THE WEAVE SPRINT SERIES

TITLE

Weave Sprint, Paper III: Speciality Psychiatry

Part of the Weave Sprint series, MD and DNB psychiatry theory revision.

WRITTEN BY

Dr. Wilfred D'souza and Dr. Niharika Reddy

PUBLISHED BY

Weave, Centre for Integrative Psychiatry · weave.clinic

EDITION

First compiled 2026. Free to read, share and print for study.

The clinical content is written for doctors and doctors in training. It is a study and revision aid, not a substitute for current guidelines or clinical judgement. Verify doses and thresholds against the current references and your local protocols before any clinical use.

For every resident who has ever sat up the night before,
afraid it will not be enough.

ACKNOWLEDGEMENT

A word of thanks

I want to begin by thanking something I cannot quite name. Call it whatever you like. I have never been certain what to call it, and I have stopped needing to be. There is a part of this work that does not feel like mine. The line that arrives before I have thought of it, the connection I did not plan, the steadiness on a morning I had no reason to be steady. I only hold the pen. Something moves through the holding, and I have learned to thank it without asking it for a name.

Someone once asked me why I give all of this away. Why hand out the notes I sat up making, to the very people sitting the same exam beside me. It is a fair question. If I had kept them, I would probably have scored a few marks more than the next person, and I might have been thought of as the better student. I have turned that over honestly, and I have decided it is a small thing to want. What I get instead, by putting the work in your hands, is the chance to take a little of the fear out of a great many nights. That trade is not close. Easing that fear is not a detour on the way to becoming a good psychiatrist. It is the thing itself. I did not come here to be the best student in the room. I came here to be a good psychiatrist.

And to Niharika, who reads everything first and knows when to be honest and when to wait; and to the residents who study from these pages and write back with the corrections and the questions: thank you. The book is better for you, and so am I.

Dr. Wilfred D'souza

Foreword

This is the third paper of the written examination, gathered into one book. Where the first paper laid the ground the discipline stands on and the second was the discipline at work on the disorders themselves, this one is psychiatry practised at its edges: the child who is still becoming, the patient the law has an interest in, the treatments given under anaesthesia, the mother and the emergency, and the patient who belongs to another ward, another decade or another explanation of what is wrong. These are the settings where general psychiatry stops being general.

The notes were written to be understood, not just revised. Each chapter is a full account of its subject, from the mechanism up to the point the exam tests, so that you can read to learn the first time and read to recall every time after. Where a fact is worth holding exactly, it is marked. Where a mistake is easy to make, it is named before you make it. The colour code on the next pages tells your eye what kind of fact it is looking at before your mind has to decide, and after a few pages it stops being a key you consult and becomes a sense you carry.

Read it in order if you are meeting the material, or open it anywhere if you are returning to it. The contents at the front and the index at the back both jump to the page you want. However you use it, the hope held in these pages is plain: that one ordered, trustworthy place to study from makes the work a little lighter, and that you walk into the hall steadier than you would have otherwise.

HOW TO USE THIS BOOK

The colour memory code

Every note in this volume speaks one visual language, so once you learn it in the first chapter you read the rest without thinking about it.

Concept and rule	The core idea and the principle that follows from it. When a line is petrol, it is the thing to understand, and the thing worth being able to state.
Key number	A figure to hold exactly: a dose, a threshold, a prevalence, a cut-off. Amber means memorise this number, not just the shape of it.
Trap	The mistake the exam is waiting for. When a line is coral, it is warning you off an error that looks right until it costs you the mark.

Hold this is the single line from a topic you must carry out of it. **Good to remember** gathers, for each named thing, what it is, when it matters, and the one number or formula worth keeping. Both help a tired brain find the centre of a dense page fast.

The contents at the front is clickable, and so is the index at the back: every entry jumps to its page. Read to learn once, and to recall as often as you need.

