, processing speed, memory and psychomotor ability, peak in the third decade of life and thereafter decline at an estimated **0.02** standard deviations a year. The crystallised abilities remain stable or gradually improve, at a rate the review prints as **0.02 to 0.003** standard deviations a year, through the sixth and seventh decades of life. Notice what that pairing means: across middle and later adulthood the two curves move in opposite directions inside the same skull, so a single global impression of a patient as sharp or as failing is almost always wrong about one half of them.

The fluid and crystallised distinction itself, its origin, its lifespan trajectory and the hold versus no-hold logic of testing that follows from it belong with the psychology of intelligence and are not re-derived here. What this section owes is the clinical use of the split. Preserved crystallised performance is what allows an estimate of what the patient used to be, and the gap between that estimate and current fluid performance is the quantity a cognitive assessment is really trying to measure. A patient whose vocabulary and general knowledge have gone is not showing you an exaggerated version of ageing; they are showing you something ageing does not do.

DOMAIN	WHAT NORMAL AGEING DOES TO IT	HOW TO READ A POOR PERFORMANCE
Overall language	Remains intact	A genuine language deficit is a finding, not a concession to age
Vocabulary	Resilient, and may improve with age	Loss here is among the strongest arguments against normal ageing
Visual confrontation naming	About the same until age 70, declining in subsequent years	Interpret against age before calling it anomia in an older patient
Verbal fluency	Declines	Weak on its own, and confounded by slowing
Processing speed	Begins declining in the third decade and continues through life	The likeliest single explanation for a broad, shallow, timed-test deficit

DOMAIN	WHAT NORMAL AGEING DOES TO IT	HOW TO READ A POOR PERFORMANCE
Rate of acquisition	Declines across the lifespan	Slow learning of a word list is compatible with normal ageing
Retention of what was learned	Preserved where cognition is healthy	Failure to hold material that was demonstrably learned is not ageing
Delayed free recall, source and prospective memory, retrieval	Decline with normal age	Expected; weigh them lightly without a retention failure alongside
Recognition memory with cueing, temporal order memory, procedural memory	Stable with normal age	Deficits here carry more weight than an equivalent recall deficit
Simple auditory attention span	Falls only slightly, and late	A markedly reduced simple span deserves an explanation
Selective attention, divided attention, working memory	Decline more noticeably	Poor performance under distraction or dual demand is weak evidence of disease
Conceptual reasoning	Declines gradually	Expected, and heterogeneous enough that a single score means little

13.4 Slowing is the common cause, and it contaminates the rest

The point that changes how you read a score. **Processing speed** is not one deficit sitting alongside the others. The review is explicit that many of the cognitive changes reported in healthy older adults are the result of slowed speed, and that the slowing depresses performance on tests built to measure entirely different domains, verbal fluency among them. That single observation reorganises the whole of bedside cognitive interpretation.

The mechanism is not mysterious. Almost every cognitive instrument is timed, or carries an implicit time limit set by the examiner's patience, or asks the patient to hold material while operating on it. Each of those designs converts slowness into a lower score without any deficit in the domain being tested. The patient who produces fewer words in a minute may have intact semantic access and a slower retrieval engine. A profile of shallow deficits spread evenly across many domains is therefore the signature of a speed effect, and reads quite differently from a deep deficit in one domain with the rest preserved.

Two things follow at the bedside, and both are things the examiner can ask you to do rather than describe. Give time, and say in the note that you did, because a result obtained under time pressure and a result obtained without it are different measurements. And when a score comes out low, ask what proportion of that instrument's marks depended on producing something quickly before you record a domain deficit against the patient's name.

TRAP **Reading a low score as a domain deficit when it is a speed artefact.** Candidates learn cognitive testing as a map of domains and assume each subtest measures the domain it is named after. In an older person that assumption fails in a specific direction, because slowing pulls down scores across instruments that have nothing to do with speed. The answer that wins the mark names slowed processing speed as a competing explanation for the whole profile, rather than accepting the profile at face value and reporting a scattered multi-domain impairment.

13.5 Memory in normal ageing: slower to learn, not quicker to forget

The memory findings are the most examinable material in the topic, because they are the ones that separate an expected complaint from a diagnostic one. Normal ageing reduces the **rate of acquisition**: material takes more exposures and more time to get in. What it does not do is dissolve material that got in. Retention of information that has been successfully learned is preserved in cognitively healthy older adults, and that asymmetry is the baseline against which any complaint of memory failure has to be read.

The practical consequence is that the interesting question is never whether the patient forgot something. It is whether the item was ever learned. A patient who could not repeat a name back at the time of registration has not forgotten it thirty minutes later, and the examiner who watches a candidate record that as delayed recall failure has already found the mark. This is why an adequate registration step is not a formality, and why an examination that skips it produces a delayed recall figure that cannot be interpreted.

The direction of the normal changes is worth holding as two lists rather than one, because the second list is what makes a finding meaningful. Declining with normal age: delayed free recall, source memory, prospective memory, the rate of acquisition and retrieval. Stable with normal age: **recognition memory** when cueing is given, temporal order memory and procedural memory. A patient who cannot retrieve a word list freely but recognises every item when choices are offered is displaying a retrieval pattern, which is what ageing produces. One who does not recognise them even when offered has failed at something ageing does not touch.

Two boundaries belong here and are not crossed. What a rapidly failing memory in a patient with psychotic symptoms should push you towards is dealt with where late-onset psychosis is taken up in these notes, and the fine-grained cued-recall discriminators between the neurocognitive disorders belong to the Dementias and neurocognitive disorders notes. What this section supplies is the thing both of them stand on: the description of what memory does when nothing is wrong.

13.6 Language and attention: where candidates over-call and under-call

Language is the domain most often mishandled in both directions. Overall language ability remains intact with ageing, and vocabulary remains stable or improves, so a genuine language deficit in an older patient is a finding to be explained rather than a concession to be made. Against that, the review names two exceptions and both are common enough to trip an unwary examination. **Visual confrontation naming** stays about the same until the age of **70** and declines in the years after it, so naming failures in the eighties are read against a moving norm. And **verbal fluency** declines, which matters doubly because fluency tasks are also timed and therefore carry the speed confound described above.

Attention divides along a similar line. Simple auditory attention span shows only a slight decline in late life, whereas selective attention, divided attention and working memory decline more noticeably. That asymmetry is directly useful in a busy clinic. A patient who cannot hold a short span of digits at all has produced an abnormal finding worth pursuing; a patient who loses the thread when two things are asked at once, or when a corridor conversation intrudes, has produced an expected one. It also explains why the same patient looks impaired on a ward round and unimpaired in a quiet room, with no change in their brain between the two.

Sensory, frailty, abuse	3rd	0.02	2
THE HISTORY DOMAINS ADDED BECAUSE THE PATIENT IS OLD, THE LAST OF THEM NEEDING SUSPICION RATHER THAN ENQUIRY	DECADE OF LIFE IN WHICH FLUID ABILITIES PEAK, BEFORE THEIR LONG DECLINE	STANDARD DEVIATIONS A YEAR, THE ESTIMATED RATE OF THAT FLUID DECLINE	EXCEPTIONS TO OTHERWISE PRESERVED LANGUAGE: CONFRONTATION NAMING AFTER 70, AND VERBAL FLUENCY

13.7 The history items that exist only because the patient is old

Beyond the redistribution of weight, the geriatric history acquires domains an adult history does not routinely ask about. The same national guideline names them, and they are worth memorising as a set because a candidate who produces all three has demonstrated the point of the whole question. Due importance is to be given to the assessment of **sensory deprivation**, visual or auditory, and to a review of frailty; and the assessment of elder abuse requires a high index of suspicion.

Take the modal verbs seriously, because they differ. Sensory status and frailty are enquiries you make. Elder abuse is not an enquiry that succeeds by being made, since nobody volunteers it and the person who brought the patient may be the person concerned; what is asked for is active suspicion, the possibility raised by the clinician on the strength of discrepancy rather than of complaint. That topic's forms, its named instrument and what a clinician is then obliged to do are taken up where elder abuse and neglect are dealt with in these notes.

Sensory deprivation earns its place for two separate reasons and only one of them is about the patient's experience. Degraded hearing and vision impoverish the information reaching an older person, so more of the world has to be inferred and less of it is received. Independently of that, an uncorrected deficit invalidates the examination you are about to perform: a patient who cannot hear an instruction looks inattentive, and one who cannot see an object looks unable to name it. What that does at the bedside of a confused inpatient belongs to the section on delirium in later life. What belongs here is the history step and its order: establish what the patient normally uses, establish whether they have it, and correct it before the mental state examination rather than after.

On the sensory changes themselves, this section stops short deliberately. What normally happens to hearing and to vision with age, the pattern in which it happens, the age at which it becomes clinically material, and how many older adults in India are affected are all facts a complete answer would carry, and for each of them no comparable standard is available to quote, and none is invented here. Say what is defensible: that sensory decline is expected, that it is frequently

correctable, and that its uncorrected presence makes a cognitive result uninterpretable. Do not attach a prevalence or an age threshold you cannot source, because that is precisely the sentence an examiner will ask you to justify.

Frailty is named here as a review, not as a construct to be taught. Its definition, its scoring and the multidisciplinary assessment it triggers are dealt with where the comprehensive geriatric assessment is taken up in these notes; in the psychiatric history it is a question about reserve.

MNEMONIC

Hear it, Weigh it, Count it, Suspect it

The four acts that turn an adult history into a geriatric one. **Hear** it: establish and correct sensory deprivation before any cognitive item is administered. **Weigh** it: give the comorbid physical history the same weight as the psychiatric one, and review frailty as part of it. **Count** it: produce a cumulative anticholinergic total from the drug history rather than a list of drugs. **Suspect** it: raise elder abuse yourself, because it is not volunteered.

13.8 The medication history has to produce a total, not a list

Every candidate takes a drug history. The geriatric requirement is different in kind: the guideline treats assessment of the **total anticholinergic burden** of all ongoing medications as a critical part of evaluating the medication history, and gives the reason plainly, which is that a high burden is one of the crucial causes of delirium. The output of the history is therefore a quantity, not an inventory, and an answer that says the drug history was taken without saying what it produced has not met the requirement.

The word doing the work is total. The clinical problem is rarely one strongly anticholinergic agent prescribed in error, which anyone would spot. It is the sum of several mild contributors accumulated across years and across prescribers, each individually defensible, none individually alarming, and nobody holding the addition. Note what is owed here and what is not: the assessment step is to arrive at the total. How that total then constrains prescribing, and what scales exist for scoring it, belong to the section on psychopharmacology in later life.

IN INDIA

Whose drugs get counted is where an Indian history diverges from the textbook version. The same guideline explicitly extends the medication history to medications from other pathies, naming homeopathy and ayurvedic preparations, alongside what has been bought over the counter. In practice the older Indian patient arrives on a physician's prescription, something from a second system of medicine that the family regards as harmless and so does not mention, a sleeping tablet running for years on repeat, and a topical or ophthalmic preparation nobody counts as a drug at all. The question that recovers all of it is not what medicines are you taking. It is a request to bring in every strip, bottle, sachet and tube in the house, from every doctor and every shop.

13.9 What the assessment has to leave behind

Because none of this is a separate procedure with its own form, what marks a geriatric assessment as competently done is what appears in the record at the end of it. Four entries carry the topic,

and each of them is the written trace of something taught above.

- The premorbid cognitive and functional baseline, with its source named, since a current performance without a baseline is a number without a comparator.
- The physical history and examination findings placed inside the psychiatric formulation rather than appended after it, with the differential they raise made explicit.
- A reconciled drug list from every source, with its cumulative anticholinergic burden stated as a judgement.
- A sentence saying which of the findings you have read as ageing and which as illness, and on what grounds, because that is the reasoning the question was testing and it is invisible unless written.

Two habits of conduct make those entries possible and are worth naming in a viva. Interview at the patient's pace, which is not courtesy but measurement discipline, given how much of what looks like deficit is slowing. And take an informant history routinely rather than as a rescue when the patient proves a poor historian, because the baseline everything else is read against usually exists only in somebody else's memory.

GOOD TO REMEMBER

Before the words cognitive impairment go into an older patient's notes, two sentences have to precede them: what this person was like before, and who told you. If neither is there, what has been recorded is a performance and not a finding, and every clinician who reads the note afterwards will inherit the conclusion without the evidence that would let them revise it.

Whatever form the question takes, it asks whether you can hold two frames at once. A candidate with only the assessment produces a competent adult clerking of an old person; one with only the norms produces a lecture on gerontology. The mark is in the join.

In normal ageing the rate of acquisition falls while retention of what was successfully learned is preserved, and vocabulary holds or improves while processing speed has been falling since early adulthood: so slow learning and slow performance are age, and losing what was learned or losing words is not.

14 · Principles of psychopharmacology in the elderly

Why the marks sit here. A prescription for a woman of seventy-eight is not a smaller version of the prescription for a woman of thirty with the same syndrome. The drug may be identical and the arithmetic is still different, because the body it enters has changed in how much arrives, how long it stays and how hard it lands.

The principles of psychopharmacology in the elderly are prescribing logic rather than a drug list; the agents belong to the Mood disorders: pharmacotherapy notes and the Anxiety, OCD and trauma-related disorders notes. Four things change with age: the kinetics, the dynamics, the number of other drugs already in the patient, and the prescriber's willingness to stop one.

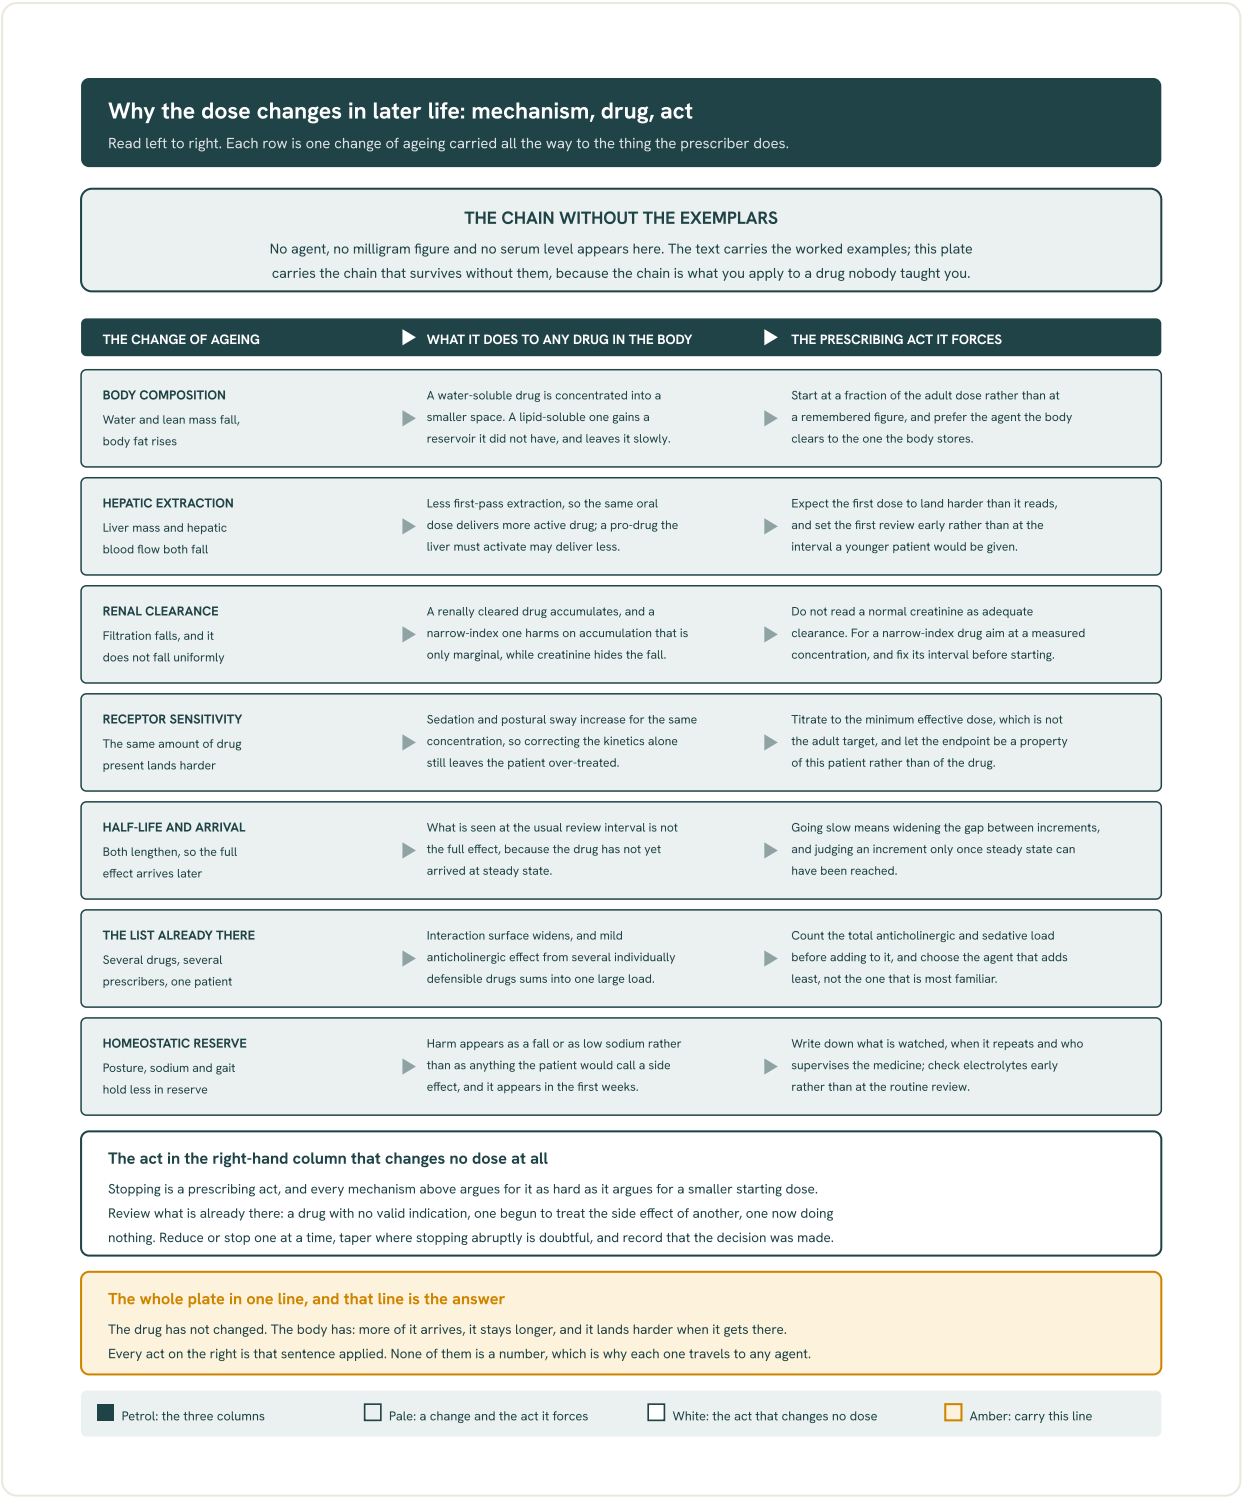

Fig 29.6. Why the prescription changes in later life, drawn as seven chains rather than as a list of changes, each beginning with one pharmacokinetic or pharmacodynamic shift of ageing, passing through what that shift does to any drug in the body, and ending in the act it forces on the prescriber, with no agent, milligram figure or serum concentration anywhere on the plate, and with the act that adjusts no dose at all, the review and withdrawal of what is already there, given its own panel because every mechanism above argues for it.

14.1 The kinetic shift

The whole kinetic change states in one line. Renal clearance falls, hepatic clearance falls, the **volume of distribution** rises for lipid-soluble drugs, and elimination half-life lengthens as a consequence. The review that states it this way also names psychotropic drugs, with anticoagulants and cardiovascular agents, as a class to which sensitivity is altered and usually

increased, which is why this is a psychiatric topic and not only a geriatric-medicine one. It hedges throughout, and a candidate who hardens its "probably" into a mechanism has overstated it.

WHAT CHANGES WITH AGE	CONSEQUENCE FOR THE PRESCRIPTION
Body water and lean mass fall, fat rises	Smaller volume of distribution for water-soluble agents; larger volume and longer half-life for lipid-soluble ones, diazepam the exemplar, so the sedative cleared by breakfast at forty still circulates at teatime at eighty
Liver mass and hepatic blood flow fall	First-pass metabolism reduced, so bioavailability can rise for a drug extensively cleared on first pass, while a pro-drug the liver must activate might be activated more slowly
Renal flow and filtration fall, not uniformly	Clearance falls for renally cleared agents, lithium among them, and marginal accumulation of a narrow-index drug harms
Sensitivity to several classes is altered upward	Sedation and postural sway increase with diazepam and postural sway with temazepam, so the same plasma level buys a bigger effect

PITFALL

A normal serum creatinine in an older patient is not evidence of adequate renal function. Filtration falls while plasma creatinine does not rise, because muscle mass falls in parallel, so creatinine is not a reliable indicator of glomerular filtration rate in the elderly subject, and serum cystatin C offers no significant advantage over it. The same source is explicit that the decline is not uniform or consistent, which warns against the familiar per-decade figure. No rate of decline is asserted here, and no percentage for the fall in body water, lean mass or liver blood flow: none of those magnitudes is available to quote, and none is invented here.

14.2 The pharmacodynamic shift

Kinetics can be reasoned from first principles. Dynamics cannot, and the honest source says so: because the effect of age on drug sensitivity varies with the drug studied and with the response measured, generalisations are often difficult. Quote that rather than paraphrase it. Within the caution the direction is loud for the benzodiazepines: one at seventy-eight is not merely longer-acting but intrinsically more destabilising at the same concentration. It is not loud everywhere: the same table's scopolamine row runs the other way, its effect on cognitive function decreasing with age.

MNEMONIC

Fewer litres, slower exit, sharper target

Fewer litres is the body-composition shift, **slower exit** the fall in clearance and the longer half-life, **sharper target** the rise in sensitivity that includes psychotropics.

14.3 Start low and go slow, as a quantity

Start low, go slow heads the Indian list of general prescribing principles for the elderly. Quoted alone it is nearly useless: it says nothing about how low or how slow. Current Indian guidelines do quantify it, and differently for different drug classes, which is the examinable point rather than an inconsistency to smooth away.

half OF THE ADULT STARTING AND TARGET DOSE FOR ANTIDEPRESSANTS IN THE ELDERLY, INDIAN DEPRESSION GUIDELINE	**25 to 50% lower** THAN THE ADULT ANTIPSYCHOTIC STARTING DOSE IN OLDER ADULTS, INDIAN SCHIZOPHRENIA GUIDELINE	**more than 5** MEDICATIONS, THE POLYPHARMACY COUNT TRIGGERING A DEPRESCRIBING REVIEW IN INDIA	**every 6 months** OR MORE FREQUENTLY, THE GENERAL FILTRATION AND THYROID SCHEDULE ON LITHIUM, OLDER AGE BEING A REASON TO GO MORE OFTEN

The first two figures are not the same rule. The antidepressant rule is a flat halving that moves the target dose as well as the start, so the destination itself moves; the antipsychotic rule is a range of reduction, stated for the starting dose only. Neither states an upper ceiling for older adults and neither states a milligram figure, so a correct answer attaches the class and the guideline to each figure.

Going slow has an endpoint as well as a rate, and the endpoint is what candidates drop. The Indian obsessive-compulsive disorder guideline states it plainly for older adults: start low, increase slowly, stabilise at the **minimum effective dose**, which is not the adult target. It also says clomipramine may be avoided on cardiac, sedative, constipating and falls grounds, and that high-dose selective serotonin reuptake inhibitors should be used cautiously because of falls and hyponatraemia, "high dose" meaning the supratherapeutic anti-obsessive range that guideline itself recommends.

The clearest quantified illustration of slowness is not a psychotropic. For digoxin, time to steady state rises from 7 days in the young to 12 days in the elderly, so digoxin loading doses should be **reduced by approximately 20 per cent**. The arithmetic transfers: such a drug cannot be titrated on a younger patient's schedule.

RULE **The age adjustment is a fraction, not a figure.** Every quantified dose rule for older adults in current Indian guidance is a proportion of the adult dose or a serum-concentration target, and none states an absolute milligram starting dose: the adult dose is the only fixed point guideline and prescriber share.

TRAP **Converting a relative instruction into a remembered absolute one.** Told the elderly antidepressant dose is half the adult dose, a candidate reaches for a milligram number. The instruction has no milligram content; the moment it acquires one, it came from the candidate and not the guideline.

In an older adult the starting dose is a fraction of the adult dose, the titration endpoint is the minimum effective dose rather than the adult target, and the monitoring that decides the outcome is sodium, renal function and the ability to stand up without falling.

14.4 Lithium, and a guideline that disagrees with itself

Lithium is where every strand of this topic meets. It is renally cleared, its clearance falls with age, and it is separately named with the aminoglycosides and digoxin as a drug of **narrow therapeutic index** likely to cause serious adverse effects if it accumulates only marginally more than intended. Those two properties together are the argument for a lower target in old age.

PHASE AND POPULATION	SERUM LITHIUM TARGET AS PRINTED	WHERE THE GUIDELINE STATES IT
Acute mania, medically healthy	0.8 to 1.0 meq/l	the acute-mania dosing table
Acute mania, older adults or relevant medical issues	0.6 to 0.8 meq/l	the same dosing table
Acute phase, general	0.6 to 1.2 meq/l	the lithium narrative of the same document
Acute phase, older adults	0.4 to 0.8 meq/l, which the guideline says "may suffice"	the same narrative
Maintenance, medically healthy	0.6 to 0.8 meq/l	the maintenance section
Maintenance, older adults or relevant medical issues	0.4 to 0.6 meq/l	the same section

Two things there need saying aloud. First, the current Indian bipolar disorder guideline states the older-adult acute target in two places and they do not agree: the dosing table sets the lower bound at 0.6 meq/l while the narrative of the same document sets it at 0.4 meq/l, both agreeing on an upper bound of 0.8 meq/l. Averaging them gains nothing: name the location you quote, or give both ranges. The narrative also carries the softer modal verb, that the lower range "may suffice" rather than that it should be aimed for.

Second, what the guideline does not say. The dosing table prints a milligram-per-day range for the adult and prints no milligram-per-day figure for the older adult at all, so the older-adult figure available to quote is a serum concentration and never a starting dose. A candidate asked for milligrams of lithium at seventy-eight should name the serum target and the monitoring, and say the dose is whatever achieves that level.

Monitoring is where the age effect refuses to become an interval, and the population is the trap. Six-monthly is the general schedule for filtration and thyroid function on lithium, with or more frequently attached, not an older adult's schedule. For the older adult the guideline says only that more frequent monitoring of urea and creatinine may be needed, in older adults and where a diuretic, a non-steroidal anti-inflammatory drug or an angiotensin converting enzyme inhibitor is co-prescribed or there is renal impairment. May be needed is the source's own modal, and how much more often is nowhere stated.

14.5 Anticholinergic burden: a mandate without an instrument

Indian guidance makes assessment of the total **anticholinergic burden** of all ongoing medications a critical part of the medication history in an older patient, and gives the reason as delirium: high anticholinergic burden is one of its crucial causes. The word total is load-bearing: the problem is rarely one strongly anticholinergic drug prescribed in error, but the cumulative effect of several mild ones from several prescribers, each defensible alone.

The same guidance names no scale, no score and no cut-off, and a candidate should say so. Instruments exist outside India: the **Anticholinergic Cognitive Burden scale**, the Anticholinergic Drug Scale and the Anticholinergic Risk Scale, the first the most frequently validated of the expert-based scales against adverse outcomes. No numeric threshold from any of them is asserted here: no comparable standard is available to quote, and none is invented here.

Two practical consequences follow even without a score. The Indian schizophrenia guideline makes lower anticholinergic burden and lower sedative property the selection criteria for a first-line antipsychotic in older adults, gives the purpose as preventing falls, tells the prescriber to avoid anticholinergic co-prescription so far as possible, and requires more frequent metabolic monitoring without saying how much more. Anticholinergics are also the one class Indian deprescribing guidance names as generally high risk in the elderly. The cognitive endpoint belongs to the Dementias and neurocognitive disorders notes.

14.6 Falls and hyponatraemia

When Indian guidance quantifies the elderly antidepressant rule it attaches two monitoring targets and only two: hyponatraemia and falls. They are the two adverse effects that turn a psychiatric improvement into a medical admission. On falls, the drug-side risks named are the need for a mobility aid, sedative medication, and drugs causing a postural fall in blood pressure; after a fall the history asked for is structured:

- where the fall happened, what the patient was doing, and the type of fall
- dizziness or fainting around it
- weakness on changing posture, such as standing from sitting or lying
- walking difficulty, recent previous falls, and visual or auditory impairment, each a checklist item in its own right

No falls instrument or score is named in the Indian sources, so naming a falls tool goes beyond them. On hyponatraemia the mechanism is stated: these drugs are associated with it through the **syndrome of inappropriate secretion of antidiuretic hormone**, and the risk factors begin with old age, then female sex, co-administration of drugs that themselves cause hyponatraemia, reduced filtration and comorbidity. Timing is as examinable as mechanism: in elderly and frail patients the risk sits especially in the first weeks of treatment, which is why electrolytes are checked early rather than at a later review. First weeks is not a number of weeks. Referral to a specialist is set at a serum sodium **below 125 mmol/L**, a laboratory threshold and not a dose.

A third harm needs a clause because its age relevance is inferential rather than stated. These agents may increase the risk of upper gastrointestinal bleeding, particularly with non-steroidal anti-inflammatory drugs or antiplatelet agents, and caution is advised where aspirin or oral anticoagulants are co-administered. The source does not stratify that risk by age; what makes it geriatric is that those co-prescriptions are commonplace at seventy-eight.

GOOD TO REMEMBER

Two answers must be in the note before an older patient leaves with a new prescription: who will supervise the medication, and which investigations repeat and when.

14.7 Interactions, class choice and the citalopram trade-off

Interaction matters here for an unglamorous reason, and Indian guidance names it: the elderly are likely to be on many medications for other medical conditions. All selective serotonin reuptake inhibitors are metabolised by the cytochrome P450 system, and they divide in two:

- fluoxetine, fluvoxamine and paroxetine also significantly inhibit P450 enzymes, so they may interfere with a wide variety of other medications
- citalopram, escitalopram and sertraline do not substantially inhibit those enzymes and are associated with fewer drug interactions

That reads as a clean recommendation until you turn to the same guideline's cardiac table. As a class these drugs are reported to have no effect on QTc and no association with arrhythmia, with one exception: citalopram and escitalopram show a dose-related increase in QTc and torsades de pointes in overdose and should be used with caution in those at risk for arrhythmia, while sertraline appears safest. Two of the three interaction-safer agents are therefore the conduction-riskier ones, and an answer naming one ground must carry the other.

What that guideline does not supply is a number: no millisecond QTc threshold and no age-specific dose cap appear in it, so Indian guidance cannot be cited for a QTc cut-off. The only age-triggered maximum available comes from elsewhere and it is a ceiling rather than a starting point. Secondary reports of a United States regulatory safety communication describe it as advising against citalopram above 40 mg per day generally, and as reducing the maximum to 20 mg per day in older patients, in hepatic impairment, in CYP2C19 poor metabolisers, and with a CYP2C19 inhibitor, the age threshold being sixty years in both reports, and neither report attaches that ceiling to any single indication, obsessive-compulsive disorder included. Three limits belong with that figure: it is a daily maximum and carries no starting dose; the reports are not the issuing regulator's own document but a journal article and a second country's medicines agency stating the same cap; and they disagree over whether a patient of exactly sixty falls inside the ceiling, so neither wording is adopted here. Which of these agents a given older patient is started on, and at what dose for which disorder, is settled in the notes that own the antidepressants; what belongs here is only that age by itself lowers a ceiling.

Class choice may itself shift with age. The current Indian depression guideline states that in older adults these agents may be less effective and that serotonin and noradrenaline reuptake

inhibitors such as duloxetine may be more suitable, while the obsessive-compulsive disorder guideline reports that in older adults they appear to be as effective as in the adult population. Between them they make the flat sentence that these drugs are first-line in the elderly unsafe to write: attach the disorder, and keep the modal verb.

14.8 Deprescribing: stopping as a prescribing act

Why stopping is the harder skill. Every incentive in a consultation favours addition, and stopping a drug someone else started means owning a decision you did not make. **Deprescribing** is defined in Indian guidance as a systematic process of recognising, dose-reducing, stopping or replacing medicines when the risks of continuing outweigh the benefits, judged against this patient's medical morbidity, functioning, values and preferences, its stated aim being not necessarily to stop medications entirely but their judicious use. The same principle appears independently in the current Indian bipolar disorder guideline, among its principles for polypharmacy generally rather than in any geriatric section: periodically reassess the need for multiple agents and taper the non-essential or non-effective ones through careful review of history and shared decision making, which may reduce adverse-effect burden and increase adherence. That statement names no branded framework and attributes its principles to non-Indian work, so a framework name offered as the Indian position would be an invention.

Operationally the guidance answers three questions. *When*: nine triggers are listed, the first numeric, receiving more than five medications, with older age and frailty each counting in their own right alongside multimorbidity, renal impairment, multiple prescribers and transient care, non-adherence, limited life expectancy and dementia. Read the operator: more than five, not five or more, and a threshold for review rather than a permitted maximum. *Which* drug: those with no valid indication, those contributing to the presentation, those generally high risk in the elderly, ineffective ones, preventive drugs in a patient now palliative, and those begun as a **prescribing cascade**, meaning a medication started to treat a side effect of another medication. *How*: stop first the drugs causing or most likely to cause harm and those of most concern to the patient; stop one drug at a time, unless an adverse reaction is suspected or withdrawal risk is minimal, when two or more may go together. Where there is any doubt about stopping abruptly it is safer to taper over weeks to months, the plan being shaped by severity of risk, duration of use with benzodiazepines flagged, dose and half-life, and the likelihood of an adverse withdrawal reaction.

Explicit lists naming drugs as **potentially inappropriate medication** in older adults sit alongside this reasoning rather than replacing it. One such list is the American Geriatrics Society Beers Criteria, whose 2023 update places the non-benzodiazepine benzodiazepine-receptor-agonist hypnotics at Avoid, because their adverse events in older adults resemble those of benzodiazepines, including delirium, falls and fractures, for minimal improvement in sleep latency and duration. Two caveats travel with it: the copy available was a third-party mirror rather than the issuing society's own document, so its strength-of-recommendation labels are not asserted here, and neither an Indian equivalent list nor any other explicit-criteria set is described here: no comparable standard is available to quote, and none is invented here.

14.9 The Indian frame, and what is not available to quote

Indian guidance on prescribing to older adults is explicit and entirely qualitative. The canonical statement is a table of **fifteen** general principles headed by start low and go slow, not one of which carries a number. Among them: mandatory baseline investigations; review of all prescriptions including over-the-counter medicines; review of the anticholinergic load before prescribing; evaluation for sensory deprivation as a determinant of adherence; the simplest possible prescription; identifying who will supervise it; avoiding polypharmacy; the shortest possible duration; and regular monitoring of investigations.

IN INDIA

Two scope facts change how that table is cited. It was written for the emergency setting and states that it can also be applied to elderly patients seen in a consultation-liaison setting, so calling it an outpatient prescribing guideline overstates it. And it is published in the Indian Journal of Psychiatry, the official publication of the Indian Psychiatric Society, which makes it the Indian answer rather than an imported one.

Indian guidelines do name Indian constraints in terms, though none of the examples is specific to older adults. One current guideline records an agent approved abroad for agitation in bipolar disorder as not yet introduced in India, and another states that selective serotonin reuptake inhibitors are preferred first-line for obsessive-compulsive disorder in the Indian context because resources for delivering cognitive behavioural therapy are limited. The second is the Indian formulary argument in miniature: what counts as first-line here is decided partly by what can be delivered here. For the older adult specifically, the facts a prescriber would most want, whether marketed strengths permit a clean halving, whether liquid or dispersible formulations exist, and what any of it costs out of pocket, are not established here and none is invented here.

The last piece of currency is the state of the evidence, which one guideline states without flattery for its own disorder. Specific management strategies for older adults with obsessive-compulsive disorder have not been evaluated; the pharmacological evidence comes primarily from open-label trials and case studies; and because of high rates of physical illness and multiple medications, psychological approaches are often recommended first-line in this age group. That is disorder-specific and must not be lifted into a general claim, but its logic is portable: where the evidence in old age is thin and the risk thick, the threshold for reaching for the prescription pad rises. One caution on currency: the kinetic and dynamic account rests on a review published in 2004, which should be qualified rather than assumed current.

15 · Elder abuse and neglect

Why the marks are here. Elder abuse and neglect is the geriatric topic where a candidate can know the clinical picture well and still lose the question, because what is examined is a sequence of acts: how the possibility is raised, how a history is taken when the person who brought the patient may be the person harming them, which instrument is named, and what the clinician is then obliged to do and on whose authority. The last of those is where most answers collapse,

because they are written by analogy with child protection, and that analogy does not hold in India.

The subject also carries an unusual split in its evidence. The clinical half is largely unlegislated and the legal half is largely unclinical, so the two parts of a complete answer come from different kinds of authority and carry different force. An answer that keeps them apart, and says which is which, is doing precisely what the question tests.

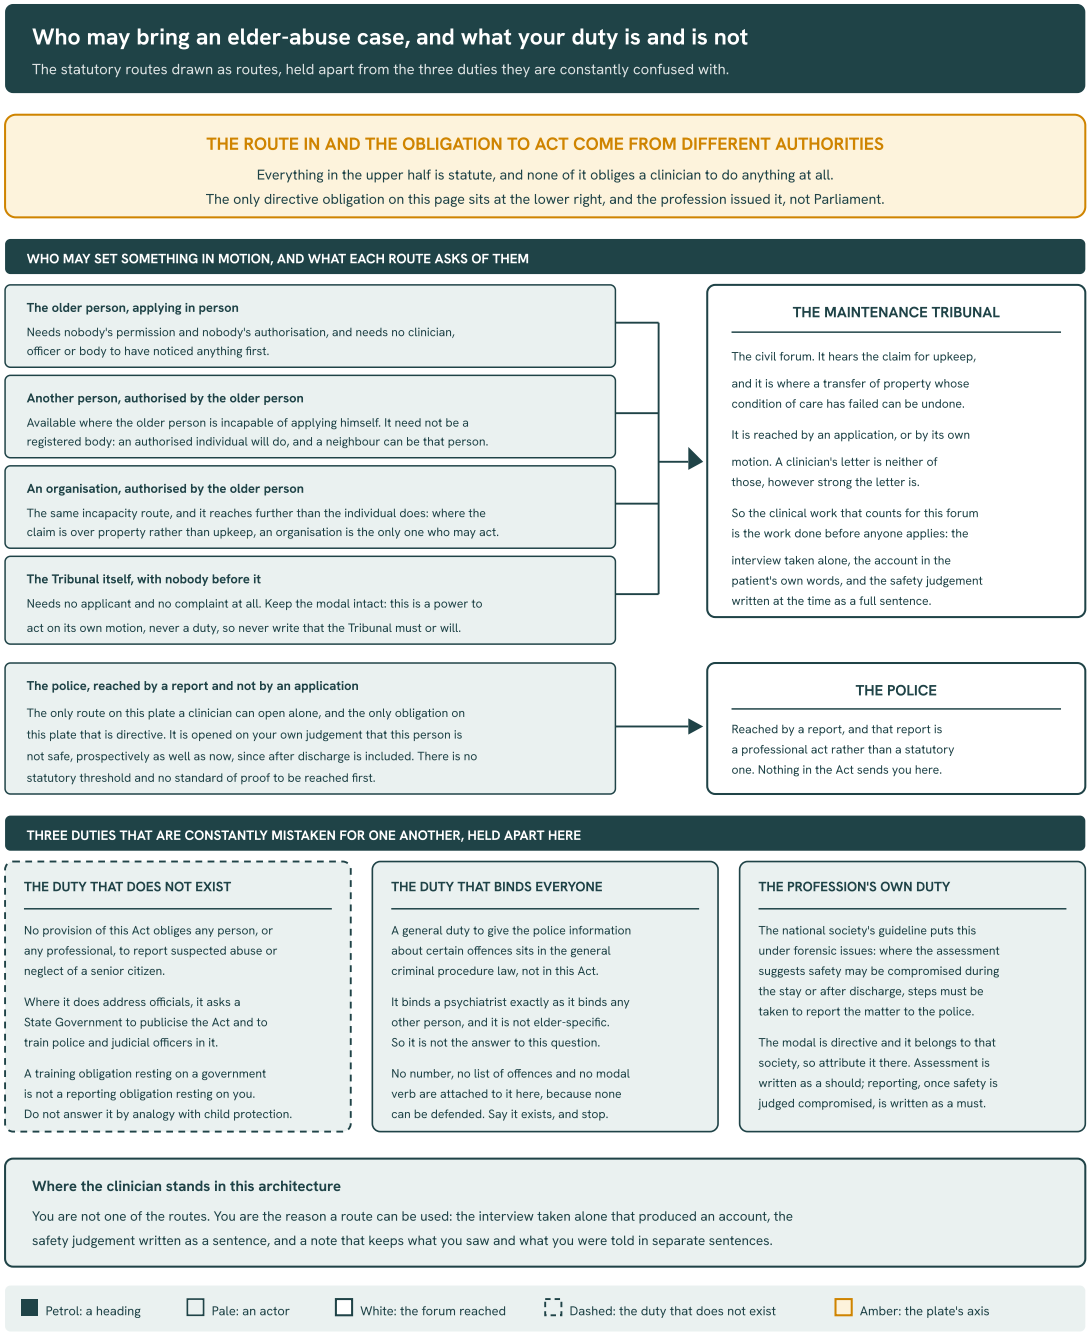

Fig 29.7. Who may set an elder-abuse matter in motion, drawn actor by actor rather than provision by provision: the older person applying in person, an authorised individual where he is incapable, an authorised organisation which alone reaches the property protections, and the Tribunal acting with nobody before it, all converging on the maintenance forum, with the police shown as a separate destination reached by a report rather than by an application, and the three duties that are constantly mistaken for one another set out beneath, the elder-specific reporting duty that does not exist, the general duty that binds every person and is not elder-specific, and the professional obligation whose trigger is the clinician's own judgement that safety is compromised.

15.1 The definition you will be asked for, and what it leaves out

The most quotable Indian definition sits inside a parenthesis in the 2023 clinical practice guideline on older patients presenting with psychiatric emergencies, issued by the Indian Psychiatric Society and published in the Indian Journal of Psychiatry. It treats **elder abuse** as

acts of omission that result in harm, or threatened harm, to the health or welfare of an older person.

Three phrases do the work. Threatened harm sets the threshold at risk rather than damage, so a clinician need not wait for an injury, and an arrangement that has not yet hurt anybody can still meet it. Health or welfare is wider than health alone, and welfare is where loss of money, of a home and of company enter a definition that would otherwise read as a purely medical one. And the harm is defined against the older person rather than against a relationship, so it does not depend on establishing who did it, which matters because attribution is usually the last thing to become clear.

Then say plainly what it does not cover, because a viva will push on exactly that. As printed, the parenthesis captures omission: the things not done. Elder abuse in ordinary clinical use also covers acts of commission, so offering that parenthesis as a complete definition narrows the subject in the act of defining it. Quote it, attribute it to the guideline it comes from, and add that acts of commission are conventionally included. For how common any of this is in India, no comparable standard is available to quote, and none is invented here; estimates move very widely with the definition and the instrument used.

15.2 The forms it takes, and the discrimination each one demands

Categories help only when each is paired with the thing it is actually confused with, and in Indian practice the confusable is rarely another form of abuse. It is a normal feature of family life, or a shortage of money. The grouping below is a working clinical frame rather than a quoted national standard.

FORM	HOW IT REACHES A PSYCHIATRIST	WHAT IT MUST BE DISCRIMINATED FROM
Physical	Injuries of different ages, marks of restraint, a mechanism that does not fit the injury, sedation used to keep someone manageable	Falls, fragile skin and anticoagulation. Not whether the sign is explicable, but whether the explanation is proportionate to it
Psychological	Threats, humiliation, being discussed in the third person while present, isolation from visitors, the telephone taken away	Ordinary family friction. Pattern, an intent to control and the effect on the person separate the two
Financial and material	Pension or bank account operated by another, an abrupt transfer or change of will, a patient who cannot afford drugs in a household that can	Pooled family income, normal in Indian households. Consent and benefit are the tests, not who holds the passbook
Sexual	Very rarely disclosed. May arrive as unexplained genital injury, or as changed behaviour around one particular person	Behavioural change attributed wholesale to a neurocognitive disorder
Neglect	Dehydration, pressure damage, untreated conditions, spectacles or a hearing aid never repaired, appointments missed	Poverty. The test is whether care available to the household is withheld from this member
Abandonment	Left at a hospital, an institution or a public place. Nobody collects the patient once discharge is ready	A genuine collapse of resources, which is a social problem and not an intention
Institutional	In residential care: rigid routines, restraint by drug or by rule, no privacy, no route to complain	Understaffing. Both need action; only one is answered by naming an individual

Two rows carry most of the difficulty in an Indian clinic. Financial control inside a joint household is not by itself abuse, and treating it as such will end the consultation; what makes it abuse is that the older person neither agreed to the arrangement nor benefits from it. And neglect cannot be diagnosed from the standard of care alone, because a household with nothing cannot care well for anyone. What identifies neglect is a gradient inside the household: food, medicine, warmth and attention reaching everybody except the oldest person there.

15.3 Recognition: it does not present as abuse

Nobody arrives complaining of elder abuse and neglect. It arrives as a fall, a confusional episode, weight loss, poor adherence, a request for admission the family is unusually keen on, or a discharge that keeps being deferred. Every one of those has an ageing explanation immediately available, and that is the diagnostic problem: an innocent alternative is always to hand, so the finding is never forced on the clinician and must be looked for.

What can be looked for is discrepancy, better taught as one discipline than as a list of signs. Between the injury and the mechanism described. Between the severity of a problem and the delay before help was sought. Between the family's resources and the patient's condition. Between the account given alone and the account given with relatives present. Between what the carer says the patient can do and what the patient is seen doing on the ward. None of these proves anything; each is a reason to take the history again, separately.

The interaction in the room is itself evidence. Watch who answers, whether the patient looks at the accompanying person before replying, whether that person declines to leave, whether the account becomes fuller once the door closes, and whether the minimising sounds rehearsed. Note too that the direction of harm is not fixed: the carer may be exhausted, unwell and unsupported, and may also be the one being struck, which happens in dementia care and is taken up with the behavioural and psychological symptoms in the Dementias and neurocognitive disorders notes. A formulation that identifies a villain and stops has missed how the household works.

PITFALL

Writing a suspicion into the record as a finding. What was observed and what was alleged belong in different sentences, with the source named for each: the bruise you saw is your observation, the explanation for it is somebody's account. Notes that fuse the two are useless as evidence and unfair to a family that may have done nothing.

15.4 Taking the history: the patient is seen alone

The procedural point that is actually marked. The same national guideline calls this a sensitive matter whose history should be carefully evaluated, and gives one instruction about technique: the patient should be interviewed separately and given time and reassurance to open up. Keep that modal in mind, because it changes later in the same document.

The separate interview carries such weight because this topic inverts the usual value of collateral history. Across geriatric psychiatry the accompanying relative is the safeguard, supplying what the patient cannot; here that same person may be the hazard, and the more dependent the patient, the more completely the account is theirs to shape. Time and reassurance are in the instruction for a reason too: someone who depends on that household for food, medicine and shelter is being asked to put all three at risk, and will not do it inside two minutes of brisk questioning.

Practically, separate the interview for a reason that is not about the family. An examination, a blood pressure, a walk to the ward toilet: any of these routinises the separation without announcing a suspicion to people you may still have to work with. Three things must come out of it.

- The patient's own account, in the patient's own words, of how the injury or the shortage or the arrangement came about.
- Whether the patient feels safe returning to where they came from, asked directly and answered before anyone else re-enters the room.

- What the patient wants done, which is frequently much less than the clinician wants done, and which is recorded even when it will not be followed.

Where cognitive impairment or acute illness prevents an account, the assessment does not stop; its source changes. The questions move to observable care, to informants outside the household, and to what the ward sees over a few nights. Whether the patient can make the decisions that follow is a capacity question, assessed as one, using the approach set out for the general hospital elsewhere in these notes.

> **GOOD TO REMEMBER**
>
> The step that gets skipped is the simplest. At some point in the encounter the patient has been alone with a clinician, and the note says so in as many words. If that sentence is missing, no conclusion about safety at home is defensible, because every account in the record was given in front of the people the question is about.

15.5 The named instrument, and the limits of what it gives you

The same guideline carries a table of suggested rating scales, and against the elder abuse domain it puts the **Caregiver Abuse Screen Evaluation**. The guideline names the instrument and gives nothing else about it: no item count, no cut-off and no validation data, and none are supplied here. Scales as a class, with their construction and psychometrics, belong to the Psychotherapies, clinical assessment, MSE and nosology notes.

Two things follow. The instrument's own title puts the caregiver, and not only the patient, inside the frame of the screen. And the guideline attaches a qualifier to that whole table: the selection of scales is influenced by the diagnosis and by the need of the individual patient. Read alongside the absence of any published threshold, that makes the screen a prompt to ask rather than a test to pass. Naming it earns the mark; treating it as though a score settled the question does not.

15.6 What Indian law does not provide

Here is the finding most answers get wrong. The Maintenance and Welfare of Parents and Senior Citizens Act, **2007**, the central Indian statute on this subject, creates no elder-abuse-specific mandatory reporting duty. It contains no provision of the kind familiar from child protection legislation obliging any person, or any professional, to report suspected abuse or neglect of a senior citizen.

Where the Act does address officials, at section 21, what it asks for is different in kind. The State Government is to ensure wide publicity for the Act, and to ensure that Central and State Government officers, including police officers and members of the judicial service, are given periodic sensitisation and awareness training on the issues relating to it. That is a training obligation resting on a government, not a reporting obligation resting on a clinician, and the distinction is worth having ready.

Scope the negative correctly, because it is easy to overstate. It concerns this Act. It is not the wider claim that no reporting obligation of any kind can reach a doctor in India: a general duty to give the police information about certain offences sits in the general criminal procedure law rather

than in this Act, and binds a psychiatrist as it binds any other person. For the text of that provision, its section number, the closed list of offences it is keyed to and its modal verb, no comparable standard is available to quote, and none is invented here. Say that a general duty exists and is not elder-abuse-specific, and attach no number to it you cannot defend.

RULE **The safeguarding answer for an older person has two halves, and only one of them is law.** The statute supplies remedies and names who may seek them; it does not tell a clinician when to act. Professional guidance supplies the trigger to act and carries no legal force. A complete answer gives both, says which is which, and never lets the modal verb of one migrate into the other.

TRAP **Answering by analogy with child protection.** Candidates have been drilled on a safeguarding architecture in which a named statute imposes a reporting duty on a named professional, with a penalty for failing. Transplanted onto an older person it produces a confident, well-organised answer that is factually wrong, and wrong in the direction that costs most: it invents an obligation and leaves the routes that do exist untaught.

15.7 The obligation that does exist, and where it comes from

The directive half of the answer comes from the profession rather than from Parliament. The 2023 national guideline places elder abuse under a heading of forensic issues, and states that where the assessment suggests the patient's safety may be compromised during the hospital stay or after discharge, appropriate steps must be taken to report the matter to the police to initiate legal action. The modal is directive, and it belongs to the society that issued the guidance. Attribute it there, not to a statute.

Three features repay attention. The trigger is the clinician's own judgement that safety may be compromised, not a statutory threshold and not a standard of proof, so what the note must answer is what made you think this person would not be safe. It is prospective as well as present, since after discharge is expressly included, so the assessment must reach into the household the patient is going back to. And no timeline, form or consequence for not reporting is specified, which cuts both ways: it leaves the judgement with the clinician, and leaves the clinician with nothing but the record to show it was exercised.

Notice the internal grading, examinable in itself. Assessment of abuse is written as a should; reporting to the police, once safety is judged compromised, is written as a must. That is a sensible hierarchy: asking is always appropriate, escalation is reserved for the point at which the answer is that the person is not safe.

IN INDIA

There is no adult protective service to refer to. Two doors exist in practice: the police, where the national guideline points once safety is in doubt, and the maintenance machinery of the senior citizens Act, which handles food, shelter, money and property. That Act is national legislation, assented in December 2007, and as enacted its extent excluded one State; it commences in a State on a date that State Government notifies, so the machinery a patient can reach is state machinery. The respondent is usually the relative who accompanied the patient and will take them home again, which is why the sequence of separate interview, record, safety judgement and only then escalation matters more here than the escalation itself.

15.8 How a case actually starts, when nobody is obliged to report

If there is no reporter, something else must begin the process, and this Act's answer is an application rather than a report. Under section 5(1), an application for maintenance may be made by the senior citizen or parent, or, where he is incapable, by any other person or organisation authorised by him. Read that second route carefully: it is not confined to registered bodies, and an authorised individual will do, though the condition of authorisation attaches to individual and organisation alike.

The widest route needs no applicant at all. The Tribunal may take cognizance **suo motu**, which is the honest answer to the follow-up about what happens when nobody complains. Keep the modal intact: this is a power and not a duty, so the correct sentence is that the Tribunal may act on its own motion, never that it must or will.

Where the Act uses the word **organisation**, the Explanation to that sub-section defines it, for the purposes of that section, as any voluntary association registered under the Societies Registration Act, 1860, or under any other law for the time being in force. Those closing words keep the definition open to bodies registered under other statutes rather than tying it to one register.

5	23	24	25
SECTION OF THE SENIOR CITIZENS MAINTENANCE AND WELFARE ACT SETTING OUT WHO MAY BRING THE APPLICATION	SECTION UNDER WHICH A PROPERTY TRANSFER IS VOIDED WHEN ITS CARE CONDITION FAILS	SECTION OF THAT SAME ACT PENALISING THE ABANDONING OF A SENIOR CITIZEN	SECTION MAKING EVERY OFFENCE UNDER IT COGNIZABLE, BAILABLE AND TRIABLE SUMMARILY

PROVISION	WHAT IT DOES	WHO MAY SET IT IN MOTION
Section 5(1)(a)	Brings the application for maintenance	The senior citizen or parent
Section 5(1)(b)	The same application where the senior citizen is incapable	Any other person or organisation authorised by him
Section 5(1)(c)	Starts the matter with no application before it	The Tribunal, on its own motion
Explanation to section 5(1)	Defines organisation for that section only	Any registered voluntary association, on the terms set out above
Section 23(1)	Voids a property transfer whose condition of care has been broken	The transferor, at whose option the Tribunal declares it void
Section 23(3)	Enforces those property protections where the senior citizen cannot	Organisations only, as defined in that Explanation
Section 24	Makes exposure and abandonment of a senior citizen an offence	Prosecution, on an intention of wholly abandoning
Section 25	Makes every offence under the Act cognizable and bailable, and triable summarily	A Magistrate

One sentence of your answer should carry the structural point. Under this Act there is no report and no reporter; there is an applicant, or a Tribunal acting on its own motion, and the clinician's contribution is to make that application possible and to document what would support it.

15.9 Property, and the provision that does the proving for you

The commonest financial abuse a psychiatrist meets in Indian practice has a specific legal answer. A parent transfers a house or land to a child on the understanding that they will be looked after, and then is not. Section 23(1) provides that where a senior citizen has transferred property after the commencement of the Act, by gift or otherwise, subject to the condition that the transferee provide the basic amenities and basic physical needs of the transferor, and that transferee then refuses or fails to provide them, the transfer is deemed to have been made by fraud or coercion or undue influence, and shall, at the option of the transferor, be declared void by the Tribunal.

Two points are examinable and both are commonly stated backwards. The first is the **deeming provision**: the older person does not have to prove fraud, coercion or undue influence as a matter of fact, because the Act deems it once the condition of care has been broken. That converts an almost unwinnable evidential problem into a simpler factual question about whether basic amenities and basic physical needs were provided. The second is that avoidance is at the transferor's option, so the transfer is not an automatic nullity; it is a right the older person may choose to exercise, and one who wants the relationship more than the property may decline to.

Where the senior citizen cannot enforce those property rights, action may be taken on his behalf by any of the organisations referred to in that Explanation. Set it against the maintenance route and get the difference the right way round: the incapacity route in the earlier section admits an authorised individual as well as a body, while this one admits organisations only and reaches only the property protections. A neighbour who could carry a maintenance application cannot, on this provision, carry the property one.

The psychiatric contribution here is evidential rather than therapeutic. Whether an older person understood a transfer, and whether they were free when they made it, arrive as capacity and undue-influence questions, and a contemporaneous note of the mental state and of the patient's own account is often the only usable evidence years afterwards.

15.10 Abandonment as an offence, and how it is tried

Section 24 carries the Act's penal provision, and its wording is narrow. Whoever, having the care or protection of a senior citizen, leaves that senior citizen in any place with the **intention of wholly abandoning** them is punishable with imprisonment of either description which may extend to **three months**, or with a fine which may extend to **five thousand rupees**, or with both.