PAPER III

Normal child development & milestones

Three bands . one complete notes document

The developmental frameworks

1 . Piaget stages of cognitive development

Jean Piaget described cognitive development as an active construction of knowledge, not the passive accumulation of facts. The child acts on the world, builds organised patterns of understanding, finds that some patterns no longer explain experience, and modifies them. The theory therefore asks a more useful question than "What does the child know?": *what form of reasoning is available to the child, and what kind of problem can that reasoning solve?* Piaget proposed an invariant sequence of four broad organisations of thought: sensorimotor, preoperational, concrete operational and formal operational. The sequence is the examinable backbone. The age bands attached to it are textbook descriptors with source variation, not developmental screening cut-offs and never referral thresholds.

How to use this page. First learn the direction of change: action becomes mental representation; representation becomes logical but remains tied to concrete situations; logic then extends to possibilities, propositions and hypotheses. Next learn the characteristic achievement and characteristic error of each stage. Finally, separate three questions that are often collapsed in examinations and clinics: Piagetian stage theory describes the *organisation of cognition*; milestones describe observable developmental attainments across several domains; developmental surveillance and screening decide whether a child's course needs closer evaluation. A child does not "fail Piaget" because one conservation task is failed, and a Piagetian task is not a developmental screening instrument.

Must memorise: sensorimotor action becomes preoperational representation, concrete operations make representation logical for real and tangible problems, and formal operations extend logic to abstract and hypothetical possibilities.

MNEMONIC

"Sensorimotor - Preoperational - Concrete operational - Formal operational"

Sensorimotor action becomes preoperational representation, concrete operations make representation logical for real and tangible problems, and formal operations extend logic to abstract and hypothetical possibilities.

4	birth to 2 years	2 to 7 years	7 to 11 years
BROAD ORGANISATIONS OF THOUGHT	SENSORIMOTOR (BERK)	PREOPERATIONAL (BERK)	CONCRETE OPERATIONAL (BERK)

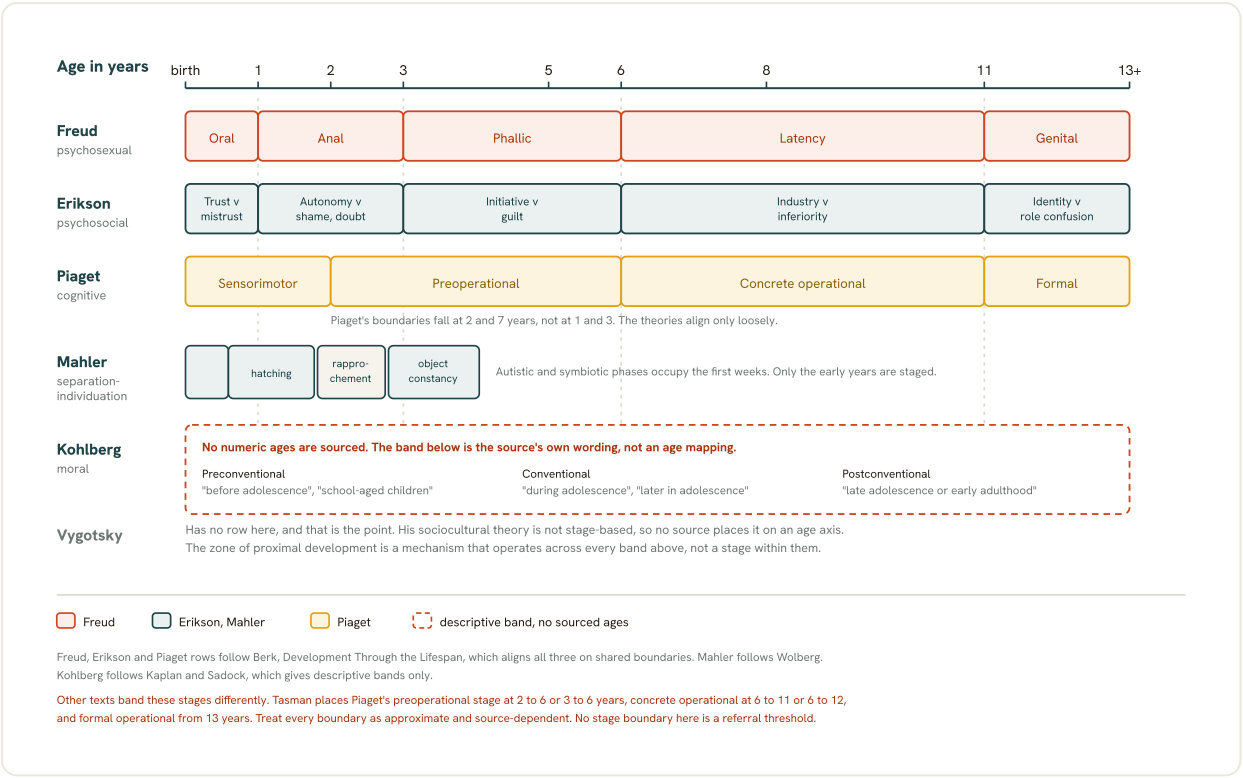

Fig 20.1 The developmental theories aligned on a shared age axis. Freud, Erikson and Piaget after Berk; Mahler after Wolberg; Kohlberg's levels as descriptive bands, since no numeric ages are sourced. Vygotsky carries no row because his theory is not stage-based. Boundaries are approximate and differ between texts.