The mental element is where answers fail, and they fail predictably. The offence requires an intention of wholly abandoning, so neglect falling short of that intention is not this offence, however grave it is clinically. A family whose care is poor, or whose care keeps failing, has not committed it; a family that leaves a parent at a hospital gate and does not come back has. That gap between what is clinically serious and what is criminally caught is why the professional and civil routes carry most of the weight in practice, and saying so is a better answer than implying the penal section covers the field.

How such an offence is handled sits in section 25, which operates notwithstanding the Code of Criminal Procedure, 1973. Every offence under the Act is **cognizable** and **bailable**, and is tried summarily by a Magistrate. In Indian criminal procedure those words describe a deliberately light route: the police may take the matter up directly, the accused is not held pending trial as a matter of course, and the trial is the short form. For a clinician a report to the police can therefore start something, and what it starts is quick and small rather than grave.

MNEMONIC

Start it, Undo it, Punish it, Try it

The four provisions of the senior citizens Act to be able to place without hesitating. **Start** it: section 5, who may apply, and the Tribunal's own motion. **Undo** it: section 23, the conditional property transfer set aside. **Punish** it: section 24, exposure and abandonment. **Try** it: section 25, cognizable, bailable and summary.

15.11 What the encounter has to leave behind

Because nothing here is triggered by a statutory form, the record is the only durable product of the encounter, and it is what a tribunal, a police officer or a colleague reading months later will work from. Three entries are not negotiable.

- That the patient was interviewed alone, with their own account in their own words.
- The safety judgement as a full sentence, saying what led to it and whether it concerns the admission, the discharge or both, since that judgement is what the obligation to report turns on.
- What was done next: whom you informed, what you told the patient and the family, what the patient wanted, and when the question will be reviewed.

None of that needs a service that does not exist, a statute that has not been passed, or an instrument with a threshold nobody has published. It needs what the whole topic needs: that the possibility was raised deliberately, asked about privately, judged explicitly and written down.

> There is no elder-abuse-specific mandatory reporting duty in the Indian senior citizens Act; the obligation to act is professional, its trigger is your own judgement that safety is compromised, and the statutory route is an application to the Maintenance Tribunal or the Tribunal taking cognizance on its own motion.

16 · Sleep disturbances in the elderly

Why the marks are here. A referral about an older patient's sleep usually arrives with its own answer attached: she is seventy-eight, she sleeps badly, and the age is offered as the explanation. That sentence is where the marks are lost. What is examined here is the reasoning a clinician runs when the complaint is made at seventy-eight: which features of this patient's sleep are the ordinary arithmetic of ageing, which belong to the diseases and the drugs that arrive alongside ageing, whether the complaint is overstated or quietly understated, and what to do about the hypnotic that is often already being taken.

The entity work is done elsewhere. Insomnia disorder and the primary sleep disorders, with their criteria, instruments and drug treatment, are taught in the Eating and sleep-wake disorders notes, and sleep physiology from the neurological side in the Neurology foundations for psychiatrists notes. Sleep disturbance as a feature of a neurodegenerative illness belongs with the Dementias and neurocognitive disorders notes, and a new nocturnal disturbance with fluctuating attention is a delirium question before it is a sleep question, taught with the delirium material in this chapter. What follows is the geriatric lens on sleep disturbances in the elderly: what changes, when it changed, what may be attributed to age, and what each answer obliges you to do at the bedside.

16.1 What changes with age, and when the change actually happened

The standard list names six changes, and it is not closed. Sleep timing advances, nocturnal sleep shortens, daytime naps become more frequent, awakenings within the night become more numerous, the total time spent awake during the night increases, and **slow-wave sleep** is reduced. Candidates reproduce that list and then stop, which is where its clinical value is thrown away, because the same work adds a second finding that reverses the meaning of the first: most of that change occurs between young and middle adulthood, and among healthy older adults the parameters are largely unchanged.

RULE **By the time a patient is old, the age-related change in sleep has mostly already happened.** Ageing rearranges sleep in the middle of life rather than in later life, so a change the patient dates to the last year or two is a change ageing does not account for. This is why "poor sleep at her age" is not a formulation: it invokes a process that had largely finished before the patient reached the age being blamed, and it makes the one informative feature of the history, the date of onset, disappear.

The parameters below are drawn from a 2017 review of sleep in normal ageing in Sleep Medicine Clinics. Read the location column before the direction column, because in the consultation the direction of a change matters far less than where in the lifespan it is located. Three parameters carry a quantified rate. The most quoted, **wake after sleep onset**, matters less for its rate than for its age window.

SLEEP PARAMETER	DIRECTION WITH AGE	WHERE THE CHANGE IS ACTUALLY LOCATED	WHAT THAT MEANS AT SEVENTY-EIGHT
Timing of the sleep period	Advances to earlier hours	Mostly before old age	Early evening sleepiness and early waking, not a new illness
Nocturnal sleep duration	Shortens	Mostly before old age	A short night is not by itself a disorder
Daytime naps	More frequent	Mostly before old age	Ask what the naps are costing the night
Wake after sleep onset	Rises	Quantified from 30 to 60 years, then mostly unchanged after 60	The rate does not reach a patient of seventy-eight
Proportions of NREM stage 1 and stage 2 in nocturnal sleep	Both rise	Not significant among healthy adults above 60	A fragmented hypnogram is not explained by age alone
Proportion of slow-wave sleep	Falls	1.7 per cent per decade in men, and no change with age in women in one cohort	The blanket claim needs a sex qualifier
Proportion of REM sleep	Falls, at 0.6 per cent per decade	From 19 to 75 years, with small increases between 75 and 85	The band that contains seventy-eight is not a band of decline
REM latency	Association with age is minimal	Reported without an age window	A shortened REM latency asks for another explanation

TRAP **Quoting the rate of increase in wake after sleep onset as though it applied to the patient in front of you.** It is the most quotable figure in this field, carrying the largest effect size of any sleep parameter studied, and it is **ten minutes per decade**. The sentence that supplies it also supplies its window, beyond which the parameter is reported as mostly unchanged. Carried forward to a patient of seventy-eight, a mid-life rate becomes an allowance for wakefulness that no measurement supports, and that allowance licenses precisely the reassurance the patient should not be given.

One caution belongs with this table rather than with the disorders. The loss of slow-wave sleep is not uniform between the sexes: one European cohort found no change at all in women against a measurable per-decade fall in men, and the review concludes only that men may be more prone to that decline. It also leaves a tension unresolved, since the meta-analysis it cites has women carrying a greater proportion of slow-wave sleep than age-matched men; levels compared at one age are not rates of change compared across ages, and the two must not be read as one. Knowing that a well-worn one-liner is contested is worth more than reciting it.

16.2 Why the patient is awake before dawn: the circadian account

The commonest presenting complaint in this age group is not difficulty getting to sleep but waking too early, and it has a candidate mechanism that is not a diagnosis. Older people commonly feel sleepy earlier in the evening and wake earlier than they wish. That earlier timing may be due to an age-related **phase advance** in the circadian rhythm, and the hedge is the source's own. The advance is **about one hour** across the markers together, and it is not confined to the sleep-wake cycle. The body temperature rhythm and the timing of melatonin and cortisol secretion are advanced with it, which marks it as a shift in the clock rather than in the bedroom.

Two refinements stop this becoming a lazy explanation for everything. The advance in sleep timing is larger than the advance in the other circadian markers, which is why **sleep homeostasis** is offered as an example of what else may be involved rather than as a settled answer. And overall melatonin secretion falls with ageing, with the nocturnal rise significantly reduced against young adults while daytime melatonin, already at a low base, may be unchanged. Be exact about what that second observation is: a mechanism, not a prescription. The therapeutic use of melatonin is taught in the Eating and sleep-wake disorders notes, and nothing in the physiology above licenses it at the bedside.

This account changes the target. A patient who falls asleep in the early evening and wakes long before dawn has slept a normal quantity at an abnormal hour, so the complaint is about the hour: a problem of timing and of what fills the evening, and not one answered by a drug that shortens sleep latency in a patient whose latency was never the problem.

16.3 Age, or what arrives with age: what the prevalence figures actually attribute

This is where the referral letter is answered, and the answer is an attribution rather than a number. Sleep complaints are genuinely common in later life, and the same literature says the excess does not belong to the age.

About 50%	Up to 50 to 60%	About 67%	About 90%
OF OLDER ADULTS HAVE INSOMNIA SYMPTOMS, A PREVALENCE ATTRIBUTED TO COMORBIDITY RATHER THAN TO AGE	REPORT POOR SLEEP QUALITY, A WIDER CONSTRUCT THAN INSOMNIA SYMPTOMS	OF OLDER ADULTS CARRY MULTIPLE COMORBIDITIES, IN UNITED STATES DATA	OF ADULTS AGED 65 AND OVER TAKE PRESCRIPTION DRUGS, AGAIN IN UNITED STATES DATA

The decisive sentence is the comparison, not the prevalence. Medical and psychological comorbidity is what the review holds responsible for the insomnia-symptom figure, and in older adults in excellent health the prevalence of insomnia is similar to that of younger adults. Age with

nothing else attached does not raise it. The two figures must not be collapsed into one: self-reported poor sleep quality and insomnia symptoms are different constructs, and averaging them loses the distinction.

The same review states in terms that poor sleep quality and sleep disturbance in older people are not necessarily due to ageing alone, even though schedule, quantity and architecture do change with age. What it lists alongside age is, in effect, the history you are obliged to take:

- medical conditions
- psychiatric conditions
- the environment the patient sleeps in
- social engagement and lifestyle change

One boundary keeps this honest: those architecture findings describe adults who are healthy and ageing well, so a frail multimorbid inpatient is not who they were measured in.

16.4 The reporting gap, and it runs in both directions

The consultation has a measurement problem before it has a treatment problem. Older adults are less likely, not more likely, than younger people to report poor sleep, especially once comorbidity and health are controlled for, and one offered explanation is that they may expect less consolidated sleep with age and may accept the change as normal. Set against that, among 150 healthy older adults who reported no sleep problem at all, **33 per cent** of the women and 16 per cent of the men had impaired **objectively measured sleep**.

So the discordance runs two ways, and each direction carries its own error:

- the complaint may be absent while measured sleep is impaired, so an unremarkable history does not establish unremarkable sleep
- the complaint may be understated when it is present, so sleep has to be asked about rather than waited for

Two provisos belong with that pair of proportions. The sample was healthy, selected because it reported no trouble, and not Indian, and the figures reach the review second-hand from work one of its own authors conducted, so they support a direction rather than a rate. The instruction survives both provisos: ask about sleep in the systems review, and do not let a patient's acceptance of her sleep stand as evidence that it is intact. Measured impairment in a patient who has no complaint is not by itself a reason to prescribe.

16.5 The drug chart is part of the sleep history

What this changes at the bedside. Medication burden in this age group is not a footnote to the sleep history, it is a substantial part of it. **More than a third** of older adults who take prescription drugs routinely take over five medications, and multiple medications can produce three separable outcomes: **excessive daytime sleepiness**, worsening of a primary sleep disorder already present, and **comorbid insomnia**. Three problems with three different next steps:

collapsing them into "the tablets are affecting her sleep" throws away the distinction that earns the mark.

The reasoning matters more than the figures, and it is circular. A drug that produces daytime sleepiness produces daytime sleep; daytime sleep shortens the following night; the shortened night is reported as insomnia; and the insomnia is treated with a further drug that produces daytime sleepiness. Somewhere in that loop a clinician has to read the chart rather than the complaint. The figures quoted are United States data, and the population is part of the number: they establish that the burden is large, not what proportion of your clinic carries it.

GOOD TO REMEMBER

Before "should she have something to help her sleep" is even reached, three things belong in the note: the medication list with the time each dose is actually taken, what the patient took last night as against what is prescribed, and how much she slept between waking and the evening. A sleep plan written without those three is a plan written about a night nobody has described.

16.6 The hypnotic that is already being taken

The reflex this topic exists to interrupt is the prescription, and in this age group the harder question is usually not whether to start a hypnotic but what to do about one taken for years. **Deprescribing** in an older person is a planned act rather than a decision taken at the door, and among the things Indian guidance requires such a plan to weigh is the **duration of use**, where benzodiazepines are named as the particular concern. Read that as a statement about which patient is difficult: the long-standing hypnotic is the hard case.

That is why the reflex is wrong twice over. Starting a hypnotic at seventy-eight creates, in one prescription, the patient the guidance warns about, in a person likely to be taking several other drugs and sleeping in the afternoon. And withdrawing one already established is not a matter of stopping it: the order in which drugs come off and how slowly is taught with the geriatric prescribing material in this chapter, while hypnotic doses belong to the Eating and sleep-wake disorders notes. What belongs here is the decision preceding both, that a sleep complaint at this age is an invitation to review the drugs already present before adding one.

IN INDIA

The Indian anchor here is the 2023 clinical practice guideline on the assessment and management of elderly patients presenting with psychiatric emergencies, published in the Indian Journal of Psychiatry, which is where the deprescribing plan and its benzodiazepine flag sit. Notice what it does not supply: no duration beyond which use counts as long, no taper rate, no dose. Since the flag turns on duration, the history must establish it explicitly, including who first prescribed the drug, when, and whether it has been continued from any source other than the prescription in front of you. The prevalence and architecture figures here are Western. For the Indian older population there are no normative polysomnographic values, no prevalence figure for the sleep complaint, no professional standard on sleep in old age, and nothing on whether customary Indian sleep-wake schedules and shared sleeping arrangements alter how the phase advance presents: no comparable standard is available to quote, and none is invented here.

A new sleep complaint at seventy-eight is a symptom to be explained, not an age to be accepted.

17 · Comprehensive geriatric assessment and cognitive screening (MMSE, MoCA, ACE)

Why the marks are here. Comprehensive geriatric assessment and cognitive screening is a question most candidates answer by reciting instruments, which is the smallest and least defensible part of the subject. What is examined is a procedure: which older patients enter it, who carries it out, across which domains, what document it produces, and what obliges anyone to open that document again. A cognitive screen is one line inside one of those domains, and a candidate who reaches for it first has answered a different question.

The instruments themselves belong to other chapters and are named here without being taught. Administration, scoring and interpretation of the Mini-Mental State Examination, the Montreal Cognitive Assessment and the Addenbrooke's Cognitive Examination, with the bedside batteries and formal neuropsychological testing, are taught with the dementia material and with the rating-scale and higher-mental-function material: the Dementias and neurocognitive disorders notes and the Psychotherapies, clinical assessment, MSE and nosology notes. What follows is the assessment they sit inside, which a psychiatrist is more often asked to contribute to than to lead.

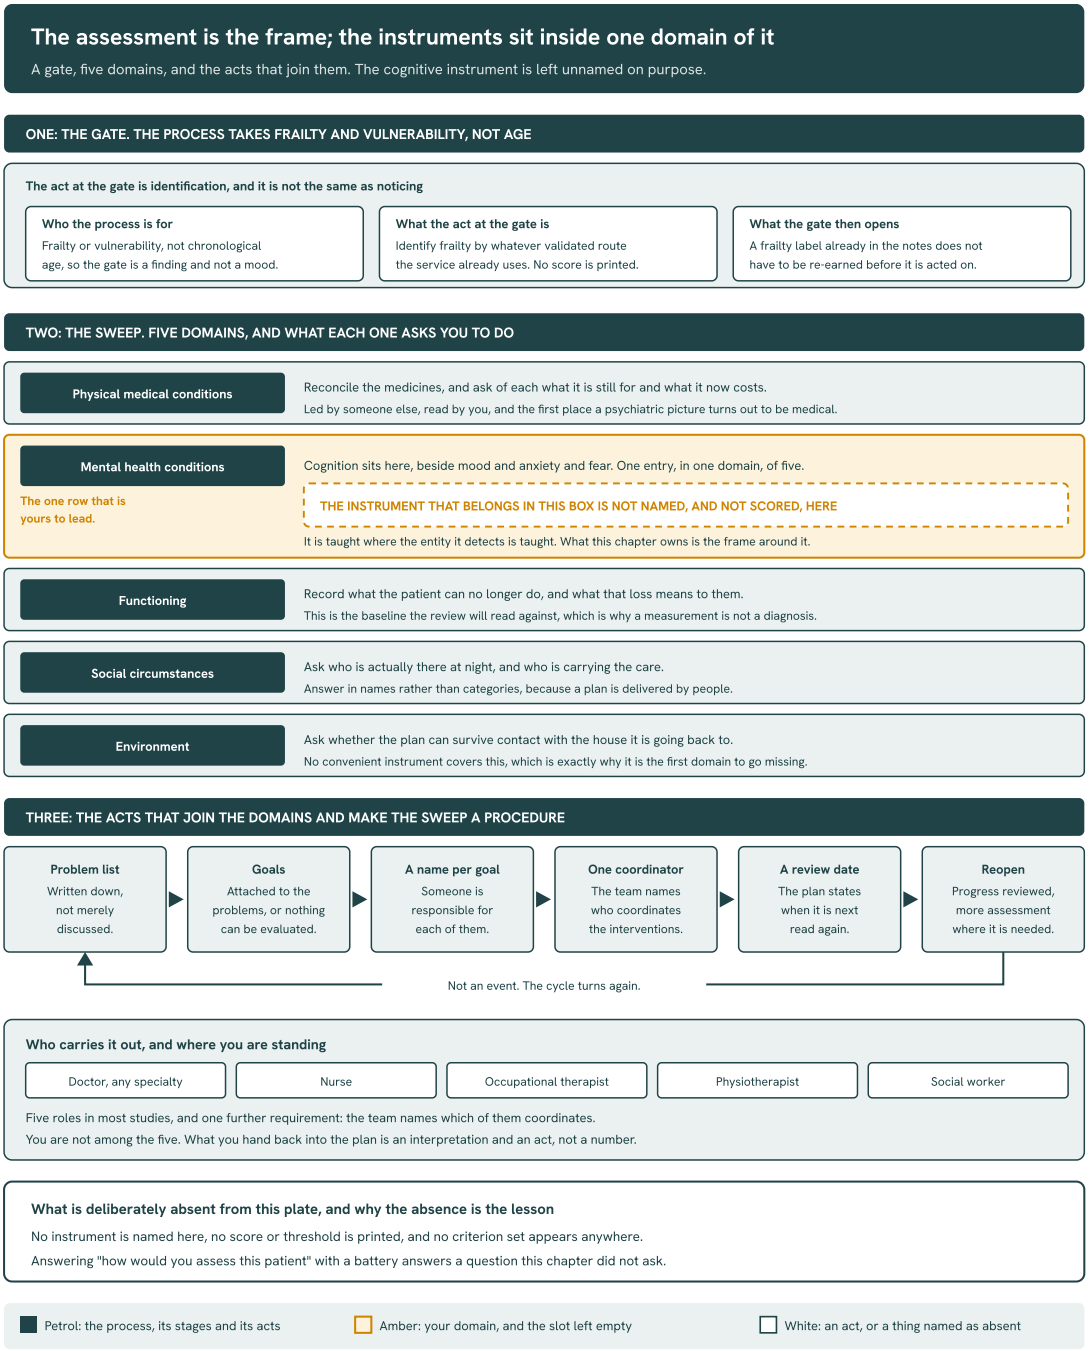

Fig 29.8. The comprehensive geriatric assessment drawn as a frame rather than as a battery: the gate that admits a patient to the process, the five domains swept across it with the act each one asks for rather than the contents each one holds, the chain of joining acts that turns a sweep into a procedure and then returns it to its own beginning, and the team that carries it, with the cognitive instrument shown as one deliberately unnamed and unscored box inside a single domain, because the instrument belongs to another chapter and the frame around it belongs to this one.

17.1 The definition, and the two adjectives that carry it

Comprehensive geriatric assessment is a process used to manage frail or vulnerable older people, and every word of that is load-bearing. A process is not an encounter, so it cannot be finished in an afternoon or written on a proforma. Its target is frailty or vulnerability rather than chronological age, so identifying frailty is the gate and not an incidental finding. And it manages

a patient rather than describing one, so an assessment that ends in a description has stopped short of the definition.

Two adjectives are given explicit meanings in that definition and both are examinable. **Interdisciplinary** means the assessment takes in what nurses and allied health professionals contribute and not only what doctors contribute. **Multidimensional** means it takes in functional impairment and the environmental and social circumstances bearing on wellbeing, and not only medical diagnoses. Candidates routinely use the two as synonyms: one is about who is in the room, the other about what is being asked.

A 2014 article for the non-specialist in the International Journal of Clinical Practice, the source of this definition, is blunt about one misreading. The term is often taken as a synonym for geriatric medicine, and it is not one. Geriatric medicine is a specialty; this is a method, and a method can be run by people who are not geriatricians in settings that have none. The same literature carries an older name for it, **geriatric evaluation and management**, worth recognising when it appears in trial titles.

RULE **A comprehensive geriatric assessment is defined by its product and its cycle, not by its content list.** Any clinician can generate a list of domains. What separates this from a thorough clerking is that it terminates in a written plan with named goals, named responsibility and a review date, and that the plan is then reopened. A candidate who can describe the domains but cannot say what document was produced, who owns it and when it is next read has not understood the procedure.

17.2 What it produces, and why that makes it a procedure

The output is where this topic earns its marks. The assessment generates a **problem list**, develops goal-driven interventions against those problems, and then provides and coordinates an integrated plan spanning treatment, rehabilitation, support and long-term care. Problems first, goals second, coordination last but not optional. A plan naming interventions without the goals they serve cannot be evaluated, and a plan nobody coordinates is a set of separate referrals under one heading.

It is explicitly not a one-off event but an iterative process. A **case manager** carries responsibility for ensuring a care plan exists at all, and that plan must state explicit goals, state who is responsible for each, and state a timeline for review. Progress is then reviewed, further assessment is done where needed, and the cycle turns again. This is what most distinguishes the method from the multidisciplinary meeting a candidate has actually attended, where a great deal is discussed and nothing is owned.

The settings in which it has been studied show it is not confined to a geriatric ward:

- in hospital, where it can start on admission, and where it has been evaluated in emergency departments, medical admissions units and trauma and orthopaedic wards
- in the community, in patients' own homes, in long-term care, in community hospitals and in intermediate care

On outcomes, be careful in the way the evidence requires. Hospital-based assessment of this kind has been reported in systematic review to reduce the combined outcome of death or functional decline, and to raise the chance that a patient is alive and living in their own home rather than in residential care. No effect estimate is printed here. The figures usually quoted reach the reader secondhand through review articles, and the systematic review behind them has been updated since the version those figures came from. Quoting a superseded odds ratio confidently is a worse error than saying the direction of effect is established and the current magnitude must be read at origin.

17.3 The five domains of health, and where a cognitive screen actually sits

The structure of the assessment is set out as domains of health, and the psychiatrist's contribution is confined to part of one of them. That is the answer this item is really asking for, and it is structural rather than psychometric.

5
DOMAINS OF HEALTH ACROSS WHICH A COMPREHENSIVE GERIATRIC ASSESSMENT IS ORGANISED

5
PROFESSIONAL ROLES NAMED AS THE CORE ASSESSMENT TEAM IN MOST STUDIES OF THE METHOD

18
DOMAINS ENUMERATED IN A MULTIFACTORIAL FALLS RISK ASSESSMENT FOR A HIGH-RISK OLDER ADULT

60
AGE IN YEARS FROM WHICH ANNUAL OPPORTUNISTIC FALLS SCREENING IS ADVISED IN LOW- AND MIDDLE-INCOME SETTINGS

DOMAIN	WHAT THE SOURCE PLACES INSIDE IT	WHAT THE PSYCHIATRIST READS OR SUPPLIES
Physical medical conditions	Comorbid conditions and disease severity, medication review, nutritional status, the problem list	The drug chart, and the medical contributions to a psychiatric presentation
Mental health conditions	Cognition, mood and anxiety, fears	The whole of this row, and it is the only row the psychiatrist owns
Functioning	Core functions such as mobility and balance, activities of daily living, life roles important to the patient	What the patient can no longer do, and what that loss means to them
Social circumstances	Social networks, meaning informal support from family, the wider network of friends and contacts, and statutory care; poverty	Who is available at night, and who is bearing the care
Environment	Housing including comfort, facilities and safety; use or potential use of telehealth technology; transport; accessibility to local resources	Whether the plan can survive contact with the home it is going to

Read the second row carefully, because it settles the relationship this item exists to teach. Cognition appears as one entry under mental health conditions, alongside mood and anxiety and

fears. A cognitive screen therefore samples a small fraction of the territory the assessment covers, and a normal screen closes almost none of it.

The same source warns against the opposite error. Standardised scales encourage consistent practice, but they can also be time consuming and clinically constraining. That caution names the failure mode of an instrument-led assessment: the domains with no convenient scale, chiefly the patient's own life roles and the environment they are returning to, quietly drop out.

TRAP **Answering "how would you perform a comprehensive geriatric assessment" with a list of scales.** Candidates make this error because the instruments are the part they have been drilled on. But a battery is not an assessment, and the method is explicitly not the specialty that popularised it. The answer that survives a follow-up names the domains, the team, the problem list and the plan, and places the cognitive screen inside one domain and downstream of the reason for asking.

17.4 Who is in the team, and where the psychiatrist stands in it

The method is by necessity multidisciplinary and cannot be practised by a geriatrician, a nurse or a therapist in isolation. Most studies report a core team of five roles, each with a defined remit: a doctor, who need not be a geriatrician, to ensure medical treatments are given safely; a nurse covering all aspects of care; an occupational therapist for activities, aids and appliances; a physiotherapist focused on transfers and mobility; and a social worker for social support mechanisms and the interventions that follow from them. One further requirement is easy to skip and is exactly what a viva turns on: the team identifies which member is in charge of coordinating the various interventions. Composition varies with the setting, and these five describe a well-resourced health system.

The psychiatrist is not in that list, and this is the teachable point rather than an oversight: on this model the psychiatrist contributes one domain to somebody else's process. Two consequences follow. An opinion asked for inside a geriatric assessment is being asked for cognition, mood, anxiety or fear, so it should be returned in a form the plan can use, meaning an interpretation and a recommended action rather than a score. And the occupational therapist's account of activities and the physiotherapist's account of transfers usually hold the functional evidence a psychiatrist needs; ignoring them repeats work already done better.

17.5 Measuring function: the instruments that are actually yours to use

What this changes at the bedside. The functional domain, unlike the cognitive one, has instruments a psychiatrist is expected to name and use without trespassing. Indian guidance on assessing older patients presenting with psychiatric emergencies, published in the Indian Journal of Psychiatry in 2023, names them by purpose: the **Katz Index of Independence in Activities of Daily Living** for basic activities of daily living, the **Lawton Instrumental Activities of Daily Living Scale** for instrumental activities, and a Frailty Index for frailty. The same guidance makes the wider point that structured scales apply not only to the mental state but to the history and the physical examination.

What is grounded is the mapping of instrument to purpose and nothing more: no item content, no scoring method and no cut-off for these three instruments is available to quote, and none is supplied from memory. That matters less than it looks: the mark is usually for choosing the right instrument for the right question, not for reciting its items.

One boundary needs stating plainly, because instrumental activities are used in two different ways. As a diagnostic hinge, the point at which a person needs help with complex instrumental tasks marks the step from a milder to a major neurocognitive disorder, and that use belongs to the Dementias and neurocognitive disorders notes. Inside this assessment the same construct is a measurement step: it establishes where the patient currently sits, so the plan has a baseline and the review has something to compare against. Treating the measurement as the diagnosis is the commonest way a functional assessment gets misreported.

17.6 Frailty: the entry criterion, defined and then scored

Since the assessment targets frail or vulnerable older people, frailty is the entry criterion and needs a definition rather than an impression. Indian guidance defines **frailty** as a biological syndrome characterised by lower reserve and lower resistance to stress, arising from cumulative functional decline across multiple physiological systems and leading to vulnerability to adverse outcomes. Two things repay attention. It is a syndrome of reserve, so the frail patient is not necessarily the sick patient but the one with nothing left over when something goes wrong; and it is multisystem by definition, so no single organ measurement identifies it. The same source names its consequences: frailty is associated with falls, hospitalisation and mortality.

Its characteristic features are unintentional weight loss, impaired grip strength, self-reported exhaustion, slow walking speed and reduced physical activity. The 2022 World guidelines for falls prevention and management for older adults, published in Age and Ageing, describe the same five as a frailty phenotype and attach a scoring rule: **three or more** of the five categorises a person as frail, one or two as prefrail, and none as not frail. That an Indian and a global guideline converge on the same five is worth knowing; neither text read here attributes them to a named author, so no eponym is attached to them.

MNEMONIC

Slow, Weak, Thin, Tired, Still

The five phenotype criteria as they present: **slow** walking speed, **weak** grip or muscle weakness, **thin** from unintentional weight loss, **tired** from self-reported exhaustion, **still** from low physical activity. Count them rather than impressing them: the count carries the threshold.

The alternative in routine use is the Clinical Frailty Scale, a semi-quantitative scale with pictograms running from very fit at one end to terminally ill at the other, on which a score of **4 or above** is considered frail. For risk stratification the falls guideline accepts either previously identified frailty or a positive result on a validated instrument used to detect it, a permission worth having: a frailty label already in the notes does not have to be re-earned before it can be acted on.

17.7 Falls: the single question, the definitions, and the triage before the assessment

Falls enter the assessment through one question, and the reason is a measurement problem rather than a clinical one. Falls are often not reported spontaneously, which is why asking about them routinely is a strong recommendation at GRADE 1A. Older adults in contact with healthcare for any reason should be asked at least once a year about a fall in the last 12 months, and about the frequency, characteristics, context, severity and consequences of any fall; conditionally, also about dizziness, loss of consciousness or disturbance of gait or balance, and about concerns regarding falling that limit usual activities. The asymmetry is examinable: asking at all is a strong recommendation, while the detail of what to ask carries only GRADE E, the expert-recommendation tier. Anyone answering yes should be offered an objective assessment of gait and balance, again at GRADE 1A.

Four definitions give that history a denominator. A fall is an unexpected event in which a person comes to rest on the ground, floor or a lower level. **Recurrent falls** means **two or more** falls reported in the previous 12 months. A severe fall is one with injuries needing a physician consultation, or leaving the person on the ground unable to get up for at least an hour, or prompting an emergency visit, or associated with loss of consciousness. An unexplained fall is one where a multifactorial risk assessment finds no apparent cause. Without these, "she has had a few falls" is an unusable history.

The objective test that follows carries the two printable numbers of this topic. Assessment of gait and balance is recommended at GRADE 1B. For stratification the guideline recommends gait speed, with a cut-off of **below 0.8 m/s**, at GRADE 1A, chosen for predictive ability and simplicity and measured over a 4-metre walking length. The Timed Up and Go test is the stated alternative, with a cut-off of **more than 15 seconds** at GRADE 1B, and the guideline says in the same breath that evidence for its use in fall risk stratification is mixed. Quote that cut-off with the qualification attached or not at all.

What those tests feed is a triage, not an assessment. Low risk is an older adult with no history of falling, or a single non-severe fall and no gait or balance problem; the response is education about falls prevention and exercise with annual reassessment, on the explicit ground that low risk does not mean no risk at all. Intermediate risk is a single non-severe fall together with gait or balance problems, answered by strength and balance exercise or physiotherapy referral. High risk is a fall plus any of five features: accompanying injury, two or more falls in the previous 12 months, known frailty, inability to get up unaided for at least an hour, or suspected transient loss of consciousness. Only the high-risk tier is offered the full multifactorial assessment, and suspicion of a syncopal fall triggers syncope evaluation and management instead.

GOOD TO REMEMBER

Before an older patient leaves any clinical encounter, one question and its answer belong in the note: has there been a fall in the last 12 months. It costs nothing, it is a strong recommendation, and it is the only step here a solo psychiatrist without a team can complete unaided. If the answer is yes, the obligation that follows is equally single: an objective look at gait and balance, before any conclusion about why the patient fell.

17.8 Inside the multifactorial assessment, and why its components are not equal

The **multifactorial falls risk assessment** is offered to community-dwelling older adults identified as high risk, as a multiprofessional assessment intended to guide tailored interventions, at GRADE 1B. Its domains are enumerated in a single sentence, and the list is long: gait and balance; muscle strength; medications; cardiovascular disorders including orthostatic hypotension; dizziness; functional ability and walking aids; vision and hearing; musculoskeletal disorders; foot problems and footwear; neurocognitive disorders, glossed as including delirium, depression, dementia and behavioural issues such as impulsiveness and agitation; neurological disorders; underlying acute and chronic disease; concerns about falling; environmental hazards; nutritional status including protein intake and vitamin D; alcohol consumption; urinary incontinence; and pain.

The most important sentence here is the disclaimer following that list: the strength of the evidence differs per component. The grade attaches to the recommendation to offer the assessment, not to each domain, and reading the enumeration as a set of equally strong recommendations misstates the source. The component recommendations span the full width of the grading scheme.

COMPONENT	WHAT THE GUIDELINE ASKS TO BE DONE	GRADE OF THAT COMPONENT'S OWN RECOMMENDATION
Concerns about falling	Use a standardised instrument	1A
Gait and balance	Assess; use gait speed for stratification	1B for assessment, with the stratifying cut-off at 1A
Cognition	Assess as a component of the falls workup	1B
Cardiovascular	Cardiac history, auscultation, lying and standing orthostatic blood pressure, and a surface electrocardiogram	1B
Environmental hazards	Identify the hazards where the person lives and assess their capacities and behaviours in relation to those hazards, by a clinician trained to do it	1B
Fall-risk-increasing drugs	Use a validated tool	1C

COMPONENT	WHAT THE GUIDELINE ASKS TO BE DONE	GRADE OF THAT COMPONENT'S OWN RECOMMENDATION
Vision, and hearing separately	Enquire about impairment, measure visual acuity, examine for hemianopia and neglect where appropriate; enquire about hearing, measure, examine and refer where appropriate	E
Urinary symptoms and incontinence	Enquire, with no instrument, threshold or referral trigger specified	E
Dizziness, pain, depression and nutrition	Assess, each under its own component recommendation	E
Footwear and environment in low- and middle-income settings	Prioritise these as risk factors; screen for inappropriate footwear including bare-footedness, assess foot problems, consider podiatry referral	2C, a conditional recommendation

Two things follow that a careful candidate can use. Vision, hearing, dizziness, urinary symptoms, pain, depression and nutrition rest on expert recommendation rather than trial evidence, so presenting them as strongly evidenced is wrong about the source even when it is right about the practice. And the cardiovascular component, where an unexplained fall most often turns out to have its answer, is not merely a blood pressure reading: if the initial cardiovascular assessment is normal no further cardiovascular assessment is required unless syncope is suspected, and further assessment of an unexplained fall should be the same as for syncope, at GRADE 1A.

Bone health is the one thing candidates expect here and do not find, and its absence is deliberate. The guideline states that managing fall-related injury is beyond its scope and treats bone health as a separate, reciprocal assessment: adults with low-trauma fractures or osteoporosis should have a falls risk assessment, and conversely those at moderate to high falls risk should have a bone health assessment using local protocols. The named fracture-risk tools are FRAX, Garvan and QFracture, with bone densitometry to confirm osteoporosis. So do not list bone health as a domain of the multifactorial assessment, and attach no grade to that reciprocal pairing, which is given as justification and not as a graded recommendation.

Falls work is joined to the wider assessment explicitly. The falls guideline describes its own product as identifying and measuring risk factors across multiple domains to indicate potentially modifiable areas for intervention, and states that this combines with the other components of a comprehensive geriatric assessment to enable a person-centred approach, while declining to cover the rest of that assessment. It also supplies the sentence that makes falls a psychiatric concern rather than an orthopaedic one: a fall in an older adult, particularly one living with frailty, should be treated as a warning sign of potentially unidentified underlying conditions, and may be the presenting feature of an acute medical illness.

17.9 The Indian and low-resource reading, and what is missing from it

Two of these sources speak directly to practice in a resource-constrained system. The falls guideline carries recommendations written for low- and middle-income countries, a class that includes India on the classification the guideline itself uses. Community-dwelling adults aged 60 years and over should be screened opportunistically for fall risk during any clinical encounter, at least once a year, by asking about falls in the past 12 months, and a strong recommendation at GRADE 1B requires local context to be considered when falls-prevention programmes are implemented in such settings. Alongside it sits the conditional recommendation at GRADE 2C to prioritise cognitive impairment, obesity including sarcopenic obesity, diabetes, lack of appropriate footwear and environmental hazards as risk factors. Footwear is the component most directly transferable to an Indian clinic, and the guideline's own word for the exposure, bare-footedness, is the one to carry; it also notes that footwear practices and environmental safety differ culturally and that assessment and education should account for that difference.

The Indian guidance contributes the history rather than the triage, and the two are complementary rather than competing. When an older patient presents with a fall, it asks for the place of the fall, the activity the patient was engaged in, the type of fall, and symptoms such as dizziness, fainting and weakness on change of posture. It also names who is predisposed: older people who need mobility aids to walk, who take sedative medication, or who take drugs that can produce a postural fall in blood pressure, with substance intoxication and psychotropic-induced postural hypotension named alongside. That last clause is the uncomfortable one, because the prescriber of the drug producing the postural drop is frequently the person taking the falls history.

IN INDIA

The assessment process, its team and its falls component are taught above from a 2014 explanatory article in a British journal and a 2022 global consensus guideline. The Indian contribution is the 2023 clinical practice guidance in the Indian Journal of Psychiatry, supplying the falls history, the frailty definition and the functional instruments, plus the global guideline's low- and middle-income-country recommendations, which are internationally recommended practice applicable to Indian settings and are not an Indian standard. For an Indian national statement that this assessment is expected practice, for an Indian multidisciplinary staffing norm, and for an Indian falls-screening cadence, no comparable standard is available to quote, and none is invented here. Say that in a viva rather than inventing a programme requirement.

The practical consequence is for the ward rather than the examination. Where the five-role team does not exist, the method does not become unavailable; the division of labour does. The domains still have to be covered, the problem list written, someone named as coordinating it, and the plan given a review date. A clinician running the process alone is doing something harder than the model describes, not something different, and the first thing to slip is the review, which is the feature the definition insists on.

A comprehensive geriatric assessment is a process with a named coordinator, a written goal-driven plan and a review date; the cognitive screen is one line inside one of its domains.

The late-life presentations

18 · Dementia in the elderly (overview, behavioural and psychological symptoms)

Why the bracket is the instruction. The heading is set as dementia in the elderly (overview, behavioural and psychological symptoms), and a candidate who reads it as a request for an account of the disease has read past the only unusual part of it. What the condition is, how it is classified, how it is investigated and staged, and what is prescribed for it and for the behavioural disturbance belong to the Dementias and neurocognitive disorders notes, which carry all of it, the work with families included. A compressed second version of an account that exists in full is a rival, not a summary, so none of it is repeated here.

What is left over is what these notes owe. Most headings in psychiatry name something a patient is referred for; this one names something a patient usually already has when they are referred for something else, and that difference organises everything below.

18.1 Where the condition sits once the question is about later life

These notes are built around who is asking, in whose ward, and what changes when the patient is old. Read that way, this is seldom the question asked and almost always the **background condition** it is asked against. The acute confusion arriving on a brain already changing is taken up where delirium in later life is dealt with here; the flat, slowed presentation read as decline, and the decline read as depression, where late-onset depression and the depressive presentation that mimics it are dealt with. The suspiciousness in a person living alone, the prescribing decision for a patient who cannot report an adverse effect, the nocturnal disturbance that is an evening behavioural pattern, and the neglect unreported because the only witness cannot describe it each have their own place here. In every one the answer moves when this condition is in the background, and that is why the subject belongs here at all.

RULE **Treat it as the context of the consultation, not as its subject.** A geriatric station rarely opens with a request to diagnose the condition; it opens with a behaviour, a family, a fall, a drug or a crisis, in a person who has it. A candidate who begins by establishing the diagnosis is answering a question settled before anyone was called, and runs out of time before the one that was not.

18.2 What actually generates the consultation

Who decides that today is the day. The **referral threshold** is set by what the household can absorb, not by how impaired the patient is. People equally affected reach a clinic years apart, one living with a daughter who has given up paid work, the other with a spouse who is himself unwell. The corollary is examinable: a referral carries as much information about **carer capacity** as about the patient's brain, and a request arriving abruptly after years of stability usually records a change in the household rather than in the illness.

So why now is answered by asking about the house, and answering it badly is why a consultation yields a prescription and no plan. Establish these before the cognitive examination, not after:

- what changed recently, in the patient, in the household or on the drug chart, and in what order;
- who is present by day, who is present at night, and who has lately stopped being present;
- which behaviour the household has decided it cannot absorb, in their own words rather than as a symptom list.

IN INDIA

The family is the service. Most districts have no old-age psychiatric provision to refer on to, so the request reaches a general psychiatrist and the plan must be one the household can run. **Diagnostic delay** is built in: presentation comes by way of a crisis, a wandering episode or a bodily complaint rather than a memory complaint, because forgetfulness in an old person is heard as ordinary and the diagnostic word carries the weight of madness in everyday speech. Neither the provision nor the delay is given a figure here: no comparable standard is available to quote, and none is invented here. That inverts **disclosure**, which is asked for upward, to relatives, before the person it concerns, and families often ask that nothing be named at all; how that conversation is conducted is taken up where breaking bad news is dealt with in these notes. The work is usually done unpaid by a woman in the same house, so asking what the household can sustain is an enquiry into her, and it is where the protection question first appears, dealt with where elder abuse and neglect are taken up.

18.3 Where each part of the subject is taught

A reader wanting the disease is sent, not served a thinner copy, including the **behavioural and psychological symptoms** in the bracket, whose description and pharmacology are the owner's.

WHAT IS BEING ASKED FOR	WHERE THE FULL ACCOUNT SITS	WHAT THESE NOTES ADD
Definition, criteria, subtypes, investigation, staging, and the behavioural symptoms with their pharmacology	**the Dementias and neurocognitive disorders notes**	Nothing but the reason the referral came when it did
Cognitive instruments and neuropsychological testing	**the Psychotherapies, clinical assessment, MSE and nosology notes**	The assessment they sit inside, taken up with geriatric assessment here
Telling it from an acute confusional state	**the Stroke, TBI, delirium and focal brain syndromes notes**	What ageing contributes, taken up with delirium in later life
Telling it from a depressive presentation	**the Mood disorders: pharmacotherapy notes**	The discrimination as examined, with the depressive mimic here

18.4 How the heading is asked

Set as a short note it wants breadth held briefly, and the marks go missing when a candidate spends the answer on classification and never reaches the bracket. Set as a long case or a viva it is

never asked alone: it arrives attached to an old patient with a behaviour, and the condition is the frame the case is read through rather than the thing to be diagnosed. Either way:

- name the condition and where its account belongs, in a sentence, without lingering;
- say what its presence changes about the question actually asked;
- finish on **the pending decision** and on who carries it.

TRAP **Examining the patient thoroughly and never examining the household.** Candidates make it because the patient is in front of them, the cognitive examination is rehearsed and scoreable, and the family is treated as a source of history rather than as a subject of assessment. The result is an immaculate account of impairment that explains none of the timing, and a plan that could have been written before the patient arrived.

Context, not subject	The household, not the stage	Named and handed on
WHAT THE CONDITION IS IN A CONSULTATION FRAMED BY THE ENCOUNTER	WHAT DECIDES WHEN THE REFERRAL IS ACTUALLY MADE	WHAT THESE NOTES DO WITH THE ENTITY ITSELF

Dementia enters here as the condition an older patient already has when the consultation is called: the entity, its criteria, its instruments and its drugs are read in the Dementias and neurocognitive disorders notes, and what is answered here is why the referral came now, what changes because it is there, and who decides.

19 · Late-onset depression and its features

Why it matters clinically. An older patient with depression is a common presentation and the syndrome is well described, so the marks here are not for describing it. They are for the question that follows: is this the first time in this person's life it has happened, and if it is, what does that oblige you to do that a recurrence would not? The syndrome, its criteria, the screening instruments and their scoring, and the agent-by-agent geriatric prescribing caveats are set out in the Mood disorders: pharmacotherapy notes. What is taken up here is the part candidates skip: onset.

19.1 Onset, not age, is the variable

Two patients of the same age sit in the same clinic with the same complaints. One has had episodes since her twenties and is having another. The other has never been depressed in his life and is depressed now. They may be indistinguishable on the mental state examination, and only the history separates them. **Late-onset depression** means a first episode arising in later life; a long-standing illness whose current episode merely falls in later life is **early-onset recurrent depression** in an older person, a different clinical problem wearing the same face. What makes late-onset depression and its features examinable is not the symptom list but the fact that the timing of the first episode changes the workup, what the family is told, and what follow-up is for.

The age at which an episode counts as late-onset is a matter of convention and the conventions differ: no cut-off is available to quote here, and none is invented. Nothing below depends on a

number, only on whether an episode has happened before, which is a historical fact rather than a threshold.

RULE **Establish whether this is a first episode before you decide anything else about the case.** Onset is not a descriptive detail collected for completeness. It is the variable on which the direction of the assessment, the weight given to the medical enquiry, what the family is told about recovery and the content of follow-up all turn. Every later decision inherits the answer, so an onset settled late is settled after the plan was written.

WHAT IS BEING DECIDED	FIRST EPISODE, ARISING NOW	OLD ILLNESS, RECURRING NOW
What the history must establish	That no earlier episode occurred at any age, checked with someone who knew the patient young	When the episodes fell, what was given, and how well the patient was between them
Where the diagnostic effort goes	Into why this brain and body have produced the syndrome now, never having done so before	Into why it has recurred, and what was lost from whatever had been holding it
What the family is asked for	The patient as they were decades ago, which nobody has asked them to describe	The pattern they have already watched, usually given in a sentence
What the treatment decision rests on	Published guidance and physiology, there being no record of what worked	The agent and dose that produced remission before, if tolerability allows
What follow-up is for	Resolving the question the first episode raised, which the treatment response does not	Preventing the next recurrence of an illness whose course is known

TRAP **Recording a first episode on the patient's word alone.** Candidates make this error because the patient is often the only informant in the room and answers confidently. An episode decades earlier that was never named as an illness, that a physician treated as weakness or a stomach complaint, or that was simply endured at home, leaves no record and no memory the patient recognises as psychiatric. Everything above rests on that one fact, which makes it worth a telephone call to a sibling or an old neighbour, and the note should say who supplied it.

19.2 The presentation that misleads, and who it misleads

Why the mask works better the first time. That older patients present with bodily and cognitive complaints rather than with a complaint of sadness, and the rule of recognition built on it, belong to the Mood disorders: pharmacotherapy notes. What onset adds is why the same mask defeats everybody in a first episode and almost nobody in a recurrence. In a long-standing illness the family has watched this before; they often make the diagnosis themselves and say so in the first minute. In a first episode nobody has seen them like this, so nobody holds a template, and everyone in the room has a non-psychiatric explanation that fits the facts: the physical illness that began around the same time, a bereavement, a move into a child's household, the end of working life, or simply age. The patient offers one first, because it is the only account they have, and the presentation is filed under the explanation rather than examined.

This is why the referral, when it comes, arrives from a physician rather than the family, often after an investigation for weight loss, pain, giddiness or forgetfulness returned nothing. Read that sequence as information: the complaints were taken seriously by someone competent and were not explained, and the illness is older than the date on the letter.

An **informant history** settles onset, and a general enquiry about past psychiatric illness will not get it, because the informant is being asked about labels when what you need is behaviour. Ask instead:

- whether there was ever a stretch of adult life, however explained then, when the patient stopped working, stopped going out or stayed in bed for weeks;
- whether they were taken to a doctor for sleep, nerves, weakness or a stomach nobody could account for, and what was given;
- whether anything of the kind followed a childbirth, a bereavement or a surgical illness decades ago;
- what the patient was like as a young adult, since a first episode is measured against a person and not a norm.

19.3 Why a first episode reframes the assessment

A syndrome that has never occurred across a long life and occurs now is, on its face, a statement that something is different now. That does not make the depression secondary to anything, and it does not license leaving the mood alone while the physicians work. It changes where the diagnostic effort goes, and when. In a recurrent illness the medical and drug review is a safety check run alongside treatment; in an **index episode** it is the main line of the assessment, done now rather than after an antidepressant has failed, because a contribution found late has cost the patient a trial.

The mimics, the drugs that lower mood and the investigations that exclude them sit in the Mood disorders: pharmacotherapy notes, and systemic and neurological contributions in the Neuropsychiatry of systemic and neurological disease notes. Two asymmetries belong here. A positive finding does not close the case: an untreated endocrine abnormality or a recently started drug may contribute to an episode without accounting for it, so the mood disorder is still treated on its own terms. A negative panel does not close it either, because the contribution that matters most here may be cerebral rather than systemic, and nothing routine reports on it.

19.4 The vascular contribution as a question about substrate

The proposal that cerebrovascular disease predisposes to, precipitates or perpetuates some late-life depressive syndromes, the phenotype that goes with it and the treatment expectations that follow all belong to the Mood disorders: pharmacotherapy notes; cerebrovascular disease itself to the Stroke, TBI, delirium and focal brain syndromes notes. **Vascular depression** is named at this address for one reason: it is an argument about onset and not about age, and the two are routinely conflated.

Consider the same finding in two patients. In a woman depressed since her twenties, cerebrovascular disease and long-standing hypertension found now are comorbidity: real, worth treating, and no explanation of an illness that predates them by decades. In a man depressed for the first time in old age the identical findings are a candidate explanation. The difference lies wholly in the history, which is why a substrate hypothesis is never raised or dismissed from a scan report.

Treating that hypothesis as live has three consequences, and each is an act rather than a conclusion:

- vascular risk factors become part of the psychiatric plan rather than another team's business, because you are the one who has just made them relevant to the mood;
- what the family is told about the shape of recovery is worded carefully, since a slower or more partial course is possible and neither promising nor excluding it is defensible;
- the cognitive picture is reviewed once the mood has moved rather than settled during the episode, because the treatment response alone does not answer the question the first episode raised.

The opposite error shadows all of this. Executive slowing and poor test performance get read as an early degenerative process, the mood is treated half-heartedly, and the patient is followed as a dementia. Telling those apart is taken up where pseudodementia and dementia are compared in these notes. What belongs here is that a first episode is where both mistakes are available at once, because no earlier episode exists to argue against either.

19.5 The frailty-aware decision, and a position that has moved

In a first late-life episode the treatment decision is made without the information that usually makes it easy. In a recurrent illness the agent that produced remission before, and the dose at which it did so, are most of the plan. Here there is no such record, so the decision rests on published guidance and this patient's physiology alone.

The Indian clinical practice guideline for the assessment and management of depression, published in the Indian Journal of Psychiatry in January 2026, gives the older patient a rule of its own and attaches a quantity to it: a low start, slow titration, and a dose usually **half** the adult figure at the start and at the intended destination alike, with hyponatraemia and falls named as what to monitor. The rate, the endpoint and that monitoring are worked through where the principles of psychopharmacology in the elderly are set out in these notes. What belongs here is what a moved destination does to the judgement of a trial in a patient with no treatment history.

It does this. A patient sitting at a reduced **target dose** who has not improved, and a patient quietly under-treated out of caution, generate identical entries in a record, and the next clinician cannot tell a deliberate ceiling from an abandoned titration. The remedy is administrative: before titration starts, write down the dose you intend to reach and the date the trial will be judged. That is the only way a failed trial is later told apart from an untried one.

IN INDIA

The same guideline also states that age influences the choice of agent, and here the expected answer is no longer the safe one. In older adults an SSRI may be less effective, and an SNRI such as duloxetine may be more suitable. Both clauses are hedged and the hedge is the content: this is not an instruction to prefer an SNRI in older patients, and an answer that converts it into one asserts what the guideline declined to assert. An earlier Indian position places the SSRIs first-line in late-life depression with a reduced start and slow titration, and is recorded in the Mood disorders: pharmacotherapy notes. Both are set out here and neither is adjudicated: whether the later document displaces the earlier or simply differs from it is not established, the earlier document is not examined at this address, and no supersession is asserted. State both, name the hedge, then say which you would follow for this patient and why.

GOOD TO REMEMBER

Three lines in the record of a first depressive episode in an older patient do more work than the rest: that this is a first episode, and who established it; that a medical, drug and cerebral contribution was considered, what was done and what came back; and the dose you intend to reach, with the date you will judge the trial. The third is routinely left out, and without it nobody reading the file afterwards, including you, can tell a cautious plan from an abandoned one.

19.6 What this section decides, and what it hands on

Two boundaries were not named above. The structured functional and frailty workup this reasoning sits inside belongs where the comprehensive geriatric assessment is dealt with in these notes, and formal risk assessment in the Somatic-symptom, sexual, impulse-control disorders and suicide notes. Everything else routed above stays routed: nothing here describes the syndrome, scores an instrument or names a milligram.

What is left is the reasoning, and it runs in one direction. An examiner presenting an older patient with depression is testing whether you settle onset first and from whom; what a first episode obliges you to look for that a recurrence does not, and why that enquiry precedes the trial; whether you grasp that a substrate question changes the follow-up and not merely the workup; and whether you can state the current Indian dose position and its hedged statement on agent choice without over-reading either. Answer from onset to substrate to dose to follow-up, and the description of the syndrome becomes the least of what you say.

Onset before anything else

WHETHER THIS IS A FIRST EPISODE IS A HISTORICAL FACT TAKEN FROM AN INFORMANT, NOT A JUDGEMENT MADE FROM THE MENTAL STATE

A first episode is a question

A SYNDROME NEVER SEEN BEFORE IN A LONG LIFE ASKS WHY NOW, AND THE MEDICAL, DRUG AND CEREBRAL ENQUIRY ANSWERS THAT

The ground has moved

THE CURRENT INDIAN DEPRESSION GUIDELINE HEDGES RATHER THAN ASSERTS THE CHOICE OF AGENT IN OLDER ADULTS

In an older patient with depression, settle first whether this is the first episode of their life: a first episode makes the medical, drug and cerebral enquiry the main line of the assessment rather than a safety check, keeps the substrate question open into follow-up instead of closing it on the treatment response, and is treated on published guidance alone, so the intended target dose and the date of judgement are written down before titration starts.

20 · Late-onset psychosis and paraphrenia

Why it matters clinically. When a psychosis declares itself for the first time in someone who has lived seven decades without one, the diagnostic label is the smallest part of the work and the last part of it. The entity itself, meaning the onset bands, the delusional content, the sex ratio and the sensory and social background, is set out in the Other psychotic disorders, delusional syndromes and catatonia notes and is not repeated here. What is taken up under late-onset psychosis and paraphrenia in this chapter is the act: the order a clinician works in on the day this patient arrives, what an Indian guideline requires to be excluded before anything is called primary, when imaging is owed, and what the patient's age does to every treatment decision that follows.

The examined version of this topic is procedural far more often than descriptive. A candidate who can recite the onset bands but cannot say what they would reconcile, request and arrange before writing a diagnosis has answered the smaller half of the question. The half that carries the marks is a sequence, it has an Indian source, and it is short enough to hold.

20.1 The word, and what is left for the clinician to do with it

Paraphrenia reaches a modern answer as an inheritance rather than as a working category. Its coinage, the reason the syndrome it named was separated from the deteriorating psychosis of youth, its later revival as a late-life term, and the modern onset bands that absorbed it all belong to the Other psychotic disorders, delusional syndromes and catatonia notes. Retelling that history is not what earns credit here.

What the word still does is prime recognition. It carries a clinical stereotype, and a stereotype earns its place at the door of a clinic, because it makes a clinician look properly at a patient who might otherwise be sent home as eccentric. What it must never do is close the assessment. That is the hazard of an old and vivid label: it feels like a conclusion, it is easy to write, and once it is in the file every later reader treats the question as settled. The word describes; it excludes nothing.

Where the label sits, or sat, inside a formal classification is a separate question, and this section deliberately leaves it unstated rather than guessed at: no code and no inclusion term is named here. What a classification does with the presentation, as against with the word, belongs with the nosology in the notes named above. In an answer, give the lineage a clause, say plainly that the term is historical, and spend the remaining time on the workup.

20.2 The exclusion list runs first, and it is a sequence rather than a differential

Current Indian guidance on schizophrenia in older adults does not open with treatment. It opens by requiring a thorough evaluation for a defined set of alternatives before the presentation is

treated as primary, and that set is best learnt as a sequence of acts rather than as conditions to bear in mind. A differential is something a clinician holds; a sequence is something a clinician completes and records. The enumeration is an affective psychosis, delirium, a dementia, a psychosis caused by medication, and a psychosis caused by a psychoactive substance, and its value lies in how specific it becomes at the two ends candidates skip.

At the dementia end it does not stop at the word: Alzheimer's disease, the frontotemporal group, Parkinson's disease, Lewy body disease, vascular disease and mixed pathology are each named. That granularity matters because these are not one exclusion but several, with different tempos and different first clues, and the differentiation itself is taught in the Dementias and neurocognitive disorders notes. At the pharmacological end, **medication-induced psychosis** is given as named drug classes rather than as a gesture at polypharmacy, and this is the part almost nobody has ready.