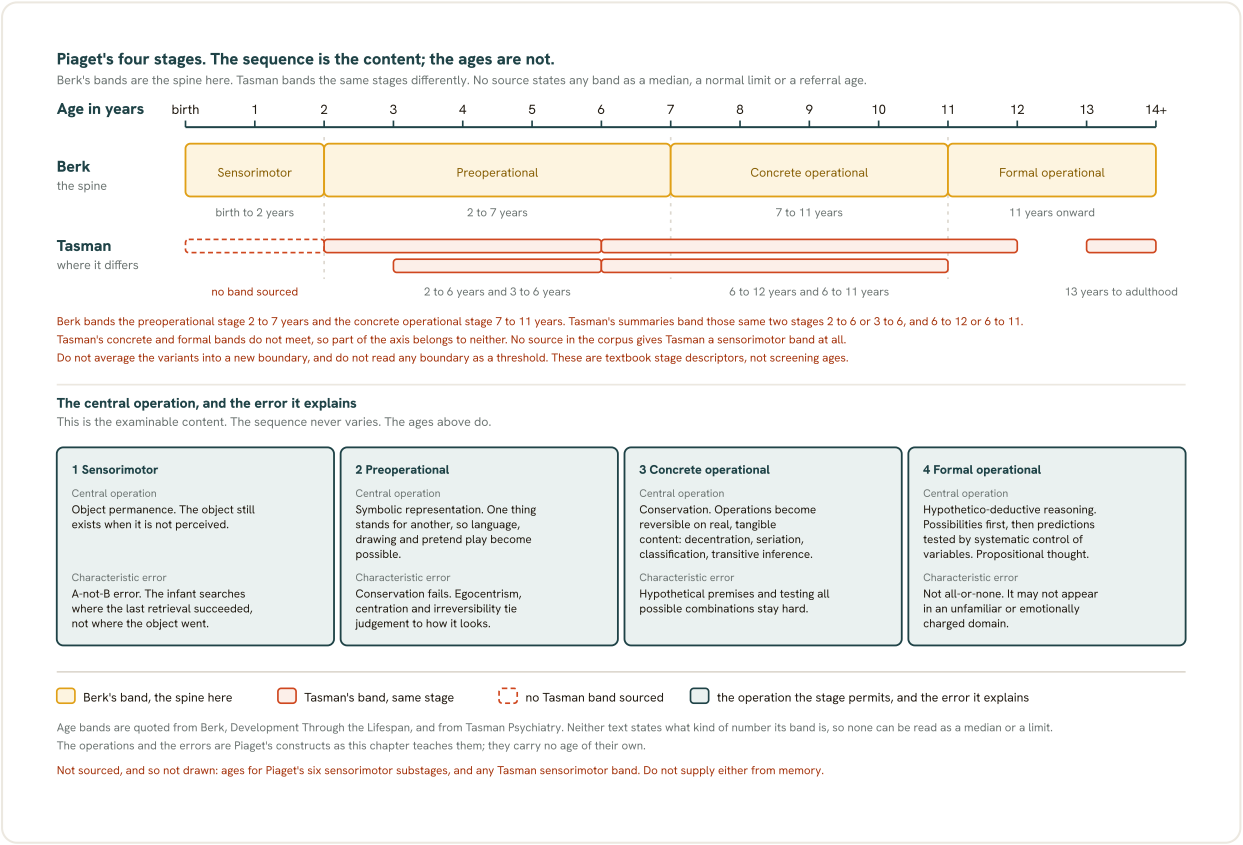

Fig 20.2 Piaget's four stages on an age axis, with the central operation each stage permits and the error it explains. The saffron spine follows Berk, Development Through the Lifespan; the coral bars are Tasman Psychiatry's differing bands for the same stages, shown rather than reconciled. No source states any band as a median, a normal limit or a referral threshold, and no source in the corpus gives Tasman a sensorimotor band.

1.1 The engine of Piaget's theory: schemes, adaptation and equilibration

A **scheme** is an organised pattern for acting on, representing or thinking about experience. An infant may have a grasping scheme; an older child may have a scheme for classifying animals or balancing an equation. Development occurs through **adaptation**, which has two complementary processes. In **assimilation**, the child interprets a new event through an existing scheme, as when every four-legged animal is initially treated as a dog. In **accommodation**, the scheme itself changes because the new event does not fit, so dogs and cows become distinct categories. Assimilation preserves continuity; accommodation permits novelty.

Organisation integrates separate schemes into larger cognitive systems. **Equilibration** is the regulatory process that moves thought from a less adequate balance to a more adequate one: a contradiction produces disequilibrium, and reorganisation restores coherence at a higher level. The theory is therefore *constructivist*. The child is neither a miniature adult nor an empty vessel, but an active reasoner whose errors disclose the structure of thought. In an examination, do not define a stage merely by its age band. Define it by the new operation it permits and the systematic limitation that remains.

RULE **Stage is inferred from the structure of reasoning, not from the answer alone.** Ask the child to explain, compare, predict and justify. A correct answer obtained by guessing or rote learning does not demonstrate an operation; an incorrect answer produced by misunderstanding the language of the task does not prove that the operation is absent.

1.2 Sensorimotor stage: knowledge through action

Berk's *Development Through the Lifespan* lists the **sensorimotor stage** as **birth to 2 years**. This wording is a textbook stage band, not a threshold. Cognition is initially organised through sensory experience and motor action. Repeated actions become circular reactions; schemes are coordinated into intentional means-end behaviour; experimentation becomes increasingly active; and, eventually, action can be represented mentally before it is performed. Piaget divided this progression into six substages, but the clinically useful principle is the movement from reflex-linked activity to deliberate action and internal representation.

The central achievement is **object permanence**, the understanding that an object continues to exist when it is no longer perceived. Before that representation is secure, searching is governed heavily by the immediate perceptual and motor situation. The classic **A-not-B error** occurs when an infant repeatedly retrieves an object from one location and then searches there again after seeing it hidden elsewhere. Later achievements include intentional problem-solving, imitation of an absent model, and the capacity to anticipate an outcome mentally. These are not isolated tricks. Together they mark the beginning of representation, which makes language, pretend play and later symbolic reasoning possible.

Clinical use. Observe how the child explores, searches, imitates and coordinates means with ends rather than relying on a verbal question. Interpretation must remain modest: visual access, motor ability, attention, fatigue, anxiety and familiarity with the task can all alter performance. Object-permanence tasks are demonstrations of a cognitive construct, not stand-alone diagnostic tests.