WHAT MUST BE EXCLUDED BEFORE THE WORD PRIMARY IS USED	WHY IT STAYS LIVE IN AN OLDER PATIENT	THE ACT THAT SETTLES IT, AND WHERE THE ENTITY IS TAUGHT
An affective psychosis	Mood is under-elicited in older patients, and psychotic content is louder than the affective change underneath it	Take a mood history from patient and informant across the whole episode, not the current week; the disorders belong to the Mood disorders: pharmacotherapy notes
Delirium	The referral arrives worded as psychosis, which describes content and says nothing about attention or fluctuation	Get a timed account of onset and of variation across the day from someone present; the syndrome is taught in the Stroke, TBI, delirium and focal brain syndromes notes
A dementia: Alzheimer's, frontotemporal, Parkinson's, Lewy body, vascular or mixed	Several can produce psychotic features before the cognitive complaint is what brings the family in	Establish the premorbid baseline and trajectory from an informant, then assess cognition formally; the differentiation is in the Dementias and neurocognitive disorders notes
Medication-induced psychosis: antihistaminergics or anticholinergics at higher doses, steroids, dopamine agonists, antimalarials, antiretrovirals, opioid analgesics, fluoroquinolones, ACE inhibitors and beta-blockers	Every class here is in ordinary use in older Indian patients, and several are bought without a prescription or continued from another prescriber	Reconcile the full drug chart yourself, including whatever the family brings in a bag, and date every start and stop against the onset of symptoms
Psychoactive substance-induced psychosis	Substance use is under-asked at this age because the clinician does not expect it, and withdrawal states are missed for the same reason	Ask patient and informant separately, about current use and about anything recently stopped

TRAP **Treating the exclusion list as a differential to consider rather than a sequence to complete, so the drug chart is never actually reconciled.** The mark is lost predictably: the referral says psychosis, the assessment therefore runs as a psychosis assessment, and the medication list is read as background rather than as evidence. It is the one item on the list that is fully reversible, and the one the Indian source makes specific by naming classes. Saying the word iatrogenic does not answer it; naming which agents you would look for, and dating each start against the onset, does.

Four places on an older patient's drug history repay being asked about by name, because none reliably appears on a chart:

- anything started or increased in the weeks before symptoms began, including by another treating team;
- anything stopped abruptly in the same window, since a withdrawal state presents as readily as an addition;
- anything bought over the counter or continued from an old prescription, which is where the sedating antihistamines and the anticholinergics usually sit;
- anything taken alongside the prescribed list, whether traditional, complementary or given by a relative, which is not volunteered unless it is asked for without judgement.

20.3 The imaging instruction, and what it converts

From an imperative to an instruction. Every textbook tells a clinician to exclude an organic cause in a late-life psychosis, which is a sentiment rather than an order, because it says neither what to do nor when. The Indian guideline is more useful. It states that neuroimaging is indicated, and attaches the emphasis to a specific situation: a first episode presenting at an elderly age, which it puts at **after 60**. That age is being used as an investigation trigger and not as a nosological boundary; where the onset bands come from is a separate matter, taught with the entity.

A trigger survives contact with a busy service in a way a sentiment does not. An instruction to consider organic causes is discharged by a clinician who considered them; an instruction that imaging is indicated at this age either happened or did not, and the note shows which.

IN INDIA

The exclusion list, the imaging trigger and the treatment changes in this section are taken from the current Indian clinical practice guideline for the management of schizophrenia, published in the Indian Journal of Psychiatry in 2025, in the row of its special-populations table dealing with older adults. Naming a national source is worth a mark in a viva, where a recalled Western habit is not. Two local frictions recur, and neither justifies skipping a step. Imaging is an out-of-pocket cost a family may defer or decline, so record the indication, the explanation given and the refusal, then arrange it again at review. And the drug history arrives as strips, folded prescriptions and several prescribers rather than as a chart, so it must be assembled by the assessing clinician and cannot be delegated to the referral letter.

20.4 What changes because the patient is seventy-eight

Once the exclusions are worked and the presentation is being treated as a primary psychosis, the age changes the treatment decision at its first step rather than its last. In a younger adult a drug is chosen for what it is expected to do, and its adverse effects are then managed. Here the order inverts: **selection is driven by the side-effect profile**, because comorbidity is the rule at this age and the adverse event being avoided is the one that ends a person's independence.

RULE **In a late-life psychosis the agent is chosen by what it must not do.** The first-line preference is for agents with **lower anticholinergic burden** and lower sedative property, and the guideline states the purpose rather than leaving it to be inferred: to prevent falls. Read that reason forward and the rest follows from it. Sedation and anticholinergic load are the two properties that produce a fall, so the same logic bars **anticholinergic co-prescription** so far as it can be avoided, which matters because that is precisely the reflex a prescriber reaches for when extrapyramidal effects appear.

Two further changes complete the picture. The starting dose is set lower than in an adult, and monitoring for metabolic adverse effects is more frequent. The quantified dose reduction, the anticholinergic burden scales, the falls evaluation and what more frequent monitoring means in practice all sit where the principles of psychopharmacology in later life are dealt with in these notes; the agents themselves belong with the entity. What belongs here is the reasoning that ties them together: one stated purpose, the prevention of falls, generates the selection rule, the co-prescription rule and the dose rule at once. That is what an examiner is listening for, and it is one sentence.

20.5 Who brought the patient, and where the treatment actually happens

The guideline does not stop at the drug. It records that the psychosocial challenges of this group are distinctive and often need psychosocial intervention in their own right, and here that clause carries more weight than it appears to, because of who is standing in the room. The patient has usually not referred themselves. The complaint has been made by a family member, a neighbour or a landlord, and the person best placed to supervise medication is frequently the person the patient's complaint is about. A plan written without noticing that is a plan for a household which does not exist.

Three consequences follow, each an act rather than an attitude. The alliance is built with the patient about something the patient wants changed, which is rarely the belief and is often sleep, safety or being left alone; arguing the belief costs the alliance and buys nothing. **Supervised administration** then has to be arranged by name, because an older person living alone with a persecutory belief will not reliably take a drug handed over by someone they distrust, and recording who holds the medication, and where, is part of the prescription. And the isolation and sensory deficits that so often accompany this presentation are targets rather than context: a hearing aid obtained is an intervention.

GOOD TO REMEMBER

Four things should exist before this first consultation ends, and none will exist unless you make it. A reconciled medication list with dates, assembled by you rather than copied from the referral. A named informant with a telephone number, recorded as the source of the premorbid baseline. A written statement of whether imaging was requested, obtained, deferred or refused, with the reason. And a named person who will actually give the medication, with the arrangement written down. Each is what the next clinician will need, and none can be recovered later.

20.6 The diagnosis is made over time, so the note has to be re-openable

What finally separates this presentation from a first psychosis in a young adult is that the exclusion list contains conditions which do not all declare themselves at once. A dementia early enough to produce psychotic features before a cognitive complaint need not be visible at a first assessment, and a medication effect becomes obvious only once the agent is withdrawn and the picture watched. The workup therefore has a component running after the consultation, and a diagnosis recorded as settled at first contact quietly removes it.

How often a late-life psychosis is later reclassified, and how long a clinician should watch before treating the diagnosis as stable, are questions this section cannot put a figure or an interval on: no comparable standard is available to quote, and none is invented here. What can be taught is the consequence for the record. Write the diagnosis with its grounds visible: what was excluded and how, what was not yet excluded and why, and what would cause it to be revisited. A colleague reading that in six months can re-open it; a colleague reading a bare label cannot, and will not.

The list before the label

THE INDIAN GUIDELINE PUTS A THOROUGH EXCLUSION EVALUATION AHEAD OF CALLING A LATE-LIFE PSYCHOSIS PRIMARY

Imaging has a trigger

A FIRST PRESENTATION IN OLD AGE CONVERTS THE EXCLUDE-AN-ORGANIC-CAUSE SENTIMENT INTO AN INVESTIGATION THAT EITHER HAPPENED OR DID NOT

Chosen by what it must not do

LOW ANTICHOLINERGIC AND LOW SEDATIVE SELECTION, NO ANTICHOLINERGIC CO-PRESCRIPTION AND A LOWER START, ALL GENERATED BY ONE STATED PURPOSE

In a first psychosis of late life the examinable work is a sequence and not a label: complete the guideline's exclusions with the drug classes named and the drug chart reconciled by you, treat a first episode at an elderly age as an indication for neuroimaging, then choose the antipsychotic by its side-effect profile and start it low, because the fall is the outcome that ends independence.

21 · Delirium in the elderly

Why it matters clinically. Delirium was the commonest psychiatric disorder in one Indian study of elderly patients screened at emergency medical outpatient settings, present in **34.1%**, and the examinable question about the confused older inpatient is almost never what delirium is. It is why this patient, why now, and what follows. The entity, its criteria, its subtypes and its treatment belong to the Stroke, TBI, delirium and focal brain syndromes notes, and telling it apart from dementia and from depression belongs to the Dementias and neurocognitive disorders notes.

What is taken up here is narrower: what ageing itself contributes, so that the same syndrome in an older person has a lower threshold, a different set of precipitants, a harder point of comparison and a longer tail.

Keep this apart from the ward referral. The call that arrives as behavioural disturbance on somebody else's service, the bedside screen, the consult note and the ownership of the decision afterwards are taken up where delirium in the medically ill is dealt with in these notes. That section answers what a liaison psychiatrist does when called; this one answers why the call is so often about the oldest patient on the ward.

21.1 What ageing brings to the bedside

Delirium in later life turns on how much insult the brain could absorb before this illness began, and on how large the insult is. The first quantity is **physiological reserve**, and its progressive loss across several organ systems at once is what **frailty** names. Frailty is not chronological age and not a long problem list: one older person can carry several diagnoses and retain reserve, another few and have almost none. Its clinical content is that homeostatic responses have narrowed, so a perturbation a younger patient corrects silently is corrected slowly or not at all. The brain sits downstream of all of them, which is why cerebral dysfunction is so often the first system to declare a failure that began elsewhere.

RULE **The frailer the brain, the smaller the precipitant needed, and the less the precipitant tells you.** In a frail older patient the trigger may be trivial by the standards of a younger ward, so a search that stops when nothing impressive is found has stopped too early. The corollary is the more examinable part: when delirium appears in a robust older person with no cognitive history, the insult was probably not trivial, and the response is to look harder, not to be reassured.

Reasoning in late life therefore runs from trajectory to trigger. The Indian Psychiatric Society's 2023 guidelines on psychiatric emergencies in the elderly list advanced age over **70 years**, cognitive impairment, a previous episode and sensory impairment among the risk factors and weight none of them, so what follows are mechanisms rather than weights, and what each earns is an act that must precede the examination.

WHAT AGEING BRINGS	WHY IT LOWERS THE THRESHOLD	WHAT IT CHANGES AT THE BEDSIDE
Loss of reserve, expressed as frailty	Correction is slower and less complete, so a modest insult is not absorbed	Search wide for a small precipitant; do not stop because nothing dramatic is found
Uncorrected hearing and vision loss	Input is impoverished and ambiguous, so more must be inferred from less	Restore the aid and spectacles before testing, and record that you did
A long and layered drug chart	Altered handling and cumulative central load make the precipitant often iatrogenic	Reconcile every agent, including whatever the family brings in
Cognitive impairment already present, recognised or not	The vulnerable substrate is there already, so less is needed to decompensate it	Get the premorbid baseline before interpreting the state in front of you

21.2 The unaided ear, and the test that is not valid

Uncorrected sensory loss acts in separate ways, and it is the second that catches candidates. The first is a contribution to vulnerability: when hearing and vision are degraded, the information reaching the patient is sparse and ambiguous, and more of their experience must be inferred than received. Ask that of someone in an unfamiliar room, with unfamiliar voices and no visual anchors, and **sensory deprivation** of this ordinary, correctable kind becomes a condition under which misinterpretation is likely. It explains why the same patient is settled with a daughter present in daylight and disorganised in a dim side room at night, with no change in the underlying illness.

The second effect is diagnostic, and it invalidates assessments rather than causing disease. A patient who cannot hear the instruction appears not to attend to it; one who cannot see the object appears not to name it. Each failure is indistinguishable from the failures that matter, and each gets recorded as a cognitive finding by whoever tested without checking. An unaided examination yields a result that cannot be interpreted in either direction. Which ward measures prevent delirium is the owning chapter's; assessing an older person generally is taken up where normal ageing and psychiatric assessment are dealt with in these notes.

> **GOOD TO REMEMBER**
>
> Before a single cognitive item is administered to an older inpatient: ask what they normally use, get it on, and get the light on. Then write that the hearing aid was in place and the spectacles worn, or that they were unavailable and the examination is limited for that reason. An unqualified cognitive result on an unaided patient is not a finding, and it follows the patient through every later team.

21.3 The drug chart as part of the physical examination

Polypharmacy earns its place for reasons that call for different acts. It is a marker: a long chart usually indicates multimorbidity, therefore reduced reserve, and the same guidelines put multiple physical illnesses and polypharmacy among the things that raise the risk. It is also the most reversible precipitant on the ward. Older patients accumulate centrally acting agents across years

and across prescribers, and the cumulative anticholinergic and sedative load of a chart assembled that way is often greater than any single entry suggests. How ageing changes the handling of each agent is taken up where the principles of psychopharmacology in later life are dealt with in these notes. Read the chart before accepting anybody's account of what precipitated this.

These places on a chart repay specific attention, because each is easy to miss on a ward round:

- the agent started most recently, including one added by another team during this admission;
- the agent stopped most recently, since abrupt withdrawal of something long established precipitates as readily as an addition;
- the agent being taken but absent from the chart, whether over the counter, traditional, or brought from home in a strip;
- the agent continued unchanged at a dose set years ago, when the patient handled it differently.

IN INDIA

The ordinary Indian bedside changes how this is done. A family attendant is almost always present, and is usually the only source of the premorbid baseline and the only person who will notice a change at night: name them in the note and ask them directly, not through the ward staff. The drug history sits across more than one prescriber and arrives as strips and folded prescriptions rather than a chart, so ask for all of it and reconcile it yourself. Glasses, hearing aids and dentures live at home: ask whether they came in with the patient at all. Each closes a diagnostic gap that nothing later in the admission will close for you.

21.4 Delirium on a brain that was already changing

An episode in a person who already has a dementia is to be expected rather than treated as a special case, and **delirium superimposed on dementia** generates most of the diagnostic difficulty in geriatric practice. The reason is structural: the diagnosis rests on an acute change from a previous state, and when that state was already abnormal, the change is invisible unless someone can describe what the patient was like beforehand. On a busy ward the enquiry stops at a sentence to the effect that the patient has been confused for a while, which is equally compatible with a stable dementia, a slow decline and an acute deterioration on top of either. It separates none of them, and it is usually the only history taken. Which of delirium, dementia and depression best explains a presentation is taught in the Dementias and neurocognitive disorders notes; what belongs here is that in an older patient the answer is often more than one of them at once, and that the **baseline** is the instrument for that judgement.

A **collateral history** taken for this purpose has to establish particular things, and a general enquiry about memory establishes none of them:

- what the person could do without help before this admission, in concrete terms rather than impressions;
- whether memory, orientation or self-care were already impaired, and for how long;
- whether the current change came on over hours or days rather than over months;

- who first noticed it and what they noticed, since the earliest observation is the most diagnostic and is rarely in the notes.

TRAP **Reading a confused older patient as the natural course of their dementia.** Candidates make this error because it is available: the label is already in the file, it accounts for the findings, and it requires no telephone call. The failure is one of history-taking, not of phenomenology, and examining the patient more carefully does not repair it, because the acute change is not in the current mental state. It is in somebody's memory of last week. The error runs in reverse when a first episode in an older person is treated as evidence of a dementia nobody has assessed.

21.5 Sundowning is a word about the clock

Why the term misleads. **Sundowning** is a ward word for agitation, disorientation or restlessness that appears or worsens as the evening comes on. It carries no agreed definition that can be quoted, and none is invented here; what it describes is timing, not a mechanism, a diagnosis or an explanation. Its usefulness lies in what it prompts you to ask, because several different situations get recorded under it: the evening exacerbation of a delirium present all day that becomes visible once structure and staffing thin out; evening behavioural disturbance in an established dementia with no delirium, which belongs with the behavioural and psychological symptoms taken up where dementia is placed in the geriatric frame in these notes; and an artefact of the ward evening itself: handover, reduced supervision, dim light, and the withdrawal of the attendant who had been orienting the patient all day.

Because the pattern is temporal, it is established by documentation across the whole cycle rather than by an impression formed on one evening: timed observations across the day and night discriminate between those situations, while a note recording that a patient was disturbed at night discriminates nothing. And because the evening presentation invites a sedating response at the hour when supervision is lowest, the reflex to prescribe rather than to look is strongest exactly when the diagnostic information is thinnest. What changes about sleep with age, and what to do with the reflex to prescribe at night, are taken up where sleep in later life is dealt with in these notes.

21.6 The tail: what happens after the ward

The assumption that quietly governs discharge planning is that the episode ends when the illness that triggered it ends. In an older person that assumption is not safe to make, and what rests on it is what the family is told, when cognition can fairly be re-examined, and what the next clinician gets from your note. Features still present on the day of discharge are easily recorded as the patient's new normal, particularly when the discharging team never knew the old one. Whether recovery tracks the medical problem, and how much of the later functional and cognitive trajectory belongs to the episode rather than to the frailty that permitted it, is exactly where a candidate is tempted to supply a proportion: no comparable standard is available to quote, and none is invented here, so the consequence for practice is taught instead.

A frail brain needs a small insult	The baseline is the instrument	Discharge is not the day to certify recovery
WHY AN INFECTION A YOUNGER PATIENT ABSORBS SILENTLY DECLARES ITSELF AS CONFUSION IN AN OLDER ONE	THE ACUTE CHANGE IS ESTABLISHED FROM SOMEONE WHO KNEW THE PATIENT, NOT FROM THE STATE IN FRONT OF YOU	THE NOTE CARRIES THE PREMORBID BASELINE AND AN ARRANGED REVIEW, NOT A JUDGEMENT MADE ON THE DAY

What the discharge summary carries decides whether any of this survives the admission. These entries are worth insisting on, and none is standard:

- that an episode occurred, named as such, with its dates and precipitant, because a summary recording only the treated infection loses the cognitive event;
- the premorbid baseline established, and from whom, so the next clinician has the comparison you had;
- whether cognition at discharge had returned to that baseline, was short of it, or could not be assessed, with an arranged review rather than a reassurance.

21.7 What this section decides, and what it hands on

The boundaries are worth stating plainly. The syndrome itself, with its criteria, subtypes, instruments, causes, treatment and prevention measures, is set out in the Stroke, TBI, delirium and focal brain syndromes notes. Prescribing belongs where psychopharmacology in later life is dealt with, and the structured assessment these vulnerabilities are measured inside belongs where the comprehensive geriatric assessment is dealt with.

What is left is the reasoning: an examiner who gives you an older patient with new confusion is testing whether you can say what made this brain vulnerable before the illness arrived, what small thing was enough to tip it, how you would establish that anything had changed, and what you would arrange for afterwards. Answer in that order, from reserve to precipitant to baseline to outcome, and the entity looks after itself.

> Delirium in the elderly is a statement about reserve as much as about the illness that triggered it: establish the baseline from someone who knew it, read the drug chart as part of the examination, restore the hearing aid and spectacles before testing, and hand the episode on in the discharge note rather than closing it on the day.

22 · Pseudodementia versus dementia (depression in the elderly)

Why a comparison settled elsewhere still needs an address. The heading is set as pseudodementia versus dementia (depression in the elderly), and it names a discrimination made at the bedside, quickly, before any specialist service has seen the patient. The construct is **depressive pseudodementia**: a depressive illness in an older person whose presenting complaint is of failing memory, concentration and intellect, set beside a degenerative process capable of the same appearance. Its features, the formal differentiation from a true dementia, and the discriminators laid out side by side are given in the Dementias and neurocognitive disorders

notes and in the Mood disorders: pharmacotherapy notes. Neither is condensed here: a shortened comparison competes with the full one.

Fig 29.9 Cognitive symptoms in late-life depression and early dementia may not be resolved in one assessment. The consultation treats reversible contributors, documents uncertainty, reviews the trajectory and addresses safety while the diagnosis is clarified.

Those accounts do not use the same name for it, and no preferred term is adopted here; the label is settled where the construct is taught. What is owed at this address is what no comparison table carries: who makes the call and in what setting, what the error costs in each direction, and what the consultation must produce when it cannot answer on the day.

22.1 Both errors are available, and they do not cost the same

Reading a depressive illness as a degenerative one withholds a treatment that could return the person to their previous level, and it does more: the household is told to expect decline, the plan turns custodial, and the **provisional label** in the first case sheet is seldom reopened by whoever reads it later. The opposite error, reading an early degenerative process as depression alone, is not

harmless either: the safety review, the driving and financial conversations and the family's preparation are all deferred while a treatment is given time to work.

The pair is not symmetrical, and the asymmetry is the examinable point: the depressive possibility must be actively excluded rather than hoped for, because it is the only member in which the deficit may lift. That is about the order of the work, not the odds.

RULE **Where the two cannot be separated at the first sitting, treat the reversible possibility and name the date on which the answer will be read.** The discrimination is often completed by what happens over a treated interval, not by anything a single examination yields, so a consultation closing with a verdict and no review point has answered a question nobody asked.

22.2 How the question reaches you, and whose account decides it

The request almost never uses the word. It arrives as a son saying his father has become forgetful since the mother died, or as a medical unit wanting an opinion before a discharge the family is resisting. What is tested is whether you notice the question is available at all: the referral names a deficit, and the referrer has already decided which of the two it is. A third possibility is easily lost between them: an **acute confusional state** gives a similar appearance, and it is taken up where delirium in later life is dealt with here.

Whose account settles it is decided before the examination, not during it. An older patient's own report of their memory cannot close the question alone, so the household's version is not corroboration but a second history, separately sourced and recorded. Where the family has already named the illness, that naming is itself clinical material: it tells you what they will agree to. Three things belong in the note before the cognitive examination begins.

- Who gave each part of the history, and which parts rest on the patient alone.
- What has already been named to the family, by whom, and what they have stopped expecting.
- Who will bring the patient back for review, and whether they are able to.

IN INDIA

Most districts have no memory service to refer to, so the discrimination is made, and then owned, by whoever the family reached first. The provisional label travels onward in a case sheet the family carries, and the next consultation is often with a different clinician in a different hospital, so nobody is placed to revise it: **diagnostic inertia** here is a property of how care is delivered, not of anybody's carelessness. The two words also land differently in a family's hearing, one as a terminal sentence and the other as weakness of character, so the review appointment must be explained as part of the diagnosis, not offered as an optional return. What proportion proves reversible, and how much old-age provision exists to refer to, are not quantified: no comparable standard is available to quote, and none is invented here.

22.3 Where each part is taught, and how the heading is set

WHAT IS BEING ASKED FOR	WHERE THE FULL ACCOUNT SITS	WHAT THESE NOTES ADD
The construct, its features, and the formal differentiation from a true dementia	**the Dementias and neurocognitive disorders notes**	Nothing; the reader is sent
The discriminators side by side, inside the depressive illness they belong to	**the Mood disorders: pharmacotherapy notes**	Nothing; the reader is sent
Cognitive instruments and their scoring	**the Psychotherapies, clinical assessment, MSE and nosology notes**	The workup they sit inside, with geriatric assessment here
The acute confusional state as the third possibility	**the Stroke, TBI, delirium and focal brain syndromes notes**	What age contributes, with delirium in later life

As a short note the marks sit in the comparison, so answer it from the owning account rather than improvising at the desk. As a viva or long case it is never asked in the abstract: an older patient with a cognitive complaint and a mood history is put before you, and the examiner watches whether both possibilities survive to the end. What scores is a fixed order.

- Name both possibilities, and the third one, before examining for either.
- Say whose history you took for each, and what you could not obtain.
- Close on the treatment you are starting and the date the label will be tested.

TRAP **Reproducing the comparison and stopping there.** Candidates make it because the side-by-side account is compact, memorable and the part that was revised, so it feels like the answer. What it produces is an answer with no decision in it: no treatment begun, no informant named, no date at which the label is tested.

GOOD TO REMEMBER

Write the review date in the same sentence as the provisional diagnosis, in the case sheet the family carries. A label with a date invites the next clinician to test it; without one it reads as settled, and where that clinician is a stranger, this is the difference between a diagnosis and a verdict.

Named and handed on
WHAT THESE NOTES DO WITH THE COMPARISON ITSELF

Excluded, not hoped away
HOW THE TREATABLE MEMBER OF THE PAIR IS HANDLED

A date, not a verdict
WHAT THE CONSULTATION IS OBLIGED TO PRODUCE

The comparison is read in the Dementias and neurocognitive disorders notes and in the Mood disorders: pharmacotherapy notes; what is decided here is that the treatable possibility is excluded rather than hoped away, and that the provisional label leaves the room with a date on which it will be tested.

Culture and the explanatory model

23 · Concepts of culture, illness and culture-bound syndromes

Why a heading whose framework is taught elsewhere still carries marks. This heading asks for a vocabulary before it asks for anything clinical, and the vocabulary was rebuilt once already. DSM-5 moved from **culture-bound syndromes** to **cultural concepts of distress**, an umbrella that holds **three** distinct ways culture shapes suffering rather than only the syndrome-shaped one. That framework is taught in full, with its definitions, its worked examples and the assessment instrument built on it, in the Psychotherapies, clinical assessment, MSE and nosology notes. Nothing here repeats it, and an answer that stops at the framework has recited a vocabulary and left the clinical question untouched.

What is left over is what these notes owe. A concept of illness is not general knowledge sitting beside the diagnosis: it decides what counts as a symptom, who is entitled to describe it, and which account of the cause a clinician has to work with before any treatment is accepted. That is a consultation problem, and it is examined as one.

23.1 Where the framework is taught, and what is deliberately not repeated

The umbrella's parts are a **cultural syndrome**, a **cultural idiom of distress** and a **cultural explanation** or perceived cause. Each is defined, discriminated from its neighbours and illustrated in those notes, alongside the classic named syndromes as a definitions list and the structured formulation that elicits all of it. This section names the parts and stops there, because a compressed definition is a worse version of a definition that already exists, and because the reader who needs the definitions needs them in one place rather than in competing versions. The argument the classification made for the change is set out with the framework and is not restated here, in any shortened form.

RULE **Name the umbrella before you name an example.** An examiner who asks about concepts of culture, illness and culture-bound syndromes is asking whether you hold a framework, and the exotic examples are the part of the answer that needs no help. A candidate who opens with a roster of syndromes has answered a question about content with a question about geography, and has to be led back to the framework by the examiner, which is the only part of the exchange that is ever remembered.

WHAT THE READER IS LOOKING FOR	WHERE THE FULL ACCOUNT SITS	WHAT THESE NOTES ADD
The terminology shift, and the parts of the umbrella	**the Psychotherapies, clinical assessment, MSE and nosology notes**	Nothing. It is named here and handed on
The classic named syndromes, as definitions	**the Psychotherapies, clinical assessment, MSE and nosology notes**	How such a presentation actually arrives, and the negotiation that follows it
Dhat syndrome, at length	**the Somatic-symptom, sexual, impulse-control disorders and suicide notes**	Named here only as the one most likely to arrive in an Indian clinic
The cultural formulation and the interview built for it	**the Psychotherapies, clinical assessment, MSE and nosology notes**	Where it belongs inside an assessment done in a general hospital
Migration, ethnicity and acculturation	**These notes, in full**	The whole of it, since it sits with the encounter and not with the taxonomy

23.2 What a chapter that owns the encounter does with culture instead

The organising question. Every other heading in psychiatry teaches what a thing is. These notes teach who asks, in whose ward, what changes with age, whose account of the cause is already in the room, and how an examiner asks for all of it. Culture enters that scheme not as a topic but as a seam that runs through the rest of it, which is why the concept is named here and then reappears, in clinical form, wherever it does work. It reappears in these notes as:

- the encounter with the classic presentations, meaning how such a presentation actually walks into a clinic and how the negotiation with a family that has already settled on an explanation is conducted;
- the structured formulation and its interview, placed where an assessment would reach for them rather than taught again;
- the patient's vocabulary for suffering, and the account of cause that vocabulary carries;
- migration, ethnicity and acculturation, which these notes carry in full;
- religion, spirituality and the healing that happens before the clinic is ever reached.

GOOD TO REMEMBER

Before writing a cultural label into the record, ask what the label changes. If it changes nothing about the plan, it is a description and not a diagnosis, and the note still has to name the disorder being treated and the account of cause being worked with. A record that says only that the presentation was cultural has documented the clinician's impression of the patient's background and no decision at all.

23.3 How the heading is asked, and the order the answer takes

Asked as a short note or a viva opener, this heading rewards a sequence rather than a store of examples: the current umbrella and why it replaced the older term, the parts it holds, the address of the definitions if a definition is wanted, and then the move to the encounter, where the marks for judgement sit. Asked as a long question, it is almost never asked alone. It arrives attached to a case, and the concept is the frame the case is read through, so the candidate who has treated the framework as a glossary has nothing to say when the case turns out to be a treatable disorder wearing an unfamiliar explanation.

TRAP **Answering a question about concepts with a catalogue of syndromes.** The catalogue is memorable, regionally exotic and easy to revise, while the framework is abstract and easy to skip, so the catalogue is what surfaces under pressure. The same error runs the other way in the clinic: a name is attached, everyone relaxes, and the assessment stops at the point where it should have begun.

IN INDIA

The older vocabulary is still the working vocabulary here. It survives in teaching, in ward usage and in the wording of examination questions, so a candidate meets the superseded label and the current umbrella in the same viva and needs fluency in the relationship between them rather than loyalty to one. Expect the examples to be Indian and the expectation to be that you move from the term to the clinic, since a roster recited to an Indian examiner invites the follow-up question of what you would do with the patient in front of you.

Named and handed on	Definitions elsewhere	The encounter
WHAT THIS SECTION DOES WITH THE FRAMEWORK	WHERE A DEFINITION IS TO BE READ	WHAT THESE NOTES ADD IN ITS PLACE

Cultural concepts of distress is the current umbrella and it replaced culture-bound syndromes, which covered only the syndrome-shaped part of it; the definitions and examples belong to the Psychotherapies, clinical assessment, MSE and nosology notes, and what these notes add is the encounter the concept is used in.

24 · Culture-bound syndromes (dhat, koro, amok, latah and others)

Why the encounter is examined here and the definitions are not. No group of headings is memorised as reliably, or handled as badly, as the culture-bound syndromes (dhat, koro, amok, latah and others). A candidate can produce the roster on demand and then have nothing to say when one of them is sitting across the table, because a name is worth little in a clinic: it tells you what the patient calls his trouble, not what he has, what he has already swallowed for it, or who sent him. The definitions, the umbrella term that replaced the older one, the classic list and the placement of these presentations in the classifications are taught in the Psychotherapies, clinical assessment, MSE and nosology notes, and dhat syndrome at length, with its figures and its

management, in the Somatic-symptom, sexual, impulse-control disorders and suicide notes. None of that is rebuilt here.

What is left over is the clinical encounter, and it holds both the marks and the mistakes: which door such a presentation comes through in India, what the man and his household already believe by the time a psychiatrist meets them, how a negotiation between two accounts of one complaint is conducted, and what arrives that the classic list never mentions. One discipline runs through all of it. The Indian evidence here is a few single-centre clinic series and individual case reports, so every figure in this field is a proportion of the people who attended one clinic, and the honest answer teaches a method rather than a set of rates.

24.1 Which door it comes through, and why the psychiatrist is not the first clinician

Begin where the patient begins, because the **help-seeking pathway** explains most of what looks puzzling about these presentations. The Indian phenomenological description this section leans on studied **100** men, and it did not recruit them from a psychiatry outpatient department at all: they were attending a sex and marriage counselling clinic run from a community medicine department at a single tertiary centre in New Delhi, and the work was published in the Indian Journal of Psychiatry in 2016. Its method is as instructive as its findings. The investigators ran focus groups with specialists in dermatology, community medicine, medicine, surgery and endocrinology, and when focus groups with traditional practitioners proved impossible to assemble, interviewed three ayurvedic and two homeopathic practitioners individually. Read that as a map of the doors this complaint knocks on before it reaches you.

The other two Indian reports say the same thing from different directions. A pair of cases of **anthropophobia** reached an obsessive-compulsive disorder clinic rather than a general psychiatry clinic, and a man with a koro-like presentation and dhat was assessed, and re-assessed, before the treatable disorder underneath was identified. By the time a psychiatrist sees such a patient, several other people have already explained it to him, so the psychiatric account is not the first one offered but a competing one arriving late.

One methodological detail of the clinic series has to travel with it, because it is a trap in both directions. Psychotic illness was an exclusion criterion, so anyone whose conviction might have reached delusional intensity was screened out before the study began. That bounds what the series describes, and it also means this sample cannot be used to settle the argument about whether such an attribution is a belief or a delusion. That argument belongs with the definitions and is taken up there.

24.2 What he has already been told, and what he has already taken

Where the belief was learned is a clinical fact, not an anthropological one, because it tells you who else has to be persuaded. The same clinic series records that this knowledge is acquired from friends, relatives and colleagues, from roadside advertisements and lay magazines, and from Hakims and Vaids. Not one of those is a clinician in the sense a hospital uses the word, and every one is more available, cheaper and less humiliating to consult than an outpatient department.

The **Hakims and Vaids** in that list are practitioners with their own coherent systems, their own diagnostic vocabulary, and a treatment they will hand over at the first visit.

The second half of that record is what patients themselves count as cures, and it is the more useful half. Reported **perceived cures** run from desi medicines and herbs, and the advice of Hakims and Vaids, through dietary correction with protein-rich and iron-rich food, B-complex tablets or injections, antibiotics, anti-anxiety drugs and aphrodisiacs, to marriage itself. Look at the two ends of it. An injection is the most concrete thing a patient can be given. Marriage is not a prescription a clinician can write and is very often one the family has already written. So he arrives with a settled expectation that something energising will be supplied, and with a household committed to a plan of its own.

How commonly that expectation is held, and in what proportion of such patients, is a figure this account will not give you: no comparable standard is available to quote, and none is invented here. The qualitative fact is enough to work with, and it is the part that changes the consultation.

IN INDIA

The parallel market is not a curiosity at the edge of the case, it is the referral pathway. A roadside advertisement, a lay magazine and a neighbouring practitioner have between them supplied a diagnosis, a mechanism and a treatment before you are consulted, at a price already paid. Two questions belong in the first interview and are almost never asked: who did you consult before coming here, and what did they give you. The answers name what has already failed, what the family counts as a real treatment, and whatever is currently being swallowed. A record stating that the patient is on no medication, when he is taking a tonic and tablets bought over a counter, is inaccurate in a way that matters.

24.3 The family's account, and why you ask for it rather than assume it

The family is not an accompanying party in these presentations, it is usually the referrer. In the Delhi report of anthropophobia, the man managed the problem himself by avoidance, and the change that produced a consultation was functional: he stopped going to work, and it was his family who noticed and who brought him to the clinic. That is the ordinary Indian route into psychiatric care in one sentence. Distress alone does not generate a referral; loss of role does, and the person who converts it into an appointment is a relative.

It follows that the household arrives with an account of the illness already formed, and that the account is a clinical object rather than background colour. What is not available is any measurement of it. Nothing here establishes what proportion of Indian families holds a biomedical explanation, whether families commonly hold several explanations at once, whether a non-medical account predicts a worse outcome, or whether it predicts that the tablets get taken. Those are exactly the propositions a clinician feels certain about. So the instruction below is argued as good practice, from the structure of the encounter, and must not be dressed up as an evidence-based intervention in an answer.

MNEMONIC

Where did you hear it? What have you taken? What do you want me to do?

Three questions, asked in that order, before any explanation is offered. The first locates the source of the belief and therefore who else holds it. The second uncovers the treatments already tried, which is both a history of failure and a current drug history. The third surfaces the expectation you are about to disappoint, which is the single most useful thing to know before you speak, because an expectation that is named can be negotiated and one that is not simply ends the consultation at the door.

24.4 Conducting the negotiation

The consultation is a meeting of two accounts of one complaint, and the psychiatric account has the less authority in the room. The patient and the practitioners he has already seen understand the trouble as a bodily disorder; the **allopathic** clinician he has now reached understands it as a psychological one. Neither party is unreasonable, and the encounter fails when the difference is treated as ignorance to be corrected first and treated afterwards. A workable sequence looks like this.

- Examine him. The complaint is bodily, and a physical examination that is skipped tells the patient more clearly than any sentence that you did not take it seriously.
- Take the history of what has already been consulted and consumed before you offer any account of your own, so that your explanation lands after his rather than instead of it.
- Do not open by correcting the belief. Correction at the first meeting costs the follow-up and buys nothing, because the belief is held by people who are not in the room.
- Say what you will do and, explicitly, what you will not do. A tonic or an injection given to satisfy the model purchases this consultation and sells the next one, since it confirms that the complaint was the kind of thing an injection treats.
- Name in the record the disorder you are actually treating, and treat it. Where the pathway has already passed through a temple, a shrine or a healer, the negotiation with that part of it is taken up in these notes under religion, spirituality and faith healing.

RULE **The name tells you what he calls it, not what he has.** A culture-named presentation is a presentation and not a diagnosis, so attaching the name completes nothing. The task after the name is the ordinary one: identify the treatable disorder, if there is one, and the expectation that will decide whether treatment is accepted. An answer, or a note, that stops at the name has recorded the patient's vocabulary and made no decision. This is also the axis the long essay is marked on, because the roster is the part that needs no help.

GOOD TO REMEMBER

Four things belong in the note and are usually missing from it: the patient's own words for the complaint, his account of what caused it, what he has already taken and from whom, and the sentence in which you told him what you would and would not prescribe. The last matters most at the next visit, because a patient who does not return has usually been refused something without being told what he was offered instead, and the clinician who sees him next cannot know that unless it was written down.

24.5 The long tail: what walks in that the roster does not list

The classic list is a list of names collected historically, not a census of what presents. The clearest Indian demonstration is a case series from Delhi, published in the Indian Journal of Psychological Medicine in 2021, reporting **two** cases of anthropophobia, a presentation classically indexed to Japan. Its authors state that to their knowledge no such case had previously been reported in the Indian context, and that hedge is theirs and should survive into any use you make of it: it is a statement about the reported literature, not about how often this occurs. Two cases license an existence claim and a narrative of how they reached care. They license nothing epidemiological whatever.

The teaching point carries into any question on this heading. The name records where a presentation was first described and described often, which is a fact about the history of psychiatry rather than about the distribution of human distress. Presentations cross those boundaries, and an Indian clinic meets what the roster does not list.

The Indian literature also carries its own named presentations outside that roster, and the Psychotherapies, clinical assessment, MSE and nosology notes name suchi-bai, the ascetic syndrome, nuptial psychosis and jhinjhinia. They are named here and nothing more is said about them. No phenomenology, no region, no sex distribution and no frequency is offered for any of the four: no dependable account of them is available to quote, and none is invented here. This is precisely the material that gets written from memory, with great confidence and no basis.

THE INDIAN REPORT	WHERE IT PRESENTED	HOW HE REACHED IT	WHAT IT CAN CARRY, AND WHAT IT CANNOT
A clinic series of 100 men, tertiary centre, New Delhi	A sex and marriage counselling clinic run from a community medicine department, not a psychiatry clinic	**Attending a non-psychiatric clinic; psychotic illness was an exclusion criterion**	The information ecology and the expected remedy. Not a population rate, and not the question of delusional conviction, since those patients were excluded
A case series of two, Delhi	An obsessive-compulsive disorder clinic	**Managed alone by avoidance, then noticed by relatives, then brought in by the family once he stopped working**	That a presentation crosses the boundary it is named for, and the Indian route into care. Nothing epidemiological
A single case letter, rural West Bengal	Assessed with two culture-named presentations at once	**Comorbid obsessive-compulsive disorder emerged only on an unscheduled review**	That these presentations ride on ordinary disorders. Not a description of the epidemic itself, which reaches this account second-hand

24.6 They ride on ordinary disorders, and the first assessment can miss it

The most useful single Indian case in this area is a letter from rural West Bengal, published in the Indian Journal of Psychiatry in 2020, describing one man who presented with two culture-named complaints together and in whom obsessive-compulsive disorder was camouflaged at the initial examination by those complaints and detected only on a later, unscheduled review. Two things in that sentence are worth more than the diagnosis itself: the comorbidity was present from the start and was not visible, and what made it visible was a second look rather than a better first one.

The authors also record that what the man showed was **koro-like** rather than classical, which is the ordinary situation and not the exception. Textbook descriptions are drawn from the clearest published cases; clinics see partial, mixed and attenuated versions, and a presentation that fails to match the description is not thereby excluded from being one. They set the case against an epidemic background they date to 2010 and describe as involving several Indian states. That background is stated here as their attribution: the epidemic report itself is not available to this account, so the epidemic is not asserted as a free-standing fact and its extent is not quantified.

Their recommendation follows, and its authority has to be carried with it. The authors of that letter state their belief that all koro and especially koro-like cases with a subacute or chronic presentation should be screened for the obsessive-compulsive spectrum. That is the opinion of a case report, carrying the modal verb its authors chose. It is worth acting on and it is not a guideline, and the difference is examinable. Obsessive-compulsive disorder itself, its assessment and its treatment, belongs to the Anxiety, OCD and trauma-related disorders notes.

TRAP **Treating the culture-named presentation as the whole diagnosis and stopping the assessment there.** The name is satisfying, it explains the striking part of the history, and once it is attached everyone in the room relaxes, including the clinician. Meanwhile the treatable disorder sits underneath it and can be invisible at a first assessment. In the exam this is an answer that describes a syndrome beautifully and never mentions screening for comorbidity; in the clinic it is a patient who was labelled, reassured and not treated.

24.7 What a number in this literature can bear

The discipline that separates a safe answer from a confident one. Every figure available in this field is bound to the group it was counted in, and the **denominator** is part of the number rather than a footnote to it. The clinic series above is 100 men attending one clinic at one tertiary hospital, so what it describes is that clinic's attenders and no wider group. The boundary-crossing report is two cases. The comorbidity report is a single letter. Where a proportion for dhat is quoted in the Somatic-symptom, sexual, impulse-control disorders and suicide notes, it is a proportion of men attending clinics and not a rate in any population.

Say that plainly in a viva. A candidate who states that a figure describes clinic attenders rather than a population, and then declines to convert it into a prevalence, has shown exactly the judgement the question is testing.

100 men, one clinic	Two cases	One case letter	No population rate
THE INDIAN PHENOMENOLOGY SERIES THIS ACCOUNT RESTS ON, AND ITS WHOLE DENOMINATOR	THE INDIAN REPORTED EXPERIENCE OF ANTHROPOPHOBIA AT THE TIME OF THAT REPORT	THE EVIDENCE FOR CULTURE-NAMED PRESENTATIONS RIDING ON A COMORBID DISORDER	WHAT NONE OF THOSE DENOMINATORS CAN BE CONVERTED INTO

PITFALL

Do not print a prevalence for a culture-named presentation, in an answer or in a note. Nothing available here samples a population: the sources are clinic attenders, a pair of cases and a single letter, and a number from any of them describes the people who walked through one door. The error is attractive because a percentage looks like scholarship, and because the figure quoted is usually a real number lifted out of its denominator. Asked where it comes from, you will produce either the denominator or silence, and silence costs more than quoting nothing.

24.8 How the heading is asked, and what an essay needs from here

This heading is asked in three recurring forms, and they want different things. As a full essay it appears as a bare instruction to discuss the culture-bound syndromes, which a western-India state health-sciences university has set in that bare form in 2011, 2015 and 2017. As a shorter question it appears as an instruction to enumerate them and then describe dhat syndrome in detail, set that way by the same university in 2013 and 2018. And it appears as a short note on the heading alone, set in 2017.

The enumeration and the detailed account of dhat are the parts that come from elsewhere. The list of classic syndromes with their definitions is in the Psychotherapies, clinical assessment, MSE

and nosology notes, and dhat in full, including its figures, its classification and its management, is in the Somatic-symptom, sexual, impulse-control disorders and suicide notes. Those two chapters will carry the first half of a short question by themselves.

What they will not carry is the essay, because an essay answered entirely from them is a glossary with an introduction and is marked as one. This section is the second half of that answer and the part that separates candidates: the doors these presentations come through in India, the information ecology behind the belief and the remedies already tried, the family as referrer and its own account, the negotiation and what is put in the record, the comorbid disorder that must be looked for a second time, the presentations that cross the boundaries they are named for, and the denominator discipline that stops an answer ending on an invented rate. Let the definitions occupy the essay's opening rather than its body, and spend the body here.

Expect two follow-ups. Asked what you would actually do with such a patient, do not answer with a classification: answer with the sequence, examination first, elicitation of what has been consulted and consumed second, explanation third. Asked what is contested, say that the boundaries the names imply do not hold, that those who report these cases recommend screening for comorbidity, and that the Indian evidence is too thin for any prevalence to be quoted from it.

> These presentations reach an Indian psychiatrist late and through non-psychiatric doors, with a belief learned from family, advertisements and traditional practitioners, a course of energising remedies already taken, and a family that referred him when he stopped working; the name is his word for the complaint and not a diagnosis, the treatable disorder underneath it must be looked for a second time, and every figure in this literature is a proportion of one clinic's attenders rather than a rate in any population.

25 · Cultural formulation and DSM-5 cultural formulation interview

Why an instrument taught in full elsewhere still has to be placed here. The heading cultural formulation and DSM-5 cultural formulation interview names two things, and candidates routinely merge them into one. The **Outline for Cultural Formulation** is the organising outline that tells an assessment what it must account for; the **Cultural Formulation Interview** is the instrument built to gather that material from the patient at the bedside. Their domains, the core question set and the additional modules that extend it for particular populations are set out in full in the Psychotherapies, clinical assessment, MSE and nosology notes, and no part of that account is repeated here.

What is owed here is the part no instrument manual supplies. A structured formulation is worth only what its placement in a real consultation is worth: who is actually asked, what survives when the clinic offers far less time than the full instrument assumes, and what has to reach the record for the exercise to have changed anything. That is also where the marks sit: a memorised roster of domains takes one sentence to deliver and demonstrates nothing.

Outline, then interview
THE TWO SEPARATE THINGS THIS HEADING NAMES

Taught in full elsewhere
WHERE THE DOMAINS AND THE QUESTION SET ARE SET OUT

Placement and use
WHAT THESE NOTES ADD IN THEIR PLACE

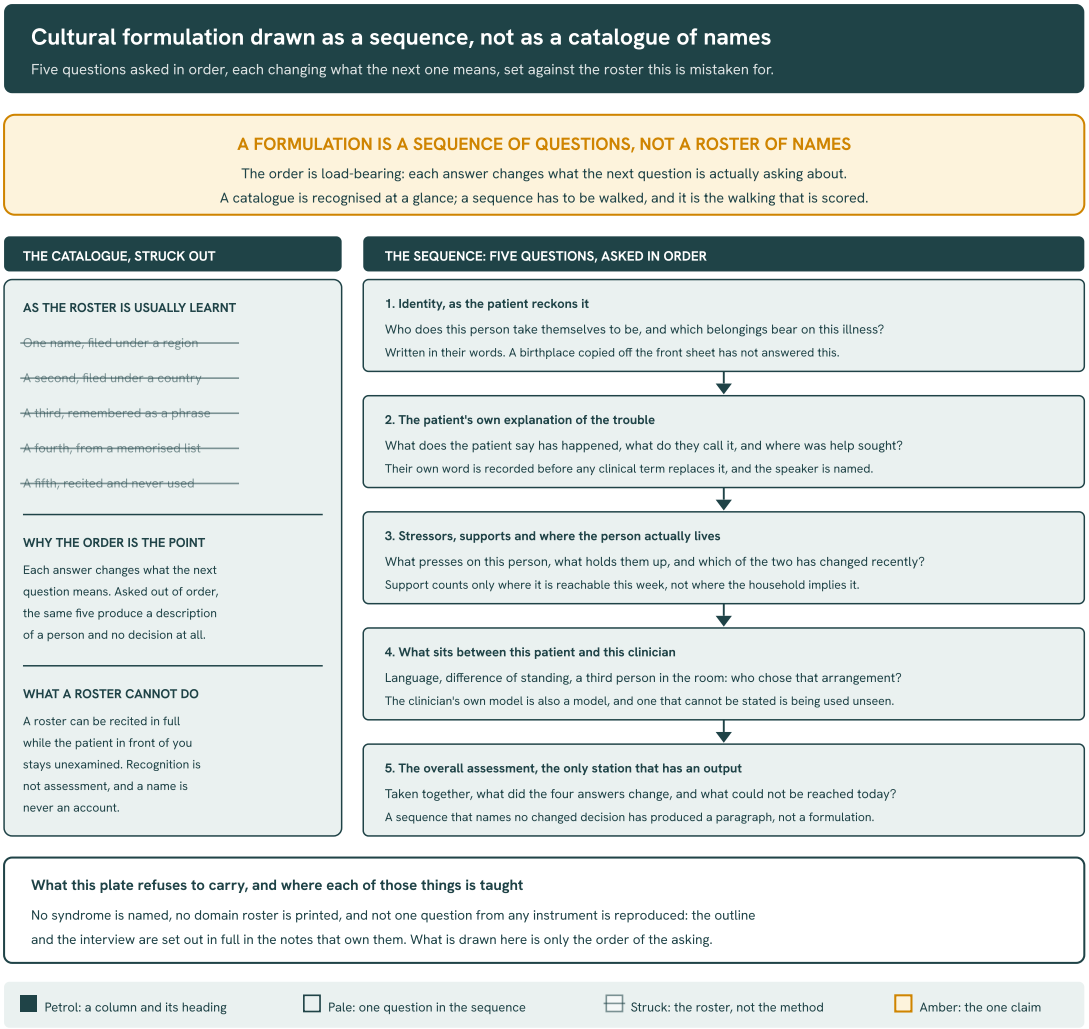

Fig 29.10. The cultural formulation drawn as five questions asked in a fixed order, from who the patient takes themselves to be, through their own account of what has happened, the pressures and the supports that are actually reachable, and what stands between this patient and this clinician, to an overall assessment that is the only station obliged to produce a changed decision, the whole set against a struck-out roster of names to show that a catalogue is recognised while a sequence has to be walked, with no syndrome named and no question from any instrument reproduced.

25.1 The outline, the interview, and the address of the full account

The outline and the interview are one construct in two forms, and the division between them decides where each belongs in a working assessment. The outline is the shape the written formulation takes, which puts it beside the **diagnostic formulation** rather than inside the history. The interview is the means of obtaining what the outline asks for, which puts it inside the assessment, before any formulation can be written. Everything that follows from that division is taught once and in one place; a compressed copy carried here would be the dangerous version,

not the convenient one. A half-remembered outline reliably produces the same failed assessment: the clinician asks the patient where they are from, records the answer, and files it as a cultural assessment.

25.2 Where the formulation belongs inside a working assessment

The placement is the whole of the difficulty. Two errors sit at opposite ends of it. The first treats the formulation as a supplement written after the plan is settled, so it is decorative and everybody knows it. The second treats it as a substitute for diagnosis, so a treatable disorder is admired as a cultural presentation and left untreated. The instrument is neutral between them; the clinician's placement of it is not.

RULE **The cultural formulation is appended to the diagnostic formulation, never substituted for it, and it must name the one thing in the plan that it changed.** Without a named consequence the exercise cannot be audited, by an examiner or by the clinician who inherits the patient. If the account genuinely changed nothing, write that too: a recorded negative tells the next reader the question was put, and a silence tells them nothing.

Whose account is being taken is the second decision, and it is settled before the first question, not during the interview. The patient's own account and the family's are frequently different, and the difference is often the clinical material. Where the interview passes through a relative, that relative is at once informant, interpreter and a stakeholder in the explanation, so the **collateral account** and the patient's cannot be recorded as one voice. Time forces the third decision. When the full instrument cannot be administered, the honest compromise is not to shorten every part equally but to take the questions whose answers could change what you do, and to record what was left undone.

POINT IN THE ENCOUNTER	WHAT THE CULTURAL ACCOUNT CHANGES THERE	WHAT THE NOTE MUST CARRY
Before the first question	Who will speak, in which language, and who chose that arrangement	Who interpreted, and their relationship to the patient
The complaint	Whether the patient's word for the trouble and the clinician's word mean the same thing	The complaint quoted, before it is translated into a symptom
The account of cause	What the patient and the family believe has happened, and where help was sought before this clinic	The **explanatory model** as given, and who in the room holds it
The plan	Whether an agreed plan can survive contact with the explanation the family already holds	What was negotiated, what was declined, and the review point

IN INDIA

The instrument assumes a patient who speaks for himself, in his own language, to a clinician who shares it. In a general hospital clinic here the family commonly speaks first and speaks most, the interview is often conducted in a second or third language for one or both parties, and a healer or a shrine has often been reached before the outpatient department was. None of that makes the formulation less usable; it makes the sourcing of each account the thing that must be written down, because a record that merges patient, relative and interpreter into one narrator cannot afterwards be untangled. A national protocol setting out how these instruments are to be used, translated and validated in Indian practice would settle several of these questions; no comparable standard is available to quote, and none is invented here.

25.3 What the examiner is actually scoring

As a short note it is a definition question with a practical tail, and the tail is where the discrimination shows. As a long case or a bedside station it is never asked in the abstract: a patient whose account of the illness is not biomedical is put in front of you, and the examiner watches whether the assessment bends around that account or ignores it. The answer that scores runs in a fixed order.

- Name both, and say which is the outline and which the interview.
- Place the formulation beside the diagnostic formulation, and say what it is for.
- Name whose account you obtained, and whose you did not.
- State what the account changed in the plan.
- Say what you could not complete, and when it will be finished.

GOOD TO REMEMBER

Record the parts of the formulation you did not reach, by name. A partial formulation that says so is usable by the next clinician; one that does not is indistinguishable from a completed one with negative findings, and the missing questions are then never asked at all.

TRAP **Reserving the formulation for the visibly different patient.** Candidates make this error because the instrument is introduced with unfamiliar examples, so it is filed as a tool for other people's patients. The consequence is that the majority-culture patient's account of cause is never examined, and the clinician's own model is treated as though it were not a model at all. Every patient arrives with an explanation; the only variable is whether the clinician noticed that it differed from his own.

Name the outline and the interview separately, obtain the account before the plan rather than after it, source it to the person who gave it, and write down the one decision it changed.

26 · Migration, ethnicity and mental health

Why this sits in a transcultural chapter and not in an aetiology one. Migrant status is one of the most reproducible social signals in psychiatric epidemiology, and one of the most abused. The

figures are quoted as though they described a mechanism, and attached to patients whose move bears no resemblance to the moves that generated them. The cultural concepts of distress themselves, and the cultural formulation built to elicit them, are taught in the Psychotherapies, clinical assessment, MSE and nosology notes; what belongs here is the frame around them, the epidemiology of the transcultural axis, migration and acculturation, which is to say who moves, why they move, what the population figures license, and what changes in the room when the person in front of you has had their social world reorganised by a move. Migration, ethnicity and mental health sit in one section and not three, because the literature that raises the question uses the three words almost interchangeably and the clinic has to take them apart again.

One seam runs through the whole topic and decides most of the marks: the epidemiology that makes migration famous is host-country epidemiology, and the Indian answer is not inside it. So this account teaches the reasoning and the frame, and it does not put a risk multiple on the page in either direction: no dependable figure for the risk of psychotic illness in migrants is available to quote, and none is invented here.

26.1 What the migration question is actually asking

Migration is not a state a person is in, it is a process a person has been through, and the psychiatric question separates into parts a history has to answer independently. Who left, and what were they like before they left. What the leaving and the journey consisted of, including whether it was chosen. And what the arrival is like now, which is usually where the illness sits. Collapsing them is the commonest error in a formulation, because each supports a different causal story and only the third is modifiable by anything a clinician does.

The word also covers movements with almost nothing in common. A doctor who takes a post in another country, a woman who moves into her husband's household in the next district at marriage, a seasonal labourer who spends most of the year on a construction site in another state, and a person who has fled and cannot return are all migrants. They differ in whether the move was chosen, whether it can be reversed, whether the family moved with them, whether language and food and worship changed, and whether they are legally secure where they now live. Any of those differences can plausibly matter more than the fact of movement, which is why "migration" on its own is a poor formulation term and a good screening question.

RULE **Migrant status is an epidemiological signal, not a mechanism and not an explanation.** A raised rate in a migrant group tells you where to look and nothing about what to look for. The clinical work is to name which of the many things bundled inside the word applies to this patient: a selection effect operating before departure, a loss sustained during the move, a social position occupied after arrival, or a diagnostic process happening in front of you. A formulation that stops at "migrant, therefore at risk" has taken an epidemiological label and used it as a substitute for the history.

26.2 What the international literature establishes, and what it does not

Migration has been treated in the international psychiatric literature as a risk factor for psychotic illness for decades, and the claim is made in two places at once: for people who moved, and for

people born in the host country to parents who moved. That is the shape of the finding, and no magnitude is attached to it here for either generation.

That is a more useful position than it looks, because it lets the frame be taught instead of the digits. Four things bound any such figure and none is optional: which diagnosis was counted, since an estimate for schizophrenia and one for all non-organic psychotic disorders are different quantities; which host countries the studies were done in; which generation it belongs to; and how wide the interval was, since an estimate resting on a handful of studies can be compatible with a risk barely above the population and with one many times it. A multiple recited without those four is a decoration.

The argument that changed the field concerns **second-generation migrants**. Those people did not migrate: their exposure is being the child of migrants rather than the act of moving. A purely selective account predicts that the signal belongs to the generation that left and fades in the children who never did. Raised risk is discussed in that second generation as well, which is why the field moved from arguing about who migrates to arguing about what happens after arrival. The reasoning is what an examiner listens for: a signal in people who never moved is not explained by selection at departure. What it cannot do is size that risk, and an answer that makes the second generation the higher one has gone past what can be shown.

One feature of the sampling frame belongs with the claim wherever you meet it. Those studies concern international migration into predominantly Western, high-income host countries, so what is counted is the crossing of an international border into a society in which the arriving group is a visible minority. That bounds what they are estimates of, and it is what decides the Indian question.

26.3 Ethnicity: what the second word is doing, and what it marks

The second word in the title does different work from the first, and candidates treat the two as synonyms. Migration is an event and it has a date. **Ethnicity** here is a position a person occupies in the society they are currently in, meaningful only relative to that society: the same person is majority in one place and minority in another. So when a host-country literature reports higher rates in some migrant or minority groups than in others, the comparison is not between kinds of people. It is between kinds of position.

Two disciplines follow. A subgroup contrast inside a pooled literature is the weakest thing that literature produces: groups were not randomised into their origins, studies differ in how cases were found, and the diagnostic habits of host-country services differ by the ethnicity of the patient in front of them, so a subgroup difference can be manufactured by the measuring instrument rather than found in the risk. No subgroup magnitudes appear here, for that reason and because none is available to quote. The second discipline is that the careless reading of any such gradient is racial where the careful reading is social: what it marks is the position of the arriving group in the receiving society, not a property of the people who arrived.

For Indian practice the useful move is to ask what the local analogue of that position is, because it is not usually skin colour. Caste, language group, tribal status, religion and the rural origin of an

urban worker all mark a family out in an Indian city, and any of them can place a household in the position host-country studies describe. No Indian figure of that kind is available to quote along those axes, and none is invented here, so they are asked about in a history rather than scored.

26.4 Treated incidence, and what a rate from a host country is a rate of

The modern replacement for that older literature is the multinational first-episode incidence study, in which psychosis is counted prospectively across catchment areas in several countries at once. Treated incidence varies markedly from one catchment area to another, and within those areas rates are reported as raised in racial or ethnic minority groups. Whether the variation between places is larger than the difference within them is not settled here: no dependable figures are available to quote, and none are invented here. What a large between-place variation does establish is a direction for thinking. Whatever raises the rate is partly something about places and about positions within them, so minority status reads better as a marker of occupying a bad position than as a cause in its own right.

Then there is the word treated. These are **treated incidence** rates, counted from people who reached services, so any difference in how easily a group reaches care sits inside the estimate alongside any difference in how often the disorder occurs. A group arriving late, by way of the police rather than a first-contact clinician, can generate a higher treated rate without a higher true incidence. Treated incidence cannot separate the two, which is why an answer that ignores the point is incomplete. And there is no Indian catchment area anywhere in this literature, so the ethnicity axis is grounded entirely in host-country settings.

AXIS OF COMPARISON	THE MIGRATION QUESTION	THE MINORITY QUESTION
What the estimate is of	Risk of psychotic illness in people who moved and in their children, against the population they settled among	Treated incidence of psychotic disorders, against the majority of the same catchment area
Exposure that defines the group	Having migrated, or being the child of migrants	Belonging to a racial or ethnic minority group where one lives
Where the evidence was gathered	Incidence studies of migration into predominantly Western, high-income host countries	Catchment areas in several countries, not one of them Indian
What it can support	That raised risk in the generation that never moved is not explained by selection at departure alone	That variation between places is large, so place and social position belong in any explanation
What it cannot support	Any statement about internal migration, and any magnitude this account can print	Any separation of true incidence from access to care, and anything at all about India

26.5 Arguing the mechanisms without overclaiming

How to structure the answer when asked why the rate is raised. Three families of explanation compete, and a good answer names all three, says what each predicts, and then says which

prediction the data have already tested.

- **Selection.** The people who migrate differ from those who stay, whether by illness already present, by early prodromal drift, or by traits associated with risk. This predicts that the signal belongs to the generation that left and fades in their children, and the second-generation discussion is the reason it cannot be the whole story.
- **Post-migration adversity.** Something about occupying a disadvantaged, visibly different position after arrival raises risk: chronic exclusion, insecure work and housing, and the accumulated experience of being treated as an outsider. This predicts a gradient by visible difference and disadvantage rather than by distance moved, and by place rather than by person, which is the direction the host-country literature points in.
- **The diagnostic encounter.** Some of the excess is made in the clinic, by unfamiliarity with how distress is expressed, by interpreting culturally normative belief or behaviour as psychotic, and by differences in the route through which a group reaches care. Treated incidence cannot exclude this, which is why an answer that ignores it is incomplete.

What the evidence cannot yet adjudicate is worth stating as plainly as what it can. Whether living among many others of the same background protects a person is a real question, and it is not answered here: no dependable estimate of it is available to quote, and none is invented here. An answer that names the question and leaves it open is stronger than one asserting a protective effect it cannot cite.

26.6 Cultural bereavement: naming what the move actually cost

The concept that links the move to the illness at the level of one person is **cultural bereavement**, a term worth having because nothing else in the psychiatric lexicon names what it names. The idea is grief for a way of life rather than for a person. What a move takes from someone is the ordinary machinery of a life: the norms that told them how to behave, the religious observance that organised the year, the people consulted when a household member fell ill, the language spoken around them, and the standing they held in a community that already knew them. It is not the bereavement that follows a death, which belongs with grief and end-of-life care rather than here.

Two disciplines matter when using it. The first is modal. That cultural bereavement is what converts a move into an illness is a hypothesis, it is written here as one, and it is not an established causal pathway; write it the same way in an answer and in a formulation, because no dependable account of the pathway is available to quote, and none is invented here. The second is that there is no uniform migrant effect to claim. Where raised rates are discussed they are discussed for some migrant groups rather than as a property of migration itself, and a candidate who flattens that into a single migrant risk has strengthened the claim past anything that can be shown.

Clinically the concept earns its place because it converts a demographic fact into questions. What did this person do on a given day of the week that they can no longer do. Who did they consult when a child was ill, and is that person reachable now. What did they eat, what did they hear

spoken around them, and at what point in the year did the household do something together. These are not pleasantries. They locate what has been lost with enough precision that it can be named in front of the patient, and often they explain the timing of a presentation better than any life event on a checklist.

GOOD TO REMEMBER

Two sentences change the quality of a migrant patient's record. Write which move you are talking about, dated, with who moved and who did not. And write what has not been replaced since: the person consulted first about illness, the place of worship, the language spoken at home, the work that matches the training. A note that says "migrant" and stops has recorded a category. A note that records the move and the unreplaced losses has recorded an exposure, and the next clinician can act on it.

26.7 Acculturation: two questions, four strategies, and the limits of the typology

What happens after arrival is usually taught through **acculturation**, and specifically through the two-dimensional model associated with Berry. It rests on two independent questions rather than one continuum running from foreign to assimilated. The first asks whether the person places value on holding on to their own culture and identity. The second asks whether they place value on relationships with the wider society they now live in. Because the two answers are independent, they generate four positions rather than a scale, and the four are positions a person can occupy rather than stages a person passes through.

VALUES MAINTAINING OWN CULTURE	VALUES RELATIONSHIPS WITH THE LARGER SOCIETY	STRATEGY	WHAT IT LOOKS LIKE IN THE ROOM
Yes	Yes	Integration, or biculturalism	The host culture is adopted while the culture of origin is maintained; the patient moves between two settings without treating either as a betrayal of the other
No	Yes	Assimilation	The host culture is adopted in place of the culture of origin; distress often surfaces around the family left behind, or around a child being raised differently
Yes	No	Separation	The host culture is rejected in favour of the culture of origin; the practical cost is usually access, to services and to work, rather than identity
No	No	Marginalisation	Both are rejected; the person belongs to neither reference group, which is the position that most often warrants a closer look in an assessment

MNEMONIC

Keep mine? Join theirs?

Two questions, answered yes or no, give the four positions and their names. Yes and yes is integration. No and yes is assimilation. Yes and no is separation. No and no is marginalisation. Answer the two questions in that order and the names follow, which is safer than carrying them as a list.

Now the qualifications, which are as examinable as the model. The same person can use different strategies in private and in public life, so a man who is entirely separated at home and functionally assimilated at work has not contradicted himself and is not a diagnostic puzzle. A model borrowed from cross-cultural psychology also carries its own frame: it was built around individuals moving between two identifiable cultures, which is a poor description of a household in which three generations are moving at different rates and in different directions, and a poorer

one still of a woman who has moved between two districts of the same state and two versions of the same religion.

TRAP **Presenting the four strategies as a validated typology, or as a single scale.** The two questions are independent, so what they generate is a two-by-two and not a continuum running from foreign to assimilated, and a candidate who recites the four as an ordered list loses the discrimination between separation and marginalisation. The heavier error is predictive: the scheme has been criticised for having very little predictive validity, because people do not always fall neatly into those categories. Use it to say precisely where a person stands, never as an instrument that tells you what will happen to them.

26.8 Migration in India: the scale, the reasons, and the outcome evidence that does not exist

India is not a footnote on this topic, it is a different topic. The **migration rate** at the all-India level from the Periodic Labour Force Survey of 2020 to 2021 was **28.9 per cent**, and the reasons split sharply by sex. Marriage accounted for about **86.8 per cent** of all female migrants. Migration in search of employment or better employment was the largest single reason among male migrants, at **22.8 per cent**. Read those last two carefully, because their denominator is migrants and not the population: they say what the people who moved moved for, not what proportion of women or of men has moved.

28.9%	86.8%	22.8%
ALL-INDIA MIGRATION RATE FROM THE NATIONAL LABOUR-FORCE SURVEY OF 2020 TO 2021	SHARE OF ALL FEMALE MIGRANTS WHOSE REASON FOR MOVING WAS MARRIAGE	SHARE OF MALE MIGRANTS MOVING FOR EMPLOYMENT OR BETTER EMPLOYMENT

Sit with what that does to the picture. Migration in India is predominantly the marriage migration of women, and the **labour migration** that the word "migrant" summons in a Western clinic is not the dominant pattern here and is mostly a male one. So the commonest migrant in an Indian outpatient clinic is a young woman who has moved at marriage into a household not her own, frequently into a different language area, having left the people she would previously have consulted when unwell, and with no legal or administrative marker of having migrated at all. Nobody labels her a migrant. Every element of cultural bereavement is nonetheless available to be asked about, and the reason for her move is precisely the relationship inside which her distress is now occurring.

Then the hard part, which is what the epidemiology does not give us. All of the incidence evidence discussed above concerns international migration into high-income host countries. What is established for India is the scale of internal movement, with no comparable Indian outcome estimate to quote, and none is invented here. No national picture of internal migrants, of rural-to-urban migrants or of interstate labour migrants is available to cite, in incidence, prevalence or morbidity, so this topic carries Indian scale without Indian outcome. The honest examination answer states that gap rather than filling it, and notes that what is missing concerns the commonest kind of movement in the country.

PITFALL

Do not carry a host-country risk figure across to an Indian internal migrant. Every risk estimate in this literature comes from host-country studies where the exposure was crossing an international border, being the child of someone who did, or being counted as a racial or ethnic minority there. An interstate labour migrant from Bihar working in Karnataka, or a woman who moved two districts at marriage, is not that exposure, and no Indian study licenses the transfer. Quoting a remembered ratio and then applying it to the patient in front of you is the single most likely way to be wrong in this topic, and it is wrong in the direction of pathologising ordinary Indian mobility.

IN INDIA

There is no Indian guideline cover for this topic. The Indian Psychiatric Society clinical practice guidelines of 2025 for schizophrenia, depression, bipolar disorder and obsessive-compulsive disorder carry no recommendation on migration or acculturation, so no transcultural position can be attributed to them and every India-specific figure in this topic comes from official statistics rather than from clinical guidance. Nor is there a dedicated national migration survey: the rate above comes from a labour-force survey, and the Ministry of Statistics and Programme Implementation has proposed a Survey on Migration for July 2026 to June 2027. The consequence for practice is direct. If the guideline does not prompt the question and the record does not code the move, the migration history exists only if the clinician takes it.

26.9 What the examiner is testing, and the answer that survives a follow-up

Questions on this topic are marked on whether the candidate can hold a reproducible finding and a weak inference in the same hand. Three moves earn most of the marks, in this order.

- **Give the finding with its frame, and let the frame do the work.** Raised rates of psychotic illness are reported in migrants and in the children of migrants, from population-based incidence studies of migration into mostly Western, high-income host countries. If you quote a multiple you have met elsewhere, be ready to bound it on the four axes set out earlier; if you cannot, give the direction and decline the magnitude.
- **Use the second generation as an argument, not a decoration.** Say what it excludes and why it excludes it, because the examiner is listening for the inference rather than for a number.
- **Move from person to place.** Incidence varies markedly between catchment areas, so ethnicity is best read as a marker of social position in a particular place rather than as a property of a group, and treated incidence keeps access to care inside every one of these estimates.

Then land the Indian answer, because that is where most candidates stop and repeat the Western figure. Give the national migration rate, give the split by sex between marriage and employment as reasons, and say that no Indian outcome estimate exists onto which the risk figures could be transferred. An examiner who hears the gap named accurately learns more about the candidate's reasoning than any recalled ratio can show.

Two further follow-ups are common enough to prepare. Asked for a mechanism, give cultural bereavement, name the losses, and keep the modal verb hypothesised. Asked what you would do

differently, do not answer with a scale. Answer with the history: which move, who moved, what has not been replaced, and where this person now sits on the two acculturation questions. That answer is clinical, it is defensible, and it does not require a number that has not been measured in this country.

Migrant status is an epidemiological signal and not a mechanism: raised rates are reported in migrants and in their host-country-born children, so selection at departure cannot be a sufficient explanation; the mechanism is offered as the hypothesis of cultural bereavement, the aftermath is described by two acculturation questions with four positions, and in India the scale of internal migration is known while its mental-health outcomes are not.

27 · Idioms of distress and explanatory models of illness

Why two definitions taught elsewhere still have to be placed inside the encounter. The heading idioms of distress and explanatory models of illness names two constructs that stand side by side and are routinely collapsed into one. An **idiom of distress** is the vocabulary a patient and those around him use for suffering, a way of saying. An **explanatory model** is his own theory of what has gone wrong and why, a claimed cause, and it is the construct Kleinman attached to that third kind of cultural concept. Eliciting it is not a courtesy at the end of the history; it is the engine of the cultural assessment. Both constructs, the family of cultural concepts they belong to, and the questions that draw the model out are set out in full in the Psychotherapies, clinical assessment, MSE and nosology notes, and none of that is reproduced here.

What is owed in a chapter about the consultation is what a definition cannot carry. An idiom governs how you listen and how you record. A model governs what the patient will accept, what he does next, and when he decides he is well. Different levers, and marks are lost by pulling one and calling it the other.

A way of saying	A claimed cause	Defined in full elsewhere
WHAT AN IDIOM OF DISTRESS IS	WHAT AN EXPLANATORY MODEL IS	WHERE THE DEFINITIONS AND ELICITING QUESTIONS SIT

27.1 The division, and where the definitions sit

The two travel differently, which is why they must be kept apart. An idiom is usually shared: a language community may use one bodily phrase for everything from ordinary demoralisation to psychosis, so hearing it tells you little about severity and a good deal about how the complaint will be worded. A model is particular. Two patients using the same phrase may hold different accounts of its cause, and the household may hold a third. Collapse the two and you get the classic incomplete assessment: the clinician has learned the family's word for the trouble, assumed he therefore knows what they believe caused it, and never asked.

27.2 The idiom in the room: two wrong translations

An idiom fails clinically in two opposite ways, both examined. In **over-translation** the clinician hears a bodily or metaphorical phrase, converts it at once into the nearest symptom term, and

records only the conversion. Lost are the severity gradient the phrase carried and any later ability to check the translation; where the idiom is somatic, the same reflex converts a way of speaking into a somatic disorder. In **under-translation** the phrase is recognised as culturally shaped, the presentation is filed as a cultural matter rather than a clinical one, and a treatable disorder is admired instead of treated. Opposite mechanics, identical result: the assessment stops at the vocabulary.

RULE **An idiom is a form of words, so its presence neither establishes a disorder nor excludes one.** Record the complaint verbatim in the patient's own phrase before you translate it, keep both lines in the note, and decide the diagnosis on phenomenology as for any patient. Translate without leaving the original and you destroy the only thing that would let the next clinician find your error.

27.3 What the explanatory model predicts

The payoff is prediction, not description. Each part of a model forecasts a behaviour you will otherwise meet as an unexplained non-attendance. Ask for the parts separately: patients rarely volunteer them as a set.

WHAT THE MODEL ANSWERS	WHAT IT FORECASTS	WHAT THE CLINICIAN DOES WITH IT
What the trouble is, and its name	Which complaints get reported and which are thought irrelevant	Ask directly for what is not being mentioned
Why it began, and why now	Whether treatment must address a cause or a consequence	Say openly which of the two the plan offers
What it does to the body or the life	The course and severity expected, often not yours	Set the trajectory before the first prescription
Who can treat it, and who was consulted already	Whether treatment runs alongside another form of help	Ask what else is being done, without requiring it to stop
What counts as cured, and when treatment may stop	The point of unilateral discontinuation	Negotiate review against the patient's stopping rule

GOOD TO REMEMBER

Ask what the patient believes is wrong and what he believes will help before you offer the plan, never after. Asked afterwards it reads as an audit of a decision already taken and earns a polite answer. Asked before, it tells you which part of the plan will be quietly dropped, while there is still time to negotiate it.

What must reach the record, and rarely does:

- the untranslated complaint, quoted;
- the account of cause, and who in the room holds it;
- help sought earlier, and whether it continues;
- his own criterion for being well again;

- the single point where his account and yours disagree.

IN INDIA

Three features of ordinary practice make this heading unusually practical. The model is commonly held by the family rather than the patient alone, so the account you elicit may not be the one deciding whether tablets are given at home. The route to an outpatient department has usually passed through other forms of help, so the useful question is what runs alongside your treatment, not what was given up for it. And the idiom is generally spoken in a language the record is not written in, with a relative translating, so the phrase is lost at the first hop unless somebody preserves it. A measured national figure for how often help is sought elsewhere first would sharpen all three; no comparable standard is available to quote, and none is invented here.

27.4 How the heading is asked

As a short note it is a discrimination question: define both, keep them apart, attribute the model correctly, and close with what eliciting it changes. As a long case or a bedside station it is never asked as a definition. A patient whose account of his illness is not biomedical is put in front of you, and the examiner watches whether you obtained that account before proposing a plan, whether you can state it back in his own words, and whether you can name the one place the two accounts diverge. Revise only the definitions and you can name the constructs and say nothing about the divergence, which is the whole question.

TRAP **Eliciting the model and then correcting it.** The sequence feels like thoroughness and is its opposite: having asked for the belief, the clinician explains why it is mistaken, and it goes underground rather than changing. It survives, stops being reported, and now acts on adherence invisibly. The aim is a plan that can coexist with the account already in the room, not a conversion.

An idiom of distress is how the trouble is said and an explanatory model is what the patient holds to have caused it; their definitions belong to the Psychotherapies, clinical assessment, MSE and nosology notes, and what these notes add is that the model forecasts help-seeking, adherence and when the patient decides he is cured.

28 · Religion, spirituality, faith healing and mental health in India

Why the route a patient took before reaching you is a clinical fact and never a verdict on them. Of every heading in this chapter, religion, spirituality, faith healing and mental health in India is the one where the Indian answer is not a local variation of a Western one but the whole of the subject. A great deal of psychiatric help-seeking in this country begins at a religious site, and not at one kind of site: the single sustained piece of Indian research in this area opens by observing that people troubled by emotional distress or by more serious mental illness go to Hindu, Muslim, Christian and other religious centres, and that the healing power identified with these institutions may reside in the site itself rather than in the religious leader or in any medicines provided at the site. Keep that modal verb where the authors put it. It is a proposition

they advance about where a tradition locates its own power, not a finding they went on to establish.

Two failures of register are available here and both are penalised. The first is dismissal, in which the healing pathway is recorded as ignorance or delay, and the family, having heard the tone, stops mentioning it. The second is romanticisation, in which a practice is admired rather than assessed and a treatable psychotic illness is left untreated somewhere that has no doctor. What makes the topic examinable is that the evidence bearing on it is mixed, thin and almost entirely Indian, and that the boundary between a **sanctioned religious practice** and a disorder has to be drawn somewhere. It is drawn here, in the patient's words and the family's account, and not in a list of features.

28.1 Religion in the history: four different things wearing one word

Religion enters a psychiatric history in at least four ways that behave differently, and a candidate who runs them together will give one answer where four were wanted. It can be a source of structure and support, a daily and weekly scaffolding that survives when everything else has stopped. It can be the vocabulary in which suffering is spoken, the words a family reaches for before any clinical term is available to them. It can be the explanation held for the illness, the account of what has gone wrong and why. And it can be the pathway, the sequence of places help was actually sought, of which your outpatient department is usually not the first.

Only the last two change a management plan, and only the last two are commonly missing from the record. The explanatory model as a construct, and the structured way of eliciting it, belong to the cultural assessment set out in the Psychotherapies, clinical assessment, MSE and nosology notes, and none of that is reproduced here.

- Where has help been sought already, in what order, and who in the family chose each place.
- What is still going on alongside this consultation, because the commonest situation is concurrent rather than sequential use.
- What the family understood from what was done there, since that account, and not yours, is the one operating at home.
- Whether anything is currently being restricted: food, fluids, movement, sleep, or medication already prescribed.
- What would count as being well, in their terms, because that is the point at which treatment will be stopped without telling you.

GOOD TO REMEMBER

Ask these before you offer a plan, not after it. Asked afterwards, the pathway question reads as an audit of a decision already taken and earns a courteous denial. Two lines in the record change what the next clinician can do: the sequence of places help was sought, dated, and what is still running alongside. A note that records only that the patient "went to a temple first" has recorded a stereotype. A note that records who took him, what was done, what is continuing and what is being restricted has recorded an exposure and a risk.

28.2 The boundary between a sanctioned practice and a disorder

This is the discrimination the rest of the syllabus hands to this chapter, and it is easier to state than to perform. The question is never whether the belief is true, and it is never whether the practice is rational. Those are not clinical questions and no examiner is asking them. The question is whether what you are being shown is a form the person's own community recognises and sanctions, occurring in its proper setting, or whether something has broken out of that frame.

The method follows from that. You do not settle it against a textbook description, which was written from published cases and not from this community. You settle it by asking the people who would know. Does the family recognise what they are seeing as the thing their tradition does, or as something that frightened them because it was not that. Does it begin and end with the occasion, or has it stopped ending. Is the person able to do what they were doing before, outside the setting, or has role function fallen away. And, most simply, is the person themselves distressed by it, and unable to stop it when they wish to. Those four questions are asked of the family and of the patient in their own words, and their answers are recorded in those words before any translation into clinical terminology.

RULE **Whether a practice is sanctioned is a question for the patient's community; whether this person is ill is a question for you; and the two are answered separately.** The error in both directions is to let one answer settle the other. A sanctioned practice does not exclude a disorder in the person performing it, and an unfamiliar practice does not establish one. Take the community's answer on the first question as authoritative, because on that question it is, then do the diagnostic work on phenomenology exactly as you would for any other patient.

PITFALL

The compression failure. A religious practice summarised into a list of features has, in the act of summarising, been converted into a symptom cluster, and the reader who learns it that way will recognise the practice and diagnose it. The same reflex reaches backwards: it is a short step from an ethnographic account of a revered figure to naming a disorder in that figure, and it is a step with no clinical purpose and a real cost to the relationship with the family sitting in front of you. Describe the practice in the community's terms, quote the patient, and keep the diagnostic reasoning in the phenomenology where it belongs.

28.3 The one measured Indian study: the site, and what the temple actually does

Almost everything quoted about faith healing in Indian psychiatry traces to a single report published in the BMJ in 2002 by Raguram, Venkateswaran, Ramakrishna and Weiss. It is worth reading at origin rather than recalling, because what it says is more interesting and more careful than what it is usually made to say. The setting was a Hindu **healing temple** in South India: the temple of Muthusamy in the village of Velayuthampalayampudur, Dindugal District, Tamil Nadu, in the foothills of the Palani range of the Western Ghats, built more than 60 years before the study, on the outskirts of the village in the middle of a graveyard, over the tomb of Muthuswamy. One site.

The tradition's account of its own origin is that towards the end of his life a mere touch of Muthuswamy's hand was noticed to cure many ailments, especially mental illnesses, and stories spread about his healing powers; the temple was built over his tomb after his death. That is recorded as ethnography, as the community's memory of a revered figure, and it carries no diagnostic content of any kind.

What the temple does is unusually well described, and two of its features matter clinically. People may stay without charge, and a close relative stays with them and takes care of their daily needs: the family is not relieved of the person, it moves in with them. And the paper records something in both directions at once, which is the reason it can be trusted on this point. Physical restraints for agitated people are used at many other healing temples, and are not used at this one. Neither half may be quoted alone. Taken together they say that a healing site is a particular institution with particular practices, not a category with uniform standards, and that where a patient stayed is a question with an answer.

28.4 Who was studied, and what they had already tried

Read the denominator before the result, because it governs everything the study can be used for. Thirty-one people sought help and stayed at the temple over the course of the study. Twenty-three were diagnosed with paranoid schizophrenia, six with delusional disorders and two with bipolar disorder with a current manic episode. Twenty-one were male farm labourers from rural areas, and all were Hindu. There is no non-psychotic presentation in the group at all, so this work says nothing about common mental disorders, distress states or possession presentations at religious sites.

The exposure history is the second half of the picture. The average duration of illness was 71 weeks, the mean duration of stay in the temple six weeks with a range of 1 to 24 weeks, and only one of the group had ever received any prior medical care, that being from a general practitioner rather than a psychiatrist. This is therefore a largely **treatment-naive** group with illnesses of well over a year's standing, observed across a stay of a few weeks. That is what makes the group informative and it is also precisely what limits it, because natural course and regression towards the mean are left entirely uncontrolled.

31	29	6 weeks	1
PEOPLE STUDIED AT THE HEALING TEMPLE, THE DENOMINATOR FOR EVERY RESULT THE STUDY REPORTS	OF THAT GROUP CARRYING A NON-AFFECTIVE PSYCHOTIC DIAGNOSIS, PARANOID SCHIZOPHRENIA OR DELUSIONAL DISORDER	MEAN DURATION OF STAY IN THE TEMPLE ACROSS THE WHOLE GROUP STUDIED	NUMBER IN THAT GROUP WHO HAD EVER RECEIVED ANY PRIOR MEDICAL CARE, AND THAT FROM A GENERAL PRACTITIONER

28.5 What changed, and the spread that cannot be taught

The same rater assessed everyone on arrival and again at departure using the **brief psychiatric rating scale**. The mean total fell from **52.9** on arrival to **42.9** at departure, $P < 0.001$, a relative reduction of **18.9 per cent**, which the paper itself describes as nearly 20 per cent. Two standard deviations are printed in the same sentence, and they cannot be reconciled with the paper's own subscale table, so the dispersion of the total score is not established and no figure for it is asserted

here. That is not a quibble: a pre-post mean difference whose spread is unknown cannot be turned into an effect size, and much of what this study is used to argue depends on one nobody can compute from it.

SUBSCALE	ON ARRIVAL, MEAN (SD)	AT DEPARTURE, MEAN (SD)	T	P
Thinking disturbance	12.45 (3.21)	9.81 (4.42)	3.701	0.001
Hostile suspiciousness	12.26 (4.30)	9.39 (4.90)	4.631	< 0.001
Withdrawal retardation	8.32 (5.31)	7.16 (5.03)	3.574	0.001
Anxious depression	7.32 (5.09)	6.58 (4.74)	2.101	0.044

Values are as the paper prints them. All four factors fell, which is the honest headline, and the internal pattern repays a second look. The largest absolute movement is in thinking disturbance, from 12.45 to 9.81, and the strongest test is hostile suspiciousness at t 4.631. The one nobody should lean on is anxious depression, at P 0.044, which would not survive any correction for four comparisons. Note also, so that you do not file it as an error, that the four factor subscales do not cover all 18 items of the scale, which is why the subscale means do not add up to the printed totals.

There is a second outcome, and it needs its denominator kept in view. According to the evaluation by family caregivers, 22 of the group had improved and three had recovered fully, which accounts for 25 of the 31. The rating offered four options: recovered, improved, no change and worsened. Two categories existed for people who did not do well, neither is ever reported, and the remaining six are not accounted for in the printed result. This rating is also unblinded and made by the same relatives who brought the person and lived with them throughout, so it is not independent of the scale change and is not a second confirmation of it.

28.6 The exposure under study, and where the authors locate the healing

Here the paper becomes genuinely surprising, and this is the part most often lost when it is quoted. The people studied received no psychopharmacological or other somatic intervention during their stay in the temple. And no specific ceremonies were performed to promote anyone's recovery: residents merely attended the simple morning prayers, the puja, at the shrine for about **15 minutes**, and spent the rest of the time in light maintenance routines of the temple. So the exposure under study was not a healing rite and was not a drug. It was residence in a valued place, with a relative present, a short daily prayer, and something useful to do.

That is also, remarkably, what the tradition itself says. The community's own account, in the technical sense of an internal view of illness held by patients and by the local population as against the external view of doctors and epidemiologists, is that it is the experience of residing in the temple for a period of time, rather than therapy provided by a healer, that brings relief from

mental illnesses. The tradition and the researchers point at the same thing from opposite directions, and neither points at a procedure performed on a person.

MNEMONIC

Residence, Relative, Routine; no Rite, no Restraint

The five features of the exposure that was actually measured, and the reason a candidate should never describe this study as an evaluation of a healing ritual. Residence over a period of weeks; a close relative living alongside; light daily routines of the temple; no ceremony performed for anyone's recovery; and no physical restraint at this particular site, though the paper is explicit that restraint is used at many others.

The authors' own conclusion is hedged, and the hedges are the most examinable words in the paper. Their summary is that the research shows that a brief stay at one healing temple in South India improved objective measures of clinical psychopathology; that, in the absence of any specific healing rituals, the observed benefits appeared to result from a **supportive non-threatening environment**; and that this may indicate the value of a **culturally valued refuge** for people with severe mental illness. Not shows that a supportive environment causes recovery. Not demonstrates the value of refuge. An answer that strengthens those verbs has misreported the source, and an examiner who knows the paper will hear it.

28.7 The comparability claim, and the authors' own bar on their findings

The sentence that made this paper famous is the authors' interpretation, not their finding: that the observed reduction of nearly 20 per cent represents a level of clinical improvement matching that achieved by many psychotropic agents, including the newer atypical agents. Two things must be said whenever it is used. It is attributed to the authors, and its entire support is a single citation, Umbricht and Kane's 1995 review of the efficacy and safety of risperidone, Schizophrenia Bulletin 1995;21:593 to 606: one atypical agent, reviewed seven years earlier, in a different population under a different design. There was no drug arm in the temple study, so what is being compared is a milieu against a medicine, across two literatures, and not one against the other in the same patients.

TRAP **Quoting the twenty per cent as evidence that temple healing works as well as antipsychotic medication.** Candidates do this in good faith, because that is how the study circulates. Three facts dismantle it in one sentence each: the design is an **uncontrolled pre-post comparison** at a single site with the same rater at both time points; the group was largely treatment-naive with illness of over a year's standing, so natural course and regression to the mean are untested alternatives; and the comparison with medication is the authors' interpretation resting on one review of one drug. Say instead that a real and statistically significant pre-post change was observed under a design that cannot attribute it, which is also what the authors say.

Because they do say it. Theirs is the first study to use a standard clinical assessment to evaluate the effectiveness of temple healing, and their own verdict on their findings is that they are only suggestive owing to the limitations of their methods: there were no comparison groups, and although they endeavoured to keep the second assessment by the same rater independent of the

first, standards fell clearly short of rigorous double blind research methods. A candidate who reports the finding and the authors' own caveat in the same breath is doing better history of the paper than most published citations of it.

Two further disciplines belong here. The first is the authors' bar on generalising: because temples operate in different ways, they hold that it would be inappropriate to generalise findings from the study of one site to other regions or to other healing temples in the same region. The study is therefore expressly not about temple healing as a class, which is the one thing it is habitually used to talk about. Their further argument, that comparison groups and randomisation would be difficult to incorporate and would add little to the generalisability of findings, deserves careful reading rather than agreement or dismissal. It is an argument about external validity, reasonable on its own terms, and it does not answer the internal validity problem that a comparison group would have addressed and that they concede separately. The second discipline is arithmetical vigilance: the paper's Discussion refers to a stay of five weeks and to a mean duration of illness of one year, neither of which matches its own Findings, and the paper never reconciles them. Teach the Findings values.

28.8 Acceptability rather than access, and what a service does about it

The most consequential sentence in the whole report is one that gets quoted least. Set against those illness durations, only one of the people studied had ever consulted a doctor in the government primary health centre, which is located in the same village as the temple. The biomedical alternative was not distant. It was adjacent, and it was unused.

That single fact moves the question from access to **acceptability**, and the distinction is the examinable one. An access problem is solved by putting a service somewhere. An acceptability problem is not, because the service is already there and is not what people found usable, intelligible or trustworthy for this kind of trouble. Nothing in that observation implies error on anyone's part: a family choosing a place where a relative may stay free of charge, where they may stay alongside, and where the trouble is described in words they already use has made a defensible choice about a real problem. The service-development question that follows is what a primary health centre would have to change to become a place that family would use, and it is a question about explanation, continuity, cost and welcome rather than about siting.

IN INDIA

Three practical consequences follow for Indian practice. First, ask the pathway question of every patient and record the answer, because there is no register, no coding field and no guideline prompt that will do it for you. Second, treat concurrent religious help as the normal case rather than as non-compliance: a plan that requires the family to abandon the shrine before treatment begins is usually the plan that gets abandoned. Third, the safety line is not the belief and not the site, it is what is being done to the person. Restriction of food, prolonged restraint, restriction of prescribed medication or confinement is a safeguarding matter wherever it occurs, and where the pathway has passed through such a setting the clinician asks about it directly. How commonly Indians seek religious healing first, how long it delays psychiatric contact, and how common custodial practice is at religious healing institutions are all questions a service planner needs answered; no comparable standard is available to quote, and none is invented here.

28.9 Working alongside the pathway, and how the topic is asked

How to answer when this comes up, in a long note or across a viva table. The examiner is testing whether you can hold reverence and rigour in the same hand, and the answer that fails is the one that picks a side. Open with the position rather than the study: religious help-seeking is a fact about the route to care and a legitimate question in every history, never in itself a finding about pathology. State the boundary and how you draw it, in the community's terms. Then give the evidence, and give it accurately, which means naming it as one uncontrolled study at one site, giving the direction and the significance of the change, giving the authors' own hedged attribution to a supportive environment and their own refusal to generalise from it, and saying that no comparable measured evaluation exists for a shrine of any other faith.

Clinically, the working posture is collaboration without endorsement and without confrontation. You do not have to agree with an explanation to work alongside it, and you do not have to displace it to treat. What you must do is make your part of the plan compatible with the rest of the person's life: name what your treatment addresses and what it does not, agree what would count as improvement and by when, and keep the door open so that when a family returns from a shrine they return to you rather than to nobody. Where the religious setting is providing what the study describes, a place to stay, a family alongside, and something useful to do, the honest clinical judgement is that these are not the enemies of treatment; the enemy of treatment is untreated psychosis, and the two can occupy the same weeks.

Finally, be exact about what is not known, because on this heading the gaps are large and stating them is not weakness. There is no measured Indian evaluation of a dargah, a church or any non-Hindu healing site with a standard clinical instrument. There is no outcome evidence at all for the non-psychotic presentations that make up most of a real clinic. There is no Indian guideline position on collaboration with religious healers to attribute to anyone. And there is no quantified national picture of how often, or for how long, the religious pathway is travelled before psychiatric contact. A candidate who names those gaps precisely has shown the examiner something no recalled percentage can show.

Religious help-seeking is a fact about the pathway to care and never in itself a finding about pathology: the only measured Indian evaluation is an uncontrolled single-site study of a South Indian healing temple in which the mean brief psychiatric rating scale total fell from 52.9 to 42.9 in 31 largely treatment-naive people who received no drug and attended no healing ceremony, whose authors attribute the change, hedged, to a supportive non-threatening environment and expressly forbid generalising it to other temples.

Cancer, dying and grief

29 · Psychological reactions to cancer diagnosis and treatment

Why the marks are here. A candidate is asked about the psychological reaction to cancer because it is the commonest situation in which a psychiatrist is called to see a patient who is not, in the ordinary sense, mentally ill. The referral says distress. The task is to decide whether what you are looking at is a person adjusting to catastrophic news or a disorder that has grown out of it, and then to do something about the conversation in which the news was delivered, or was not delivered at all. In an Indian oncology ward the second half of that task usually arrives first, because the person who knows the diagnosis is often not the person who has it.

Psycho-oncology is the mental health of the patient with cancer and of the family around them: adjustment reactions, depression and demoralisation, anxiety about procedures and about prognosis, delirium in advanced disease, and the communication and palliative-care skills that carry all of it. What this topic owns is the psychological reactions to cancer diagnosis and treatment, and the conversation in which those reactions begin. The recognition and treatment of depression, anxiety and delirium in a patient with advanced disease, grief and end-of-life care, and demoralisation and the wish for death are each taught in companion topics of this chapter, and the adjustment disorders as a diagnostic category belong to the Anxiety, OCD and trauma-related disorders notes.

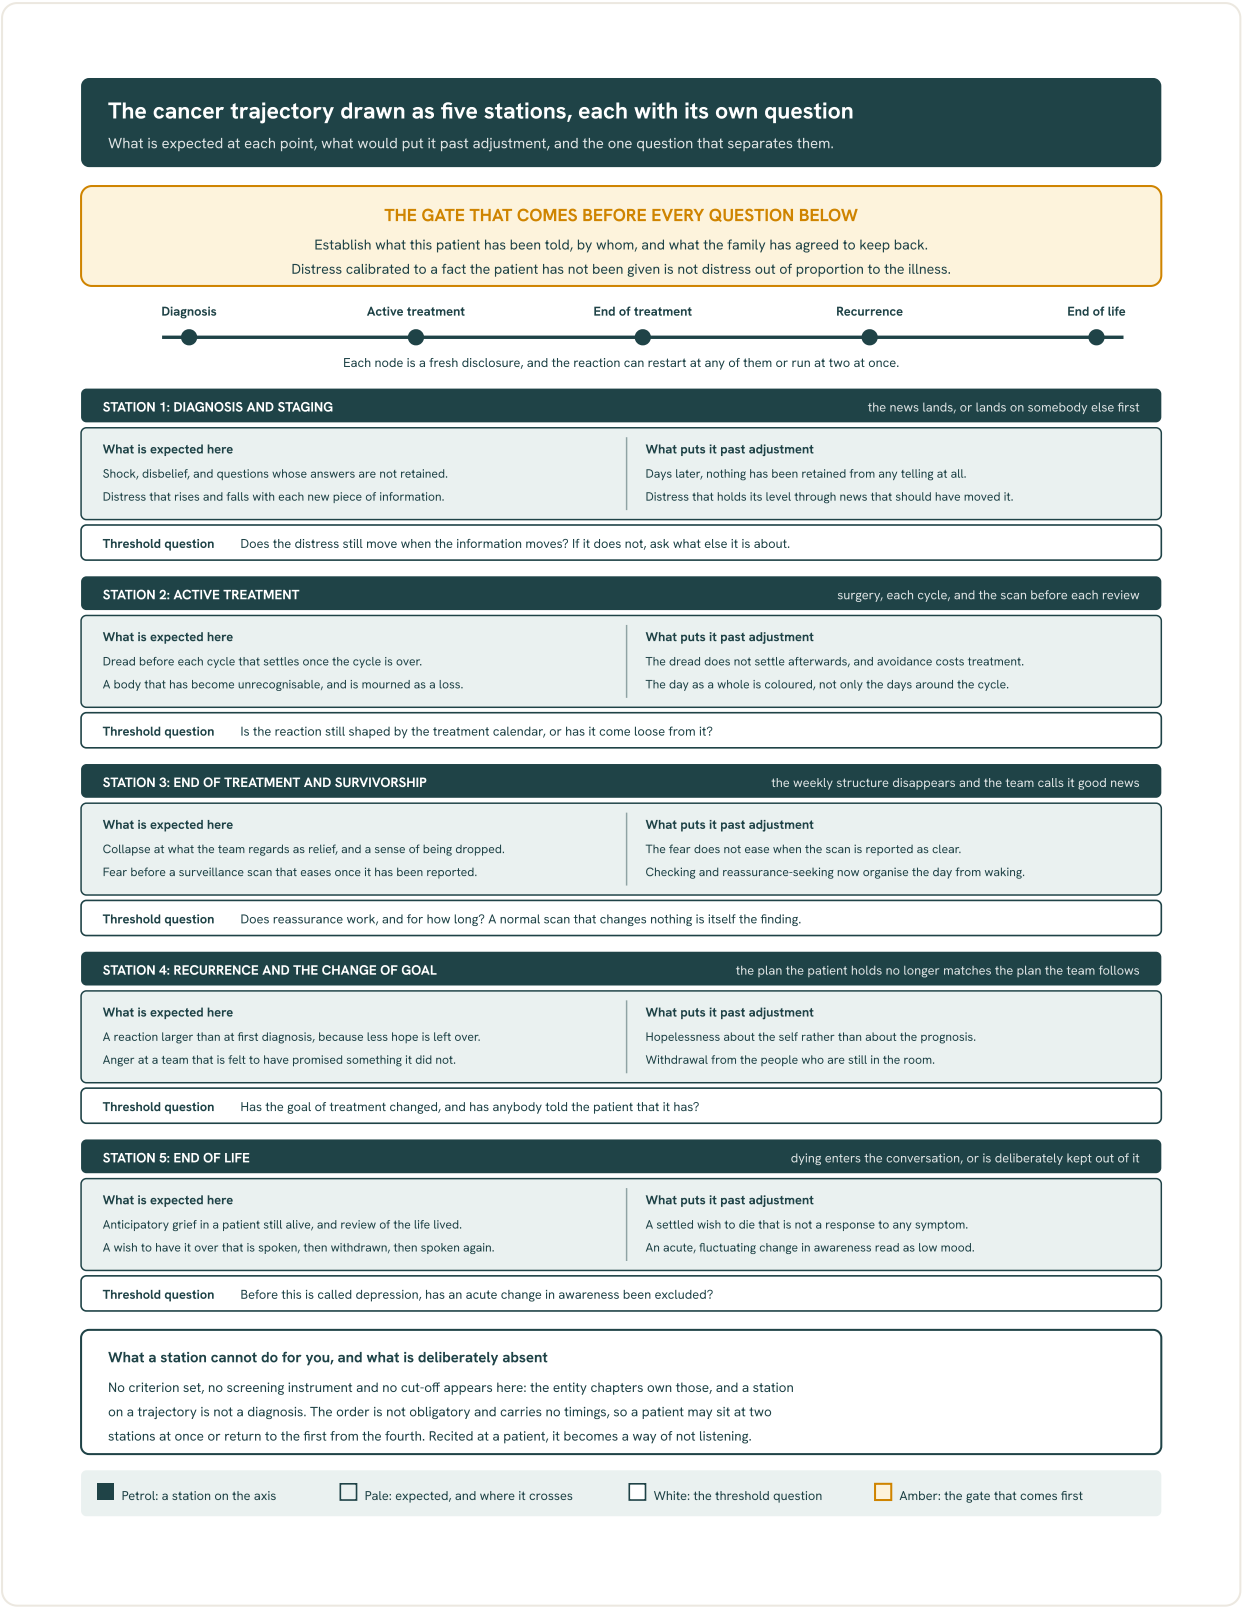

Fig 29.11. The reaction to cancer drawn along one axis as five stations, from diagnosis and staging through active treatment, the end of treatment and survivorship, recurrence and the change of goal, to the end of life, with each station carrying what is expected there set against what would put the reaction past adjustment, and one threshold question stated for each rather than a list of diagnoses, the whole gated by the prior question of what this patient has been permitted to know, and with criteria, instruments and cut-offs named as absent because they belong to the chapters that own the entities.

29.1 The reaction as a trajectory, and what a trajectory is not

The reaction to hearing that one has cancer is conventionally described as a sequence: shock and disbelief, then anger, depression, loss and grief. The description is clinically useful and worth

being able to reproduce, but be careful what you claim for it. It is a textbook account of what is commonly seen rather than a staged model with evidence behind it, so it carries no timings, no obligatory order, and no implication that a patient who has arrived at anger has finished with disbelief. Patients move back and forth across it and many never look angry at all. Recited as a schedule it becomes a way of not listening, because the clinician then checks the patient against the stage instead of asking what the patient has actually understood.

What the sequence is genuinely good for is vocabulary. It tells you that the affect in front of you at the second visit is not necessarily the affect that will be there at the fourth, that anger directed at the treating team is usually part of the reaction rather than a complaint about the team, and that loss and grief begin long before anyone dies. The anticipatory grief of a patient still under active treatment, and the grief of the family afterwards, are taught with the grief and end-of-life material in this chapter.

RULE **The reaction is normal until it is not, and in Indian practice you cannot judge which until you know what the patient has been permitted to know.** Distress that is exactly calibrated to a fact the patient has not been told is not distress out of proportion to the illness; it is distress about something else, and it will not respond to reassurance about the illness. Establish what has been disclosed, and by whom, before you decide whether the reaction in front of you is disordered.

29.2 Adjustment or disorder, which is the discrimination that carries the marks

The most useful single thing to know about psychiatric morbidity in cancer is which diagnosis sits at the top of it, and it is adjustment disorder and not depression. An Indian cross-sectional survey of consecutively admitted adult cancer inpatients in the radiotherapy department of a tertiary teaching hospital in Kerala, over 2011 and 2012, found a substantial minority carrying a psychiatric diagnosis, and the largest single group within that minority was the adjustment disorders, a clearly bigger group than major depressive disorder in the same sample.

384	41.7%	22.6%	10.9%
ADULT CANCER INPATIENTS ASSESSED, INDIAN TERTIARY RADIOTHERAPY SERVICE	CARRIED ANY PSYCHIATRIC DISORDER, SAME INPATIENT SAMPLE	ADJUSTMENT DISORDERS, THE LARGEST SINGLE DIAGNOSTIC GROUP	MAJOR DEPRESSIVE DISORDER IN THAT SAME SAMPLE

What the setting does to the number. These are inpatients on a radiotherapy service in one tertiary centre. They are not a community sample, not an all-India figure, and not an advanced-disease or hospice population, and a palliative inpatient unit would not be expected to look like this. Quote the proportion with its setting attached or do not quote it at all, because a figure from a treatment ward asserted about the dying is a different claim. Two further features are worth carrying into a viva. Diagnoses were made by structured diagnostic interview, using the MINI International Neuropsychiatric Interview rather than a distress screen, which matters because screening instruments in oncology count symptoms while diagnostic interviews count disorders, and the space between those two operations is where inflated prevalence claims are manufactured. And the sample was consecutive rather than referred, so it is not the enriched population a liaison psychiatrist meets on a consult list.

Conceptually the **adjustment disorders** are emotional and behavioural symptoms arising in response to an identifiable stressor, and in an oncology clinic the stressor is never in doubt. That is what makes the category both easy to reach for and easy to misuse. The examinable discrimination is not between sadness and depression as lists of symptoms, which the mood and anxiety chapters own; it is between a reaction that tracks the illness and a syndrome that has acquired its own autonomy. The reaction moves with events, remits when the news improves, leaves the capacity for pleasure intact between episodes of distress, and responds to information, time and company. The syndrome persists when the news improves, colours the day as a whole, holds a fixed view of the self rather than of the situation, and does not lift when the family arrives.

The practical consequence of adjustment being the commonest finding is that the commonest correct action is not a prescription. It is time, accurate information at a pace the patient sets, a named person to contact, and a review appointment that actually exists. The two errors that follow from getting this wrong are symmetrical and both are common: medicating every appropriate reaction, which teaches the oncology team that the psychiatrist is a source of sedation, and dismissing every reaction as understandable, which is how a treatable depression in a patient with cancer goes untreated on the grounds that anyone would be sad.

29.3 What the treatment itself does to the reaction

The reaction is not one event at one interview. Diagnosis, staging, surgery, each cycle of chemotherapy, the scan taken before a review appointment, the end of treatment when the structure of weekly attendance disappears, and any suggestion of recurrence are each a fresh disclosure, and each can reopen the whole sequence. This is why a patient who coped well at diagnosis can present in crisis at what the team regards as good news, and why the end of treatment can be a point of collapse rather than of relief.

One transition reorganises the psychological work more than the others, and it is the one where the goal of treatment changes. The Indian review that names the communication problem in this setting singles out two moments at which it surfaces: **the curative-to-palliative transition**, and the point at which death and dying enter the conversation at all. Both are moments when what the patient has been told stops being sufficient, because the plan the patient was given no longer matches the plan the team is following.

Some of the treatment-related material a full account would want is not settled enough to quote here. Body image after mastectomy or head and neck surgery, sexual function, fear of recurrence as a persisting preoccupation, distress at the end of treatment and in survivorship, and the financial catastrophe that treatment inflicts on an Indian family are all real clinical themes and all belong in a history, but no comparable Indian standard is available to quote for their magnitude, and none is invented here. Procedural and prognostic anxiety, and delirium arising in the course of advanced disease and its treatment, are taught in the companion topic of this chapter on depression, anxiety and delirium in cancer and palliative care.

29.4 Collusion, which is the name for what is actually happening

Collusion is the name for information about diagnosis, prognosis or medical detail being withheld, or shared selectively, within the triangle of patient, family and treating team. Its most important property is that it is graded rather than binary. The family may allow the physician to tell the patient about the recommended treatment while asking that the diagnosis not be revealed, or the physician may disclose the diagnosis to the patient and withhold what is known about the prognosis. So describing a case requires three answers and not one: who is being kept in the dark, what exactly is being withheld, and how complete the withholding is. The review that names the construct puts the point memorably: "Collusion is not always a conspiracy of silence, it may be a conspiracy of lopsided communication as well!"

Two patterns are named in the same source and both are worth recognising by name in a viva, because both look like coping and neither is. In **the recovery plot**, patient and relatives together focus on treatment and recovery and do not address prognosis, disability, relapse or death; the conversation is busy, hopeful and entirely about the next appointment. In **medical activism**, the doctor does exactly the same thing, offering the next investigation and the next line of treatment in place of the conversation that is due. The second is the more dangerous, because it is the one the team mistakes for professionalism.

WHAT IS WITHHELD	WHO IS KEPT IN THE DARK	HOW IT LOOKS AT THE BEDSIDE	THE CLINICIAN'S FIRST MOVE
The diagnosis, while treatment is openly discussed	The patient	Consent is given for radiotherapy without the word cancer being used; the patient asks the nurse what the machine is for	Establish what the patient already believes is wrong, before answering anything
The prognosis, after the diagnosis has been given	The patient	The patient plans as though cure were certain; the relatives already know it is not	Ask what the patient understands this treatment is trying to achieve
Everything, completely	The patient	Relatives answer for the patient throughout the consultation; the patient stays silent and watchful	Interview the family first by agreement, then see the patient alone
The patient's own knowledge and fear	The family	The patient knows, protects the relatives from knowing that they know, and each side performs hope for the other	Offer to be present when the two of them speak openly for the first time

Note what the last row does to the standard teaching. **Partial collusion** is not always the family protecting the patient. It runs in the other direction often enough that assuming the patient is the ignorant party is itself a clinical error, and the family is not the only possible party in the dark:

the treating team can be the one that has not been told, when the patient and relatives have agreed between themselves what the doctor will be allowed to hear.

29.5 The Indian family-disclosure reality, in numbers

Two structural facts make collusion the ordinary case in Indian oncology rather than the exception. An Indian palliative-care review reports that nearly one half of patients seeking cancer treatment in India are unaware of their diagnosis or their treatment, and that most patients attend accompanied by a close relative. That proportion is the review's own summary of the literature it surveyed rather than something it measured, so it should be quoted as a magnitude and in its own words; it does not convert into a percentage, and converting it would be inventing a measurement. The second fact does more work than the first, because the accompanying relative is not merely present. In the Indian family scenario a responsible family member is the decision-maker who directs and discusses most treatment matters, and collusion with the healthcare team follows from that structural position rather than from any wish to deceive.

The figures that make this examinable come from a prospective Indian study by Gautam and Nijhawan, which assessed 100 cancer patients, as reported in the Indian Psychiatric Society's clinical practice guideline on breaking bad news, published in the Indian Journal of Psychiatry in 2023. Among the patients who already knew about their condition, **71 per cent** wanted to be told the truth. Among relatives, **81 per cent** wanted the diagnosis disclosed to them, while **77 per cent** did not want it disclosed to the patient. Hold those three together and the shape of the problem becomes visible. The patients who know want the truth; the relatives want the truth for themselves; and the same relatives do not want the patient to have it. The contradiction is not between the doctor and the family. It sits inside the family's own position, which is why arguing with the family rarely resolves it and why naming the contradiction gently sometimes does.

TRAP **Quoting the patients' figure as though its denominator were all the patients in the study.** It is not. It is the proportion of those who already knew about their condition who wanted to be told the truth, a narrower group and one already selected for having found out somehow. The figure therefore says nothing at all about what the unaware want, and used the other way round it becomes an argument for universal disclosure that the study never made. Candidates lose the mark by dropping the denominator, and clinicians lose the argument at a family meeting for the same reason: a relative told that most patients want to know can correctly reply that their patient is not among those patients.

IN INDIA

Before any decision about disclosure, establish three things and write them down: who accompanied the patient today, who in this family actually makes treatment decisions, and what has already been said to whom. In a service where the accompanying relative is usually also the decision-maker, a clinician who opens with the diagnosis has not been brave; they have walked into a conversation whose terms were set before they arrived, and have often ended the family's willingness to leave the patient alone with the team again. The order in which you interview the patient and the relatives is a clinical decision in its own right, and it deserves to be taken deliberately rather than by whoever reaches the chair first.

29.6 The ethics, which cut both ways

The defensible position is not that family-first disclosure is simply bad practice awaiting correction. The Indian source that grounds this picture argues both sides of it, and a candidate who argues only one side has answered half the question.

What collusion costs the patient:

- It obstructs the patient's autonomy, because decisions are then made about a person by people who are better informed than that person is.
- It can deprive them of health services and care they would have accepted had they understood what was wrong.
- Trust can break when the truth is discovered later, and the discovery may be followed by fear, depression and anger directed at everyone who kept it.

What the family is protecting, and it is not nothing:

- Collusion may defend the person from potential maleficence, as this family judges what this particular person can carry.
- It may minimise the patient's concerns about the future, which is precisely what the relatives believe they are being asked to do.
- It expresses an idiom of care in which relatives are involved in making the patient get better rather than in making the patient feel better.

The two sides do not cancel out, and the source's own resolution is about timing rather than principle. What it argues is that breaking the collusion in good time matters, because a patient left unchecked is the more likely to end up distressed, morbidly anxious and depressed. That reframes the clinician's question into something answerable at the bedside. It is not whether a family may ever withhold, it is how long this particular silence can hold before it costs the patient more than it protects them, and who will be sitting with the patient when it fails.

One thing this topic deliberately does not assert. Whether any Indian regulatory instrument imposes a duty to disclose a diagnosis to the patient rather than to the family, and with what exceptions such as therapeutic privilege, is not established here: no comparable standard is available to quote, and none is invented here. Argue the ethics and the clinical consequence, keep the argument about autonomy and harm, and do not attribute to an Indian doctor a legal obligation you cannot cite.

29.7 Working through collusion, which is the clinician's actual task

The source that names collusion also describes how it is dismantled, and the description is a way of working rather than a validated protocol: it carries no acronym, no step count and no trial behind it, and it should not be recited as though it did. The reasons for the collusion are established early, because a family withholding out of terror needs something quite different from a family withholding because of a promise made at a bedside years ago. The relatives are then given an explicit undertaking that nothing will be told to the patient without their consent, and a contract to that effect. Only after that is the patient's own level of awareness assessed,

through direct questions and by following the cues the patient offers about what they think is happening to them. The observation that makes the whole sequence work is that patients usually show considerably more awareness of their condition than their relatives believe they do, which means the conversation the family is dreading has frequently already taken place inside the patient's own mind.

What follows is pacing rather than revelation. The clinician is physically present when the patient and the relative first speak openly, so that neither of them is left alone afterwards with what was said. The pace is set by what all parties can tolerate rather than by the clinician's timetable, which in practice means that a single conversation is rarely the unit of work. And the feelings of both parties are reassessed periodically, because a family that agreed to disclosure at one meeting may need the agreement rebuilt at the next, particularly after a scan.

GOOD TO REMEMBER

The undertaking to the relatives is the act that makes everything after it possible, and it is the easiest step to skip. Said aloud it sounds like this: nothing will be said to your father that you have not agreed to, and I will tell you before I say it. It costs nothing, it removes the family's reason to keep the patient away from the team, and it converts an adversarial negotiation into a shared one. Record what was agreed and with whom, so that the next clinician on the ward does not undo it by accident in the first minute of a ward round.

Before deciding what to disclose, establish what the patient already knows and what the family has agreed to keep, because in Indian practice the disclosure decision has usually been taken before the psychiatrist arrives.

The structure of a breaking-bad-news interview as an examined station, and the way such a station is marked, is taught with the practical-examination material in this chapter. What belongs here is the substance that station is testing, which is the ability to work out which of two quite different problems is in the room.

30 · Depression, anxiety and delirium in cancer and palliative care

Why the marks are here. A question about the patient with advanced cancer who has stopped eating, cannot sleep and says there is no point is not asking for a criterion set. It asks whether you can still reach a diagnosis once the illness has taken away most of the evidence diagnosis rests on, and whether you will still treat when the prognosis is short and the drug chart is crowded. Candidates fail in two opposite directions: one records a diagnosis the body has manufactured, the other declines to diagnose at all, because in a dying patient everything is attributable to the disease.

What follows is the recognition and treatment of depression, anxiety and delirium in cancer and palliative care, on the assumption that each entity has been learned elsewhere. Delirium itself, with its subtypes, instruments, causes and treatment, belongs to the Stroke, TBI, delirium and focal brain syndromes notes; the anxiety disorders as diagnostic categories to the Anxiety, OCD

and trauma-related disorders notes; antidepressant choice, dose and schedule to the Mood disorders: pharmacotherapy notes. The reaction to the diagnosis, grief and bereavement, and the wish for a hastened death are taken up in companion topics of this chapter.

30.1 The evidence the illness takes away

Ordinarily much of the case for depression is carried by the body: appetite gone, weight falling, sleep broken, energy absent, movement and speech slowed. In advanced malignancy each of those is also produced by the tumour, by cytotoxic and radiation treatment, by opioid analgesia, by anaemia, by unrelieved pain and by the metabolic disturbance of the illness. The problem this **somatic confound** creates is not that the features are hard to read in one patient. It is that they lose their discriminating power across the whole ward, and a feature everybody has separates nobody.

Two symmetrical errors follow and an examiner is usually probing for one. Count the somatic features at face value and the apparent prevalence of depression on a palliative unit approaches its census; attribute them all to the disease and nobody there is ever diagnosed. Both are failures to notice that a decision about **attribution** is being taken silently, and that whichever way it goes it fixes the answer before the interview begins. How the criteria should be handled here, whether the somatic items are discounted, replaced by affective and cognitive substitutes, or counted regardless of cause, is not settled on this page. No comparable standard is available to quote, and none is invented here.

RULE **In advanced disease the diagnosis of depression is carried by what the patient believes about themselves, not by what the body is doing, because the body is answering to the illness.** That relocation drives everything practical here: the interview turns early to self-attitude, guilt and the capacity for pleasure rather than to sleep and appetite, and the attribution reasoning goes into the note rather than staying in the clinician's head.

30.2 What still discriminates, and the order in which to look

Move the weight of the assessment onto content the disease does not manufacture. Advanced cancer explains fatigue, but not a settled belief that one is a burden who deserves what is happening; poor appetite, but not guilt about matters unconnected with the illness; withdrawal, but not **anhedonia** in the strict sense, the loss of any capacity to be pleased, including by a grandchild arriving or a scan better than expected. Hopelessness about the prognosis may be an accurate reading of the facts; hopelessness about oneself is not something a tumour produces.

The second discriminator is sequence rather than content. Distress driven by an unrelieved physical symptom generally moves when that symptom moves, so pain, breathlessness, nausea and constipation are treated first and the mood re-examined afterwards, both examinations timed and recorded. Where no investigation settles the question this is the only experiment available, and it turns an argument about attribution into an observation somebody else can check.

Which screening question or brief instrument is defensible in a patient too breathless or too exhausted for a full interview is not answerable here: no comparable standard is available to

quote, and none is invented here. What can be said is what such a screen has to survive:

- it must be answerable by someone whose concentration fails quickly, since an instrument the patient cannot finish returns nothing;
- it must stay interpretable when the patient stops because of the illness rather than the mood, a distinction almost no instrument draws for you;
- it needs somewhere to hold what the person at the bedside overnight has noticed, since that person holds most of the observation.

30.3 Whether to treat at all, and what the national guideline settles

The commonest reason depression goes untreated in advanced disease is not that it was missed but that it was recognised and judged not worth treating, on two grounds rarely said aloud:

- the prognosis is too short for an antidepressant to work, so nothing is started and the question is never revisited;
- the drug chart is already full and the oncology team will not welcome another agent on it.

The Indian position on the first is explicit. The clinical practice guideline for the assessment and management of depression in India, prepared for the Indian Psychiatric Society and published in the Indian Journal of Psychiatry in 2026, states that where depression sits alongside medical illness pharmacotherapy remains indicated. Name what that rests on as well as what it says. It cites an umbrella systematic review and meta-analysis of randomised controlled trials in major depressive disorder, spanning **27** comorbid medical conditions, in which antidepressants were more effective than placebo across a range of illnesses including myocardial infarction, coronary artery disease, stroke, inflammatory bowel disease, diabetes mellitus and cancer.

One qualification travels with that recommendation wherever it is quoted: patients with psychiatric and medical comorbidities tend to have a poorer response to antidepressants than those without. Read the wording exactly. It gives a direction and not a magnitude, and a poorer response is not an absent one. It is a reason to be honest about what to expect and to plan the review, not a reason to withhold.

The psychological arm carries its own limits and they are examinable. Despite study heterogeneity, which the guideline names in the same sentence, meta-analyses are said to support cognitive behavioural therapy and behavioural activation for patients with medical comorbidities such as coronary heart disease and neurological disorders. Those illnesses are examples, not a closed set. But cancer, named among the illnesses on the drug side, is absent from the examples on the psychological side, so offering structured psychological treatment in advanced cancer on this evidence is an extrapolation and is better presented as one.

None of this licenses the prescription itself, which belongs to the Mood disorders: pharmacotherapy notes. The constraints that actually decide the choice appear here only as questions, with no answer asserted for any: how fast an agent can act against a prognosis that may be short, impaired hepatic and renal clearance, interaction with opioids and with anti-emetics,

and anticholinergic load in a patient already close to delirium. No comparable standard is available to quote, and none is invented here.

TRAP **Carrying a treatment finding across from the population that produced it to the patient in front of you.** The trials gathered into that umbrella review recruited people with major depressive disorder and a comorbid physical illness, and such a participant is generally well enough to consent, attend and complete ratings across the study period. That is not the patient in the final phase of the illness. The direction stands and should still be quoted, but presenting the evidence as though it came from a hospice overstates it.

30.4 Anxiety, which has several sources and one appearance

Anxiety on a cancer ward looks much the same whatever generates it, and the task is to work out which process is running. Sorting it by what the fear tracks is more useful at the bedside than sorting it by severity, because the tracking tells you what will answer it. **Procedural anxiety** attaches to an event and **prognostic anxiety** to a question the patient has not been able to ask, and both are often present in the same patient at different hours.

WHERE THE FEAR COMES FROM	WHAT IT TRACKS	WHAT ANSWERS IT	WHAT IT GETS MISTAKEN FOR
An event	The cannula, the mask that immobilises the head for radiotherapy, the scan and the wait for its report; it settles once the event is over	Changing how the procedure is done and who is present	A pervasive anxiety needing regular medication
A question	Review appointments and changes of plan; it does not settle when the procedure ends, because the procedure was never what it was about	Establishing what the patient has understood and what they have not been able to ask	Poor coping, or a patient the team starts to call demanding
The body	Breathlessness, hypoxia, unrelieved pain, sepsis, and the fear that opens a delirium before anything else about it is visible	Finding and treating the physical cause, after which the fear commonly goes too	An understandable reaction to being ill, which nobody looks past
The drug chart	What was started and what was stopped; the onset dates from a dose rather than a conversation	Reviewing the chart with whoever prescribes on it, before adding to it	Worsening anxiety, answered with a further prescription

The bottom row is the one candidates leave out, and a patient who locates the fear in the legs rather than the mind points straight at it. The discrimination that carries marks, though, is the third. Fear accompanied by a fluctuating level of alertness, or by attention that slides off the

question, is managed as delirium until shown otherwise, and the anxiolytic reasonable in the first two rows is the wrong instrument there.

30.5 Delirium once the goal of treatment has changed

The decision belonging to this setting and to no other is how far to look for a cause once the illness is no longer being treated for cure. Earlier in the disease that is not in doubt. Late in it the search carries its own costs: venepuncture, a transfer for imaging, a catheter, a move back to a ward from the home the patient wanted to stay in. Its extent becomes a clinical judgement rather than a protocol.

The failure to guard against is not that too little was done but that nobody decided. The search quietly stops, no reason is entered anywhere, and afterwards the team cannot say whether a reversible cause was excluded or never sought. A recorded decision to limit investigation, carrying its reasoning and whoever took it, is defensible to a family and to an examiner; an absence of decision is defensible to neither.

Indian data are thin and must be quoted with the setting attached. A hospital-based cross-sectional survey published in the Indian Journal of Psychiatry in 2016 found delirium in **6.5 per cent** of adult cancer inpatients on a tertiary radiotherapy service in Kerala. Those patients were admitted for active treatment, so the proportion describes an oncology treatment ward and nothing beyond it. What it is in advanced or terminal disease in India is not established here: no comparable standard is available to quote, and none is invented here. The instrument is not named either, the report identifying it only in general terms.

The restlessness of the final hours is spoken of at the bedside as **terminal restlessness**. Whether it is properly a distinct entity, how it should be described, and how antipsychotic choice differs there are not settled on this page: no comparable standard is available to quote, and none is asserted. What is safe to teach is the explanation given to the family. A relative who understands that a frightened, confused patient is ill in the brain, rather than possessed or being punished, stops restraining, stops arguing with the content, and begins supplying the observations the search depends on.

IN INDIA

The continuous observer at an Indian bedside is **the family attendant**, present through the whole of a night the clinical team samples once. Two consequences follow. The history of fluctuation, of what the patient was like earlier and whether anything changed, comes in a detail no observation chart will match, provided the attendant is asked in their own language and asked about changes rather than symptoms. And the attendant usually decides whether the tablet is given after discharge, so a treatment decision explained only to the patient, or only to the referring team, may never be carried out.

30.6 What has to be settled before the interview ends

What an examiner is checking. Three questions are open in every one of these consultations and all three can be answered in a single visit. Which presenting features are being counted towards a

psychiatric diagnosis and which attributed to the disease. Whether treatment is being started, and if not, on what ground and who will look again. And whether this is a disturbance of mood, of anxiety or of consciousness, since the third rewrites the management of the other two.

The body cannot testify
APPETITE, WEIGHT, SLEEP AND ENERGY ARE ALL CLAIMED BY THE DISEASE, WHICH IS WHY THE INTERVIEW MOVES TO GUILT, WORTHLESSNESS AND THE CAPACITY FOR PLEASURE

Poorer, not absent
RESPONSE TO ANTIDEPRESSANTS TENDS TO BE POORER WHERE MEDICAL COMORBIDITY IS PRESENT, WHICH IS A REASON TO PLAN THE REVIEW AND NOT TO WITHHOLD

A decision, not a drift
LIMITING THE SEARCH FOR A CAUSE OF DELIRIUM LATE IN ILLNESS IS DEFENSIBLE WHEN IT IS RECORDED WITH ITS REASONING

GOOD TO REMEMBER

Write the decision not to treat as carefully as the decision to treat, with a reason and a review attached. An unwritten decision cannot be told apart from an oversight. The sentence that does the work is short: the low mood is judged to be driven by unrelieved pain, analgesia has been optimised, and the mood will be reassessed at the next review by the clinician named as doing it.

In advanced disease the somatic evidence belongs to the illness, so the diagnosis rests on the patient's view of themselves, and a short prognosis with an attenuated expected response is an argument for planning the review rather than for withholding treatment.

31 · Grief, bereavement and end-of-life psychiatric care

Why the marks are here. Nobody is called to see a bereaved person because bereavement is a disease. The psychiatrist is called because a team, or a family, has run out of ways of being with someone, and the examinable skill is deciding which of two very different requests has arrived: company through something ordinary and terrible, or assessment of something that has stopped being ordinary. Err towards treatment and you medicalise a family's worst month. Err towards reassurance and you leave a treatable illness inside a story everyone finds sufficient.

What follows is grief, bereavement and end-of-life psychiatric care written as a set of acts: what the clinician does before a death, in the conversation where the news is given, and in the months that follow. The entity belongs elsewhere: prolonged grief disorder as a diagnosis, the criteria and the duration written into them, and the point on which the two classification systems disagree, are taught in the Anxiety, OCD and trauma-related disorders notes. Depression, anxiety and delirium in advanced disease, and demoralisation and the wish for an earlier death, belong to the companion topics of this chapter on those subjects, and the ethics of withdrawing treatment are argued in their own place.

31.1 Grief is not the referral question

Normal grief is what most of this work consists of, and the default posture towards it is **accompaniment**: presence, accurate information, a named person to contact, and a review that actually exists. That is not a lesser intervention held in reserve. It is the intervention, and for the great majority of bereaved people it is the whole of it.

The referral is hard to read because it is rarely generated by the bereaved person. It is generated by somebody watching them: a ward sister who has run out of things to say, an adult child who wants a sedative for a parent so the household can function again. Establish who is asking, what they want changed, and what they believe happens if it is not. Many then resolve without a psychiatric formulation, because the problem was never located in the person referred.

RULE **Intensity is not the axis on which this decision is made.** Grief that looks unbearable to a watching team may be exactly proportionate to what was lost, and grief that looks restrained may conceal someone who has stopped eating and stopped speaking. The axes that carry the decision are function, safety, and whether the picture is qualitatively different from sorrow rather than merely larger than expected. A candidate who answers with adjectives about how sad the patient looked has answered a different question.

Mourning as a set of observances, and the boundary between a sanctioned religious practice and a disorder, are drawn where culture and the explanatory model are taken up in this chapter. What carries into the interview is procedural: establish what this family expects to be doing at this stage, and who is expected to do it, before deciding anything is unusual. A relative who has not left the house is obeying an instruction in one family and withdrawing in another.

31.2 Anticipatory grief, and the loss that starts before the death

Anticipatory grief is the mourning that begins while the person is still alive, once it is clear to patient or family that the illness will end in death. It is not a rehearsal and should not be sold to a family as one. What it does is redistribute the psychological work across time, so that some reorganising of roles and plans happens while the dying person can still take part. Whether it reduces the intensity or duration of what follows the death is the question this literature is built around, and no comparable standard is available to quote, and none is invented here.

Two consequences carry the marks. It is readily mistaken for coldness at the deathbed by staff who arrive late and see only the calm. The second is the hinge of this topic: a family cannot grieve in advance for a death nobody has told them is coming, and neither can the patient. Where the prognosis is held back, the work anticipatory grief would have done early and slowly is deferred whole to the hour of the death and the months after it.

31.3 Breaking the news to a family rather than to a patient

Every framework for delivering serious news that a candidate has read was designed for two people in a room, a clinician and a patient. That assumption does not hold in most Indian consulting rooms, and the Indian palliative-care literature says so directly: in filial cultures the patient is almost always accompanied, relatives are reluctant to leave when asked, and an instruction that the patient is not to be told is routine. A dyadic protocol applied unmodified there fails by putting the clinician into a negotiation with people it does not acknowledge.

The adaptation is small to state and hard to do. A cross-cultural analysis published in the Indian Journal of Palliative Care in 2009 by Chaturvedi, Loiselle and Chandra recommends conducting the disclosure with **more than one** family member present alongside the patient, because more than one relative is already involved in the care and all will want the clinical detail. The second

half is the part candidates omit. Where several relatives are in the room, the clinician identifies **the key relative** by asking whom the patient regards as the key relative or head of the family. Not the loudest voice, not whoever booked the appointment, and not the clinician's guess from the seating.

> **IN INDIA**
>
> Three questions before the news is given do most of the work. Who does the patient want in the room for this. Who does the patient regard as the one who speaks for the family. What has already been said, by whom, and to whom. In that order the third is usually answered without a struggle, because the family has heard they are not about to be excluded. A clinician who reaches for the diagnosis first has not been braver, only faster, and has often ended the family's willingness to leave the patient alone with the team.

There is a named hazard on the clinician's own side. The same source warns that the doctor may be quite comfortable with the recovery plot and enter this conspiracy too readily, because the conversation about the next investigation is easier than the one that is due and the family will reward it. That pattern, and the method for dismantling it, belong to the companion topic of this chapter on psychological reactions to cancer diagnosis and treatment. What belongs here is that the multi-party meeting is where a clinician joins it, invisibly to themselves.

The stepwise conduct of the interview, the order of delivery and the criticism made of that order are taught with the communication and risk-assessment station material in this chapter. No step count, expansion or sequence appears here, deliberately: what this section owns is the shape of the room, not the script.

31.4 What a silence held to the end leaves behind

Concealment has a near-term cost and a long-term one, and the second is why grief and disclosure sit in one topic. Near-term, an unaddressed silence leaves the patient morbidly anxious and depressed, and lowers the threshold for physical symptoms such as nausea and pain, so symptom relief becomes harder to achieve. That is the argument a palliative team accepts when the ethical one has failed: the concealment is interfering with the analgesia.

The long-term cost falls on the survivors. Where the silence holds to the death, what is left is **unfinished business**: practical and emotional matters never attended to, because attending to them would have meant admitting what was happening. The arrangements only the dying person could make, and the things each of them meant to say and could not without conceding the diagnosis. The source states the consequence plainly: this failure makes it harder for relatives to work toward resolving their own grief. Withholding intended as protection is therefore not neutral for the protectors. It is a debt falling due after the funeral, on the people who took it on.

TRAP **Arguing disclosure purely as the patient's right, in front of a family whose motive is love.** Candidates lose this exchange because the family is not making a claim about autonomy and cannot be defeated on one. What moves an Indian family is the consequences they already care about: symptoms harder to control while the silence holds, the things their father will not get to arrange, and the grief they will themselves be doing with all of it undone. Argue the ethics in the viva, but recognise that in the room it is the second argument that works.

31.5 The hours after a death, and what is honestly known about them

A boundary worth stating aloud. What a clinician does at a death and just afterwards, meaning how the news of the death is given, how the meeting that follows is conducted, what enters the record, whether a condolence contact is made, and which relatives are offered **bereavement follow-up** and on what basis, is not settled here. No comparable standard is available to quote, and none is invented here. That matters because it is the part of the work most often improvised.

What can be reasoned rather than quoted is a priority, and it follows from the mechanism above. If unfinished business is what makes the survivors' work harder, the families to look for afterwards are those in which the silence held: the prognosis never discussed, one relative carrying the decision to withhold alone, or disclosure too late for anything to be arranged. That is reasoning in the absence of a standard, offered as such.

Ask who is asking
THE BEREAVEMENT REFERRAL IS USUALLY RAISED BY THE OBSERVER, NOT BY THE PERSON NAMED ON IT

The room holds more than two people
DISCLOSURE IN INDIAN PRACTICE IS MULTI-PARTY BY DEFAULT, AND THE PATIENT NAMES WHO LEADS IT

Unfinished business is the debt
A SILENCE HELD TO THE DEATH MAKES THE SURVIVORS' OWN GRIEF HARDER TO RESOLVE AFTERWARDS

31.6 When accompaniment becomes assessment

This is the discrimination the examiner is testing, and it is made without the diagnostic apparatus, because in most of these encounters reaching for it is itself the error. The table is written the way a referral arrives, not the way a criterion set is.

WHAT THE REFERRAL SAYS	WHY THAT ALONE DOES NOT SETTLE IT	THE ACT THAT DOES
She cries all the time and cannot be consoled	Intensity tracks what was lost and how recently, and consolability describes the visitor as much as the patient	Ask what she has managed to do since: eating, washing, sleeping, caring for whoever depends on her
He talks to his dead wife and hears her	Such experiences occur in ordinary bereavement, and in many families are expected rather than alarming	Ask whether it is sought or intrusive, whether it is held to be real, and what the family makes of it
She says she wants to go with him	A wish to have died alongside is not an intention to act, and neither is inferred from the other	Ask the suicide question directly; the assessment is taught in the Somatic-symptom, sexual, impulse-control disorders and suicide notes
He was fine at the funeral and fell apart weeks later	The ritual period supplies structure, company and a role, so its ending is a predictable collapse point	Locate it in the trajectory: ask what changed when it began, not what is wrong now
The family wants something to help her sleep	A solution has been offered before any problem was stated, and it is often the household's problem	Establish what the sleeplessness consists of, and who is troubled by it, before any prescription
She has had a depressive illness before	Here the threshold genuinely moves, because a previous episode makes recurrence under this load likely	Assess for recurrence on its own terms; treatment of a depressive episode is set out in the Mood disorders: pharmacotherapy notes

Two further findings should move a clinician however recent the death: alcohol or sedatives recruited to get through the evenings, easy to normalise early and hard to stop later, and a settled conviction of worthlessness that is about the person rather than the loss. Neither arrives as a referral sentence, which is why neither is in the table. Both have to be asked for.

31.7 End-of-life psychiatric care as a way of working

A psychiatrist attached to a palliative service works differently from one holding an outpatient clinic, and the difference is examinable. Referrals arrive as behaviour or as communication rather than as diagnoses. Reviews are short, frequent and at the bedside with relatives present, because a patient who cannot sustain one long interview can sustain several brief ones. The drug chart is read for what is sedating the patient as much as for what is treating them. And the goal shifts from clearing a symptom to making the time tolerable, which changes what counts as a good outcome.

- What the patient has been told, by whom and when, or the next clinician repeats the disclosure or contradicts it.
- Whom the patient identified as the relative who speaks for the family, and what was agreed with that person.

- What remains unattended that the patient still has the capacity and the time to attend to.
- Who is likely to need finding afterwards, and who has agreed to look for them.

GOOD TO REMEMBER

The most useful question in an end-of-life interview is not about mood. It is a version of: is there anything you still want to say to somebody, or anything you still want arranged. A very ill patient can answer it, it takes under a minute, and it turns an abstract worry about unfinished business into a list somebody can act on this week. Whether it can be answered at all also tells you how much the patient has been allowed to know.

Grief needs accompaniment far more often than it needs treatment, and the decision to move from one to the other turns on function, safety and a qualitative change rather than on how intense the sorrow looks to whoever made the referral.

32 · Demoralization and desire for hastened death

Why the marks are here. A patient with advanced disease says, quietly and without drama, that there is no point going on and that they would rather it ended. Nothing in that sentence tells you which of several quite different clinical situations you are in, and the examiner is testing whether you can hold them apart, whether you know that one of them has a name and a literature of its own, and whether you know what the law in this country permits the treating team to do once the sentence has been said. This topic pairs demoralization and desire for hastened death because the proposal that named the first identifies the second as where it predictably leads, and because a candidate who can only reach for depression will medicate a problem that is not primarily a disorder of mood and will still not have answered the patient.

Two boundaries are worth fixing first. The recognition and treatment of depressive and anxiety disorders in a patient with advanced disease, and of delirium in that setting, belong to the companion topic of this chapter on depression, anxiety and delirium in cancer and palliative care; anticipatory grief and bereavement belong to the companion topic on grief, bereavement and end-of-life psychiatric care. The assessment and management of the suicidal patient in general psychiatric practice is taught in the Somatic-symptom, sexual, impulse-control disorders and suicide notes. That subject is adjacent to this one and is not the same as it, and the difference is examined more often than the resemblance.

2001	2005	9 March 2018
YEAR THE DEMORALIZATION SYNDROME WAS FIRST PUT FORWARD AS A PALLIATIVE-CARE DIAGNOSIS	YEAR THE WRIT PETITION THAT SETTLED THE INDIAN END-OF-LIFE POSITION WAS FILED IN THE SUPREME COURT OF INDIA	DATE OF THE CONSTITUTION BENCH JUDGMENT DECIDING THAT PETITION

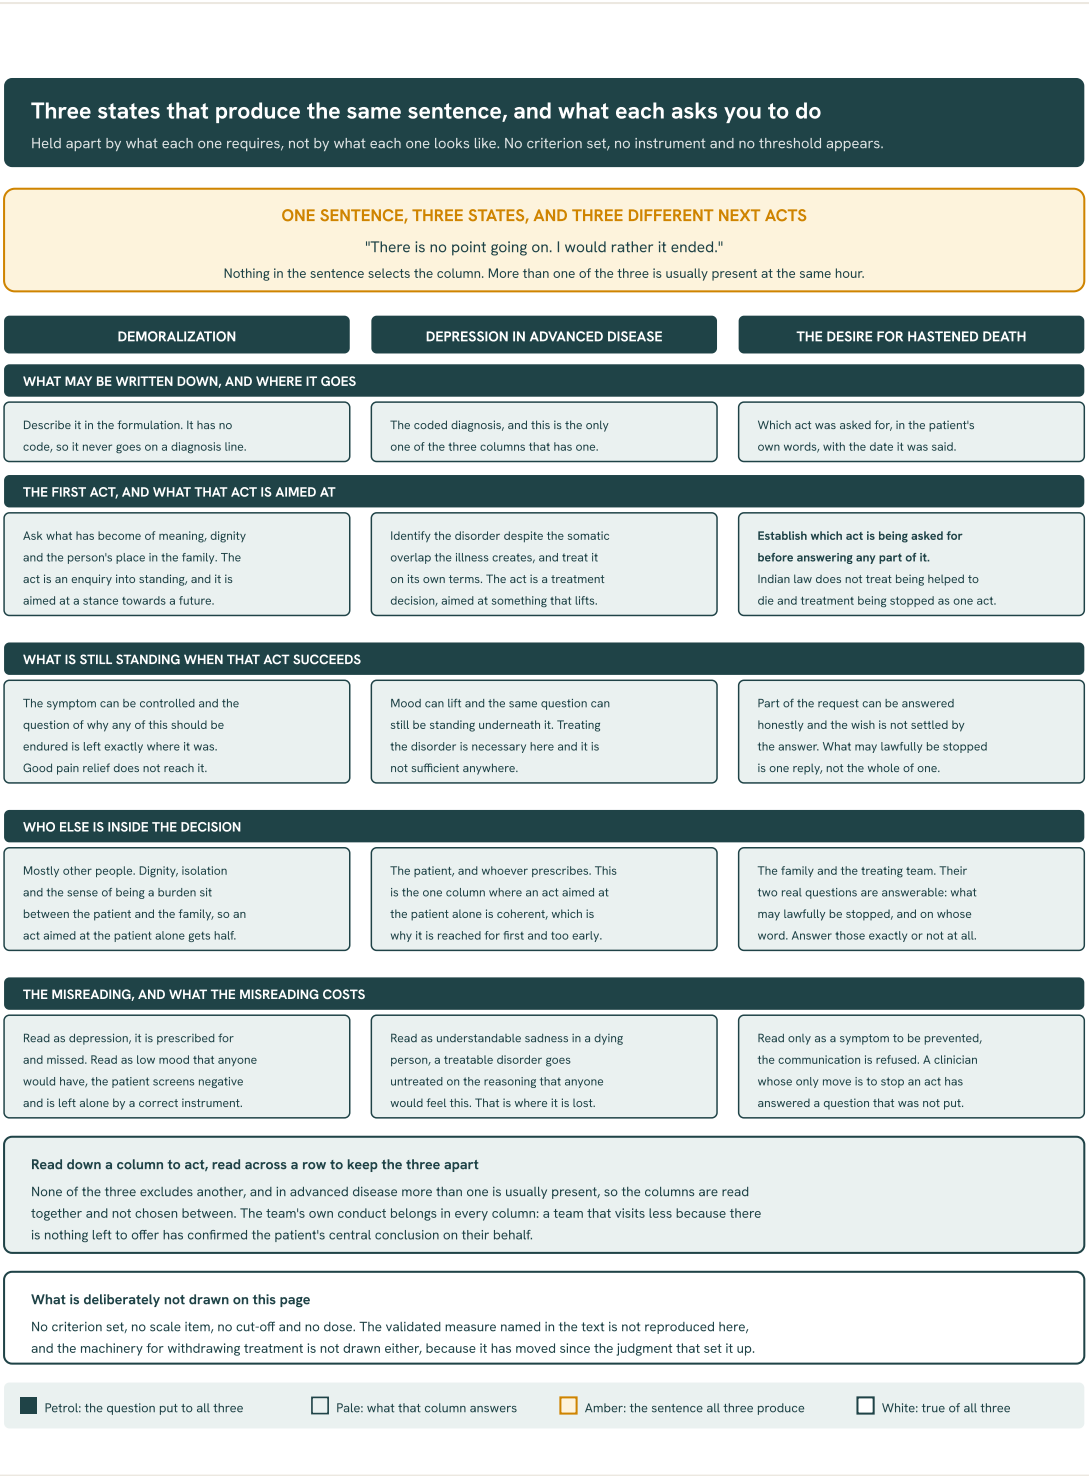

Fig 29.12. Demoralization, depression in advanced disease and the desire for hastened death set in three columns and separated by act rather than by feature, giving for each what may be written down and where it goes, what the first act is and what it is aimed at, what is still standing once that act has succeeded, who besides the patient is inside the decision, and what the characteristic misreading costs, with the single sentence all three can produce placed above them and the criteria, instruments and thresholds that belong to other chapters named as absent.

32.1 Demoralization as a named construct, not as an ordinary word

Demoralization is ordinary English, and clinical writing uses it loosely to mean discouraged, flattened, worn down. That is why the technical sense has to be introduced deliberately: a term with a colloquial meaning is read colloquially unless the reader is stopped.

One older technical use is worth knowing, and it comes from a different literature. In the account of what the psychotherapies share, **remoralization** is named as the antidote to demoralization,

the patient's restored expectancy and hope being one of the common factors that operates whatever the modality. That is a claim about every consulting room, and it is taught in the Psychotherapies, clinical assessment, MSE and nosology notes. What is added here is narrower, and belongs at the bedside of a person whose illness will not be cured.

The palliative-care proposal came from Kissane, Clarke and Street, working from a centre for palliative care in Australia, and was published in the Journal of Palliative Care. It put forward demoralization syndrome as a diagnostic category for palliative care, resting on **three** core features:

- **Hopelessness.** Not sadness about the illness, but the absence of any expectation that anything ahead can be different or better.
- **Loss of meaning.** The collapse of the answer to why this is being endured, which is a question a person under active treatment can usually answer and a person no longer under it often cannot.
- **Existential distress.** Suffering that is about the person's situation and standing in the world rather than about a symptom, and which therefore does not move when the symptom is controlled.

Read together, the three describe not a mood state but a stance towards a future, and it is that stance rather than any particular affect which the proposal argues can be separated from a depressive disorder and recognised in a palliative-care setting. The proposal went further and claimed the syndrome had satisfactory face, descriptive, predictive, construct and divergent validity, which is the argument for treating it as a diagnostic category rather than a good description. Whether that argument was accepted is dealt with below.

RULE **Hopelessness in advanced physical illness is a clinical target in its own right, not merely a severity marker of depression.** Read only as an item within a depression scale, the sole decision it can drive is whether to treat depression harder. Read as the core of a separate construct, it opens questions about meaning, dignity and the patient's position in the family, which are the questions the patient is already asking themselves.

32.2 What the construct is associated with, and the mechanism that carries it forward

The original proposal names the company demoralization keeps, and the list is worth learning in clusters rather than as a flat run of risk factors, because grouped this way it stops being a checklist and starts describing how the state is produced.

- **The illness and the body.** Chronic medical illness, disability and bodily disfigurement. What these share is permanence: each is a loss that will not be given back, and each is visible to the patient every day without any clinical event to prompt it.
- **Standing in the world.** Fear of loss of dignity and social isolation. Both are about how the person is seen and by whom, and both worsen precisely as the illness advances and the circle of people who visit contracts.

- **Position in the family.** Greater dependency on others and **the perception of being a burden**, which the proposal ties to a subjective sense of incompetence rather than to the objective level of care being provided.

That last qualification is the one candidates drop and the clinically decisive one. Burdensomeness here is a perception, not a measurement. It does not track the hours a family actually spends, and it can be most severe in a household that is coping well and complaining least. A clinician who reasons from the visible care burden to the patient's distress gets exactly those patients wrong, because a family that manages without visible strain is the family in which a patient concludes the strain is being hidden.

The mechanism the proposal offers is the hinge of this topic. Because of the sense of impotence or helplessness, those with the syndrome predictably progress to a desire to die or to suicide. That is framed not as a comorbidity but as the endpoint of a state whose defining property is that the person can no longer see themselves acting effectively on anything. The wish to die is therefore the far end of a process that began with meaning, not an independent symptom that happens to have arrived.

32.3 Demoralization and depression, and the limits of what can be claimed

The differentiability of the two is the examinable claim, and it should be stated at the strength its source states it. The proposal holds that demoralization syndrome can be differentiated from depression and is recognisable in palliative-care settings. It does not hold that they are mutually exclusive, and nothing here permits saying that a demoralized patient is therefore not depressed. Both can be present, and in advanced disease both often are.

What is useful in an answer is why the separation was proposed at all. Depression in advanced disease is difficult to identify because its somatic criteria are confounded by the illness itself, a problem the companion topic on depression, anxiety and delirium in cancer and palliative care takes up. Demoralization does not solve it, but it names a group for whom counting somatic symptoms is beside the point: the trouble is not that they cannot enjoy things, it is that they cannot see why anything should be endured. A service screening only for depressive disorder registers them as negative, correctly by its own instrument.

How often the two dissociate is not something this account will put a number on. The proportion of patients with advanced disease who are seriously demoralized without being clinically depressed, and the correlates that predict which patients those are, have a research literature behind them, but no comparable standard is available to quote, and none is invented here. Carry the dissociation as a qualitative possibility with clinical consequences, which is what the construct's own proposal supports, and do not attach a figure to it in a viva.

TRAP **Writing demoralization syndrome on the diagnosis line as though it were a classified disorder.** It was proposed, and it has not been adopted: neither the current revision of the American classification nor the eleventh revision of the international classification carries it. Candidates err because the construct is taught in criteria-like language and because its own validity claim reads like an argument already won. Describe the state in the formulation, use the accepted category for whatever disorder the patient also meets, and say in a viva that this is a proposed construct and not a coded diagnosis. That is not a hedge; it is the accurate answer.

32.4 The desire for hastened death as a presentation

The wish to die in a person whose death is already expected is a different clinical object from suicidal ideation in general psychiatric practice, where the wish is understood as a symptom of a treatable disorder in someone who would otherwise be expected to live. Here the person is dying anyway, the request is often about manner and timing rather than the fact, and the reasons given are more often about meaning, dignity and dependency than about mood. None of that removes the psychiatric task; it changes what the task is, because a clinician whose only move is to prevent an act has misread a communication.

What the same sentence can carry. At least three different things arrive in the same words. There is the wish to be dead, which is a state and not a plan. There is a request for assistance in dying, which asks another person to act. And there is a request that treatment be stopped, which asks another person to desist. These are not gradations of one thing: Indian law, set out below, treats the second and the third as different acts, so confusing them is a legal error and not only a clinical one. The enquiry that separates them, meaning the wording, the order of the questions and what follows from each answer, is not settled by any source quoted here and is not invented here. Published instruments and interview approaches exist for this purpose and a candidate should read one; a plausible protocol manufactured from memory would be a procedure nothing supports.

The same restraint applies to what such a request means in this country, and here the gap is larger. No Indian study of the desire for hastened death in advanced illness is available to quote here, and none is invented. That absence matters, because the meaning of the request is not constant across jurisdictions. Where assisted dying is lawfully available it can be a step in a defined process. Where it is not, the same words cannot be a procedural request at all and are doing something else: expressing suffering, testing whether the clinician will stay in the room, or asking that a burden be lifted from a family. Importing a Western prevalence figure, or a response framework built around a legal option that does not exist here, describes a practice that is not Indian practice.

32.5 Measurement, and what a scale can and cannot settle

A validated measure of the construct exists. The **Demoralization Scale**, developed by the same originating group, is the instrument to name if asked how demoralization is assessed formally. Name is all that is offered here: its item count, its subscale structure, its response format, its cut-offs and its later revision are not reproduced, because no comparable standard is available to

quote, and none is invented here. A candidate who quotes a threshold for this scale is quoting something unverified, and a threshold is exactly the kind of specific an examiner follows up.

What matters is what a scale of this kind is for. Demoralization was proposed because a group of patients in palliative care were being missed by the instruments already in use, so a measure of it earns its place by identifying that group rather than by grading severity within it. Two consequences follow without any numbers. A positive screen is not a diagnosis and does not by itself justify a prescription, since the construct is not a coded disorder. And a negative screen in a patient who has said they want to die settles nothing, because the request has already given you information no instrument can subtract.

32.6 What the request runs into: the Indian legal position

Every clinical response to a wish for hastened death here is bounded by one Constitution Bench judgment of the Supreme Court of India, Common Cause (A Registered Society) v. Union of India. The ethical vocabulary this area is usually taught in, meaning autonomy, double effect and the distinction between withholding treatment and actively killing, is treated with the ethics material and is not repeated here. What is set out here is the legal position itself, which is what a clinical question about a request to die turns on.

Three propositions from it are the ones to hold, and the accompanying table sets out how the Court itself characterises each of the acts they concern. The first is about **active euthanasia**, which the Court records is to be treated as legally impermissible, at least for the time being, there being no statutory law permitting it. That qualification belongs to the Court's own sentence and should be reproduced with it, because dropping it converts a dated position into a timeless one.

The second is the line between that act and **passive euthanasia**, which the judgment treats as an inherent difference rather than a matter of degree, and what follows once the second applies: when passive euthanasia becomes applicable as a situational palliative measure, the best interest of the patient overrides the State interest. That is the sentence to have ready when a viva turns to whether a ventilator may lawfully be withdrawn.

The third concerns the **advance medical directive**, for which the Court laid down a procedure in exercise of its power under **Article 142**. The consequence is the examinable point, and candidates routinely get it backwards: the Indian advance directive at the end of life rests on judicial direction and not on legislation, and the Court expressly provided that its directions remain in force only until Parliament legislates in the field.

WHAT IS BEING ASKED FOR	HOW THE COURT CHARACTERISES THE ACT	WHAT THIS ACCOUNT DOES NOT STATE
A positive act to end life	A positive affirmative act, an overt act done to end the patient's life	Whether Parliament has since legislated on the subject
That life-prolonging treatment be stopped or not started	Withdrawal of life support measures, or withholding of medical treatment meant for artificially prolonging life	The steps, authorisations and safeguards through which it is given effect
That the patient's own prior refusal be honoured	An advance medical directive, for which the Court records there was no legal framework in the country	The current form of the execution procedure and its safeguards

The last column is not decoration. The procedural machinery that judgment set up, meaning the steps by which a decision to withdraw treatment is authorised and recorded, has been revisited since, and this account does not specify it. Modal verbs are where that error does its damage: saying that a treating team shall approach a particular authority asserts a current obligation, and that is exactly what a revision changes. Know the three propositions above, know that the procedure has moved, and check the operative steps against the Court's own current text before advising a team.

One further separation must be made explicitly, because the two instruments share a name. The advance medical directive discussed here concerns life-sustaining treatment at the end of life and arises from this judgment. The advance directive under India's mental healthcare legislation is a different instrument for a different purpose, concerning a person's preferences about mental healthcare, and it is taught with that legislation. Conflating them is a serious error and an easy one to make under pressure, because both are called advance directives and both concern a decision taken ahead of incapacity.

IN INDIA

Because the Court has placed an act done to end a patient's life outside what is legally permissible, a request for one cannot be a procedural request, and the clinician is not being asked to start a process. That changes what the response is for, but not what the psychiatrist must state accurately when a family or a treating team asks, and their two real questions are answerable from the judgment: what may lawfully be stopped, and on whose word. Indian evidence on how often such requests are made and with what course is not something this account can supply, so an answer opening with an Indian prevalence figure has invented one.

32.7 What is actually done, and what the direction of travel is

The construct arrived with a treatment approach attached, and the honest statement is short: the original proposal states that an approach is described, the approach itself is not established by anything quoted in this account, and nothing is invented in its place. What can be reasoned safely is the direction, and it is named in the older literature this topic opened with. If demoralization is the state, remoralization is the movement out of it, and what does the work there is restored

expectancy and hope, a factor operating across every psychotherapy rather than belonging to one. That is not a technique. It is a specification of what any technique used here has to achieve.

Three consequences follow that a candidate can defend without a protocol. Treating a comorbid depressive disorder is necessary and not sufficient: it is indicated where the disorder is present, with the drug detail belonging to the Mood disorders: pharmacotherapy notes and its use in advanced disease to the companion topic of this chapter, but a good response in mood can leave the same unanswered question about why anything should be endured. Next, the associations here are mostly interpersonal rather than symptomatic, so an intervention aimed at the patient alone addresses the smaller half: dignity, isolation and burdensomeness sit between the patient and other people. Last, the team's own behaviour is part of the clinical field, and a team that stops visiting because there is nothing more to offer has confirmed the patient's central conclusion for them.

GOOD TO REMEMBER

Before the conversation about a wish to die goes further, be clear which act is actually in question, because Indian law does not treat them as one. A request that treatment which is only prolonging dying be withdrawn falls within a category the Supreme Court has recognised and given effect to; a request that someone act to end life does not. That is not legalism at the bedside. It is what allows a clinician to answer part of the request honestly instead of deflecting all of it.

Demoralization is hopelessness and loss of meaning in a patient who may not be depressed, its predicted endpoint is a wish to die, and in India that wish arrives in a system where a positive act to end life is impermissible while withdrawal of treatment that only prolongs dying is not.

Both halves of this topic guard against the same failure, a purely symptom-based reading. A patient is counted as not depressed and is left alone; a request to die is counted as a symptom and is only prevented. Both readings are defensible from a list of criteria and both leave the patient where they were.

The OSCE and practical exam bridge

33 · Structure of OSCE stations in psychiatry (history, MSE, management)

Why the marks sit here. Every other part of a clinical examination lets you choose your own words and your own order. An observed station does not. It hands you a written instruction, a fixed span of time and a person to work with, and scores what you are seen to do with them. That design reached Indian postgraduate psychiatry from the regulator, not from departmental custom: the national Post-Graduate Medical Education Regulations, 2023, made by the National Medical Commission's Post Graduate Medical Education Board, name the **objective structured clinical examination** inside the criterion by which the practical is passed, beside the clinical

examination and the viva voce. A component named in a pass criterion is not a teaching exercise, whatever your department has been calling it.

What follows is the structure of OSCE stations in psychiatry (history, MSE, management): what a station is built from, what each of those three task families asks you to produce, how a watched performance is scored, and where the format sits in the instruments that govern an Indian postgraduate examination. It also sets out the parts of that picture no retrievable document fixes. The topic has a firm centre and an unsettled edge, and knowing which is which beats a confident schedule that belongs to another university.

50% AGGREGATE REQUIRED ACROSS ALL FOUR THEORY PAPERS BY THE NATIONAL POST-GRADUATE MEDICAL EDUCATION REGULATIONS, 2023	**50%** REQUIRED IN THE PRACTICAL, WHICH THOSE SAME REGULATIONS DEFINE AS CLINICAL PLUS OBJECTIVE STRUCTURED CLINICAL EXAMINATION PLUS VIVA VOCE	**Nil** GRACE MARKS PERMITTED IN A POSTGRADUATE EXAMINATION, IN THEORY OR IN PRACTICAL	**Not fixed** STATIONS, MINUTES OR MARKS FOR AN OBJECTIVE STRUCTURED COMPONENT, BY ANY INSTRUMENT QUOTED ON THIS PAGE

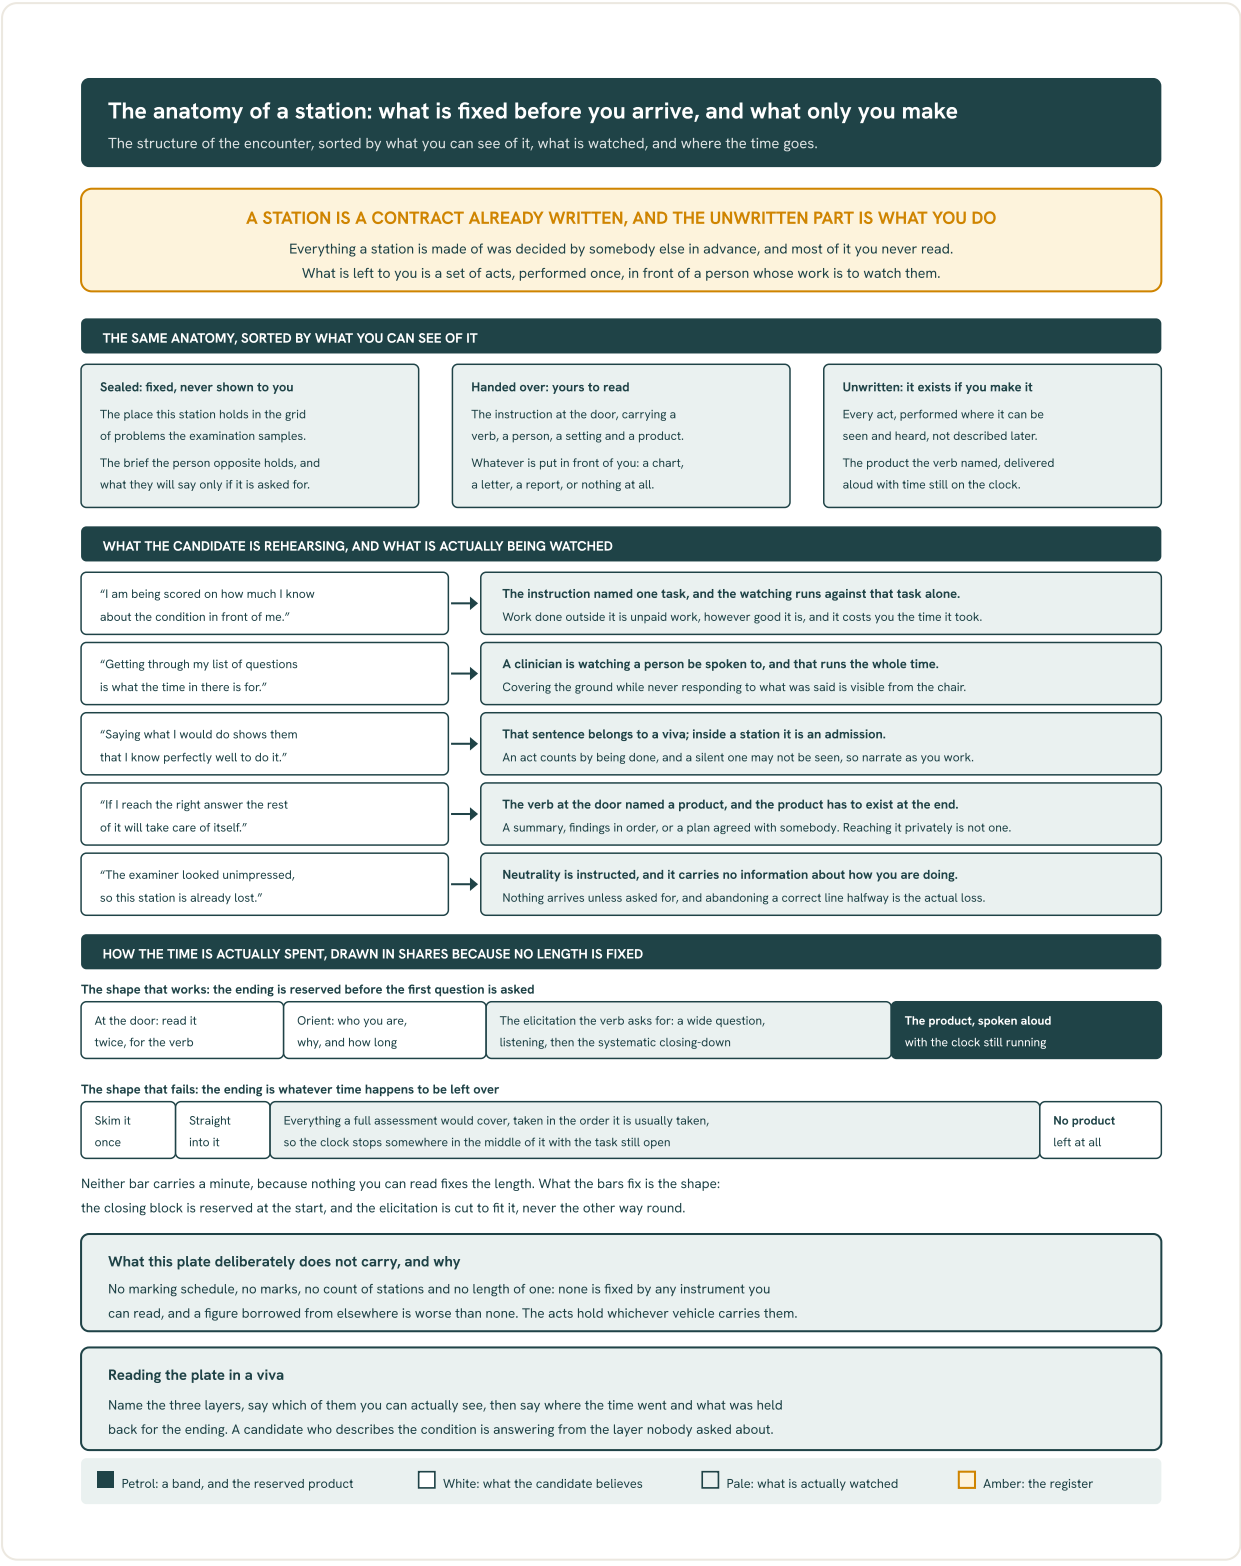

Fig 29.13. The station drawn as a structure rather than as a list of its parts, with the same anatomy sorted into what is sealed from the candidate, what is handed over at the door and what exists only if the candidate performs it, five ordinary beliefs about what is being scored set against what a watching clinician is in fact following, and the time drawn twice in shares rather than in minutes, once with the closing product reserved from the start and once with it crushed out by an elicitation that was never cut to fit.

33.1 What an objective structured station is, and the problem it was built to solve

Standardise the task, and the differences you measure become differences between candidates. In a conventional clinical examination the patient, the pathology, the examiner and the questions all vary, so two candidates given the same mark have not necessarily been asked the

same thing. A station removes those variables one at a time: every candidate meets the same written instruction, the same task, the same time and the same marking schedule, and where a real patient cannot be standardised the station substitutes a briefed person who can be.

The second gain is breadth. Clinical competence is not a single trait that transfers cleanly from one problem to another, and a candidate strong on a psychotic presentation may be weak on an alcohol history. This is **case specificity**, and it is the argument for sampling many short tasks rather than examining one case deeply: a circuit trades depth for coverage, deliberately.

So is the cost, which is why the format sits beside the traditional clinical rather than replacing it. A short task cannot test a whole clinical argument: the summary that stands alone, the differential defended against its alternatives, the formulation that earns the plan. Those need a long case, and that presentation is taken up in the section of these notes on long and short case presentation.

33.2 The anatomy of a single station

Six things exist before you arrive, and five of them are written down. Knowing them tells you where the marks are, because each is something somebody had to decide in advance:

- the place it occupies in the **blueprint**, the grid of problems and skills the examination has undertaken to sample, which is why stations feel unrelated to one another;
- the **candidate instruction** posted at the door: the task, the person, the setting, and what must exist by the time you leave;
- the brief carried by the patient or the **simulated patient**: an opening statement, information released only when asked for, cues shown rather than volunteered;
- the setting and any material handed to you, which may be a chart, a prescription, a report or nothing;
- the marking schedule the examiner holds, itemised against the task rather than against the diagnosis;
- the standard that schedule is read against, a decision of the examining board and not of the examiner in the chair.

Two consequences follow. Because the patient's information is released on request, silence is yours to fill: the person opposite is not withholding, they are waiting to be asked. And because the schedule is written against the task, material that is clinically excellent but outside it earns nothing. A station is a contract, and the instruction at the door is its text.

MNEMONIC

Instruction, Introduction, Information, Interpretation, Invitation

The five acts of any station, in order. **Instruction**: read it twice at the door, naming the verb, the person and the product. **Introduction**: name, role, purpose, consent, time. **Information**: the elicitation the verb asks for, and nothing outside it. **Interpretation**: say aloud what you found and what you make of it. **Invitation**: hand back to the patient with a question and to the examiner with a finished product. A station that fails has usually skipped the first or the fourth.

33.3 The task verb, and why the whole station turns on it

Read the instruction for its task verb before its clinical content. The verb names the product that must exist when time runs out, and the station is scored against that product. "Take a focused history of" asks for a defined territory covered and a closing summary. "Elicit and describe" asks for a technique performed in front of somebody and findings reported in the language of the phenomenon. "Explain" and "discuss with" ask for something delivered to a person who must understand it, which means checking that they did. "Assess" asks for a judgement, stated, not for the material from which one could be made.

Candidates lose stations by substituting an adjacent verb they have practised more. Asked to explain a plan, they take a history first, because history-taking is what they are fluent in. Asked to assess, they gather and never conclude. Asked for a focused history, they run the full ward assessment and reach the end of the time somewhere in the personal history. The correction is mechanical: after reading the instruction, say the product to yourself in one sentence, and let that sentence dictate your first question.

33.4 The history station: a focused history is not a shortened long case

A focused history is defined by what it deliberately leaves out. The long-case history is comprehensive because there is time to be, and because the argument you build later needs all of it. A history station names a territory and expects it covered to the depth a decision would require, with everything outside it acknowledged rather than explored. Where the instruction says a focused history of a first-episode psychosis, the marks are in onset and course, the phenomena, substance use, organic screening, risk and the effect on function and family, not in a developmental history that leaves no time for any of them.

Open by orienting the patient: who you are, why you are speaking to them, and how long you have. This is a scored act, not politeness, and it buys you the right to interrupt later. Then work from open to closed: a question wide enough to let the person say what is actually wrong, a period of listening without steering, then the systematic closing-down that covers the territory. Signpost the change of gear, and it reads as method rather than impatience.

Two elements are forgotten under time pressure and are almost always on the schedule. Risk is one: ask it, in plain words, wherever the presentation admits it, rather than saving it for a station labelled as a risk station. Corroboration is the other: an informant is rarely available inside a

station, so say whom you would seek, what you would ask and why it would change your view. Naming the collateral you cannot obtain scores; assuming it does not.

33.5 The mental state station: examining rather than interviewing

In this station the examination has to be made visible. The mental state examination as a construct, its domains and the vocabulary of its findings, is taught in the Psychotherapies, clinical assessment, MSE and nosology notes and is not repeated here. What changes when it becomes a station is that the examiner must be able to see you doing it. On the ward much of the mental state is gathered passively while you talk about something else; under observation, passive gathering is indistinguishable from not having gathered.

So the work becomes explicit. Separate what you observed from what you elicited, and say which is which. Where you find a phenomenon, probe it far enough to establish its form rather than its content alone, then stop: the schedule credits the probe, not the tour. Ask the discriminating questions: whether the voice was heard through the ears or inside the head, whether the belief is held against evidence the patient accepts as evidence. Then report in a fixed order, so nothing is lost to improvisation.

Two boundaries. A mental state station often reaches cognition, and the conduct of a named scale or bedside cognitive test under observation is set out in the section of these notes on demonstrating clinical scales and bedside tests. And the examiner is watching for damage as well as coverage: a probe pressed too hard on a frightened patient scores on the schedule and sinks the overall judgement, and both marks come from the same station.

33.6 The management station: a plan spoken to a person

Management is examined as an act of communication, not as a list. This station puts you with a patient, a relative or a colleague and asks you to explain what you propose and reach agreement about it, and the same plan delivered to those three is three different performances. The clinical content is the easy half. What is scored is whether the plan arrived in a form the person could act on: in sequence, the immediate step first, what happens where and who does it, the risks that matter to this person rather than a recitation of all of them, and an explicit invitation to disagree.

Structure it so nothing essential is crowded out. Safety and the immediate decision first, because if time runs out that is the part that must already have been said. Then the setting of care and why. Then the plan proper, biological, psychological and social, each in a sentence. Then follow-up: who reviews, when, and what brings the person back sooner. Then ask them to tell you what they have understood, the most reliably credited act in the station and the one most often skipped.

Two neighbouring station types are not developed here. Where delivering serious news or conducting a risk assessment is the whole purpose, those conversations are set out in the section of these notes on communication, breaking bad news and risk-assessment stations; where the task is to interpret something handed across the table, in the section on interpreting investigations and instruments.

STATION FAMILY	WHAT THE INSTRUCTION ASKS FOR	WHAT IS ACTUALLY SCORED	THE PRODUCT DUE BEFORE TIME ENDS
History	A defined territory covered to the depth a decision needs, with risk and missing collateral named	Question craft: open before closed, signposting, the discriminating question at the right moment	**A spoken summary, and what you would seek next**
Mental state	An examination performed and reported, observation separated from elicitation	Whether it was visibly done, whether phenomena were probed to their form, and the manner of the probing	**Findings in a fixed order, with domains not examined named as such**
Management	A plan explained to a named person and agreed with them	Sequence, specificity to this person, the invitation to disagree, the check of understanding	**An agreed immediate step, a follow-up, and a trigger for earlier review**

33.7 How a watched performance is scored

Two instruments, one performance. Observed clinical assessment is conventionally marked in two layers at once. The first is itemised: a schedule of acts specific to the task, ticked as they occur, which makes the format reproducible between examiners. The second is a **global rating**, one overall judgement made by a clinician asking whether they would be content to have this seen by a colleague at this stage of training. Neither alone is sufficient: an itemised schedule alone rewards a candidate who never notices the person answering, and an overall impression alone reintroduces the variability the format was built to remove.

Three consequences follow. An act you did not perform is not credited because you said you would have performed it, so do the thing rather than describe it. An act performed silently may not be credited either, so narrate the examination as you conduct it. And the examiner is usually instructed not to help: silence is not disapproval, and information will not arrive unless it is asked for. Candidates read that neutrality as failure and abandon a correct line halfway through.

The limit of all this should be explicit. No Indian regulatory instrument retrievable for this chapter prescribes a marking schedule, a rubric or a standard-setting method for a psychiatry station. What is written above is the general logic of observed assessment, not your board's published rubric, because no comparable standard is available to quote, and none is invented here.

RULE **A station scores the act, not the knowledge behind it.** This is the difference between a station and a viva, and where prepared candidates lose marks they had the knowledge to earn. In a viva, saying what you would do is the performance. In a station, it is an admission that you did not do it. Convert preparation into sentences you would say to a patient and acts you would perform, and rehearse it in that form.

PITFALL

Performing to the schedule and losing the person. A candidate who has memorised a list of questions gets through it, ticks a satisfying number of items and is still marked down, because the overall judgement is made by a clinician who has just watched a distressed person be processed. The tell is a station run without a pause and without any response to what the patient said. Cover the schedule by knowing the territory, not by reciting a sequence.

33.8 Where the station sits in the Indian postgraduate practical

Three instruments govern this, a fourth is only a contrast case, and they span a generation. The oldest is the MD Psychiatry ordinance of a Karnataka state health-sciences university, dated 2000. It makes no provision at all for an objective structured clinical examination, its clinical examination being entirely long cases and short cases. That is a finding about the document, not about your examination, and it is superseded on this point.

The national regulations of 2023 changed the position by naming the objective structured clinical examination inside the practical pass criterion, alongside the clinical and the viva voce. That placement is load-bearing: a component named in the sentence deciding whether the practical is passed is part of the practical. Then the state health-sciences university acted. By a notification dated 16 December 2024, made under section 35(1) of its governing Act of 1994 as amended in 2013 after a special meeting of its Syndicate on 22 November 2024, it decided to apply the 2023 regulations to the 2021-22 academic batch and to the upcoming broad-specialty postgraduate examinations, subject to relaxations on attendance, publications, the district residency programme and the courses in research methodology, ethics and cardiac life support. What carries new regulations onto candidates admitted before they were made is recorded in the same notification: the university states that it received a clarification from the National Medical Commission dated 28 November 2024, that the 2023 regulations apply to all students appearing in the forthcoming postgraduate examination. That is the university's account of the letter, not the letter itself.

The operative clause on the station is narrower than candidates assume. The notification provides that an objective structured clinical examination or a short case shall be included from the ensuing postgraduate examinations. The obligation is mandatory and the vehicle disjunctive: one or the other shall be included, and nothing establishes that you will face a circuit rather than a short case. The same notification puts valuation of theory scripts and computation of results under the 2023 regulations, and a 2025 judgment of that state's High Court records that evaluation of marks is governed by the notification of 16 December 2024, confirming it is in force and not a proposal.

INSTRUMENT	DATE	WHAT IT SETTLES ABOUT THE STATION	WHAT IT LEAVES OPEN
MD Psychiatry ordinance of a Karnataka state health-sciences university	2000	Nothing: no objective structured component, and a clinical examination of long cases and short cases only	**Superseded on this point, and never a source for a station's format**
MD Psychiatry ordinance of a private university in Karnataka	edition year 2019-20	That one institution listed it among training activities, a weekly interviewing-skills programme with no mark line	**Everything about examination use: a contrast case, not evidence of anybody else's practice**
National Post-Graduate Medical Education Regulations	2023	That it is named inside the practical pass criterion, beside the clinical examination and the viva voce	**Station number, length, marks and marking schedule**
Notification of the state health-sciences university applying the 2023 regulations	16 December 2024	That an objective structured clinical examination or a short case shall be included from the ensuing examinations, so such a component is now mandatory	**Which vehicle, and the weight of either: the division of practical marks is referred to a board of studies**

IN INDIA

Because the clause is disjunctive and the marks division referred onward, the answer for your own examination sits in a departmental decision rather than in any document you can read. Put three questions to your department and the examination section, in writing, early enough that the answers can still change your plan: whether a station component will be conducted at all or the requirement discharged by a short case; if stations, how many and how long; and how those marks sit inside the practical total. Expect the answer late or informally, and prepare for the heavier possibility meanwhile.

TRAP **Reading the acronym instead of the instrument.** The same four words denote two different things in two Indian documents: a component named inside the national practical pass criterion of 2023, and a weekly interviewing-skills training programme with no mark line at all in a private university's ordinance of 2019-20. Candidates take their seniors' usage for the regulation's, hear that the station in their department is a teaching session, and conclude nothing is at stake. What decides it is the instrument governing your own examination, read in its own words.

33.9 The arithmetic that decides the result, and where a station's marks land

Three conditions, all of them conjunctive. Under the 2023 national regulations, passing the examination as a whole requires a minimum of **40 per cent** in each theory paper, then the aggregate across all four papers set out in the strip above, and then the separate line in the

practical. Failing any one fails the examination: a strong practical does not repair a paper below the per-paper floor. That floor is the new element. Under the superseded ordinance of 2000 the rule was not less than half the marks in each of two heads of passing, theory, and practical including clinical and viva voce, with no per-paper requirement, so a weak paper could be carried by strong ones. It cannot now.

Where a station's marks land follows from that criterion's wording. Because the practical is expressly composed of the clinical examination, the objective structured clinical examination and the viva voce, marks won or lost in a station sit inside the same practical line as your long case. There is no separate station threshold and no separate station failure, which is also why the station cannot rationally be written off.

Two further provisions decide results. No grace mark is permitted in a postgraduate examination, in theory or in practical, so a shortfall is a shortfall. And scripts are handled under the national machinery the notification adopted: every theory script receives two valuations, a third follows where the two differ by **15 per cent** or more of that paper's total marks, the best two are then averaged, and there is no revaluation once results are declared.

The board is fixed by the same regulations: at least **four** examiners for a postgraduate examination, of whom at least two shall be external, and at least one of those external examiners shall be from a different university outside the state. At least half the people marking you have never taught you and will read an unexplained local abbreviation as an error rather than a convention.

One point of revision strategy belongs with that floor. The older ordinance placed consultation-liaison psychiatry, geriatric psychiatry and psycho-oncology in the second theory paper and cultural psychiatry in the third, adding that its distribution of topics against papers is suggestive only. Its fourth paper is displaced: under the current instruments the fourth carries recent advances and the first basic medical science. With a floor in every paper, recent advances cannot be written off against strength elsewhere.

GOOD TO REMEMBER

Convert revision into rehearsal by building your own stations. Write a one-sentence instruction on a card carrying the verb, the person and the time. Give it to a colleague, let them hold the clock and play the patient from a brief you did not write, and require yourself to deliver the product aloud before time ends: the summary, the reported findings, or the agreed plan. Then swap, and mark each other against what the instruction asked for rather than what you would have liked to say. This does more for a practical than the same hours spent reading: the failures that cost marks here are failures of shape, and shape only changes under a clock.

33.10 What is not settled, and how to prepare when the format is not fixed

Name the unknowns rather than guessing them. Four things about an Indian postgraduate psychiatry station are not established by any instrument quoted here, and a confident figure for any of them is somebody's local arrangement until you have seen the document it comes from:

- how many stations a circuit contains, if a circuit is used at all;
- how long a single station runs;
- what a station is worth, as marks or as a share of the practical, the division of practical marks being referred to a board of studies;
- whether the requirement will be discharged by stations or by a short case, the instrument being disjunctive on its face.

That is unsatisfying, and better than the alternative. Numbers circulate for all four, usually borrowed from another state or from an undergraduate examination, and a schedule built on a borrowed pattern is worse than one built on none. What is settled is enough to work from: such a component is now mandatory, its marks sit inside the practical line, and the acts it scores are the same whichever vehicle carries them.

That last point is the resolution. A short case and a station both put you in front of a person with a narrow brief and an examiner watching, and both score the performance rather than the account of it. So prepare the behaviour, not the format: read instructions for their verb, introduce yourself and take consent, ask before assuming, narrate the examination as you do it, reach a stated conclusion before time ends, and check that you were understood.

> A station scores what you are seen to do, inside one practical pass line that also holds your long case and your viva; the component is mandatory for the ensuing examinations while its vehicle, count, length and marks are fixed by nothing you can read, so rehearse the acts under a clock and ask your department which vehicle it will use.

34 · Long case and short case presentation format

Why the marks sit here. The clinical examination is the one part of a postgraduate examination that cannot be got up in the week before it, and the part that decides whether a candidate is judged fit to work unsupervised. Its purpose is stated in the regulations, not left to custom: the clinical examination in a clinical-science subject is conducted to test the candidate's knowledge and competence for undertaking independent work as a specialist and teacher. That aim tells you what is being listened for: not whether you can take a history, which is assumed by this stage of training, but whether the account you give of the patient afterwards could be handed to a ward and safely acted upon.

Two formats carry that assessment. The **long case** gives you one patient and expects a whole clinical argument, from the history to a plan in sequence. The **short case** gives you a narrow task and expects competence rather than narrative: elicit this, demonstrate that, interpret what you find, answer for it. The examiner's attention moves accordingly, from your reasoning in the first to your hands and your questions in the second. What follows is the long case and short case presentation format itself, from the shape of the time with the patient to the last answer you give.

1 + 2	2 + 2	300	100
LONG CASE PLUS SHORT CASES REQUIRED OF A CLINICAL-SCIENCE SUBJECT BY THE NATIONAL POST-GRADUATE MEDICAL EDUCATION REGULATIONS, 2023	LONG CASES PLUS SHORT CASES SET BY THE MD PSYCHIATRY ORDINANCE OF A KARNATAKA STATE HEALTH-SCIENCES UNIVERSITY DATED 2000, A MARK SPLIT SINCE SUPERSEDED	MARKS FOR THE PRACTICAL EXAMINATION, THESIS INCLUDED, UNDER A KARNATAKA STATE HEALTH-SCIENCES UNIVERSITY NOTIFICATION OF 16 DECEMBER 2024	MARKS FOR THE VIVA VOCE UNDER THAT SAME KARNATAKA NOTIFICATION OF 16 DECEMBER 2024

34.1 What the two formats are for, and why no single allocation is universal

The format is national; the arithmetic is local. The national regulations governing postgraduate medical education, made in 2023 by the National Medical Commission's Post Graduate Medical Education Board, state that candidates in the clinical sciences shall be examined for **one long case and two short cases**. A university ordinance can set out something heavier. One Karnataka state health-sciences university's MD Psychiatry ordinance, dated 2000, sets a second long case in neurology worth the same as the psychiatry one, with two psychiatry short cases at 25 marks each; those four cases account for the whole of that ordinance's clinical examination, which it sets at 200 marks. That split has since been overtaken at its own university: a notification of 16 December 2024 sets the practical examination at 300 marks including 20 for the thesis and the viva voce at 100, and expressly leaves the division of marks inside the practical to be settled in consultation with its board of studies. The totals are fixed and the per-case figures are not, so no long-case or short-case mark value can honestly be quoted for it now, and none from an older document may be carried across to fill the space.

The relation between the national regulation and the older ordinance is not something either text settles. The national provision is cast in the mandatory form and the older ordinance sets more cases than it specifies; whether that extra long case is a permitted enhancement of a national minimum or a divergence from a national specification is not resolved by the words of either instrument, and it is not resolved here. Prepare for the heavier pattern, because a candidate ready for two long cases is ready for one and the reverse is not true.

DOCUMENT AND DATE	LONG CASES	SHORT CASES	MARKS AND BOARD AS THAT DOCUMENT STATES THEM
The national Post-Graduate Medical Education Regulations, 2023 (India)	One	Two	**The provision that sets the case count carries no mark allocation and no board composition; both are governed by separate provisions of the same regulations**
MD Psychiatry ordinance of a Karnataka state health-sciences university, dated 2000	Two: one psychiatry at 75 marks, one neurology at 75 marks	Two, both psychiatry, 25 marks each	**Clinical examination 200 marks; a board of four members, of whom one should be a neurologist or clinical psychologist**
Notification of the same Karnataka state health-sciences university, 16 December 2024	Not stated	Not stated	**Practical 300 marks including 20 for the thesis, viva voce 100; the division of marks inside the practical is referred to consultation with the board of studies, so no per-case figure is published**

RULE **The clinical examination tests whether you can be left alone with the patient.** Both the national regulations and the university ordinance state the aim in the same terms, competence for independent work as a specialist and teacher, and every marking decision descends from it. A presentation that proves you gathered information but never commits to what happens next has answered a question nobody asked. Commit, then defend the commitment.

34.2 Read the document that governs your own examination

The act that comes before any revision. The single most useful hour of preparation is spent not on a textbook but on the **ordinance** under which your university examines, together with any later notification amending it, because between them they tell you what you are walking into, and because departmental custom drifts from both in either direction. Obtain what your university publishes for your degree and your subject, and read the examination provisions in full rather than the summary a senior has drawn from them. Extract, in writing:

- how many long cases there are, and whether one of them is a neurology case rather than a psychiatry case;
- the marks on each long case and each short case, if the governing document states them at all rather than fixing only the totals and leaving the split to be settled later;
- how many short cases there are, and whether they are drawn from psychiatry alone;

- whether any objective structured component is marked as part of the practical, which is set out in the section of these notes on the structure of objective structured stations in psychiatry;
- the composition of the examiner board, including whether a non-psychiatrist sits on it;
- how your marks are grouped when the result is decided, which is a separate provision and is treated in that same section rather than assumed here.

Do this early enough that it can still change your plan.

IN INDIA

Ordinances are published unevenly. A university may host a scanned regulation many years old, amended since by notifications and circulars that are not printed alongside it, while the department examines to a pattern that has moved on again. Two consequences follow. The published instruments, ordinance and amendment together, are what an appeal, a grievance or a query to the examination section has to rest on, so read them even where you expect them to be stale. And ask the department directly, in writing if you can, whether the pattern in force differs from what is published, well before the final months.

34.3 The time with the patient, and what must be finished before it ends

The long case is decided before you open your mouth. How long you are given with the patient is set locally, and no comparable standard is available to quote, and none is invented here. What is general is how the time should be shaped. Consent and a workable rapport come first, because a patient already examined by several candidates will give a thin history to the next one unless that candidate troubles to be human about it. Then the history, taken in the order you always take it, because a familiar order is what protects you from omission under pressure. Then the examination, mental state and physical, actually performed. Then, and this is the part candidates sacrifice first, a period in which nothing new is collected and the case is turned into an argument.

That last period is not optional. It is where you write the summary you will speak, decide the diagnosis you will lead with, name the alternatives you will dismiss and the grounds for dismissing them, and rehearse your opening until it is fluent. A candidate who spends the whole allotted time collecting arrives with a full notebook and no position, and then reads it out. The corroborative history is part of this work rather than an appendix to it: seek the informant, record who they are, how long they have known the patient and how much they witnessed themselves, because **informant reliability** is a judgement the examiner expects you to have made and stated, not a box filled.

GOOD TO REMEMBER

Do the general physical and neurological examination on the long-case patient, every time, even when the case is plainly psychiatric and the time is short. It is the element most often skipped and, precisely because it is skipped, among the most reliably asked about. An examiner who finds you have not looked at the fundus, the gait, the pulse or the thyroid has been handed a way to test whether the rest of your account was gathered or assumed.

34.4 The presentation: a summary that stands on its own

The examiner should know the case by the end of your third sentence. The presentation opens with a **summary statement**, and its test is severe: if the examiner stopped you there and heard nothing else, they should be able to say what kind of illness this is, roughly how long it has run and what shape it has taken. That means the opening carries the patient's identifying particulars and social position, who gave the history and how reliable it is, the duration and the course, and the dominant syndrome named in phenomenological rather than diagnostic language. It does not carry the diagnosis yet, and it does not carry chronology for its own sake.

Two habits of speech matter as much as the content. Expand every abbreviation aloud; shorthand that saves time on a case sheet reads as imprecision when spoken, and some of it is genuinely ambiguous across specialties. And report phenomenology in the patient's own words before translating it into a technical term, so the examiner can hear the raw material and check your translation. A candidate who says the patient described a voice speaking about him in the third person, and then names the phenomenon, has shown two things. A candidate who names the phenomenon alone has shown one, and has invited the examiner to ask what the patient actually said.

MNEMONIC

Whose, What, Why, What next

The four questions a long-case presentation has to answer, in order. **Whose** problem this is: the patient, their circumstances, the informant and the reliability of the account. **What** is wrong: the phenomenology, then the diagnosis argued against its alternatives. **Why** it has happened to this person now: the formulation. **What next**: investigations and a plan in sequence, with a prognosis you can justify. A presentation that stalls does so almost always because it never left the first question.

34.5 Marshalling the evidence, including what you did not find

Group your findings by the argument they serve, not by the order you collected them. After the summary, the body of the presentation is evidence, and evidence persuades in proportion to its arrangement. Take the positives supporting your leading diagnosis together, then the features that would ordinarily point elsewhere and what you make of them, then the course and the treatment history with an explicit statement of whether previous treatment was adequate in dose and duration and whether it was actually taken. Chronology belongs inside each of these, not across the whole.

The element that separates a competent presentation from a strong one is the **pertinent negatives**: the findings you specifically sought and did not obtain. Stating them is how the examiner learns that your differential existed before your conclusion did. A candidate who says there was no head injury, no seizure, no sustained elevation of mood and no substance use in the relevant period has closed doors deliberately. A candidate who omits them leaves the examiner unable to tell whether those doors were closed or never opened, and the examiner will find out by asking. Risk belongs here too, stated rather than waited for; the assessment of suicidal risk itself

is developed in the Somatic-symptom, sexual, impulse-control disorders and suicide notes, but the fact that you have made one, and what you concluded, is yours to say before anybody asks.

> **PITFALL**
>
> Never state a finding you did not elicit. Under pressure, and especially when an examiner asks about something the presentation omitted, there is a strong pull towards supplying the answer the case seems to require. The correct answer is that you did not ask, or did not examine for it, and, if you can, what you would ask now and why. An examiner who catches one invented detail has a reason to distrust the entire account, including the parts that were true and carefully obtained. The cost of the honest answer is one mark; the cost of the invented one is the case.

34.6 From diagnosis to formulation, which is what the second half of the questioning is about

A diagnosis is a claim, and a claim invites the question "what else?" State the diagnosis you have reached, with the classificatory system you are using, and then do the work that earns it: name the serious alternatives and give the grounds on which each is set aside. Alternatives are set aside on evidence, not on adverbs, and the evidence is what you have just presented. Where you genuinely cannot decide, say so, say what would decide it, and say what you would do in the meantime. That answer is more mature than a false confidence and is usually marked as such.

Then move to the **formulation**, which asks a different question: not what this illness is but why this person has it now, and why it is taking this shape and this course. Predisposing, precipitating, perpetuating and protective factors are the frame, and the substance is reasoning that ties them to the person in front of you, not a list applied generically. The construct itself, and how a formulation is built and written, is taught in the Psychotherapies, clinical assessment, MSE and nosology notes; what belongs here is the discipline of presenting one. Keep it short and specific to this patient, and make sure it does work: a formulation that explains nothing about the plan you are about to propose has not been used. Then give the plan in sequence, with the investigations you would send and, more searchingly, the ones you would not and why. Deciding not to investigate is a clinical decision and is examined as one.

34.7 The neurology long case, and the commonest error of preparation

Where a second long case is neurological, half the long-case marks are not psychiatric. In the Karnataka ordinance of 2000 the neurology long case carried **75** marks, exactly what the psychiatry long case carried, and that equality is the part worth holding on to even where the current figures are unpublished. A revision plan built entirely from psychiatry is therefore not cautious; it has conceded a substantial block of marks before the examination begins. This is the commonest strategic error on this format, and it is invisible to the candidate making it, because psychiatry revision feels like the responsible use of the time.

A neurological long case asks for a different sequence, and the difference is worth rehearsing rather than reading about. The history is taken to localise before it is taken to diagnose. The examination is then not merely performed but demonstrated, in a sequence the examiner can follow, with signs elicited cleanly and described in the language of the system involved. The presentation ends with an anatomical statement and then a pathological differential, in that

order: where the lesion is before what caused it. The neurological syndromes themselves, and the examination that discloses them, are taught in the Neurology foundations for psychiatrists notes and the Stroke, TBI, delirium and focal brain syndromes notes, with the seizure disorders in the Epilepsy and psychiatry notes and the cognitive syndromes in the Dementias and neurocognitive disorders notes. What is owed here is the instruction to prepare for the case as a case: on real patients, out loud, in the order you will use in the hall.

34.8 The short case: competence under a narrower brief

A short case is a task, not a story. The two instruments that state a case count agree on the number of short cases: two in the national regulations and two in the older Karnataka ordinance. What changes is not the standard of clinical work but its scope. You are given a defined brief, usually to elicit and then to show: a mental state examination of one domain, a cognitive assessment, a set of neurological signs, an interview segment with a stated purpose. The examiner is often present while you work, and that is the point: in the long case your technique is inferred from your account, in a short case it is watched.

So **demonstration** becomes the marked activity. Say what you are about to do and why, do it in a sequence, describe what you find as you find it, and offer an interpretation that is proportionate to the amount you were able to examine. Do not deliver a full formulation for a short case, and do not open with a summary designed for a long one; both read as a candidate with one script and no judgement. Where the brief involves eliciting motor or catatonic phenomena, the phenomena themselves are taught in the Other psychotic disorders, delusional syndromes and catatonia notes, and the bedside conduct of scales and structured tests is set out in the section of these notes on demonstrating clinical scales and bedside tests. What is examined here is whether you can do a small thing correctly while observed, and stop when it is done.

AXIS	THE LONG CASE	THE SHORT CASE
What you are given	One patient and an open brief: assess and present	**A narrow, stated task on a patient or an interview segment**
What you do with the patient	Full history, informant account, mental state and physical examination, then time to build the argument	**The specified elicitation or examination, performed while it is watched**
What you present	Summary, evidence with negatives, argued diagnosis, formulation, plan in sequence, prognosis	**Findings as they were obtained, then an interpretation proportionate to the brief**
What is actually marked	Clinical reasoning: whether the plan could be acted on unsupervised	**Technique and economy: whether the procedure was done correctly and cleanly**
What ends it	The examiner's questions, which begin where your argument stopped	**The completion of the task, after which a candidate should stop talking**

34.9 The board across the table, and what a mixed board changes

Not everyone examining you is a psychiatrist. Under the Karnataka ordinance of 2000, the **board of examiners** for the clinical examination consists of **four** members, one of whom should be a neurologist or a clinical psychologist. Note the ordinance's own verb: the requirement is expressed as what should be the case rather than as an absolute, so the board you actually meet may be composed either way, and preparing on the assumption of a mixed board costs nothing.

The consequence is practical. If a neurologist sits on the board, your neurological examination is watched by somebody who performs it daily and will notice a manoeuvre done for form rather than for information. If a clinical psychologist sits on it, expect more exacting questioning around assessment instruments, including what a test measures and what its result does not license you to conclude; that material is developed in the Psychotherapies, clinical assessment, MSE and nosology notes. Either way, pitch the presentation to a competent colleague from outside your own subspecialty interest, another reason to expand abbreviations and give phenomenology before jargon.

34.10 Where the marks are actually lost

The failures on this format are few and repetitive. Each is avoidable by a decision rather than by more knowledge:

- the summary never arrives, because the candidate began at the beginning of the history and is still there when the examiner intervenes;
- the negatives are missing, so the differential appears to have been constructed after the conclusion;
- the diagnosis is asserted, not argued, and the alternatives are named without grounds for dismissing them;
- the physical and neurological examination was not done, and the candidate is asked about it;
- the plan is a list of everything rather than a sequence, with no statement of what comes first and what would change it;
- risk is not mentioned until the examiner raises it.

Only one of these is a knowledge failure. The rest are failures of shape, and shape is trainable: present real cases aloud, to a colleague who will interrupt, against a clock, until the summary and the argued diagnosis arrive early enough to be heard.

TRAP **Presenting the case sheet instead of the case.** The commonest failure is to narrate the written record in the order it was written, treating completeness as the virtue being marked. It is not: the case sheet is the raw material and the presentation is the argument built from it. The candidate who reads the record runs out of time in the personal history, delivers the diagnosis and plan as bare assertions, and is then examined on precisely the reasoning that was crowded out. Write the record in full, and then present something else.

34.11 Currency, disagreement, and the part of this that does not vary

The honest position on the documents. The instruments discussed here do not sit comfortably together, and a reader is better served by seeing that than by a tidy synthesis. The Karnataka ordinance is dated 2000 and applies from that academic year, and both of its arithmetics have since moved. Its written papers were four of three hours each, carrying two long essay questions at 20 marks and six short essay questions at 10, and that pattern is not what the same university now sets: under the notification of 16 December 2024 each of the four theory papers is set at **ten questions of ten marks**. Revising to the older pattern would be revising to the wrong shape. The national regulations of 2023 supply the frame the newer notification works inside: the theory examination may be of descriptive or multiple-choice type of equal duration, the descriptive form runs to four papers, and the first and the fourth are on basic medical sciences and recent advances respectively. The newer notification does not give a paper's duration and does not say what the middle two papers contain, and neither is supplied here. What the older ordinance remains good for is shape rather than schedule: it is evidence that allocations differ between universities, not a table to memorise for your own examination.

What does not vary is what this page is for. Whether you face one long case or two, whether one of them is neurological, whatever the short cases turn out to be worth, the presentation that earns the marks has the same architecture: a summary that stands alone, evidence arranged as an argument with its negatives stated, a diagnosis defended against named alternatives, a formulation that does work, a plan in sequence, and a candidate who says what they did not find. The arithmetic, where a document publishes it, tells you how to divide your preparation. It does not change how you present a patient.

> Read the ordinance and any later notification that governs your own examination before you plan a single revision session, and prepare for the heavier of the patterns you find: how many long cases there are, whether one of them is neurological, who sits on the board, and whether the marks on each case are stated at all rather than left to be settled later.

35 · Demonstration of clinical scales and bedside tests

Why the doing is its own competence. A candidate can describe an instrument accurately, say what it was built for, and still be unable to run it on a real patient while somebody watches. Knowing an instrument and conducting one are different competencies, and only the second shows at a bedside. In the demonstration of clinical scales and bedside tests, what is on display is not the instrument's content, which could have been read the night before, but a procedure: whether you obtained permission, whether you set the conditions the instrument assumes, whether you delivered its instruction unaltered, whether the patient was left with their dignity intact, and whether you could then say out loud what you had and had not established.

Set the boundaries first. The instruments themselves, the bedside cognitive screens among them, together with the rating scales and the detailed neuropsychological batteries, are taught in the Psychotherapies, clinical assessment, MSE and nosology notes and in the Dementias and

neurocognitive disorders notes. No item, scoring rule or cut-off is reproduced here, and none is needed for the skill this section teaches. The second boundary is a silence, and it is stated at the front rather than buried: how a demonstration of this kind is called for, whether it is marked as a thing of its own, in what time, and against what weighting cannot be stated, because no comparable standard is available to quote, and none is invented here. A reader not told that will assume a marking scheme exists which they were simply never shown, and will prepare for the tariff instead of the act.

35.1 What you can be handed, and why it matters which

The instruction can arrive in more than one form, and they are not the same task. A **rating scale** is a published instrument with fixed items, a fixed order and a scoring convention, so its demonstration is mostly a question of fidelity: you are showing that you can run somebody else's procedure without deforming it. A **bedside test** is a manoeuvre drawn from the clinical examination, elicited and described rather than scored, so its demonstration is one of technique and accurate description: the burden shifts from following a script to eliciting a sign cleanly and reporting exactly what you saw.

A third instruction is thinner and carries more risk: assess this patient's cognition, or show how you would quantify this patient's depression, with no instrument named. Here the choice of instrument is itself part of what you are demonstrating, and it has to be defended in one sentence before you begin: what the question is, what the patient can physically and linguistically do, and how much the task will take out of someone who is unwell. Choosing an instrument the patient cannot complete, and discovering it mid-administration, is an avoidable failure that begins before the first item.

35.2 The conditions the instrument assumes, and whose job they are

Every instrument silently assumes conditions, and the person administering it owns all of them. A patient who cannot hear the instruction has not failed the item; the administration has. The **conditions of administration** are therefore fixed first, visibly, and named aloud so that anyone watching knows they were fixed rather than assumed:

- Spectacles and hearing aids in place and working, and if they are not available, that fact stated before the task rather than after the result.
- Adequate light on the page and on your face, and a position where the patient can see your mouth while you speak.
- A firm writing surface and a working pen for any task requiring drawing or writing, arranged before the instruction is given, not searched for mid task.
- The language of administration settled, and a decision made about whether you or somebody else will speak it.
- A patient who is awake, not in pain and not mid-procedure, with a clear agreement that the task stops if that changes.

The last is regularly skipped because it feels like a courtesy rather than a technical prerequisite. It is technical: a drowsy or distressed patient generates a result that describes the drowsiness, and reporting it as the patient's performance is a substantive error, not a soft one.

35.3 The words before the first item

The opening should be short, said once, and delivered as though the patient rather than the observer were the only person in the room. It has to do a few things at once: identify you, describe what is about to happen, warn that some tasks will feel easy and others harder, remove the sense that a wrong answer has consequences, and make explicit that the patient may stop. Then stop talking and wait for an answer, because permission that is not actually given is not permission, and a task begun while the explanation is still running was agreed to by a patient who did not yet know what they were agreeing to.

Keep this at the level of ordinary clinical courtesy. The separate legal question of the patient who cannot give a valid consent to being assessed at all is a different subject, treated on its own elsewhere in these notes. What matters here is that permission was sought, that it was audible, and that it was obtained before anything was administered.

35.4 Fidelity: the instruction as written

The core of the whole act is delivery of the instrument's own wording, at its own pace, as often as it permits and no more. **Verbatim instruction** feels stilted to a clinician who has spent years learning to speak in a patient's idiom, and the temptation to improve on it is strong. Resist it. The improved instruction is a different instruction.

RULE **An instrument administered differently is not that instrument.** Every deviation, however kindly meant, moves the result off the standard procedure the published version rests on, so the result you obtain belongs to your improvised version rather than to the instrument you are about to name in your report. This is a clinical matter and not a formality: a generous administration produces a reassuring result on a patient who is not reassured, and the next clinician to read the record has no way of knowing that it happened.

The mirror of fidelity is tolerance of failure. **Coaching** is the reflex to rescue a patient who is struggling, with a hint, a gesture, a slower repetition, an encouraging partial answer, or a generous reading of a near miss. It comes from decency and it destroys the observation. An item the patient cannot do is left undone and recorded as undone, and the discomfort of watching that happen is part of the skill. If the patient becomes distressed, the correct act is to stop the task, not to soften it: a stopped task with a stated reason is interpretable, whereas a completed task that was quietly assisted is not.

35.5 The patient and the observer in one room

A demonstration asks you to be intelligible to somebody standing behind you while remaining engaged with the person in front of you, and the tension is usually resolved badly in one direction or the other. Turning towards the observer converts the patient into an exhibit, and the discourtesy is visible. Turning away entirely leaves nobody able to tell whether the instruction was given correctly at all, which is the part an observer cannot reconstruct afterwards.

The workable answer is positional and vocal rather than verbal. Sit where your voice carries past you, keep your eyes and your body oriented to the patient, deliver instructions at a volume that carries behind you, and do all commentary about the patient after the task and away from the bed. Nothing about a finding is discussed over the patient's head. If something must be said mid-task, it is said to the patient.

GOOD TO REMEMBER

One line in the record does most of this work, and it is written at the time or not at all: which instrument and which version was used, the language it was administered in and by whom, the sensory aids that were in place, and any item not attempted with the reason it was not. A result recorded without them cannot honestly be compared with the same patient's result on another day, and a comparison you cannot trust is worse than no baseline.

35.6 The act, step by step, and what deforms each step

The table sets the sequence against its characteristic failure. The right-hand column is the operative one: each entry is a deviation that looks small at the bedside and changes what the result can be used for.

STEP	WHAT HAS TO BE VISIBLE IN THE DOING	THE ALTERATION THAT MAKES IT A DIFFERENT TEST
Permission and framing	The patient hears who you are and what the task is, and agrees, before anything is administered	Starting the first item while still explaining, so the permission covers a task the patient had not yet heard
Conditions	Aids, light, seating, writing surface and language settled and stated aloud	Running the task through an uncorrected sensory deficit and reporting the output as the patient's performance
Instruction	The instrument's own wording, at its own pace, repeated only as it permits	Paraphrasing, simplifying, repeating a single-presentation item, or translating on the spot without saying so
Response handling	What the patient did, recorded as they did it, including refusals and near misses	Rescuing a failing item with a hint, a gesture or an encouraging repetition
Failure	An item the patient cannot do left failed and noted as failed	Reading it generously because the patient is old, tired or unwell
Closure	The patient brought out of the task, thanked, and told what happens next	Turning away to report while the patient is still sitting in the middle of it
Report	Conditions, procedure, observation and limits, in that order	Opening with a total, or with a diagnosis

35.7 Stopping the task, and what the report contains

Closure is the step most often lost, because by the end of the task the candidate's attention has already moved to the report. The patient has just been asked to do things they may have done badly, in front of strangers, and leaving them there is unkind and conspicuous. Close the task explicitly, thank them, answer the question they usually ask about how they did in terms of what happens next rather than the result, and only then turn to reporting.

Conditions	Procedure	Observation	Limits
THE STATE OF THE PATIENT AND THE ROOM WHILE THE TASK WAS RUN	WHICH INSTRUMENT, IN WHICH LANGUAGE, ADMINISTERED BY WHOM	WHAT THE PATIENT ACTUALLY DID, IN THE ORDER THEY DID IT	WHAT THIS OBSERVATION CANNOT SETTLE BY ITSELF

Conditions first tell the listener how much weight the rest of the report can carry. Procedure next fixes what was actually administered. Observation is then description rather than verdict: which domains the patient managed, where the difficulty sat, and what it looked like. The limits are stated by you rather than extracted from you, and they matter, because a screening observation obtained once, at the bedside, in a patient who is acutely unwell settles very little on its own.

TRAP **Reporting a total instead of a performance.** Candidates do it because a number sounds like an answer and appears to close the task cleanly. It does neither. A single total conceals which domain the patient actually struggled in, which is the part that changes what happens next, and it puts the weight of the answer on interpreting the figure, which is a separate skill treated on its own elsewhere in these notes. Describe what the patient did, name where the difficulty sat, say what you would do next, and say what you would want before committing to any reading of the result.

35.8 When the demonstration cannot be completed as designed

The situation to expect, rather than the clean one. Real patients refuse, tire, become distressed, cannot see the page, cannot hold the pen, do not share your language, or have an attendant who answers on their behalf. **Incomplete administration** is not a failed demonstration; it is a demonstration of something harder, which is judgement under a constraint you did not choose. What converts it into a failure is concealment: an abandoned task described as though it had been completed, or a partial result presented without the conditions that made it partial. Say what you did, say where you stopped, say why, and say what you would do instead.

IN INDIA

An instrument published in English, a patient whose first language is not English, and a relative who answers on the patient's behalf are the ordinary conditions of a bedside demonstration in an Indian general hospital, and each is handled by an act rather than an apology. If a validated version in the patient's language exists and is available, use it and say which one. If it does not, say aloud that you are translating, name who is translating, and treat the output as an observation obtained under translation rather than as the instrument's own result. Where a family attendant is present, ask them courteously and audibly not to supply answers during the task, and record that you asked: an attendant's prompting is the ordinary way a bedside cognitive task quietly becomes a family interview. Schooling and literacy are recorded alongside the sensory aids as conditions of the observation. How far they move a given instrument's result is that instrument's own literature and belongs to the Psychotherapies, clinical assessment, MSE and nosology notes.

MNEMONIC

Ask, Adjust, Administer, Acknowledge, Account

The spine of the act, in the order it happens. **Ask**: name yourself, name the task, obtain permission, and wait for it. **Adjust**: aids, light, seating, surface and language settled aloud before the first item. **Administer**: the instrument's own wording, at its own pace, with failure left standing. **Acknowledge**: close the task with the patient before you turn away from them. **Account**: conditions, procedure, observation and limits, in that order, with the limits volunteered rather than extracted.

In a demonstration the product is the procedure, not the patient's score: the conditions you fixed, the instruction you gave unaltered, the performance you recorded as it happened, and the limit you placed on it yourself.

36 · Communication, breaking bad news and risk-assessment stations

Why the marks sit here. Most of a postgraduate examination asks for an account of something. Communication, breaking bad news and risk-assessment stations ask instead for the thing itself, performed once, in front of somebody whose task is to watch how it is done rather than to hear what is known about it. That difference is the whole of the assessment, and it is why these stations separate candidates whose written papers look alike. A candidate can define collusion, name a disclosure protocol and list the correlates of suicidal intent, and still be unable to sit down with a frightened man and tell him what the biopsy showed. The examination exists in part to find that out.

Fig 29.14 The SPIKES protocol structures breaking bad news through setting up the conversation, assessing perception, obtaining an invitation, sharing knowledge, responding to emotions and agreeing a strategy and summary.

There is a second reason the marks are here, and it is a claim the profession makes about itself rather than an examiner's convention. The Indian Psychiatric Society's clinical practice guidelines on breaking bad news, published in 2023, record that many physicians consider psychiatrists best suited to breaking bad news, being better at handling emotions and more effective in communication skills, and that this role becomes much more important in a consultation-liaison set-up. Read the first of those exactly as written: it is a view attributed to colleagues, not a finding about outcomes, and the guideline reports it as such. It is nonetheless why a surgical unit telephones on a Friday afternoon about a family that will not let its patient be told.

6	4	2023	13.6%
STEPS IN THE SPIKES PROTOCOL FOR BREAKING BAD NEWS	OBJECTIVES THAT SAME PROTOCOL SETS FOR THE CONVERSATION AS A WHOLE	YEAR OF THE INDIAN NATIONAL PROFESSIONAL-BODY CLINICAL PRACTICE GUIDELINE ON BREAKING BAD NEWS	OF ONE IRANIAN MEDICAL-SCIENCES UNIVERSITY'S FACULTY AND RESIDENTS FOUND TRAINED IN DELIVERING BAD NEWS; NOT AN INDIAN FIGURE

36.1 What is actually being examined, and the yardstick it is examined against

The station marks a transaction, not a recitation. What the tasks grouped as communication, breaking bad news and risk-assessment stations have in common is that an examiner is watching an exchange rather than hearing a report about one. What can be seen from outside that conversation is a short list of things: whether the patient was allowed to say what he already believed before he was told anything; whether the information was released at a rate the person in front of you could absorb; whether an emotion, when it arrived, was answered rather than talked over; and whether the two of you finished with something agreed that was not agreed at the start. Everything else is commentary. The candidate who has prepared the content of the news and not the shape of the conversation will deliver an accurate, complete and useless five minutes.

There is a published yardstick for this and it is worth holding, because it converts a vague instruction to communicate well into **four** checkable objectives: gathering information from the patient, transmitting the medical information, providing support to the patient, and eliciting the patient's **collaboration** in developing a strategy or treatment for the future. Notice that only one of the four is about telling. The first is listening, the third is emotional work, and the fourth is a joint plan. A candidate who treats the task as pure transmission has satisfied a quarter of its declared purpose and will be marked accordingly, whatever the accuracy of what was said.

36.2 Why this task falls to the psychiatrist, and why it falls hardest on the ward

The referral usually arrives after the news has already gone wrong. Two things follow from the Indian guideline's positioning of this skill. The first is that the psychiatrist is being asked to do a job other specialties own clinically: the oncologist knows the staging, the nephrologist knows what dialysis will mean, and neither is asking you to take over the disclosure so much as to make it survivable. The second is that the setting where this matters most is named, and it is the **consultation-liaison** set-up, where you are a guest on somebody else's ward with no independent authority over the patient's treatment and a very short relationship to work from. How a consultation service is configured, and what a liaison model changes about that authority, is developed in the section of these notes on the principles and models of consultation-liaison psychiatry.

That guest status is the practical difficulty, and it should shape the answer you give an examiner. You rarely control who has already spoken to the family, or what they were told. So the first act of a real consultation is almost never the disclosure. It is finding out what has already been said, by whom, to whom and in what language, because a second version of the truth delivered by a new face is not a clarification to a frightened family: it is evidence that somebody is lying. Ask the

referring team what words they used, and the patient what he has been told; the gap between those two answers is frequently the referral's actual problem.

36.3 The two ways of getting it wrong, and why the decision is not binary

Both silence and bluntness are failures, and the guideline names them symmetrically. This is the ethical spine of the topic and it is where most candidates go wrong, because they arrive holding one side of it. Withholding a diagnosis or a prognosis from the patient on the presumption that he will not be able to handle it may not always be justified in terms of the patient's autonomy and the **right to know**. Hold that modal exactly as the guideline sets it: not that withholding is never justified, but that it may not always be, which leaves the clinical judgement open rather than closing it by rule. Against that stands the opposite failure, which is **insensible disclosure**: pouring out bad news with disregard for its emotional consequences, which may harm the patient's mental health and the therapeutic relationship between patient and doctor.

Set side by side, the two propositions do something useful to the examination answer. They dispose of the question the candidate is silently asking, which is whether to tell or not to tell, and replace it with a better one: how much, to whom, at what pace, and with what support in place afterwards. The candidate who announces that the patient has an absolute right to know and proceeds to exercise it has taken half the frame. So has the candidate who defers entirely to the family. The examinable position holds both halves and then reasons about this patient, and it is available to you as a stated position of the national guideline rather than as your own opinion.

RULE **Disclosure is a process with a rate, not a decision with two options.** The clinical question is never simply whether the patient is told. It is what he already suspects, how much he is asking for today, what will be said next, and who will be with him when it lands. Framing the task as a binary is what produces both classic failures: the conspiracy of silence on one side and the corridor announcement on the other. A protocol is useful precisely because it converts a yes-or-no decision into a sequence that can be paced, paused and resumed.

36.4 The protocol, and an honest word about where this version of it comes from

Name it, then be able to do it. The protocol every examiner expects you to name is **SPIKES**, and its **six** steps are setting; perception of the condition or its seriousness; the **invitation** from the patient to give information; knowledge, meaning the giving of medical facts; exploring emotions and sympathising; and strategy and summary. The Indian guideline of 2023 describes it as the oldest and most commonly used protocol worldwide, which is the sentence to have ready if asked why this one rather than another.

One caveat belongs on the page rather than in a footnote, because a candidate who attributes a protocol wrongly in a viva has made an avoidable error. The wording of the steps given here follows a teaching adaptation issued by a Canadian university's continuing professional development office, which states in its own opening line that it is an adaptation. That document credits the original description to Baile and colleagues in 2000 and a further account to

Buckman. Saying that aloud if pressed on the source is a better answer than a confident misattribution.

MNEMONIC

SPIKES

The six steps in order. **S**etting: the room, the seat, the interruptions. **P**erception: what the patient already believes about the condition or its seriousness. **I**nvitation: the patient's own invitation to you to give the information. **K**nowledge: the medical facts themselves. **E**: explore emotions and sympathise. **S**trategy and summary: what happens next, said plainly, and a summary of what has been agreed. The order carries the teaching. Two of the first three are the patient talking, and the news does not arrive until the fourth.

36.5 The act, step by step

Each step has a condition that must be true before you may move on. The table sets out what the protocol requires and where each step is lost under examination conditions. The detail given for setting, for knowledge and for the exploration of emotion is the protocol's own; the conduct advice attached to the remaining steps is general clinical teaching and is offered as such. Setting is the step candidates believe they can skip because the room is already arranged for them. It cannot be skipped, because sitting down, silencing the interruption and asking whether the patient wants somebody present are visible acts, and the examiner is watching for them.

STEP	WHAT THE STEP REQUIRES	WHERE IT IS LOST
Setting	Arrange privacy, involve significant others, sit down, make a connection and establish rapport, and manage time constraints and interruptions	**Standing, or talking across a trolley. A candidate who stays on his feet has told the patient this will be brief before saying anything**
Perception	Establish what the patient understands of the condition or its seriousness	**Asked as a formality and then ignored. The answer should change what is said next, including whether a warning is needed at all**
Invitation	Obtain the patient's invitation to give the information	**Skipped, or made rhetorical, leaving no room for the patient to decline or to ask for less today**
Knowledge	Use language the patient understands, taking account of educational level, socio-cultural background and current emotional state; give information in small chunks; check whether the patient understood; respond to reactions as they occur; give any positive aspects first	**Delivered whole, in one breath, in the register of a case presentation. Checking understanding is the most commonly omitted act in the protocol**
Emotions	Identify the emotion the patient shows, identify its cause, allow time for it to be expressed, then respond in a way that shows you have connected the two	**Answered with reassurance or with more information. Both end the emotion rather than acknowledge it**
Strategy and summary	Agree a strategy and summarise	**Lost to the clock, because the earlier steps ran long. The patient then leaves with the news and without a plan, which is the worst possible use of the time**

Two habits make the difference on the day. Stop after each small quantity of information, because the first sentence of bad news suspends comprehension and much of what follows it is lost. And when the patient becomes tearful, the station is being marked: name what you see, connect it to its cause, and wait.

36.6 What the protocol has been criticised for, and the modifications that answer it

Know one criticism and two modifications, and the viva answer is finished. The Indian guideline records that clinicians have modified the protocol by adding steps they judged essential. In 2005 a version was published in which a preparation step was prefixed, covering the review of all information about the patient that needs to be communicated and rehearsing it if necessary. A later modification inserts the **warning shot** as a step of its own and replaces the knowledge step with a composite that juggles providing information, clarifying, and dealing with emotions.

The criticism the guideline records is that the protocol has no step on patient questions and clarifications. Be careful with the referent when you repeat it. That sentence follows immediately on the description of the version with the preparation step, so whether the criticism is aimed at the original protocol or at that modification is not settled by the text, and a candidate who asserts one reading confidently has read more into the source than it contains. The safe formulation is that the criticism attaches to this family of protocols, and that the later modification is the answer to it.

VERSION	WHAT IT ADDS	WHAT THE INDIAN GUIDELINE RECORDS
The original six-step protocol	Setting, perception, invitation, knowledge, emotions, strategy and summary	**The oldest and most commonly used worldwide**
The version published in 2005	A preparation step at the front: review everything that must be communicated, and rehearse it if necessary	**Presented as a modification clinicians made by adding a step they felt was essential**
The later modification	A warning-shot step, and an information, clarification and emotions composite in place of a plain knowledge step	**Described as a recent modification; it is the version that meets the recorded criticism about questions and clarifications**

36.7 The Indian consulting room: who is told, and who asks that the patient not be

The protocol assumes a dyad and you will usually be handed a family. In much of Indian practice the relatives receive the information first, often in the corridor, and arrive at your door having already decided what the patient will and will not be told. The request that follows is **collusion**: do not use the word for the diagnosis, tell him it is an infection, he will lose hope. This is not obstruction and it is rarely selfish. It is a protective act inside a model of illness in which the family, and not the individual, is the unit that copes, and it should be met as one.

What works is neither compliance nor confrontation. Ask the relatives what they fear will happen if the patient is told, because the answer is usually a specific and addressable dread rather than a general principle. Ask what the patient has already asked them, which frequently reveals that he knows. Offer to find out what he wants to know rather than to tell him everything, which is the invitation step doing exactly the work it was designed for, and is also the offer families most often accept. The same negotiation runs when the illness is a progressive neurocognitive one and the patient's own comprehension is in question; those syndromes are taught in the Dementias and neurocognitive disorders notes, and capacity at the bedside in the section of these notes on it in the general hospital.

IN INDIA

Do not present the family's request as an ethical error to be corrected. The national guideline's own frame gives you a better position: withholding on a presumption about what the patient can handle may not always be justified against autonomy and the right to know, and disclosure that ignores emotional consequences may damage both the patient and the therapeutic relationship. Both halves sit in the same document, so a candidate can hold the family's protective intent and the patient's entitlement in one answer without appearing to import a foreign standard. The workable route is the patient's own invitation: establish what he wants to know, tell him that much, and tell the family exactly what you did and why.

36.8 The risk-assessment station: an interview that has to arrive somewhere

A risk station examines an act of enquiry, not a list of correlates. This is the station where the mismatch between what candidates revise and what is marked is widest. The epidemiology of suicidal behaviour, the risk and protective factors and the instruments used to structure their assessment are clinical content taught in the Somatic-symptom, sexual, impulse-control disorders and suicide notes, and reciting them is not what a **risk-assessment station** is for. What is examined is whether you can ask a person directly about self-harm and death without flinching, follow what he says rather than your schedule, tolerate the answer, and then convert the conversation into a stated level of concern and a plan somebody else could act on.

Three features of the interview are visible from outside it, and all three are marked:

- whether the question was asked plainly and early enough to matter, in words the patient would use rather than in euphemism, because an oblique question invites an oblique answer and the candidate then reports an absence that was never really tested;
- whether the enquiry moved from thought to intent to plan to preparation and access to means, following the patient's disclosures rather than a checklist, and whether protective considerations were sought with the same seriousness as the risk ones;
- whether it ended anywhere at all, because a risk interview that stops at information has not finished.

That last feature is the one candidates lose. Say what you conclude, say what you will do about it now, say what would change it, and say who else needs to know before the shift ends.

TRAP **Performing the label instead of the task.** The commonest failure in both stations is the same, and it is visible from the first sentence: the candidate narrates the protocol at the examiner instead of using it on the patient. Announcing that one would establish the setting, ascertain the perception and then obtain an invitation, while the simulated patient sits unaddressed, scores nothing; nor does reciting risk factors in the examiner's direction while the person who might die that night is asked no direct question. Name the framework once if asked to, then turn your chair towards the patient and do it.

36.9 What must be in the note before you leave the ward

An unwritten risk assessment is an unmade one. On a consultation-liaison service the record is the only part of your work that persists, because the team that acts on it was not in the room. The

entry after a disclosure should state:

- who was present, and who did the speaking;
- the words actually used for the diagnosis and the prognosis, rather than a paraphrase of them;
- what the patient said he had understood;
- what he asked, and what he chose not to be told;
- what was agreed about who would be told what next, which is the line that prevents a second version of the truth reaching the family.

The entry after a risk interview needs a different spine: what was asked, what was said in reply, the level of concern reached and the reasoning that produced it, the actions taken now, and the specific changes that should trigger a fresh assessment. A note recording only that the patient denied suicidal ideation has documented an answer without documenting the question, and it protects neither the patient nor the clinician. It is also how the examiner's follow-up is answered before it is asked, because the viva after a risk station is usually a request for the plan you would write.

GOOD TO REMEMBER

Before you leave the bedside, close three loops out loud: tell the patient what happens next and when somebody will return; tell the referring team, in person where you can, what you said and which words you used, so the next clinician does not contradict you; and write the entry immediately rather than at the end of the round, while the patient's own phrasing is still available to you. The patient's words are evidence and your paraphrase of them is not.

36.10 Who teaches this, and a figure that belongs to somebody else

The guideline gives psychiatry a teaching duty, not only a clinical one. Alongside the clinical role, the Indian guideline states that psychiatrists should play a leading role in teaching communication skills and skills in breaking bad news to their fellow colleagues in other disciplines. That is a useful sentence in a viva on service development, and an unusually concrete duty for a guideline to assign: it makes the department, and not only the individual consultant, answerable for how bad news is delivered across the hospital. A candidate asked how they would improve disclosure practice in their institution has a national document to cite rather than a personal preference to defend.

Behind that duty sits an evidence problem worth understanding rather than repeating. Training in this skill is not assumed to be universal, and the guideline illustrates the point with a study of how few clinicians had been trained. The illustration comes from a population that is not ours, and it is routinely transposed.

PITFALL

The figure of **13.6 per cent** trained in delivering bad news belongs to faculty and residents at a medical-sciences university in Iran, and to nobody else. It sits close to Indian material in the same discussion, which is exactly the arrangement in which a population quietly changes on its way into an answer script. Quote it with its population attached or do not quote it at all. To assert that Indian clinicians are undertrained in this skill is a separate claim requiring Indian evidence, and no Indian figure for it is asserted anywhere on this page.

36.11 The limits of what can be said about the station itself

The honest position on the format. Everything above concerns the act. How an objective structured communication or risk-assessment station is built for an Indian postgraduate examination is a different question and should be treated separately: no comparable standard is available to quote, and none is invented here. Nothing available sets out how such a station is constructed, how long it runs or how its marks are distributed, and a candidate who rehearsed to an invented schedule would be preparing for an examination that does not exist. What is known about how objective structured stations are organised in general is set out in the section of these notes on the structure of objective structured stations in psychiatry, and the conduct of instruments at the bedside in the section on demonstrating clinical scales and bedside tests. Read your own university's ordinance for whether a structured component is examined at all, and ask the department whether the pattern in force differs from the printed document.

What does not vary is the material this page is for. Whichever format your examination uses, the same conversation is being assessed: a patient asked what he already believes before he is told anything, information released at a rate a frightened person can take, an emotion answered when it arrives, a plan made jointly rather than announced, and a record that lets the next clinician continue the same account rather than begin a new one. Practise it on real patients, with a colleague watching, and be corrected out loud. There is no other route to competence in an act, and the interview technique underpinning it is developed in the Psychotherapies, clinical assessment, MSE and nosology notes.

Ask what the patient already believes and how much he wants to be told before you tell him anything, and check what he has understood and state what happens next before you leave: the first two steps and the last two steps of the protocol are where the marks and the clinical outcome both sit, and the news itself is the easy part in the middle.

37 · Interpretation of investigations and instruments in vivas

Why the marks are here. Somewhere in almost every oral examination a piece of paper is turned around and pushed across the table: a report, a chart, a film, a printout or a completed rating form. What is tested is not whether you have memorised a reference range. It is whether you can take an object you did not order, from a patient you may not know, and convert it out loud into a clinical decision, in order, without overreaching and without going silent. The interpretation of

investigations and instruments in the viva is written into the regulations governing the examination rather than left to departmental habit.

Two boundaries first. What an abnormality signifies, what an imaging sequence demonstrates, what an electroencephalogram or a cerebrospinal fluid profile can establish, and how a rating instrument is scored and where its cut-offs fall are taught in the Neurology foundations for psychiatrists notes, in the Dementias and neurocognitive disorders notes and in the Psychotherapies, clinical assessment, MSE and nosology notes. No finding, constant or cut-off is reproduced here. The second boundary is a silence, better stated at the front than discovered late: how many such questions are put, how long you are given for one, and what share of the oral's marks they carry cannot be stated, because no comparable standard is available to quote, and none is invented here.

37.1 What the oral examination is directed at

The national regulations governing postgraduate medical education, made in 2023 by the National Medical Commission's Post Graduate Medical Education Board and applying across India, provide that the oral examination shall be thorough and shall aim at assessing the candidate's knowledge and competence about the subject, about **investigative procedures**, about therapeutic technique, and about other aspects of the specialty. That list settles an argument candidates have with themselves every year: investigations are not an intrusion of general medicine into a psychiatry viva, and the regulation places them alongside the subject itself.

A university ordinance can add how the questioning is conducted. The MD Psychiatry ordinance of a Karnataka state health-sciences university dated 2000 provides that all the examiners **will conduct the viva conjointly**, assessing comprehension, analytical approach, expression and **interpretation of data** across all components of the course contents. Interpretation of data is named there as an assessed quality rather than as a topic, so it is watched throughout and not only when a film appears; and because the questioning is conjoint, your answer must be intelligible to the whole board at once, not only to the examiner who asked.

37.2 What can be put in front of you, and why it is not folklore

That ordinance is unusually explicit about the material. It provides that candidates may also be given case reports, charts, gross specimens, histopathology slides, radiographs, ultrasound and computed tomography images for interpretation, and that **questions on the use of instruments** will be asked. Notice the two modal verbs. The interpretation material is what a candidate may be given. The instrument question is what will be asked.

The clause is not one department's tradition. It appears word for word in that ordinance of 2000 and again in the MD Psychiatry ordinance of a private university in the same state, edition year 2019-20, which marks it as inherited regulation text carried across institutions rather than a local quirk you might be spared. The material listed is therefore generic to the clinical sciences rather than tailored to psychiatry, and the candidate who protests inwardly that a slide has nothing to

do with the specialty has missed that the ward asks the psychiatrist every week to exclude a medical cause before attributing a presentation.

RULE **Describe before you interpret, and interpret before you commit.** Every recoverable answer here has that shape; every unrecoverable one skipped a stage. A description can be corrected by the examiner and the answer continues; a diagnosis offered first has nothing standing under it, so when it is wrong there is nowhere to retreat and what follows is about your error rather than the patient. The order also makes an answer auditable to a board listening conjointly.

37.3 The order of interpretation

A fixed order is faster, not slower, because it removes the decision about what to say next. The order set out below is a working discipline rather than a published convention, and it changes little with the object in front of you. One step deserves emphasis in advance because it is the one most often skipped: say whether the object is technically adequate for the question being asked of it. **Technical adequacy** decides how much weight everything said after it can carry.

STEP	WHAT THE BOARD IS LISTENING FOR	THE ANSWER THAT LOSES THE MARK
Name the object	What it is, whose it is, when it was obtained, in what context	**Reading findings aloud before establishing what is being read**
Adequacy	Whether it can answer the question asked of it at all	**Treating an inadequate study as though it were a normal one**
What is present	Description in the order the object dictates, not the order your eye jumps	**Naming the one striking abnormality and then stopping**
What is absent	The negatives the clinical question required you to look for	**Silence, which a board cannot distinguish from never having looked**
Synthesis	One sentence tying the findings to the question actually asked	**Findings with no answer, or an answer with no findings under it**
Limits and next step	What this object cannot settle, and what you would obtain next	**Closing on a conclusion the object cannot carry**

MNEMONIC

What it is, whether it reads, what is there, what is not, so what, what next

The six steps in the order they are spoken. The last two are dropped first under pressure and are the two that separate a description from an interpretation: **so what** forces the commitment, **what next** shows you know where your evidence stops.

37.4 The trap answers

The failures worth rehearsing are not failures of knowledge. They are things a well-prepared candidate says because the room is tense and a decisive-sounding answer feels safer than a careful one.

- **Accepting the premise.** An examiner who says "this patient's scan is abnormal, what is your diagnosis" has embedded a claim in the question. If you cannot see the abnormality, say what you can see and ask to be shown what is meant. Agreeing first and searching afterwards leaves you defending a finding you never identified.
- **The unpointable finding.** Never name an abnormality you could not put a finger on if the object were handed back. The follow-up is always to show it, and from there the exchange is about your credibility.
- **Supplying a number you do not hold.** A range guessed to fill a pause is the one error that survives the examination and reaches a patient. Say you would check it against the reporting laboratory's own range, which is also the correct clinical answer.
- **Reading a normal result as an exclusion.** A normal test narrows a probability; it does not delete a diagnosis. State what remains possible and what would move you.
- **Reading an instrument's total without its conditions.** A score obtained through an uncorrected sensory deficit, in a language the patient uses poorly, or with a relative supplying answers, describes the conditions rather than the patient. Ask how it was administered first.

TRAP **Leading with the diagnosis.** The commonest single error at this table, and made for an understandable reason: a named condition sounds like mastery and appears to close the question cleanly. It does the opposite. It hides the reasoning that is the only thing being marked, it invites the follow-up you are least ready for, and it leaves nowhere to fall back to when the object turns out to be something else.

37.5 Questions on the use of instruments

The instrument question is a different task and is prepared differently. It does not ask what a device measures in the abstract; it asks whether you have handled one. Which instruments a psychiatry board selects is not specified by any of the documents that create the requirement, so no list is offered here and none is guessed. What is stable is the shape of a good answer, in four moves:

- Identify the object plainly, and say so if you are unsure rather than producing a confident wrong name.
- State what it is for, in terms of the clinical decision it supports rather than its mechanism.
- Describe how it is used and what has to be true before it is used, including the check that gets skipped on a busy ward.
- Say honestly what your own experience of it is: used independently, used under supervision, or seen used. An overstatement here is tested by the next question.

GOOD TO REMEMBER

Build this answer during residency, not during revision. For every investigation you order and every instrument you handle, keep one line: why you used it in that patient, what came back, and what you did differently because of it. A candidate with that habit answers from clinical memory rather than from a list.

37.6 The dissertation viva: the one investigation that is yours

The result you cannot be handed cold. One set of findings you will certainly be asked to interpret aloud, and you generated it. The national regulations of 2023 provide that **five per cent** of the practical marks will be for the dissertation, that an external examiner from outside the state will evaluate the dissertation thesis and take the viva on it, and that marks will be given on the quality of the dissertation and on performance in the viva voce. Both halves are marked, so a sound thesis does not carry a poor defence of it.

20	Outside the state	Before it begins	100
MARKS THE THESIS SHALL BE EVALUATED FOR DURING THE PRACTICAL, UNDER A KARNATAKA STATE HEALTH-SCIENCES UNIVERSITY NOTIFICATION OF 16 DECEMBER 2024	WHERE THE EXAMINER WHO EVALUATES THE DISSERTATION AND TAKES THE VIVA ON IT COMES FROM, UNDER THE NATIONAL REGULATIONS OF 2023	WHEN A COPY OF THE THESIS SHALL REACH THE HEAD OF DEPARTMENT, RELATIVE TO THE START OF THE PRACTICAL EXAMINATION	MARKS THE VIVA VOCE IS FIXED AT BY THAT SAME 2024 NOTIFICATION, WHICH REFERS ITS INTERNAL DIVISION TO A BOARD OF STUDIES

That Karnataka state health-sciences university, by a notification of 16 December 2024 issued under section 35(1) of its 1994 Act as amended in 2013, restates that share as an absolute figure: the thesis shall be evaluated for 20 marks during the practical examinations, the student shall submit a copy to the head of department before the practical examination begins, and those marks form part of the clinical or practical examination marks. Two consequences: the submission is a deadline a candidate can miss by assuming the department will collect the copy, and a weak defence costs you in the same pot as a weak long case.

An honest word on that document. Its wording as reproduced here comes from a copy of the scanned notification rather than the university's own published file, so its authority is corroborated rather than primary: a judgment of the High Court of Karnataka dated 12 March 2025, neutral citation 2025:KHC:10432, records that evaluation of marks is governed by the notification of that date. Plan around the figures; obtain your department's copy before relying on the exact words.

Prepare the defence as an interpretation task, because that is what it is. You will be asked why this design, why this instrument and not the alternative, what the sample will and will not support, and what you would do differently. An examiner from another state shares none of your department's assumptions and no local shorthand.

37.7 Which document governs you, and what has already changed

The scope clause above is the fullest published statement of what the viva contains, and it sits in an ordinance dated 2000. Whether every part of it still governs an examination sat now is not established, and you are better served by that sentence than by a confident assurance. Some of it has certainly moved. Under the older ordinance the viva proper carried **eighty of the viva's hundred marks**; the notification of 16 December 2024 fixes the viva voce at 100 marks and refers the internal division of those marks to a board of studies, so the older split is superseded. That notification does not address the scope of the viva, so the clause listing interpretation material and instrument questions is not expressly displaced.

One further variation is named only so that it is not carried across. The MD Psychiatry ordinance of a private university in Karnataka, edition year 2019-20, splits a 100-mark viva into 80 for the viva proper and 20 for a pedagogy exercise, in which a topic is given to each candidate at the beginning of the clinical examination and presented for **eight to ten minutes**. That **pedagogy exercise** is that institution's own scheme in its own document and is not established for any other examination. Read the ordinance and any later notification your own university publishes for your degree, as the section of these notes on long and short case presentation sets out, and ask which is in force.

IN INDIA

The object pushed across the table in an Indian examination hall is usually one another unit ordered for another purpose. The report may be a line written on the film jacket rather than a formal one; the earlier study that would make the current one interpretable may never have been done, or may be travelling in a folder the family carries between hospitals. None of that is an excuse and all of it is examinable. Say what you have, say what is missing, and name what you would want beside it: the previous film for comparison, the earlier value, the reporting laboratory's own range, or an account of how the instrument was administered.

The board is not asking you to name the abnormality. It is asking you to show that a result changes what you would do next, and to say out loud where your evidence stops.

Cross-cutting synthesis

38 · Cross-cutting synthesis

Four questions, one page. These notes have taught what a consultation is and whose need it answers, what changes when the patient is old, what changes when the account of the cause was settled by the family before anyone sent for you, and how all of it is asked for across a table by examiners. That looks like four subjects. It is four questions put to a single encounter, and they converge on one object: a page written into somebody else's file and acted on tomorrow by somebody who was not in the room. That page is the **consult note**. Anything you elicited that does not reach it has not, for the purposes of the patient's care, happened.

Putting it this way is practical rather than tidy. An unfamiliar referral becomes navigable once you know the pathway it sits inside and the points at which each question has to be asked, because those points are fixed and there are few of them. Asked at the right point, each costs a few minutes. Asked late, each costs a second visit, or a plan agreed in the room and abandoned outside it, or a record that cannot show you did what you actually did.

Not the patient WHOSE FELT NEED PUT A PSYCHIATRIST AT THIS PARTICULAR BEDSIDE	**Against baseline** THE COMPARISON EVERY LATE-LIFE JUDGEMENT IN THE NOTE IS MADE AGAINST	**Already explained** WHAT THE FAMILY HAS USUALLY SETTLED ON BEFORE THE REFERRAL IS WRITTEN	**Somebody else acts** WHY THE NOTE IS AN INSTRUCTION TO ANOTHER TEAM AND NOT A RECORD OF YOUR THINKING

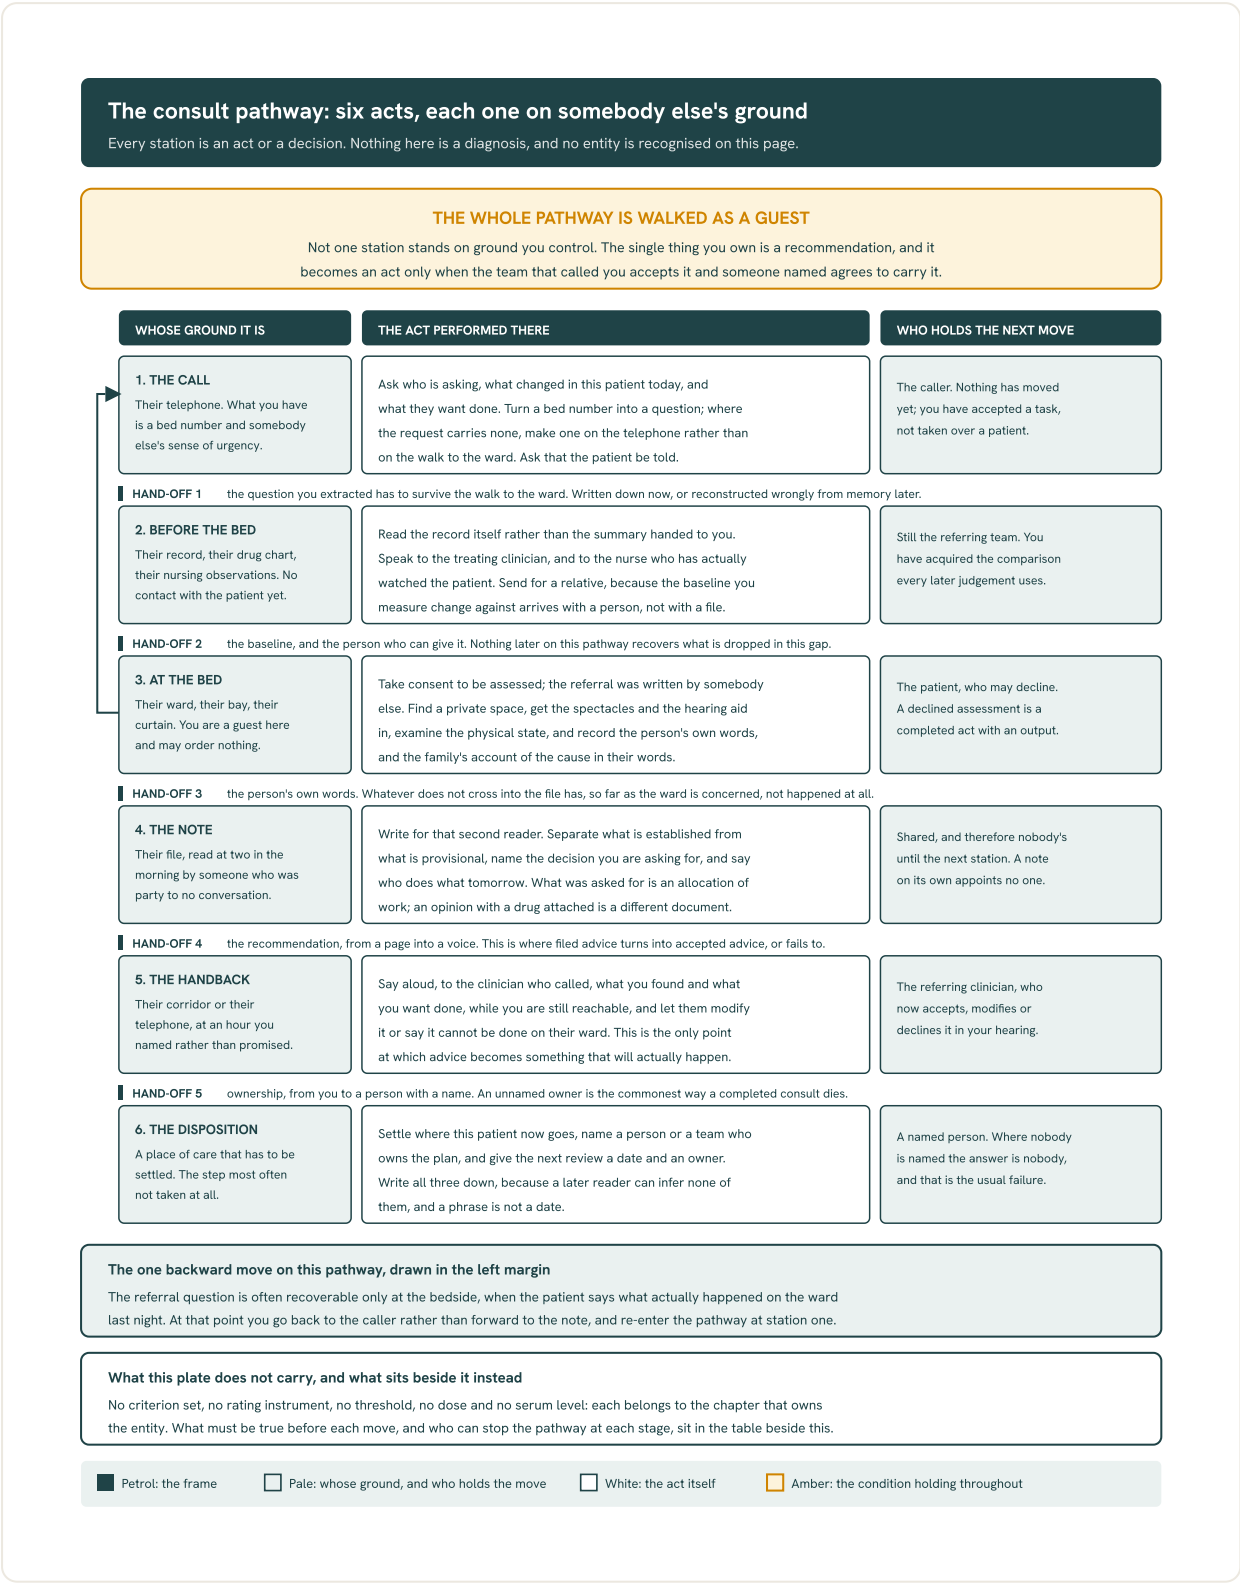

Fig 29.15. The consultation drawn as a pathway of six acts rather than as a set of entities, each station stated as something done or something decided, with the ground the act is performed on named on the left and the person who holds the next move named on the right, the five hand-offs between stations marked as the points at which information is lost, the standing condition that the whole route is walked as a guest set at the head, and the single backward move, from the bedside back to the caller, drawn in the left margin.

38.1 One artefact, and the two people who will read it

A consultation produces two outputs and they are not interchangeable. One is a conversation with the clinician who asked for you, the only point at which the team can say that what you want

is not possible on their ward, and the commonest difference between advice taken and advice filed. The other is the written record, the only output that persists after you leave the building.

The note has two readers who need different things from it. The first is the consultant who called, who wants to know whether what worried them is what you found. The second is the one nobody writes for: the **second reader**, a duty doctor at two in the morning who has never met this patient, was party to no conversation, and has your page and the drug chart. Write for the second reader and the first is served anyway. Write for the first and the note becomes a reply to a colleague, full of things that were obvious in the corridor and opaque by nightfall. That is why a good consult note names the decision it is asking for rather than gesturing at one, and separates what is established from what is provisional, since the person reading it at night cannot ask you which is which.

RULE **Everything this material teaches has to survive into a document another team will act on without you in the room.** That one constraint generates most of what looks like separate advice. Consent is established rather than assumed because a reader must be able to see the patient agreed to be seen. An informant is summoned before the visit because a judgement about change is worthless without the baseline it was measured from. The family's account of the cause is recorded in their words because the reader needs to know what will be accepted. And the decision, its owner and the next review date are written down because none of the three is inferable. An assessment that stays in your head is, to the ward, indistinguishable from no assessment.

38.2 The pathway, and the hand-offs inside it

The consult is a short sequence of acts with a hand-off between each pair, and a hand-off is where information is lost. The accompanying figure sets out the same sequence. Read the table as conditions rather than as a checklist: each row states what has to be true before you are entitled to move on, and who is placed to stop the pathway there.

STAGE	WHAT MUST BE TRUE BEFORE YOU MOVE ON	WHO CAN STOP IT HERE, AND WHAT STOPPING LOOKS LIKE
The call	You know who is asking, what has changed in this patient today, and what they want from you; and the patient has been told a psychiatrist is coming	The person who called, by leaving a bed number and nothing else. The repair is a question put back down the telephone, not a walk to the ward
Before the bed	The record has been read rather than the summary handed to you, the treating clinician has been spoken to, nursing observation is known, and word has gone to a relative to attend	You, by arriving with only the referral slip. Nothing later in the pathway recovers what this stage would have given you
At the bed	Consent taken, a private space found, hearing and language made adequate, the person's own words recorded, and the physical state examined before anything is scored	The patient, who may decline. A declined assessment is a completed act with an output, not a failure to be argued around
The note	Written into the team's own record, in implementable language, naming what is established, what is provisional, and the decision being asked for	You, by writing a diagnosis and a drug. That is an opinion; what was asked for was an allocation of work
The handback	The clinician who called has been told in words what you found and what you want done, and has had the chance to say it cannot be done here	The clock. The repair is to name the hour you will call rather than to promise that you will
The disposition	A named person owns the plan, the place of care is settled, and the next review has a date and an owner	Nobody stops this one. It is simply the step most often not taken at all

Two features of that sequence matter apart from its content. The pathway is a sequence of acts while the note is an artefact with its own spine, and the two are not the same list. And the pathway is less linear than a checklist implies: the **referral question** is often recoverable only at the bedside, when the patient says what actually happened on the ward last night, at which point you go back to the caller rather than forward to the note.

38.3 Where the other three questions enter, and what it costs to ask them late

Age, the explanatory account and decisional capacity are taught as separate subjects, which conceals what makes them manageable at a bedside: each enters this same pathway at a definite point, cheap there and expensive afterwards. The cost of lateness is not embarrassment but a specific, predictable clinical loss, and naming that loss turns three large topics into three questions you remember to ask.

THE QUESTION	WHERE IT ENTERS THE PATHWAY	WHAT IT COSTS WHEN IT ENTERS LATE
What was this person like before, and who can tell me	Before the bed, because the informant has to be summoned in advance and is rarely still there afterwards	Every cognitive and behavioural finding becomes uninterpretable. A second visit is then needed to obtain what one telephone call would have obtained
Whose account of the cause is already in the room	At the call and again at the bedside, since it governs what will be accepted; by the time the note is written the negotiation is over	A plan agreed in front of you and abandoned in the corridor. The abandonment is then misread as denial or as poor insight
Can this person make the decision actually in front of them, now	The moment a decision exists, which is usually before the referral was written	An assessment done only after a refusal reads as retaliation, and the record can no longer show capacity was presumed before it was questioned

The third row carries a trap worth spelling out. Capacity is decision-specific and time-specific, so a note recording that a patient lacks capacity, without saying which decision and on what date, has recorded nothing usable and may do harm when read months later as a settled characteristic of the person. The statutory test, the presumption it starts from and the duty to give information in a usable form are set out in the part of these notes dealing with refusal of treatment in the general hospital. What belongs here is where in the pathway the question arises, and that is earlier than most candidates place it.

38.4 What being old does to the note

Age does not add a paragraph. This is the most useful single point on the life-stage axis, and it is why appending an elderly-patient line to an otherwise unchanged note is not an answer. Age changes what the existing lines mean, and changes them in ways a reader has to be able to see.

- The history line acquires a source. Much of it comes from an informant by necessity, so the note says who gave it and how well placed they were to know: a daughter visiting monthly and a spouse in the same room are not equivalent witnesses.
- The examination line acquires preconditions. A cognitive item put to a patient who cannot hear the instruction measures hearing. Record that the spectacles and the hearing aid were in place, because a reader is otherwise entitled to disbelieve the score.
- The drug line becomes part of the physical examination rather than an administrative detail, and stopping a drug becomes a decision to be written down and justified in the same way as starting one.
- The diagnostic line becomes explicitly comparative, made against this person's own **baseline** rather than against a population, since the range of normal function in later life is wide enough that a population comparison decides nothing.
- The plan line is constrained by who will deliver it. A regimen assuming a supervising relative, a working refrigerator or a return visit next week is a proposal about a household, and the note

should say which household it assumes.

One further change is easy to miss. In an older medically ill patient much of what you write is a request for observation rather than a treatment: what the ward should watch for, when to call you back, and what would change the formulation. That is often the correct output of a single visit, and it reads as indecision only if you fail to say what the observation is for.

38.5 What a different account of the cause does to the note

By the time most of these patients meet a psychiatrist, somebody has decided what is wrong and why, something has been tried on the strength of that decision, and a view has been taken about how much the patient should be told. That is the **account already in the room**, and eliciting it is assessment rather than courtesy, because it predicts what treatment will be accepted, what the family will do next if your plan disappoints them, and what has already been spent in money, time and hope.

Getting it into the note has two halves. Record it in the patient's and the family's own words, attributed to whoever holds it, and place it beside your formulation rather than inside it. A belief held by the patient's community, expressed as that community expresses it and offered as an explanation rather than defended against evidence, is not by itself a finding of disorder; a note folding it into the phenomenology has told every later reader that it was one. The boundary between a sanctioned practice and a disorder is drawn by the ordinary questions: what changed in this person, when, whether the community itself regards the state as expected, and whether function has been lost. Drawn in those terms, the record survives being read both by someone who shares the belief and by someone who does not.

The second half is that the account must then do work. A history eliciting a prior healing episode and a family theory of causation, which then produces exactly the note that would have been written without them, has collected information and wasted it. If the family holds the cause to lie outside the body, the note should say what has been agreed about continuing what they are doing alongside treatment, because that agreement is the adherence plan and there is rarely another.

IN INDIA

The Indian pathway loads its front end. The referral commonly carries no question, so the question has to be created rather than answered. The relative is present, frequently decides, and is often told the diagnosis before the patient, so the consult happens in front of an interested third party whose agreement to the plan is in practice necessary. A patient may have spent weeks in a religious or traditional healing setting before meeting any clinician, which is a fact about the route to care and a question worth asking, never in itself a finding about pathology. Where the patient is an older person and the concern is neglect at home, the statutory route runs to a maintenance tribunal rather than to a protection service, which changes what can be promised in the room. And a consult service that looks quiet is reporting on referral behaviour, not on how much psychiatric illness the hospital holds.

38.6 Consent, capacity and the record that shows its own working

Two consent questions run through the pathway and are constantly conflated. The first is consent to be assessed, which belongs at the start and is not supplied by the referral, since the referral was not written by the person being seen. The second is capacity for a particular treatment decision, which arises only when a decision exists. A patient may agree to talk to you and still refuse the operation; a patient may refuse to talk to you at all, which ends the assessment without settling anything about capacity.

On both, the record has to show its working. What a later reader needs is not your conclusion but the route to it: that the person was told what was proposed in a form and at a time they could use, what decision was put to them, what they said in their own words, and what you concluded about that decision on that date. A refusal considered on its merits looks entirely different in a file from a refusal overridden, and the difference is visible only if the working is written down.

38.7 The handback and the disposition

The last two stages carry a disproportionate share of both the clinical value and the marks, and are the two most often left out. The **handback** is a spoken account to the clinician who called, and its purpose is not to repeat the note but to let them accept the recommendation, modify it, or say it is impossible on their ward. It is the only moment at which advice can be negotiated into something that will actually happen, and advice that cannot happen is worth nothing however correct it is.

The **disposition** answers where this patient now goes and who is responsible. It settles the place of care, the named owner of the plan and the **review interval**, and settling the owner explicitly prevents two opposite failures: a patient followed by nobody because each side assumed the other, and a team that stops referring because referral has begun to feel like losing patients.

> **GOOD TO REMEMBER**
>
> Before leaving the ward, make sure four sentences exist somewhere in the file, because each is the sentence whose absence causes a predictable failure. Who asked, and what for. What is established and what remains provisional. Who owns the next decision, named as a person or a team rather than as a specialty. And when this patient will be seen again, with a date rather than a phrase. If you write nothing else, write the last two: they convert an opinion into a plan somebody can be held to.

MNEMONIC

Called, changed, caused, capable, carried, called back

The spine of the note itself, as distinct from the sequence of acts that produced it. **Called**: who asked, and what they actually wanted, which is rarely what the request said. **Changed**: what is different in this person compared with their own previous state, when it changed, and who says so. **Caused**: where the psychiatric picture stands in relation to the medical illness and its treatment, which is the question that required a psychiatrist to attend at all. **Capable**: whether the person can make the decision in front of them now, and whether they were told what they needed in a form they could use. **Carried**: who does what tomorrow, named. **Called back**: when the patient is seen again, and by whom.

38.8 The same pathway as an examined performance

The examined version compresses this pathway without altering it, and knowing that is worth more than rehearsed phrasing. A short clinical station, a long case discussion and a viva question all ask you to walk the same route aloud, under observation, with the time cut down. The compression falls on the assessment, not on the beginning or the end, which is exactly where candidates cut.

- Say who asked and what for, before you say what you found. An answer opening with a diagnosis has skipped the part that establishes you understood the setting.
- Say what you would have established before going to the bedside, even when the patient was handed to you directly. Naming preparation you were not given time for is not an excuse; it shows you know the act has a shape.
- Separate the established from the provisional aloud, and say what would settle the difference. Follow-up questions land on certainty far more often than on admitted ignorance.
- Finish at a destination: the place of care, the person who owns the decision, and when the patient is seen again, in that order, then stop rather than trailing into further differentials.

The same structure answers the essay forms these subjects arrive in. Asked to write about psychiatric work in a particular ward or with a particular group of patients, an answer organised as pathway, entry points and note is complete and is visibly about practice. An answer organised as a list of the conditions found in that setting answers a different question, and usually one another part of the syllabus owns.

TRAP **Collecting the extra information and then writing the note you would have written anyway.** This is the characteristic failure of an answer that has learned the vocabulary of these subjects without the logic. The candidate asks about the shrine visit and records it under a cultural heading, then gives a formulation and a plan untouched by it. The candidate notes that the patient is old and prescribes at the adult dose. The candidate raises capacity and then proceeds exactly as if it had never been raised. Every item was elicited and nothing changed, so the extra questions worked as decoration. The test is direct: point to the line of your plan that is different because you asked. If no line is different, you did not ask the question, you performed it.

The pathway is call, preparation, bedside, note, handback and disposition; the note says who asked, what changed, what it stands in relation to, whether the person can decide, who acts tomorrow and when you see them again; and age, another account of the cause, or a decision on the table changes what those lines say rather than adding new ones.

Apply, consolidate and close the paper

39 · Applying the chapter

Four vignettes, and in every one of them the wrong answer arrives first. None of what follows tests whether you can name a condition. Each **worked case** is built so that a correct, well-organised and entirely defensible answer about a disorder is available within seconds, and so that this answer earns almost nothing. Work the case by itself first, aloud, in the sequence set out below; read the commentary only afterwards, against what you actually said.

No two of the four share a **pull**. On a general ward the pull is towards a psychiatric label. With an older patient it is towards adding something to a list nobody has read. With a family who have already settled the cause it is towards correcting them. Under observation it is towards reciting the entity, because reciting is what fluency feels like from the inside. Recognising the pull is worth more than learning the four answers: a pull recurs across cases you have never seen, and an answer does not.

Reach for the label	Add a drug	Correct the family	Recite the entity
THE PULL IN THE FIRST CASE, ON A SURGICAL WARD LATE AT NIGHT	THE PULL IN THE SECOND, WITH AN OLDER PATIENT AND A LONG LIST	THE PULL IN THE THIRD, WHERE THE CAUSE WAS SETTLED BEFORE YOU ARRIVED	THE PULL IN THE FOURTH, WHERE THE SAME MATERIAL IS PERFORMED AND SCORED

39.1 How to work a case, and what is actually being practised

What is practised here is the reassembly of an act from a situation, under the condition every referral in this chapter arrives in: most of what you need has not been given to you.

- Read only the case and stop. Read the commentary first and the exercise becomes recognition, which feels identical to knowledge and transfers nothing to a bedside.
- Say aloud, in order: who asked and what act they wanted; what you would establish before walking to the patient, and from whom; what you would do there; what you would write, and in whose record; and where this person is by morning, with a named owner.
- Name what you were not given, and who holds it. That is the part candidates leave out and the part that is marked.
- Commit. One explanation you would act on, one you are setting aside, and the ground for setting it aside. A descending list of possibilities is not a commitment and cannot be tested.
- Only then read the commentary.

RULE **A case here is a bedside with information missing, not a puzzle with an answer hidden.** What you are given is what a referral gives you: a bed number, one word, somebody else's diagnosis, a family's account. What is absent is what a clinician goes and obtains, and in all four cases below the decisive fact is one nobody has yet written down. So the first productive move is never to work out what the stem is pointing at. It is to say what you would obtain, from whom, and before which step. Answer only from the sentences supplied and you have agreed to be a reader of referrals rather than a clinician, leaving the marks exactly where they sit, which is in the questions.

39.2 A surgical ward telephones late at night

The case. A surgical ward telephones about a woman of seventy-eight, four nights after an operation on her hip. The slip carries a bed number and the word confused. The duty registrar asks whether you can start something to settle her, because she has pulled out her cannula and the night staff cannot manage her. Her son, outside, tells you she has been depressed for years and that this is her depression returning, and asks you not to say anything to her about her mind. Nothing else is offered.

Working it. Two things reached you before the patient did, and both are wrong to accept. The first is a request for an act rather than an opinion, and granting it means prescribing for the ward's difficulty. The second is a diagnosis from a relative who knows her past well and witnessed nothing of last night. A long history of depression makes her more vulnerable to almost everything; it does not explain a change over four nights.

What is missing is a **baseline** and a time. Before you leave for the ward: what she was like a fortnight ago, from whoever saw her then; when the change began, and what stands beside it on the chart, which may be the operation, the anaesthetic, a drug added since, a fever, poor urine output, or nothing yet identified; what the night staff saw, and at what hour; and what she has already been given for it. All of that is obtainable before you enter the bay and none of it afterwards, once the son has gone home and the shift has handed over.

At the bedside the order matters more than the content. Spectacles and hearing aid go on first, because an assessment conducted without them measures her hearing. Her own words are recorded before being translated into anything. Her physical state is examined. Only then is anything scored, and what a screening instrument is for on a ward is dealt with where these notes take up the consult on delirium in the medically ill.

The answer is delirium, and the discipline is that nothing in the account requires a psychiatric diagnosis. The condition itself is taught in the Stroke, TBI, delirium and focal brain syndromes notes; what belongs here is the decision that follows. She is not moved, because the cause is being sought where she already is and a transfer costs her the staff and the routine she has some chance of recognising. What you write names acts and owners: who searches for the cause, who reviews the chart, what the ward watches for overnight, and when you are to be called again. The son's request not to tell her is a second question with an owner elsewhere in these notes, and the error is to settle it by default, which is what saying nothing does.

39.3 An older man, pain in several places, and a cloth bag of tablets

The case. A man of seventy-one is referred from a cardiology clinic with a note saying his investigations are normal and he continues to complain. For most of a year he has had chest tightness, poor appetite, weight his family describe as a great deal lost, and he has stopped walking to the temple he went to every morning. He brings a cloth bag holding more strips of tablets than he can name; two prove to be the same drug under different trade names. His daughter says he has also become forgetful. He does not say he is unhappy: asked why he has come, he says his chest is not right and the doctors have found nothing.

Working it. The pull is to write an antidepressant. It is decisive, it answers the referral, and reading a bag of tablets feels like inaction beside it. Follow it and a drug joins a list that may be producing the picture, after which nothing can be attributed to anything.

The **drug list** is a history and not an administrative annex. Taken as one it yields what was started, when, by whom and for what; whether each item is still swallowed as opposed to still prescribed; what has been stopped and on whose decision; and what was added most recently before the change his family describe. The cumulative anticholinergic and sedative load of a list assembled by several prescribers over years is a recognised cause of exactly this presentation, dulled cognition and low mood together, and the agents, the burden and the arithmetic of a starting dose in later life belong to the part of these notes on prescribing in the elderly.

The presentation is the second half of the problem. He arrived complaining of his chest and his weight, which his physical illness and his tablets can equally produce, so the ordinary somatic signals are unavailable as evidence and recognition must be done another way. How that is done is taught where these notes deal with late-onset depression; the choice between agents is in the Mood disorders: pharmacotherapy notes. His daughter's word forgetful is not settled by administering a cognitive test to a man in this state, and the assessment it belongs inside is taken up where these notes deal with the comprehensive assessment of an older patient.

The act that separates a good answer here is small. Something comes off the list, or you write down why nothing does and what would change that. Then you tell the referring clinic what you altered and why, because they prescribe on it and a change they do not know about is reversed at the next visit. The review is set with the bag in the room.

39.4 A family who already know the cause

The case. A young man of twenty-four is brought by his father and his uncle. For close to a year he has spoken less, stopped work, stopped washing unless told, and spends the day on the roof of the house. The family have twice taken him to a healer some distance away and have spent a great deal doing so. They say without hesitation that someone has done this to him, that the healer confirmed it, and that he was a little better for a few weeks after the second visit. His father does not want tablets that will make his son a patient for life. The young man says almost nothing; asked what he thinks is wrong, he says his father knows.

Working it. The pull is to correct them, and it is strong because the explanation is not true and because correcting error feels like the job. Follow it and you spend your entire credit in the first

two minutes on an argument you cannot win, in front of the two people who decide whether your plan is carried out.

What is in front of you is the account already settled at home, and eliciting it is assessment. It predicts what will be accepted, what they will do if your plan disappoints, and what has already been spent, which measures their commitment to it. The questions are ordinary, and are asked in a tone that assumes the family were doing their best, because they were. Who first noticed, and what did they notice. When you went, what were you told the cause was, and what were you asked to do. Did anything change afterwards, and for how long. What do you think will happen if it stops. And then the one that does most of the work: what would you want him to be able to do again.

That question moves the encounter off the disagreement about cause and onto an agreement about function, where the family and the clinician usually want the same things. The **negotiation** that follows is not a request that they abandon their account. It is a proposal that what you offer runs alongside what they are already doing, and said in those terms it is the adherence plan; there is rarely another. Something can be conceded honestly too: his few better weeks are a real observation, worth exploring rather than dismissing, since whatever produced them may be usable.

Two further acts are owed. He has not been asked, and at some point he is seen alone, which is the only way his own view of the cause becomes recordable. And whether this is illness at all is settled by neither explanation: work and self-care have gone over close to a year, and that loss of function stands whatever anybody believes about its origin. Their words go into the record attributed to them, beside your formulation rather than inside it, so a later reader can tell which is which. The cultural framework and the formulation outline are taught in the Psychotherapies, clinical assessment, MSE and nosology notes, and the classic culturally shaped presentations where these notes take them up; what is owed here is the negotiation.

TRAP **Deciding who is in the room by reflex.** Candidates hold one of two reflexes firmly, and both are wrong. The first clears the relatives out at the start, in the name of confidentiality, and loses the only person who can say what the patient was like a month ago, whose agreement the plan needs, and who will fetch and give the tablets. The second never separates them, and then cannot ask about neglect at home, cannot hear the patient's own account of the cause, and produces a history in which the patient does not speak. Both are visible above, in a son who speaks for his mother before you reach the ward and a young man who defers to his father. The examinable act is not a preference between reflexes but a statement, made before the interview starts, of who you will see together, what you will ask each of them alone, and why.

IN INDIA

Three features of the room change how these cases are worked rather than merely colouring them. Somebody who knows the patient well is almost always in the corridor, so an answer resting on an informant who could not be reached will not be believed here; send for them before you go to the bed. The person paying is frequently not the patient and much of it is paid at the counter, so what a plan costs each month is a clinical variable and belongs inside the plan: a regimen nobody can sustain is stopped without anyone telling you. And the interview is usually in one language while the record is written in another, so the original phrase is kept beside the translation, because the phrase is what the family will repeat to the next clinician and a translated summary quietly loses the thing you were listening for.

39.5 The first case again, this time performed and scored

Nothing is removed by an examination; the middle is shortened. Take the woman of seventy-eight again, now in a practical examination. There is no chart, no nursing record, no son and no telephone. You have the patient, examiners and a clock, and one of them says: this lady had an operation last week and the ward says she is confused, take a history and tell us what you think. The material is identical and the act is different, because it is now an act of speech performed in front of people deciding something about you while you do it.

The **compression** falls on the assessment, not on the two ends. Candidates cut the opposite way, abbreviating the beginning, which establishes that they understood the setting, and abandoning the end, where the marks for the plan sit, in order to protect a middle the examiners can watch for themselves. So open on the referral: whose ward this is, who sent for you, what they wanted done. Then say what you would have established beforehand and from whom, and say plainly that you were not given it, which is a statement about the shape of the act and not an excuse. Then the assessment, briskly. Then the disposition and the review, in words, before you stop.

What the marking consists of is worth making explicit. Candidates imagine a running total of facts; it is a small number of decisions taken at identifiable moments, most of them before you have said anything at all about a diagnosis.

THE MOMENT	WHAT EARNS	WHAT LOSES
Your first sentence	The referral before anything else: whose ward this is, and what act was asked for	Opening with a diagnosis, which answers a question nobody asked
Before you touch the patient	What you would have obtained beforehand, from whom, and that it was unavailable here	Apologising for the gap, or filling it with a detail you did not elicit
The examination	Spectacles and hearing aid on, aloud and with the reason given, before anything is administered	Administering an item to a patient who has not heard the instruction, then reporting the result
The commitment	One explanation named, one serious alternative rejected, and the reason for rejecting it	A ranked list of possibilities, which gives the examiners nothing to test
The plan	Who does what, where she is by morning, and when she is seen again	A drug with no owner, no place of care and no review
The last thing you say	Stopping at a destination	Trailing into further differentials after the answer was complete

Two consequences follow, both counter-intuitive enough to rehearse. A wrong commitment defended on stated grounds is recoverable, because the questioning can go to the grounds and you can move; an absent one is not, because there is nothing there to examine. And the beginning repays rehearsal more than the middle, since several of those decisions are taken in the opening sentence and in the preparation you name, and both can be prepared word for word without sounding rehearsed.

39.6 What the four share, and how to make more of them

Set side by side, the four are one case. In each of them somebody else's account arrived before the patient did, the decisive information was held by a person nobody had asked, and a fluent answer was available that belonged to another part of these notes. Only the fluent answer and its cost differ.

THE CASE	THE PULL, AND WHY IT IS STRONG	WHAT FOLLOWING IT COSTS THE PATIENT
The confused surgical patient	A label, handed over by the ward and confirmed by a relative; it settles the night, and sedation is the act requested	Nobody hunts the cause while the picture is being suppressed
The somatic complaint in later life	Prescribing. Writing something is an act, where auditing a bag of strips looks like inertia	Attribution becomes impossible: no one afterwards can say which agent does what
The family with an explanation	Correction. The account is untrue, and putting error right feels like the clinician's proper work	They withdraw rather than argue, and treatment lapses where you cannot observe it
The same material under observation	Recitation. It is the prepared, fluent and entirely correct answer to a different question	The answer expires before any disposition, and the questioning goes straight to what was skipped

Four cases are not enough practice, and the supply is sitting in your own week. Building them is quick, and the building is itself useful, because writing a case forces you to notice what a referral actually contained.

- Take referrals your unit genuinely received, strip out every identifying particular, and write each as four sentences ending at the word the referrer used. Answer them cold a week later, once you have forgotten what happened next.
- Write the pull in beside each one before you write the answer. A case with no plausible wrong answer is not a case; it is something you already know, arranged as a question.
- Work them with a colleague playing the referrer, who may answer only what you actually ask. Most of what these cases teach is which questions you fail to ask, and that is invisible when you work alone.

MNEMONIC

Read the slip, read the sheet, read the story, read the room

Four things exist before you say a word, and in each case above the decisive fact was in one of them. **The slip**: who asked, in whose ward, and what act they want rather than what opinion. **The sheet**: the drug chart and the observation record, which between them hold when this began and what has already been given. **The story**: the account of the cause settled at home, in the words of whoever holds it. **The room**: who is present, who decides, who pays and, in the examination, who is scoring. Not one of the four is obtained by asking the patient a better question at the bedside.

GOOD TO REMEMBER

Keep a list of your own pulls rather than of your own wrong answers. After a case you get wrong, write down the move that produced it and not the answer you missed: reached for the label, did not send for the informant, added a drug instead of reading the list, corrected the family, stopped at the diagnosis. Within a few weeks the list stops growing, because there are only a handful of them and they are yours. A wrong answer teaches you one case; a named pull changes what you do at the next bedside, including the ones nobody has written a case about.

Work a case forward from what is missing: the referral and the act it asks for, the fact you would go and obtain and the person holding it, the explanation you are acting on and the one you have rejected with your reason, and who does the next thing by morning; then name the pull rather than the answer.

40 · Consolidation

A closing list earns its time only if it forces production rather than recognition. Everything below is an **ask-and-hold** pair: on the left the question in the form an examiner puts it, on the right what you must produce before you look at anything. Cover the right column, answer aloud, then read across. Recognition feels identical to knowledge from the inside and is worth little across a table from two external examiners, which is why this consolidation, the last in Paper III, is set in two columns.

The right column asks almost nothing about what a condition is, because the marks here sit in **the encounter** rather than in **the entity**: who asked, on whose ward, what changed because the patient is old, whose account of the cause was already in the room, and how the performance is scored. It closes on a register of addresses, because a reader who comes here for an entity and is not told where it is taught has been failed twice.

Ask, then hold	The encounter	Named in full	Never backwards
THE TWO COLUMNS EACH PROMPT IS BUILT FROM	WHAT AN ANSWER HERE IS MADE OF, NOT THE ENTITY	HOW THE REGISTER PRINTS EACH ONWARD DESTINATION	THE DIRECTION A POINTER MAY NOT SEND A READER

40.1 How to run the list

Work the three groups in order, because sequence is most of what is marked: the right acts in the wrong order satisfy nobody. Name who performs each act, since almost every failure here is an act nobody owned rather than one nobody knew, and keep talking until you have said where the patient goes and when they are seen again.

Mark two failures apart. A prompt you could not answer is ordinary, fixed by rereading that section. A prompt you answered by describing a condition is worse: it is the error this material exists to correct, and it feels like competence as you produce it.

RULE **Answer at the address the question was asked from.** Every heading here has two possible answers and only one earns anything. The first describes the condition: features, subtypes, how it differs from its mimics. The second describes what was done: who called and what they wanted, what was established first, in whose records it was written, who held the decision, and where the patient went. These notes own the second and name the address of the first; give the first and you have written a correct paragraph belonging elsewhere.

40.2 Ask and hold: the general hospital

These eleven share one structure: the psychiatrist is a guest, the notes belong to somebody else, and the request came from a treating team, not the patient.

THE ASK	WHAT YOU MUST BE ABLE TO PRODUCE
Principles and models of consultation-liaison psychiatry.	The referral as a procedure: what the caller must convey, what you establish on the call including whether the patient consented, the **preparatory phase**, the note's headings, and why writing in the file is not by itself sufficient feedback.
A medical ward calls overnight about a confused patient.	That confusion with behavioural abnormality is the commonest reason an Indian liaison service is called, the discrimination made first, and that the patient stays on the medical ward under psychiatric observation.
Psychiatric aspects of medical and surgical illness.	The signature read both ways: the psychiatric presentation a medical illness produces, and the occult medical cause behind a psychiatric one, organised by system and by drug.
Psychological reactions to physical illness and chronic disease.	That a reaction is universal and does not always reach morbid level, that separating reaction from disorder is the liaison task, and adherence as the stake.
Somatic symptom disorders in a consultation-liaison setting.	How such a patient reaches psychiatry, through a physician out of investigations, and the address of the nosology.
A physically ill patient refuses treatment.	That the national mental health legislation of 2017 presumes capacity at section 4, the ability test applied to this decision now, that section 4(2) is unsatisfied until information is given in a form the person can take in, that an unwise decision is not incapacity, and that the Act expressly reaches a general hospital.
Psychiatric work in transplant, dialysis and intensive care.	What a pre-transplant psychosocial evaluation is for, why uraemic symptoms mimic and mask depression on dialysis, and the syndrome after critical illness.
Psychiatric aspects of HIV and chronic infection.	Consent for testing as a statutory question, disclosure, adherence, stigma, and how the clinic relationship is built rather than improvised.

THE ASK	WHAT YOU MUST BE ABLE TO PRODUCE
Psychiatric aspects of cardiac, skin and kidney disease.	The bidirectional relationship in each, the burden the specialty clinic carries, the drug-safety signals constraining prescribing, and which head terms are attested.
Epilepsy and neurological disorders as they arrive on a consult.	The frame only: why they generate referrals, what is asked, and the address.
The ward believes the patient is fabricating.	What the liaison psychiatrist does and, more importantly, does not write down; and how such a referral often follows the team's frustration, itself part of the assessment.

40.3 Ask and hold: the older patient

These ten share a different structure. The condition is taught elsewhere; what is asked is what age does to the assessment, the prescription and the safeguarding question.

THE ASK	WHAT YOU MUST BE ABLE TO PRODUCE
Psychiatric assessment of an elderly patient.	That the skeleton does not change with age and the weight given to comorbid physical illness does, the added domains of sensory deprivation, frailty and elder abuse, the last needing active suspicion, and what normal ageing does and does not take away.
Dementia in the elderly.	Its place in the geriatric frame, and the address where it is taught.
Late-onset depression.	The presentation that misleads, the somatic and cognitive mask, the vascular contribution, and that current Indian guidance holds age to influence which antidepressant is chosen.
Late-onset psychosis and paraphrenia.	The exclusions run first with the drug classes named, when neuroimaging is indicated, and what changes in management because the patient is old.
Delirium in an older person.	Ageing as the predisposition: frailty, sensory impairment, polypharmacy, delirium superimposed on dementia, and that the hearing aid and the spectacles go on before any cognitive item is administered.
Principles of psychopharmacology in the elderly.	The pharmacokinetic and pharmacodynamic changes, the starting dose as a fraction of the adult dose with the agent named, anticholinergic burden as a crucial cause of delirium, falls, and deprescribing.
Elder abuse and neglect.	Recognition against a definition including acts of omission, a history taken with the patient interviewed separately and given time and reassurance, the screening instrument, and the legal position below.

THE ASK	WHAT YOU MUST BE ABLE TO PRODUCE
Sleep disturbance in the elderly.	What changes in timing and architecture, then the finding that reframes the heading: in older adults in excellent health insomnia prevalence resembles that in younger people, so the complaint is comorbid and a hypnotic the wrong reflex.
Comprehensive geriatric assessment.	That it is an interdisciplinary, multidimensional process for frail or vulnerable older people and not a questionnaire, its product of a problem list, goal-driven interventions and one coordinated plan, its domains with cognition one item inside the mental-health domain, and how falls risk is stratified.
Pseudodementia versus dementia.	The distinction, why it matters at the bedside, and the address of the table.

40.4 Ask and hold: the explanatory model, dying, and the examined performance

The last group holds the two hardest kinds of question. One asks you to work with an account of causation that is not biomedical and that the family has accepted; the other asks you to perform, observed, in a fixed time. Hold the scheme you perform inside: the national regulations make passing conditional on three things, not less than **40 per cent** in each theory paper, not less than **50 per cent** in aggregate across the four theory papers, and not less than 50 per cent in the practical examination, so a strong practical rescues nothing.

THE ASK	WHAT YOU MUST BE ABLE TO PRODUCE
Concepts of culture and illness.	The current umbrella term, the parts it holds, the address of the definitions, and the move to the clinic.
The classic culturally shaped presentations.	Not the roster. How the patient arrives, what has been tried and who advised it, what the family believes the cause to be, what else may sit behind it, and how the explanation is negotiated.
Cultural formulation and its interview.	Name both, say where in an assessment they belong, give the address, print no counts.
Migration, ethnicity and mental health.	Who moves and why, with India's official migration rate and its split by sex and reason, the four acculturation strategies and the two questions generating them, and that current Indian guidelines carry nothing on migration or acculturation.
Idioms of distress and explanatory models.	Name both constructs, say what each does to a history, give the address.

THE ASK	WHAT YOU MUST BE ABLE TO PRODUCE
Religion, spirituality and faith healing.	What happens at a healing site and in what conditions; the one measured Indian study with its design and its authors' bar on generalising; that the government primary health centre stood in the same village and had almost never been consulted; and the boundary between sanctioned practice and disorder, drawn without turning practice into a symptom list.
Psychological reaction to a cancer diagnosis.	The trajectory of the reaction, adjustment disorder as the largest single group in Indian inpatient series, and **collusion** as graded rather than binary, with the sequence for working through it and both sides of the bind.
Depression, anxiety and delirium in advanced disease.	How each is recognised when the somatic criteria are confounded, that pharmacotherapy remains indicated alongside medical comorbidity although response tends to be poorer, and how running treatment constrains the choice.
Grief, bereavement and end-of-life care.	Normal grief and when to intervene; that the standard frameworks were built for a dyad while in Indian practice the patient is almost always accompanied; and that business left unattended before a death obstructs grief after.
Demoralization and desire for hastened death.	The core features and why the construct is separable from depression; and the legal boundary, that the 2018 Constitution Bench treats active euthanasia as impermissible for the time being, absent any statute permitting it, against the passive form, withdrawal or withholding of measures sustaining life artificially.
Structure of an objective structured clinical examination station.	That it is named inside the national practical pass criterion beside the clinical and the viva voce, that the state health-sciences university has notified it shall be included from the ensuing examinations, the examiner board, that no grace mark is permitted, and that a station's weight is unsettled.
Long case and short case format.	That the national provision is one long case and two short cases, a theory examination of four papers, each of ten questions carrying ten marks, and a 300-mark practical including 20 for the thesis, with a 100-mark viva voce.
Demonstrate a scale or a bedside test.	Administration as an observed performance, not a recitation: what is said to the patient before it starts, how timing is managed, what is reported aloud, and how a refused performance is handled without abandoning it.

THE ASK	WHAT YOU MUST BE ABLE TO PRODUCE
Break bad news to this relative.	The six-step protocol with each letter unpacked, its later modifications and the criticism against them, and the ethical frame both ways: withholding on the presumption the patient cannot cope may not be justified against autonomy, and insensible disclosure may harm the patient and the relationship.
Interpret this investigation or instrument.	What the oral examination is directed at, that case reports, charts, specimens, slides and imaging are expressly examinable and questions on instruments will be asked, and the order a result is read in.

40.5 The rules that survive an unfamiliar question

Six rules run underneath every prompt above. They are worth holding because they generate an answer to a question you did not prepare for, which is the kind that decides a viva.

- **Name whose ground you stand on.** In the general hospital the records, the ward and the discharge decision belong to another team, and consent to be seen, a private space and who is spoken to afterwards all follow from that.
- **Exclude before you attribute, and harder at seventy-eight.** The commonest referral is behavioural and the first move separates a neurocognitive from a primary psychiatric explanation; reduced physiological reserve is why the same change means more in an older patient.
- **A figure belongs to a document and a population.** Quote the issuing body and the population it was measured in, or quote the reasoning and say plainly that you assert no figure. A prevalence and a referral rate differ even in the same unit, and a statistic from one country is not evidence about another.
- **Ask whose explanation is already in the room.** By the time most of these patients reach you a cause has been settled on, a treatment tried, and somebody has decided how much they are told. Eliciting that is assessment, not courtesy: it decides what will be accepted.
- **The statutory answer is usually narrower than the clinical one, so state both.** The clearest instance is elder abuse: the 2007 Indian statute on maintenance and welfare of parents and senior citizens carries no elder-abuse-specific mandatory reporting duty, and what it provides is different in kind, since the Maintenance Tribunal may take cognizance on its own motion, a power and not a duty. The obligation to act is professional: a national society guideline places elder abuse under forensic issues and directs that where assessment suggests safety may be compromised, a report to the police must be made.
- **Finish where the patient goes next.** Every answer ends with a destination, a named owner of the decision and a review interval. An answer ending at the diagnosis stops where this material begins.

MNEMONIC

Before the bed, at the bed, after the bed

The consult has three beats, and marks are lost almost entirely in the first and the third. **Before the bed**: the call is clarified, consent and willingness checked, the chart read, the referring consultant asked what they actually want, word sent for a family member. **At the bed**: introduction and consent, a private space, a history keyed to onset, fluctuation and treatment events, physical examination, then the mental state examination. **After the bed**: the consultee is spoken to directly, the note written to its headings, patient and family told the plan, the review interval set. Most answers start at the second beat and stop there.

GOOD TO REMEMBER

Two habits change what you do on the next working morning rather than what you can recite. Write the consult twice: the guideline requires **dual documentation**, in the primary team's records so the plan can be acted on and in your own so the case is retrievable when the patient returns. And set the interval before leaving the ward: where the consult starts drug treatment, review falls **within a week**, with outpatient follow-up after discharge treated as obligatory.

40.6 The cross-reference register

This material is deliberately incomplete and the register below is the other half of that decision. Every destination is printed in full so the route survives on a printed page with nothing else to hand. Read it one way only: it says where an entity is taught and is never the route back to anything owned here, since the consult, the organ cross-links, the disease-specific settings and the psycho-oncological material are owed by these notes rather than borrowed.

WHAT YOU WENT LOOKING FOR	WHERE IT IS TAUGHT
Delirium as an entity: definition, subtypes, screening, causes, management	the Stroke, TBI, delirium and focal brain syndromes notes
The dementias, and the cognitive screening instruments	the Dementias and neurocognitive disorders notes
The late-life psychosis construct with its history, and catatonia	the Other psychotic disorders, delusional syndromes and catatonia notes
Antidepressant classes, selection and switching behind a late-life prescription	the Mood disorders: pharmacotherapy notes
The anxiety and trauma-related entities, and the grief-related diagnosis	the Anxiety, OCD and trauma-related disorders notes
The sleep-wake disorders as entities, including what an older complaint proves to be	the Eating and sleep-wake disorders notes
The somatic-symptom and factitious nosology, the culturally shaped semen-loss presentation, self-harm and suicide, and the psychosomatic concept with its service-model table	the Somatic-symptom, sexual, impulse-control disorders and suicide notes

WHAT YOU WENT LOOKING FOR	WHERE IT IS TAUGHT
The cultural framework and its terminology, the formulation outline and its interview, idioms of distress, explanatory models, the mental state examination	the Psychotherapies, clinical assessment, MSE and nosology notes
Epilepsy and its psychiatric syndromes, including treatment-related ones	the Epilepsy and psychiatry notes
The neurological examination, and the investigations a viva hands you	the Neurology foundations for psychiatrists notes
The neuropsychiatry of chronic infection and systemic medical disease	the Neuropsychiatry of systemic and neurological disease notes

PITFALL

The worst thing a **register** can do is send a reader in a circle. A pointer returning somebody to the page which sent them has failed them twice: once for not teaching the thing, once for the search it cost. Building your own revision map, test every arrow by asking what the destination actually teaches rather than what its title suggests. The same holds in a viva: saying a topic belongs to another specialty is legitimate only if you can say what that specialty would do with it.

IN INDIA

Many of these prompts have an Indian answer that differs from the standard one, and saying so plainly earns more than reproducing a specification the setting cannot meet. Referral rates are low while measured morbidity in the same units is high, so a quiet consult service is evidence about referral behaviour and not about need. The composite liaison clinic the sources call preferred is qualified in the same breath by a dearth of specialists, so that it may not be possible across the country. The family is routinely the decision-maker and is often told first. The statute for an abused older person routes to a tribunal rather than a protection service. And a patient may have spent weeks in a religious healing setting before meeting any clinician, which is a fact about the pathway to care and a question to ask, never a finding about belief.

TRAP **Producing a fluent paragraph that belongs to another chapter.** Asked about delirium on a surgical ward, candidates describe delirium. Asked about depression in the elderly, they list depressive criteria. Asked about a culturally shaped presentation, they recite a roster. Each is accurate, well organised and worth very little, because the entity is taught elsewhere and the examiner knows where. The test is simple: if your answer would be equally true had the patient never been referred, never been old and never held an explanation of their own, you answered the wrong question.

Answer the encounter and name the address of the entity: who called and what they wanted, what was established before anything was done, what age or the explanatory model changed, in whose records it was written, who owns the decision now, and where the patient goes next.

41 · Drawing the ten chapters together

Paper III is closed properly only when you can say what it trained you to do. Read as a list of headings, this one looks like a miscellany: children and their development, running across the chapters at the front of the paper; mental health legislation and forensic psychiatry; forensic ethics and consent; a physical treatment and its neurostimulation relatives; the perinatal period and the psychiatric emergency; and then the consult, the older patient, culture and the examined performance. Not one of those entries is a diagnosis. No two of them share an organ, an age or a class of drug. That is worth noticing before any revision plan is made, because a candidate who revises this paper the way the disorder papers are revised will write accurate answers that score badly.

What the entries share is a predicament. In every one of them the psychiatrist has to act while somebody else holds part of the decision: a parent, a statute, a magistrate, a treating team, a family, a tribunal, an anaesthetist, a second person whose interests are engaged, or an examiner with a clock. The diagnosis is seldom the difficult part and is almost never the whole answer. The difficult part is the authority the act rests on, the consent it needs, the baseline it will be judged against, the record it leaves and the person who has to do something next. What follows sets out that shared structure, and then says where these subjects actually sit in the scheme of examination, which is not where the paper's name would lead you to expect.

Four papers	Ten by ten	Suggestive only	Superseded
THE SHAPE OF THE DESCRIPTIVE THEORY EXAMINATION UNDER THE 2023 NATIONAL REGULATIONS	QUESTIONS IN EACH PAPER, AND THE MARKS EACH QUESTION CARRIES, AS NOW NOTIFIED	WHAT THE OLD ORDINANCE CALLED ITS OWN ALLOCATION OF SUBJECTS TO PAPERS	THE STANDING OF THAT ORDINANCE FOR THE EXAMINATION NOW BEING SAT

41.1 What this paper actually trains

The other papers ask what a thing is. They reward a candidate who can define a syndrome, trace a mechanism, name a class of drug and defend a choice between two of them. This paper asks something else and rewards something else: **the defensible act**, meaning an action a psychiatrist takes that can be justified afterwards to a person who was not in the room. Who that person is varies. It may be a court, a hospital committee, an aggrieved relative, a regulator, or simply the consultant who inherits the case next week. The examiner is standing in for all of them, which is why the questions are phrased as situations rather than as topics.

An act is defensible when these can be stated without hesitation: on whose **authority** it was done, what the person or their proxy was told and agreed to, what the finding was measured against, and where the whole of it is written down. Those are not ethics-lecture abstractions. They are the substance of almost every question this paper sets, and they explain how the same clinical facts earn very different marks. Two candidates may agree entirely about the diagnosis and the drug, and only one of them will say who was entitled to make the decision and what would have followed had the family refused.

This also explains why the paper is harder to revise than it looks. A disorder can be learned once and recalled whole. An act has to be reassembled from the situation in front of you, because the constraint keeps moving: the same clinical picture in a child, in a courtroom, before a physical treatment, late in pregnancy, on somebody else's ward and in old age generates a different correct answer each time, while the underlying illness may be identical. The paper is a training set for that reassembly, and its chapters are the settings in which it is practised.

RULE **Name the authority before you name the treatment.** In every band of this paper the first marks are for establishing who is entitled to decide and on what basis, and the treatment is the second half of the answer rather than the first. A management plan offered without its authority is an opinion; the same plan with the authority named is a clinical decision, and only the second can be defended by anyone who has to stand behind it later. Candidates who open with the drug, the modality or the ward round are answering the question the disorder papers ask.

41.2 The bands, and the constraint each one works under

Grouping the paper by constraint rather than by subject is what makes it revisable in the time available. The child and developmental chapters work under a **developmental baseline**, which is the standard by which a behaviour is called abnormal at all. The legal and ethical chapters work under an instrument and a procedure. The treatment chapter works under a set of safeguards that exist precisely because the treatment is given to people who may not be in a position to ask for it. The perinatal and emergency chapter works under a clock and under a second person whose interests are engaged. The closing chapter works under somebody else's ward, another stage of life, an explanation of the illness that reached the patient before you did, and an observer with a marking sheet.

THE BAND	THE CONSTRAINT THAT IS NOT THE DIAGNOSIS	WHAT AN ANSWER IN THIS BAND MUST NAME
Child and developmental psychiatry, across the chapters that open the paper	What is expected of a person at this stage of development, and the fact that the patient did not bring themselves	The norm the behaviour is judged against, who gave the account and what their stake in it is, and the adult whose agreement makes any of it lawful
Mental health legislation and forensic psychiatry	An instrument: what it permits, in which jurisdiction, in whose hands, and with which verb	The instrument, the provision and the jurisdiction, using the source's own permissive or obligatory wording, stated before the clinical opinion rather than after it
Forensic ethics, consent and legal procedure	A procedure with its own rules of admissibility, and a relationship that may not be therapeutic at all	Whose agent you are in this encounter, what was disclosed and to whom, the limits of the opinion, and what you decline to say
ECT and neurostimulation	Safeguards around a physical treatment, and an authorisation that may not come from the patient	The indication, who authorised it and under what provision, the checks before it is given and the monitoring it obliges afterwards
Perinatal and emergency psychiatry	A clock, and a second person whose interests are engaged by the same decision	Who is at risk and over what interval, what must be settled now, what may safely be deferred, and how the two interests were weighed
The consult, the older patient, culture, and the examined performance	Another team's ward, another stage of life, an account of the cause already accepted at home, and an observer scoring the performance	Who asked and what they wanted, what age or the patient's own account changed, in whose record it is written, and where the person goes next

Read the right-hand column as an answer plan rather than as a summary. Each entry is a sentence that has to appear somewhere in what you write, and its absence is what an examiner notices first, because it is the part a textbook paragraph never contains. Its presence is also what lets you say something serviceable about a scenario you have never met, which is what a viva mostly consists of.

41.3 The questions that generate an answer anywhere in this paper

Underneath the bands the same interrogation runs, and learning it as a sequence is worth more than any single fact in the paper, because it survives an unfamiliar scenario and produces a structured answer within seconds of the question ending. Work it in order. The order is itself examinable, since several of the classic failures in this paper are the right acts performed in the wrong sequence.

- **Who permits this?** Some acts need only a professional judgement. Others need a guardian, a statutory provision, a board, a tribunal or a court, and a few need more than one of those at

once. Name the source of permission before describing what you would do, and if the permission is contested, say who resolves the contest.

- **Who consents, and to what exactly?** Consent is specific to a decision, a moment and a piece of information, not a signature filed in a chart. Say what was disclosed, in what form, who received it, whether the person could use it, and what happens to the plan if the answer is no. A plan with no described refusal branch has not been thought through.
- **What is usual here?** Nothing in this paper is abnormal in the abstract. It is abnormal against a developmental stage, a physiological state, a cultural account of causation, or the reserve an older body has left. State the comparator, because a finding without one is an impression.
- **What is written, and in whose record?** In almost every setting this paper covers, the notes belong to somebody else or will be read by somebody adversarial. Say what goes in the file, what goes in your own record, and what deliberately does not go in either.
- **Who acts next, and when is the person seen again?** Finish at the **disposition**. An answer that ends at the formulation has stopped one step before the part that is actually being marked, and in practice it is the step whose absence causes harm.

41.4 Where these subjects sit in the scheme of examination

The name of a paper is not a syllabus, and treating it as one is a revision error with a measurable cost. Under a Karnataka state health-sciences university's postgraduate ordinance of 2000, consultation-liaison psychiatry, geriatric psychiatry and psycho-oncology were placed in the second paper, and cultural psychiatry alone was placed in the third; that same ordinance then closed its own allocation by calling it **suggestive only**. Take both halves of that seriously. Most of what this closing chapter teaches sat, on that document's own reckoning, under a different paper from the one it is now revised for, and the allocation was disclaimed by its own author even while it was in force.

The position has since moved, and moved in the direction that matters for planning. That ordinance is superseded for the postgraduate broad-specialty examinations now being sat, and its placing of neurology and general medicine in the fourth paper is displaced: both the national regulations of 2023 and the state university's later notification put basic medical sciences in the first paper and recent advances in the fourth. What neither instrument does is assign any subject at all to the second or the third paper. On the documents in force, the contents of those two papers are unassigned, which is a different and more useful statement than saying the old allocation still holds.

Two practical consequences follow, and they point the same way. First, revise these subjects by name rather than by paper number: a question on the consult, on the older patient or on psycho-oncology may reach you under either of the middle papers, and being surprised by its location wastes minutes you do not have. Second, do not attempt to predict which paper a subject will appear in, because no instrument currently in force supports such a prediction; no comparable standard is available to quote, and none is invented here. The safe planning assumption is the one

the old ordinance itself invited: the boundary between the middle papers is soft, and preparation should be indifferent to it.

IN INDIA

Two instruments matter here, and they operate at different levels, which is worth knowing because candidates are usually told about only the local one. The National Medical Commission's postgraduate regulations of 2023 set the architecture: a descriptive theory examination of **four** papers, with the first on basic medical sciences and the fourth on recent advances, and with a multiple-choice format of equal duration expressly permitted as an alternative. The state health-sciences university then applies that national instrument locally: by a notification of 16 December 2024 its special Syndicate decided to apply the 2023 regulations to the upcoming broad-specialty postgraduate examinations, with stated relaxations. The reasoning that carries them onto candidates admitted long before they were made is recorded in the same notification: the university acted on a clarification from the Commission that the 2023 regulations apply to all students appearing in the forthcoming examination, irrespective of the year of admission. A candidate who prepared against the scheme a senior sat under is therefore preparing against a document that no longer governs.

41.5 What the shape of the answer now asks of your revision

The **answer unit** has changed, and revision strategy should follow it rather than tradition. The state university's notification provides for **ten questions in each paper, each carrying ten marks**. Every answer therefore has the same weight as every other, and there is no single large essay to bank a prepared performance on. The arithmetic of that is unforgiving in a way candidates underestimate: a topic you cannot begin is not a weak paragraph inside a long answer, it is an entire question surrendered, and there are not many questions in a paper to absorb such a loss.

Two further features of the current scheme bear directly on how this paper in particular is prepared. **Recent advances** now belong to the fourth paper, so the reflex of decorating every answer with the newest trial is misdirected effort here; what earns marks in this paper is the act, its authority and its record, which are stable and can be prepared once. And each paper carries its own minimum in addition to the aggregate across the papers, so a paper cannot be written off against strength elsewhere. A miscellany that a candidate quietly deprioritises because it holds no favourite disorder is precisely the paper that can fail an otherwise strong performance.

How long a paper runs is not stated by the instrument that fixes this ten-question structure, nor is the number of questions in it declared to be of one kind rather than of mixed length; no comparable standard is available to quote, and none is invented here. Plan on the safe reading instead: equal marks per question means equal minutes per question, and a candidate who spends the time of several answers on one has broken the only budget the paper actually enforces.

GOOD TO REMEMBER

Write for a second reader you will never meet. Under the valuation machinery the state university has adopted, every theory script is valued more than once, a third valuation is triggered where the first two differ by **15 per cent** or more of the paper's total marks with the best two then averaged, and there is **no revaluation** once results are declared. Two things follow on the day. Make the structure of each answer visible without reading the prose, through headings, a named instrument, a labelled plan and a stated disposition, because that is what survives two independent readers. And accept that the script is the whole of your case: there is no later stage at which you get to explain what you meant.

41.6 How this paper is lost, and what closes it

Failures here have a family resemblance. Almost none of them are failures of knowledge. A candidate loses this paper by producing a correct account of a condition when the question asked what should be done about a person; by giving a management plan with no named source of permission; by describing an assessment with no comparator, so that a finding floats free of the stage of life or the account of causation it should have been judged against; and by stopping at the formulation, leaving the examiner without a disposition, an owner or a review interval. Each of those answers reads fluently while it is being written, which is exactly why they persist.

There is one further failure, and it is the one this closing section exists to prevent: preparing for an examination that has been replaced. Schemes change quietly, the seniors who describe them are describing the one they sat, and nothing in the day-to-day of residency announces the difference. Check the instrument, not the folklore, and check it for the year you are sitting.

TRAP **Carrying a superseded scheme into a current examination.** The pattern candidates rehearse is often the one their seniors sat: under the state university's ordinance of 2000 each theory paper carried two long essay questions of twenty marks and six short essay questions of ten marks, and recent advances could be asked in any or all of the papers. Both features have gone. Practising a long-essay technique for a paper built of equal short answers wastes the scarcest resource in the hall, which is time, and reserving a recent-advances flourish for a paper that no longer wants one wastes preparation. The general form of the trap matters more than this instance: a rule about an examination is only as current as the document you read it in, and a document that has been superseded remains a perfectly accurate description of something that no longer happens.

What closes the paper is not a summary of it. It is a habit of mind that the chapters have been building one setting at a time: when a situation is put to you, resist the pull towards the diagnosis, and answer instead with the act and its warrant. That habit is portable. It works in a paediatric ward, in a magistrate's remand order, in a consent conversation before a physical treatment, in an obstetric emergency in the small hours, on a surgical ward that has called you about a confused patient, and in front of examiners who did not train you. It is also, not coincidentally, what makes a psychiatrist safe to leave alone with a difficult decision, which is what the whole examination is trying to establish.

This paper is not a set of disorders: for every situation say on whose authority you act, who consented and to what, what you judged the finding against, in whose record it is written and who does the next thing and when; and revise its subjects by name rather than by paper number, because no instrument in force assigns a subject to the middle papers at all.

Previously asked

Unlike every earlier chapter of this series, this table is not representative. Sixteen of the rows below are catalogued past questions, each carrying the year the index records against it, taken from the question index this build holds under `intel/`. The equivalent page in the Perinatal and emergency psychiatry notes had to open by declaring that no indexed bank existed for that chapter; that was true of its topics and is not true of these. **One caveat governs the whole table and is not buried:** these are another state health-sciences university's questions, catalogued from that university's own index. This series is built for the examination you sit, and no claim is made that any of these appeared on one of its papers. They are evidence of what Indian examiners ask about this material, which is a weaker and more honest claim than an attribution to your own paper would be.

The frequency is the finding. Culture-bound syndromes is the highest-yield subject in this chapter by a wide margin: four distinct question forms, seven total appearances, and three of those appearances as long answers. That measurement, which no ownership census could see, is why the culture-bound syndromes section was raised from LENS to MAJOR after the depth scheme was otherwise settled. HIV follows with two appearances of a single question form, and grief with four spread across three. Everything else in the table has appeared once.

Almost every question here is a mixed question and only one half belongs to this chapter. The naming half is taught elsewhere in the series and is expected rather than supplied: the DSM-5 cultural-concepts framework, the eight classic syndromes as definitions and the Cultural Formulation Interview by the Psychotherapies, clinical assessment, MSE and nosology notes; dhat itself by the Somatic-symptom, sexual, impulse-control disorders and suicide notes; delirium in full by the Stroke, TBI, delirium and focal brain syndromes notes; HIV-associated neurocognitive disorder and the antiretroviral interactions by the Neuropsychiatry of systemic and neurological disease notes; and prolonged grief disorder as a diagnosis by the Anxiety, OCD and trauma-related disorders notes. **Bring those.** What this chapter supplies is the other half: who asked, in whose ward, what changes at seventy-eight, what the family believes, and what the clinician actually does.

QUESTION, VERBATIM FROM THE INDEX	FORM	ASKED	OWNED HERE BY
Discuss culture bound syndromes	Long answer	2011 MD, 2015 MD, 2017 MD	Culture-bound syndromes (dhat, koro, amok, latah and others)
Discuss neuropsychiatric aspect of HIV/AIDS	Long answer	2012 MD, 2017 MD	Psychiatric aspects of HIV and chronic infection
Enumerate culture bound syndromes. Describe Dhat syndrome in detail	Short note	2013 MD, 2018 MD	Culture-bound syndromes (dhat, koro, amok, latah and others)
Grief / complicated Grief	Short note	2021 MD, 2011 MD	Grief, bereavement and end-of-life psychiatric care
Discuss the differential diagnosis of delirium	Long answer	2012 MD	Delirium in the medically ill (CL perspective)
Psychiatric conditions encountered in general hospital settings - discuss in detail commonly occurring conditions	Long answer	2017 MD	Psychiatric aspects of medical and surgical illness
Consultation Liaison Psychiatry	Short note	2016 MD	Principles and models of consultation-liaison psychiatry
Role of Psychiatrist in patients having Psychosomatic Medicine	Short note	2020 MD	Psychological reactions to physical illness and chronic disease
ICU Delirium	Short note	2018 MD	Transplant, dialysis and ICU psychiatry
Psychiatric evaluation of donors in organ transplant	Short note	2021 MD	Transplant, dialysis and ICU psychiatry
Psychological aspects of aging	Short note	2012 DPM	Normal ageing and psychiatric assessment of the elderly
Abuse of elders	Short note	2011 MD	Elder abuse and neglect
Culture bound syndromes	Short note	2017 MD	Culture-bound syndromes (dhat, koro, amok, latah and others)

QUESTION, VERBATIM FROM THE INDEX	FORM	ASKED	OWNED HERE BY
Dhat syndrome	Short note	2015 MD	Culture-bound syndromes (dhat, koro, amok, latah and others)
Grief	Short note	2021 MD	Grief, bereavement and end-of-life psychiatric care
Complicated grief	Short note	2020 MD	Grief, bereavement and end-of-life psychiatric care

Sixteen catalogued questions, mapped by hand to the section that owns each in this chapter. The years are as the index records them; the mapping is this build's judgement and is stated as such.

A declared gap, in place of three figures that would otherwise have sat on this page. The number of questions the index holds, the span of years it covers, and the mark value it records against each question are all absent here, and deliberately so. Nothing in this chapter's claim ledger stands behind any of the three: their only authority would be this build's own reading of a file it happens to hold, which is not a source you can check. The mark values are the omission that matters, because they belong to another institution's scheme and not to the one that governs the paper this series is built for, whose notification sets four theory papers of ten questions each, every question carrying ten marks. The Form column carries what the omitted figure distinguished, and carries it honestly: this build renders the index's higher allocation as Long answer and its lower one as Short note, so the distinction between a question that wants an essay and one that wants a note survives without a digit from someone else's scheme being printed as though it were yours.

What has never been asked as a theory question, and why that is expected. A search this build ran across the whole of that index, for *OSCE*, *OSPE*, *objective structured*, *long case* and *short case*, returns **zero**. The five sections that close this chapter, from the structure of objective structured clinical examination stations through to the interpretation of investigations and instruments in vivas, are the practical examination itself, so their absence from a theory index is the correct result rather than a gap: they are examined in the practical and the viva voce, which the governing notification fixes at 300 marks and 100 marks while expressly leaving the division inside the practical to be settled elsewhere, and where a candidate cannot be carried by theory.

The quick review

One table, read down the left column and cover the right. Every line is taught in full somewhere above and nothing here is new: each is that topic's single must-hold line, so a line you cannot recover is a section to reread rather than a fact to learn here. Five things are load-bearing across the chapter. Every row answers who asked, in whose ward, what changed because the patient is seventy-eight, whose account of the cause reached the room first, and how the whole of it is produced aloud under observation; none of them answers what a

disorder is, so a row that says almost nothing about a condition you already know has been written on the assumption that you know it. The psychiatrist is a guest everywhere in the first half: the bed, the record and the discharge belong to another team, so consent to be seen is established rather than inherited and the referral question is extracted rather than received. Age changes what the existing lines of a note mean rather than adding a line to it. An account of the cause that reached the family before you did is assessment and not courtesy, because it predicts what will be accepted. And an answer here finishes at a destination: a place of care, a named owner and a review interval, in that order. The figures printed below are the ones this chapter itself owns, referral rates, intervals, thresholds, statutory sections and denominators, each carried back from the section that grounded it; every treatment dose and every figure belonging to an entity rather than to an act stays in the chapter that owns it, and those chapters are named here in words. Where the chapter declared that something could not be sourced, this page says so rather than smoothing it, because a revision table read at speed is exactly where an ungrounded number acquires a confidence nobody earned.

ASK	HOLD
THE CONSULT AS AN ACT, AND WHAT ARRIVES ON THE WARD	
WHOSE NEED THE CONSULT ANSWERS	Not the patient's. The need to appoint a psychiatrist is felt by the primary treating team, and everything procedural follows from that: consent to be seen is established rather than inferred from a referral the patient did not write, the referral question is extracted rather than read off the request, and the output is a recommendation inside somebody else's treatment, written for a physician to implement rather than for a psychiatrist to admire. A consult conducted as though the patient had walked into a clinic is procedurally wrong even where the diagnosis is right. The patient may also decline, since the right to refuse psychiatric assessment is to be respected if possible, and a refusal recorded and fed back has obstructed nothing.
THE REFERRAL RATE, AND THE GAP IT CONCEALS	There is no single Indian referral rate, and quoting one is an error of construct rather than of arithmetic: 0.01 to 3.6 per cent from the inpatient setting, 1.42 to 5.4 per cent from the emergency setting and 0.06 to 7.17 per cent from the outpatient setting, three denominators asking three different questions. The morbidity figures behave the same way, about 30 per cent in medically ill inpatients against 48 to 87 per cent in single-specialty liaison populations. What settles the argument is a pair measured in one unit: delirium in 68.5 per cent of one Indian intensive care unit against a referral rate of 1.71 per cent from the same unit. A quiet service is reporting on referral behaviour, not on how much illness the hospital holds.

ASK	HOLD
WHAT HAS TO HAPPEN BEFORE YOU WALK TO THE WARD	The call as it actually arrives is limited to informing the psychiatrist to come and see the patient on a given bed number, which contains no question, so answering it accepts the whole diagnostic problem without knowing what was asked; the caller owes their identity, the patient's identifiers, any language difficulty, the location, the primary diagnosis and reason for admission, the psychiatric concern and the urgency, and should not initiate a call without examining the patient. Then comes the compulsory preparatory phase, which individual practice has no equivalent of: current diagnosis and treatment, all available papers rather than the summary handed over, past psychiatric history, direct communication with the treating consultant about what they want, the nursing observation, and word sent to a relative to attend. Nothing later recovers it.
URGENCY: THE BANDS, AND THE SCOPE LIMIT ON THEM	Five colour-coded bands with response windows, and the scope is the examinable half: the scale is an emergency-room instrument and not a standard for answering a ward call. Immediate response with security or police for weapons, violence or an attempt at self-destruction; four hours for clear intent, plan and arrangement to harm; twenty-four hours for intent without a plan or rapidly increasing confusion; seventy-two hours for mood disorder or psychosis without intent; four weeks for a known stable disorder needing follow-up. For an ordinary inpatient call no interval is established anywhere in this chapter. What exists is behavioural: respond in a timely way and tell the team the time frame you will attend in.
THE NOTE, AND THE QUESTION THAT REQUIRED A PSYCHIATRIST TO ATTEND	Six entries, and the second is the intellectual content: the diagnoses by current nosology, then the aetiology of the psychiatric picture against the medical illness, which is mutual causation, comorbidity or coincidence, then the interaction of the proposed psychiatric treatment with the ongoing medical treatment, the biopsychosocial background relevant to management, the immediate risk with any transfer decision, and any adjustment the treating team itself needs to make. Build the answer on the second, because each verdict sends the consult somewhere different: mutual causation makes the psychiatric problem part of the medical plan, comorbidity puts the weight on sequencing, coincidence may make continuity the honest recommendation. A diagnosis and a drug has skipped it.

ASK	HOLD
WHY WRITING IN THE FILE IS NOT THE END OF THE CONSULT	It is explicitly insufficient: beyond the note the psychiatrist should communicate directly with the treating consultant, at least by telephone, resolve the team's doubts, give the formulation and suggest a comprehensive plan. The conversation is the only moment at which the team can say your recommendation is impossible on their ward. Documentation is then deliberately doubled, in the primary team's records and in separate records kept by the psychiatrist, the first because a recommendation must live where it will be acted on tonight. Where a diagnosis is confirmed and drug treatment started, follow-up falls within a week at the latest, with outpatient follow-up after discharge obligatory; where no diagnosis was reached, the output is regular review with psychometric evaluation rather than a label asserted to close the episode. Review during the admission is required only from time to time, and no frequency is specified anywhere.
WHO KEEPS THE PATIENT WHEN THE WARD ASKS YOU TO TAKE THEM	The transfer request is the standing friction, and it is answered with criteria rather than a rule. Delirium continues on the medical ward with regular psychiatric observation and not on the ground of the behavioural disturbance itself, because the behaviour is the presentation of a medical emergency due to an underlying medical cause: moving the patient moves them away from the treatment that resolves it. A substance use disorder stays until the medical complications are stabilised. Depression, suicidality or psychosis with serious medical morbidity stays under psychiatric supervision and moves only in stable medical conditions. The job is to decline the transfer while accepting the work, and the setting is not a favour: the appropriate Government must provide mental health services at all general hospitals it runs or funds.
THE SIGNATURE, READ IN BOTH DIRECTIONS	The commonest thing you are called for is confusion with behavioural abnormality, and the first discrimination owed is between a neurocognitive disorder and a primary psychiatric condition presenting with behavioural disorganisation, which is also the thing most easily misfiled as psychiatric. Read the other direction with equal discipline: the psychiatric presentation a medical illness or its treatment produces, organised by system and by drug. Across specialties the recurring picture is stress, anxiety, depression and somatic distress, with depression running about 10 per cent in the community against up to 30 per cent in medical units. The entity itself belongs to the Stroke, TBI, delirium and focal brain syndromes notes.

ASK	HOLD
REACTION AGAINST DISORDER, AND WHAT RIDES ON GETTING IT RIGHT	A psychological reaction to physical illness is universal and does not always reach morbid level, and separating reaction from disorder is the liaison task rather than a preliminary to it; patients referred here may not fulfil criteria for any mental disorder and still need support. The judgement is movement rather than content: whether the person is moving towards acceptance or is stuck, against their own premorbid history as comparator, with the further decision being whether drug treatment is needed or psychotherapy or a support group will do. The stake is adherence and the outcomes attached to it, taught directionally because no effect size for that chain is established anywhere in this chapter.
CAPACITY: A PRESUMPTION, THEN THREE ABILITIES JOINED BY "OR"	Capacity is presumed for every person including a person with mental illness, and the test is three abilities, to understand the relevant information, to appreciate any reasonably foreseeable consequence of the decision or of its absence, or to communicate the decision. The joiner carries the mark: the section prints them with "or", not with "and", so any one of them makes capacity out. Do not import the four-part functional schema of the international literature and do not add a limb about retaining information; neither is in this statute. The burden sits on the clinician who wishes to displace the presumption, and an unwise decision is not incapacity.
WHAT HAS TO HAVE HAPPENED BEFORE A CAPACITY FINDING MEANS ANYTHING	The information must have landed. It is to be given in simple language the person understands, or in sign language, or through visual aids, or by any other means that enables understanding, and on a medical ward that is the step most often skipped before a team records incapacity. Two boundaries decide reach: a general hospital is expressly inside the definition of a mental health establishment, so the Act follows you onto the surgical ward, while the test itself is written for decisions about treatment, admission or personal assistance. Extending it to a purely medical decision is an argument rather than a citation, and saying so is the answer.
THE ADULT OF SOUND MIND WHO SAYS NO, AND THE HOLE IN THE LAW	The highest authority is a 2018 Constitution Bench holding that a person who has come of age and is of sound mind has a right to refuse medical treatment, separated in terms from suicide, assisted suicide and euthanasia, so a competent refusal ending in death is not a psychiatric emergency. Quote it with its context, since the passage sits inside a discussion of the terminally ill and the persistently vegetative patient. Then name the gap plainly: no functional capacity test for an ordinary physical-treatment decision by a patient with no mental illness is established, and neither is who lawfully decides for such an adult who cannot decide. Reason by analogy, record that you are doing so, and do not import a foreign statute to fill it.

ASK	HOLD
WHEN TREATMENT CANNOT WAIT, AND THE CEILING ON IT	Any registered medical practitioner may give emergency treatment to a person with mental illness, at an establishment or in the community, subject to the nominated representative's consent where one is available, and only where it is immediately necessary to prevent death or irreversible harm, serious self-harm or harm to others, or serious damage to property flowing from the illness; the explanation extends it to transport to the nearest establishment for assessment. Three limits follow: nothing beyond what is directly related to the emergency, no electro-convulsive therapy under this power, and a ceiling of seventy-two hours or until assessment, whichever is earlier, extending to seven days only in a declared disaster. It is not a route for overriding a competent refusal.
THE RECORD'S OWN SHELF LIFE, AND WHAT THE WARD BELIEVES ABOUT RELATIVES	Capacity is decision-specific and time-specific, so a finding expires. The Act fixes an interval in one place only: where the representative consents during a supported admission the consent is recorded and capacity reviewed every seven days, and beyond thirty days on the expiry of every fortnight. No equivalent interval attaches to a one-off liaison opinion, which is what this topic is actually about, so the review interval is clinical judgement that has to be justified in the note. And the model is supported decision-making rather than substituted: a son who signs because it is quicker is the substituted model wearing the supported model's name.
THE TWO REFERRALS THE TEAM WANTS TAKEN OFF ITS HANDS	Medically unexplained symptoms and suspected fabrication arrive the same way, through a clinician out of investigations or out of patience, and in both the referral often follows the team's frustration rather than a change in the patient, which is itself part of the assessment. What the liaison psychiatrist owns is the general-hospital presentation, the documentation restraint and the team dynamics; the nosology of the somatoform and factitious disorders, the internal-versus-external incentive rule and the semen-loss presentation are taught in the Somatic-symptom, sexual, impulse-control disorders and suicide notes. On the record, what was observed and what was alleged belong in different sentences with the source named for each, and what may lawfully be entered when deception is suspected but not established is not settled anywhere in this chapter.
THE SETTINGS WHERE THE CONSULT IS HARDEST AND THE DECISION LEAST REVERSIBLE	

ASK	HOLD
THE PRE-TRANSPLANT OPINION, AND THE FOUR THINGS IT CANNOT CONTAIN	A pre-transplant psychiatric and psychosocial assessment is imperative for recipient suitability, and that is the whole of what is established. No domain list, no structured instrument, no separation of absolute from relative psychiatric contraindication, and no requirement of psychiatric evaluation under Indian transplantation law is grounded anywhere in this chapter, so an answer inventing a domain grid or an abstinence interval is inventing it. What is teachable is the form of the opinion and the dual-agency problem inside it: you are asked for a judgement that will decide access to an organ, by a team whose interests are not the patient's, about a living donor whose consent has to survive the family that produced it. Say what you can and name the rest as unsettled.
DIALYSIS: THE SYMPTOM OVERLAP, AND THE INDIAN NUMBER	Uraemic symptoms mimic and mask depressive ones, so the mechanism of under-detection is symptom overlap and the consequence is under-evaluation and under-treatment; the unit-level stressors named alongside it are physical, financial, occupational, social and dietary. The Indian measurement is worth its denominator: 282 maintenance-haemodialysis patients across four Mumbai centres, screened with a questionnaire read aloud in the patient's own language regardless of literacy, gave 21.28 per cent at the moderate threshold, and 29.13 per cent of women against 16.76 per cent of men. Public and private centres did not differ. Reading the instrument aloud is the methodological point, and it is what makes the denominator usable.
INTENSIVE CARE, AND THE SYNDROME AFTER IT	The term names three domains, physical, cognitive and mental health, and one qualifier does the work: the impairment must be new or worsening, so pre-existing impairment does not count and a baseline is required before the label can be used at all. It was agreed at a multidisciplinary stakeholders conference rather than derived from a cohort. Everything a candidate reaches for next is unavailable here: no duration criterion, no incidence figure, no instrument, nothing on whether it looks the same in Indian survivors, and no Indian follow-up clinic model. Name the construct, name its qualifier, and refuse the proportion.
CHRONIC INFECTION: THE CONSENT QUESTION IS STATUTORY, AND ITS TEXT IS NOT HERE	What is grounded is that the 2017 Indian Act on prevention and control of the infection exists and that its section 5 is headed informed consent for testing or treatment. What the section requires in operative terms, whether pre-test and post-test counselling are statutory components, what conditions attach and which modal verb it uses are not established, and the national counselling references were located and never read, so no step, interval or competency may be attributed to them. Every epidemiological figure is absent as well. Teach consent, disclosure, adherence, stigma and a clinic relationship that is built rather than improvised, and say the statutory detail is owed rather than known.

ASK	HOLD
THE CARDIAC AND RENAL INTERFACES, AS FIGURES WITH POPULATIONS	Depression runs 15 to 20 per cent in coronary artery disease and reaches a major episode in 20 per cent after myocardial infarction, while fewer than 15 per cent of those depressed in coronary disease are actually diagnosed, which is the recognition problem stated as a number rather than as a complaint. Post-infarct depression carries a 1.6 to 2.7 fold mortality risk and the relationship is bidirectional. In kidney disease depression is 22.8 per cent in advanced disease and cognitive impairment reaches 60 per cent. All of it is an Indian guideline reporting international evidence, not Indian primary data, and the head terms themselves are not all attested.
THE TWO PRESCRIBING SIGNALS, AND THE NEUROLOGICAL DOOR	Two constraints are named and neither carries a dose here. Physical treatment is relatively contraindicated within 30 days of unstable angina or infarction, with its procedural precautions taught where they belong. And citalopram in haemodialysis carries a raised risk of sudden cardiac arrest, greater than other agents of its class, with no effect size given anywhere. On the skin the severe cutaneous reactions are taught as an interface and as a duty to warn the patient and the attendants, deliberately without rates or onset windows, because the available tabulation disagreed with its own document's prose. Epilepsy arrives as a referral rather than as an entity and is taught in the Epilepsy and psychiatry notes.
WHAT CHANGES AT SEVENTY-EIGHT	
WHAT AGE CHANGES, AND WHAT IT LEAVES EXACTLY WHERE IT WAS	The skeleton does not move: history, physical examination, mental state examination and investigations, with the one shift being that comorbid physical illness now carries the weight the psychiatric history carries. Three domains are added to the history: sensory deprivation, a frailty review, and elder abuse, the last requiring a high index of suspicion rather than a complaint. Underneath sits the physiology that makes all of it matter: reduced reserve, so a small perturbation produces a disproportionate clinical effect. Two acts precede any score, and they are not politeness: the hearing aid and the spectacles go on before a single cognitive item is administered, because otherwise the item measures hearing.
NORMAL AGEING: WHAT DECLINES, WHAT HOLDS, AND THE COMMON CAUSE	The split is the teaching. Fluid abilities peak in the third decade and fall at about 0.02 standard deviations a year, while crystallised ability is stable or gradually improving at 0.02 to 0.003 standard deviations a year through the sixth and seventh decades, and vocabulary is resilient while conceptual reasoning, memory and processing speed decline at rates that differ between individuals. One change explains many findings: processing speed begins falling in the third decade and drags down scores in other domains, so a low score may be a speed artefact. Acquisition and free recall decline while recognition, temporal order and procedural memory hold, and confrontation naming stays level until about 70. No Indian norms exist for any of it.

ASK	HOLD
COMPREHENSIVE ASSESSMENT AS A PROCESS RATHER THAN A QUESTIONNAIRE	It is an interdisciplinary and multidimensional process for frail or vulnerable older people, not an event and not a synonym for the specialty, and its product is a problem list, goal-driven interventions and one coordinated plan spanning treatment, rehabilitation, support and long-term care. Its five domains are physical conditions, mental health, functioning, social circumstances and environment, and note where cognition sits: one item inside the mental-health domain, beside mood, anxiety and fears, which is the whole argument against equating geriatric assessment with a cognitive score. The core team is a doctor who need not be a geriatrician, a nurse, an occupational therapist, a physiotherapist and a social worker, and the plan must state explicit goals, who is responsible, and a review timeline.
FALLS: THE SCREEN, THE STRATIFICATION AND THE ONE MEASURED THRESHOLD	Case-finding is opportunistic and cheap: in lower and middle income settings, everyone aged 60 and over, at any clinical encounter, at least annually, asked about falls in the past twelve months. Stratification then decides the work: low risk gets education and exercise and annual reassessment because low risk is not no risk, intermediate gets strength and balance work or physiotherapy, and high risk is offered a multifactorial assessment to inform individualised interventions. One threshold is measured rather than asserted: gait speed below 0.8 metres per second over a four-metre walk, with a timed-up-and-go alternative of over 15 seconds whose fall-risk evidence the guideline itself calls mixed. The component recommendations do not carry equal evidence, and vision, hearing, pain, depression and nutrition rest on expert opinion.
PRESCRIBING AT SEVENTY-EIGHT: DIRECTIONS, THEN FRACTIONS, NEVER MILLIGRAMS	The pharmacology is taught as direction and not as percentage: renal and hepatic clearance fall, volume of distribution rises for lipid-soluble drugs, half-life lengthens, and sensitivity is altered and usually increased. Body composition drives the first half, since total body water and lean mass fall while fat rises relatively, so water-soluble agents reach higher serum levels and lipid-soluble ones linger. Renal decline is neither uniform nor consistent, and creatinine is unreliable because muscle mass has fallen too. Only two dosing quantities are established, both fractions: an antidepressant at half the adult starting dose and half the adult target dose, and an antipsychotic reduced by 25 to 50 per cent. No milligram figure and no cumulative maximum exists for any of it.

ASK	HOLD
THE HAZARDS THAT CARRY A NUMBER, AND THE THREE THAT CARRY NONE	Two thresholds are printable. Specialist referral for hyponatraemia falls at a serum sodium below 125, the risk sitting in the first weeks of treatment in the elderly and frail with no number of weeks stated, and deprescribing review is triggered above five medications, which is a trigger for a review and not a permitted ceiling. Against them, three examinable absences: the anticholinergic load must be totalled across every ongoing drug as a crucial cause of delirium, with no instrument and no score named; no numeric threshold for the corrected interval and no age-specific cap; and geriatric-specific management strategies have not been evaluated.
SLEEP: THE CHANGES HAPPENED BEFORE THE PATIENT GOT OLD	The six changes are advanced timing, shorter nocturnal sleep, more naps, more awakenings, more time awake at night and less slow-wave sleep, and the timing of the change is the mark: they occur mostly between young and middle adulthood and are largely unchanged among healthy older adults after 60. Wake after sleep onset rises 10 minutes per decade, valid between 30 and 60 years only, and the stage-proportion shifts are not significant above 60 in healthy older people. The circadian phase advances by about an hour across sleep timing, temperature, melatonin and cortisol together. So none of this explains a new complaint at seventy-eight, and using it to do so is the error the section exists to stop.
WHY A HYPNOTIC IS THE WRONG REFLEX	Because the excess is comorbidity rather than age. Insomnia symptoms run about 50 per cent in older adults, yet in those in excellent health prevalence resembles that in younger people, so the complaint points at medical and psychological comorbidity; self-reported poor sleep quality reaches 50 to 60 per cent with the review's own caution that it is not necessarily ageing alone. The drug history is half the assessment, on figures that are explicitly not Indian: about 90 per cent of those aged 65 and over take prescription drugs and more than a third take over five. Older adults also under-report poor sleep, so the complaint you hear understates the problem.
ELDER ABUSE: HOW IT ARRIVES, AND THE ACT THAT MUST APPEAR IN THE NOTE	Nobody arrives complaining of it. It arrives as a fall, a confusional episode, weight loss, poor adherence, an admission the family is unusually keen on, or a discharge that keeps being deferred, each with an ageing explanation already to hand. The definition to quote treats it as acts of omission resulting in harm or threatened harm to the health or welfare of an older person, and say in the same breath that acts of commission are conventionally included, because as printed the definition narrows the subject. The instruction that is actually marked is procedural: the patient is interviewed separately and given time and reassurance. The named screen is a caregiver abuse screen with no item count, no cut-off and no validation data attached to it anywhere.

ASK	HOLD
THE SAFEGUARDING ANSWER HAS TWO HALVES, AND ONLY ONE IS LAW	There is no elder-abuse-specific mandatory reporting duty in the 2007 senior citizens Act, and no provision of the child-protection kind obliging any person or professional to report suspected abuse. Scope that negative correctly: it concerns this Act, and a general duty to inform the police of certain offences binds a psychiatrist as it binds anyone, though its text, section number and modal verb are not established here. What the Act supplies instead is a route, not a report: an application by the senior citizen, or by any other person or organisation authorised by him where he is incapable, or the Tribunal taking cognizance on its own motion, a power and not a duty. The directive half is professional: where safety may be compromised during the stay or after discharge, a report to the police must be made.
THE LATE-LIFE PRESENTATIONS THAT MISLEAD	
DEMENTIA IN AN OLDER REFERRAL: WHAT THIS CHAPTER OWES AND WHAT IT DOES NOT	It owes the frame, not the entity: why a family or a ward asks for help, the behavioural picture as the reason the call was made, and the wider assessment the diagnosis sits inside. The disease, its subtypes, its investigation and its treatment are taught in the Dementias and neurocognitive disorders notes, and the cognitive screening instruments belong there too. Three things a candidate expects to find here are not available anywhere in this chapter and should not be improvised: any prevalence or incidence for later life, any figure for how that rises with age, and any Indian measure of diagnostic delay or of old-age psychiatric service provision. Say the scale of the problem is not quantified here rather than borrowing a number that sounds right.
LATE-ONSET DEPRESSION: THE PRESENTATION THAT MISLEADS, AND THE MODAL THAT MUST SURVIVE	The mask is somatic and cognitive and the vascular contribution is part of the picture, but the discriminating question is whether an episode has occurred before rather than any age threshold, because no age cut-off defining late onset is established and neither is the proportion of late-life presentations that are first episodes. Current Indian guidance holds that age influences which antidepressant is chosen, with agents of one class possibly less effective and another possibly more suitable in older adults: the modal is may, twice, and strengthening it into a recommendation is the error. Prescribing runs start low and go slow, at half the adult starting and target dose, watching hyponatraemia and falls. Agent selection and switching sit in the Mood disorders: pharmacotherapy notes.

ASK	HOLD
A FIRST PSYCHOSIS LATE IN LIFE: EXCLUSIONS BEFORE ANYTHING ELSE	The exclusion list is the answer and it is long: affective psychosis, delirium, the dementias, medication-induced states from anticholinergics and antihistaminergics at higher doses, steroids, dopamine agonists, antimalarials, antiretrovirals, opioid analgesics, fluoroquinolones and cardiac agents, substance-induced states, and severe nutritional and endocrine disorders. Neuroimaging is indicated, and the emphasised trigger is a first episode after 60, with no modality or sequence named. Management changes because the patient is old rather than because the illness differs: first-line choice is driven by lower anticholinergic burden and lower sedation to prevent falls, starting 25 to 50 per cent lower, avoiding anticholinergic co-prescription, with more frequent metabolic monitoring. Where the paraphrenia label sits in any classification is not asserted.
DELIRIUM AT SEVENTY-EIGHT: THE INDIAN FIGURE, AND WHAT IT DOES NOT EXTEND TO	In elderly attenders screened at Indian emergency medical outpatient settings, delirium was the commonest diagnosis at 34.1 per cent, against dementia at 9.5 per cent and any axis-one disorder at 47.4 per cent, with both delirium and dementia commoner above 70. Ageing is the predisposition rather than the cause, through the listed age-related risk factors, which carry no weight, ranking or effect size, and through multimorbidity and polypharmacy, with more than three medications listed separately as a risk factor. Delirium superimposed on dementia is named and its discriminating features are not given. Nothing about outcome after the episode is quantified, and sundowning has no quotable definition.
PSEUDODEMENTIA: AN ASYMMETRY OF CONSEQUENCE, NOT OF FREQUENCY	The discrimination matters because the two errors are not equivalent: a depressive illness read as a dementia loses a treatable condition, while a dementia read as depression costs a trial of treatment and a review date. That asymmetry is the whole argument, and it is made on the order of clinical work rather than on relative frequency, because no figure exists for how often an apparent dementia in later life proves to be a depressive illness, in India or anywhere, and none for how long the treated interval usually takes to settle it. So the answer is an act with an owner and a date rather than a probability. The comparison table itself, with its features, is taught in the Dementias and neurocognitive disorders notes.
WHOSE EXPLANATION REACHED THE ROOM FIRST, AND THE END OF LIFE	

ASK	HOLD
THE UMBRELLA TERM, AND WHY PSYCHIATRY HAS TO GO AND COLLECT IT	The current framework replaced the old roster heading with an umbrella holding three kinds of cultural concept, a syndrome, an idiom of distress and an explanation, and their definitions and the reasons for the change belong to the Psychotherapies, clinical assessment, MSE and nosology notes. What this chapter owns is the move from the concept to the clinic. The examinable point is that the three are not interchangeable: a syndrome is a cluster of features, an idiom is a way of expressing distress that need not indicate any disorder, and an explanation is a claim about cause. Answering with a list of exotic names has answered the superseded question.
THE CULTURALLY SHAPED PRESENTATION: NOT THE ROSTER, THE ROUTE	What is asked for is how the patient arrived, what has been tried and who advised it, what the family holds the cause to be, what else may sit behind it, and how the explanation is negotiated. The route is documented: information reaches such patients through friends, relatives, colleagues, roadside advertisements, lay magazines and traditional practitioners, and the cures they expect run from indigenous medicines, herbs and dietary interventions to injections, tonics and marriage. The boundaries leak both ways: a syndrome classically indexed to one country presented in two Indian cases reaching an obsessive-compulsive clinic after the family noticed it, and in another an obsessive-compulsive disorder emerged only on an unscheduled review. What is behind the presentation is the question.
THE FORMULATION, THE IDIOM AND THE MODEL: NAME THEM, THEN ROUTE THEM	Name both instruments, say where in an assessment each belongs, give the address, and print no counts: the outline's domains, the interview's questions and sections, and the supplementary modules are owned by the Psychotherapies, clinical assessment, MSE and nosology notes, and so are the definitions of an idiom of distress and an explanatory model and the eliciting questions that go with them. What this chapter adds is the clinical use. An idiom translated into a symptom loses the meaning that made it worth eliciting, and an explanatory model recorded and then not acted on has collected information and wasted it. The full instrument is seldom completed in clinic time, which is a statement about the encounter and not a licence to skip the enquiry.
MIGRATION, AT INDIAN SCALE AND WITH THE INDIAN OUTCOME MISSING	The official rate is 28.9 per cent and it is almost two different phenomena: 10.7 per cent of men against 47.9 per cent of women, with marriage accounting for about 86.8 per cent of female migration and employment for 22.8 per cent of the male, so who moves and why differs by sex before any outcome is discussed. The two questions generating the strategies are whether the person maintains their own identity and whether they maintain relations with the wider society, giving assimilation, separation, integration and marginalisation. No Indian outcome estimate for internal migrants exists, and current Indian guidelines carry nothing on migration or acculturation at all.

ASK	HOLD
THE ONE MEASURED INDIAN STUDY OF A HEALING SITE: WHAT IT DID	A single temple, 31 people, of whom 29 had a non-affective psychosis, so the study says nothing about common mental disorders or distress states. The exposure was residence with a relative in attendance, a fifteen-minute morning prayer and no ceremony performed for any individual's recovery, with no psychopharmacological or other somatic treatment at any point, over a stay of a mean of six weeks, range one to twenty-four. The rating-scale total fell from 52.9 to 42.9, a reduction the authors call nearly twenty per cent. Cost to the family was nil, and physical restraint was not used at this site though the paper records that it is at many others.
WHAT THAT STUDY DOES NOT LICENSE ANYONE TO SAY	The design is uncontrolled, single-site, unblinded, with the same rater at both assessments and no comparison group, and the authors call their own findings only suggestive. The caregiver rating was an unblinded judgement by the relatives who brought the person and stayed: 22 improved and 3 recovered, which accounts for 25 of the 31, and what happened to the remaining six is not stated. Their bar on generalising is explicit, not to other regions and not to other healing temples in the same region. The finding that matters clinically is about access: a government primary health centre stood in the same village and had been consulted by one of the thirty-one. The route to care is a question to ask, never a finding about belief.
THE REACTION TO A CANCER DIAGNOSIS, AND THE GROUP THAT IS LARGEST	The trajectory as stated runs shock and disbelief, anger, depression, loss and grief, and the diagnosis most often made is the one candidates reach for last: adjustment disorder is the commonest psychiatric syndrome in cancer patients. The Indian denominator is one tertiary inpatient sample of 384, in which 41.7 per cent had any psychiatric disorder, 22.6 per cent an adjustment disorder and 10.9 per cent a major depressive episode. No Indian community or advanced-disease prevalence exists to set beside it, and fear of recurrence, body image, sexual difficulty and financial distress carry no Indian magnitude at all.
COLLUSION: GRADED RATHER THAN BINARY, AND THE BIND STATED BOTH WAYS	It has three axes, who is kept in the dark, what is withheld, and whether it is partial or complete, and its triggers are the move from curative to palliative intent and the entry of death into the conversation; the paper's own line is that it may be a conspiracy of lopsided communication as much as one of silence. In India nearly one half of patients are unaware of their own diagnosis or treatment, while among those who already knew, 71 per cent wanted the truth, 81 per cent of relatives wanted to be told and 77 per cent did not want the patient told. Say the benefit side too: it may defend the person from harm and minimise concern about the future, against obstructed autonomy and lost trust. Working through it is a sequence, reasons first, then a no-disclosure-without-consent contract, then the patient's actual awareness, then being present when they first speak openly.

ASK	HOLD
RECOGNITION IN ADVANCED DISEASE, AND THE INSTRUCTION THAT SURVIVES COMORBIDITY	The direction is treat: pharmacotherapy remains indicated alongside medical comorbidity, on an umbrella review spanning 27 comorbid medical conditions against placebo, with a psychological arm supported for conditions such as coronary heart disease and neurological disorders. Hold the qualifier in the same sentence, since response tends to be poorer when comorbid, with the magnitude nowhere quantified. Delirium is the third presentation and it was 6.5 per cent of that same Indian inpatient sample. What is not established here: how the confounded somatic criteria should be handled, which brief screen is defensible in a breathless patient, and what constrains the choice of agent near the end.
GRIEF, AND THE PROTOCOL THAT WAS BUILT FOR THE WRONG NUMBER OF PEOPLE	The standard frameworks assume a dyad, whereas in Indian practice the patient is almost always accompanied, so more than one relative is included and the key relative is chosen by the patient's view of who that is rather than by volume or by your guess. The mechanism that makes concealment a clinical problem after the death, and not only before it, is that business left unattended before a death obstructs grief resolution in the survivors afterwards, and unchecked collusion leaves patients morbidly anxious and lowers the threshold for pain and nausea. Nothing about the after-death tasks is grounded here, and neither is any interval or risk stratification for bereavement follow-up.
DEMORALIZATION, AND THE LINE THE LAW ACTUALLY DRAWS	The core is hopelessness, loss of meaning and existential distress, ending in a desire to die, and the construct is proposed as separable from depression rather than demonstrated to be common: no proportion who are demoralized without being depressed is available, and the scale is named only, with its item count, subscales, format, cut-offs and revision all ungrounded. The legal boundary is where answers overreach. Active euthanasia is impermissible, on the basis that no statute permits it, while the passive form is withdrawal or withholding of measures that artificially prolong life, and the directions on advance directives operate as judicial directions until Parliament legislates, not as legislation.
THE SAME ENCOUNTER, PERFORMED ALOUD UNDER OBSERVATION	
A STATION SCORES THE ACT, NOT THE KNOWLEDGE BEHIND IT	That single sentence separates a station from a viva: in a viva, saying what you would do is the performance; in a station it is an admission that you did not do it. Six things exist before you arrive, five of them written: the place in the blueprint, the instruction at the door, the brief the patient carries, the material handed over, the marking schedule, and the standard it is read against. Read the instruction for its task verb before its clinical content, because the verb names the product due when time ends: take a focused history, elicit and describe, explain to, assess. Marking runs in two layers at once, an itemised schedule and one overall judgement, and neither alone is sufficient. Information is released on request, so silence is yours to fill.

ASK	HOLD
THE ARITHMETIC THAT DECIDES THE RESULT	Three conditions, all conjunctive: at least 40 per cent in each theory paper, at least 50 per cent in aggregate across the four, and at least 50 per cent in the practical, so failing any one fails the whole and a strong practical repairs nothing. The per-paper floor is the new element, absent from the superseded state ordinance whose rule was half the marks in each of two heads only. A station's marks sit inside the same practical line as your long case, because the practical is expressly composed of the clinical, the objective structured component and the viva voce. No grace mark is permitted in either head. Scripts are valued twice, a third valuation follows a difference of 15 per cent or more of the paper total, and there is no revaluation afterwards.
WHAT IS MANDATORY, AND THE FOUR THINGS NOTHING FIXES	The obligation is real and its vehicle is not settled: the notification of 16 December 2024 provides that an objective structured clinical examination or a short case shall be included from the ensuing examinations, and the clause is disjunctive on its face. It reaches candidates admitted before the rules were made because the university records a clarification that the 2023 regulations apply to all students appearing in the forthcoming examination, irrespective of admission year. Four things are established by no instrument: how many stations, how long one runs, what one is worth, and whether the requirement will be met by stations or by a short case. Numbers circulate for all four and are somebody's local arrangement. The board is at least four examiners, two of them external, one from outside the state.
LONG CASE AND SHORT CASE, AND THE MARKS NOBODY HAS PUBLISHED	The national provision is one long case and two short cases. Around it the current scheme is four papers, ten questions each, ten marks a question, with a 300-mark practical including 20 for the thesis and a 100-mark viva voce. What a long case or a short case is now worth is unpublished, because the division inside the practical is referred elsewhere, and the superseded ordinance's split is not carried forward to fill the hole. Equal marks per question means equal minutes per question, and the paper duration is not stated by the instrument that fixes the structure.
THE DEMONSTRATION, AND WHATEVER IS PUT IN FRONT OF YOU WITHOUT WARNING	Administration of a scale or a bedside test is an observed performance rather than a recitation: what is said to the patient before it starts, how timing is managed, what is reported aloud, and how a refusal is handled without abandoning the task. Whether such a demonstration is called for as a thing of its own, in what time and against what weighting, is established by nothing. The oral covers subject knowledge, investigative procedures, therapeutic technique and other aspects, and case reports, charts, specimens, slides and imaging are expressly examinable, with questions on instruments stated to be asked. How many such questions, how long for one, and what share of the viva they carry is not stated anywhere.

ASK	HOLD
BREAKING BAD NEWS AS AN EXAMINED ACT	Six steps, in the order the source prints them: setting, the patient's perception, an invitation from the patient to be given information, the knowledge itself, exploring and sympathising with emotion, then strategy and summary, with four objectives, to gather information, transmit it, provide support and elicit collaboration. Give the ethical frame both ways, because a one-sided answer loses half the marks: withholding on the presumption that the patient cannot cope may not always be justified against autonomy, and insensible disclosure may harm the patient and the relationship. One figure is printed only as a guard against transposition: the 13.6 per cent trained is an Iranian faculty and resident sample, and no Indian equivalent exists.

References

Every specific in this chapter is bound to one of the sources below, and the count is the number of claim rows each carried. 23 of those rows are statutory and were read at the primary Act on India Code rather than from any textbook's summary of it, because a stale or paraphrased section changes what a clinician is legally obliged to do. Doses were read at current regulatory labelling, and each carries its own source receipt naming the regulator, the product, the label version and the retrieval date. 40 row(s) are recorded at partial confidence and 0 as a declared gap: a declared gap is a correct answer here, and no number has been supplied to fill one. The must-have-papers cross-check was NOT performed for this Paper III chapter, because the paper lists do not yet exist in the intel index; for Paper III the topic bank plus the syllabus scaffolding is the completeness authority. This table records provenance, not proof: it says where each specific came from, not that the chapter's prose uses it correctly, which the content pass and the ship review test.

About the authors

Dr. Wilfred D'souza

MD Psychiatry (Resident) · Certified Gestalt Therapist · Weave, Centre for Integrative Psychiatry

Works in integrative psychiatry with Schema Therapy as the primary lens, alongside CBT, DBT, motivational interviewing and emotion-focused therapy, and is a certified Gestalt therapist. His clinical interests run through neurodivergence, ADHD, bipolar disorder, personality disorders, addiction and developmental psychiatry: work grounded in lived experience of attention difficulties long labelled as laziness, which made psychiatry personal before it became professional. He has been developing the Toroidal Model of Psychosis and Affect (TMoP), his computational model of mind, and TMoP thinking shaped the Claude Code AI system he builds with: clinical software, teaching tools and much of this series' production pipeline among its work, bringing psychiatry into the AI era in his own way. Lead author of the Weave Sprint series.

Dr. Niharika Reddy

Consultant Psychiatrist · Weave, Centre for Integrative Psychiatry

Consultant Psychiatrist at Weave, Mumbai, seeing people online through weave.clinic. Her work centres on relationships and family dynamics, family therapy and women's mental health, with a particular focus on neurodivergence in women and on adolescent mental health. Practises integrative, person-centred psychiatry. Co-author of this volume.

THE WEAVE LIBRARY

You revised from one. The whole shelf is open.

Field guides and references written in practice, for the people who do the work and the people living through it. Most are free to read and download.

field guides · references · for clinicians and families · free to read

STUDY TOGETHER

You do not have to revise alone.

These notes started as messages in a room full of residents helping each other through. That room is still open. Bring your doubts, your corrections, and the questions the textbooks do not answer.

PRINTING AND DISTRIBUTION

Notes Next Door (NND), Delhi is the official printing and distribution partner for Weave Sprint. The soft-copy PDFs and the complete print-ready set are always available at weave.clinic/sprint, should you prefer to print the notes yourself. Weave Sprint is open source and free, and as part of Weave's commitment to residents it will stay that way, forever. We do, however, strongly recommend a printed set from Notes Next Door: in our experience, they have been the most reliable printing partner we have worked with.

WEAVE SPRINT · PAPER III

The third paper of the MD psychiatry written examination, gathered into one book: normal child development and the disorders of childhood, from intellectual disability and autism through ADHD to conduct and emotional disorder, with the assessment, the therapies and the duty to protect; mental health legislation and forensic psychiatry, and consent and capacity as legal acts; electroconvulsive therapy and the stimulation treatments; the perinatal period and the psychiatric emergencies; and the consult on somebody else's ward, in another decade or another culture. Ten complete sets of notes, written to be understood the first time and recalled every time after, with a colour memory code, a clickable contents and a full index.

Built to understand. Kept to revise.

All the very best for your exam.