1.3 Preoperational stage: symbolic thought without reversible operations

Berk lists the **preoperational stage** as **2 to 7 years**. Tasman Psychiatry summaries use 2 to 6 years and 3 to 6 years in separate presentations. These variants should be retained as source conventions, not averaged into a new boundary. The decisive gain is the ability to use one thing to stand for another. Language expands, drawings carry meaning, and pretend play allows a block to become a car or an empty cup to contain imaginary tea. Thought has become representational, but it is not yet governed consistently by logical operations.

The characteristic limitations are linked. **Egocentrism** is difficulty coordinating one's own perspective with another person's perspective; it is not selfishness. The three-mountains task illustrates this failure of perspective-taking. **Centration** is attention to one striking dimension while other relevant dimensions are neglected. **Irreversibility** is difficulty mentally undoing a transformation. Together they explain failure of conservation: after the same quantity is rearranged into a taller or more spread-out appearance, the child judges by the perceptually dominant feature rather than by identity, compensation and reversibility.

Other characteristic forms include animism, in which life or intention is attributed to inanimate objects; artificialism, in which natural events are understood as made for human purposes; and transductive reasoning, in which one particular event is linked directly to another without a valid general principle. In clinical work, such reasoning can make illness, separation or family conflict feel caused by the child's thought or behaviour. The psychiatrist should explore the child's meaning and gently correct self-blame rather than treat developmentally shaped magical explanations as delusions.

1.4 Concrete operational stage: logical operations tied to tangible content

Berk lists the concrete operational stage as **7 to 11 years**; Tasman Psychiatry summaries use 6 to 12 years and 6 to 11 years. Again, these are alternate textbook mappings, not clinical cut-offs. The child can now perform an operation, an internalised mental action that is reversible and coordinated with other actions. Perceptual appearance no longer dominates every judgement, provided the problem concerns familiar or concretely imaginable material.

OPERATION	WHAT IT PERMITS
Conservation	Becomes possible because the child can use identity, compensation and reversibility.
Decentration	Permits simultaneous attention to more than one dimension.
Classification and class inclusion	Permit an item to belong to nested categories.
Seriation and transitive inference	Seriation orders objects along a dimension, and transitive inference coordinates relations to infer an unobserved relation.

Perspective-taking becomes more flexible, rules can be understood as coordinated systems, and explanations become less dependent on a single salient feature.

The limitation is contained in the name: the operations are most reliable when they can be anchored in actual objects, familiar events or imaginable transformations. Purely hypothetical premises, propositions contrary to fact, and systematic testing of all possible combinations remain difficult. For interviewing, use concrete language, timelines, drawings, demonstrations and examples from the child's experience. Abstract labels such as "mood," "risk" or "consequences" may need to be unpacked into observable situations.

1.5 Formal operational stage: reasoning about possibilities

Berk lists the formal operational stage as **11 years onward**, whereas a Tasman Psychiatry summary lists 13 years to adulthood. The two descriptions must not be collapsed into a falsely precise onset. The qualitative advance is that reasoning can operate on propositions and possibilities, not only on directly represented objects. The person can accept a hypothetical premise, derive its implications, and judge whether the conclusion follows even when the premise is not factually true.

- Hypothetico-deductive reasoning begins with possible explanations, derives predictions and tests variables systematically.
- Combinatorial reasoning considers the possible combinations within a problem rather than changing factors haphazardly.
- Propositional thought evaluates the logical relation between statements.
- Metacognition permits reflection on one's own thinking.

These abilities support scientific reasoning, long-range planning, moral debate, identity exploration and consideration of alternative futures.

Formal reasoning is not an all-or-none possession applied uniformly across every subject. Education, cultural tools, practice, interest, emotional arousal and domain knowledge shape whether it appears in a particular task. An adolescent or adult may reason formally in a familiar academic domain and concretely in an unfamiliar or emotionally charged one. The stage should therefore guide the form of questioning, not substitute for an assessment of actual comprehension, decision-making or capacity.

TRAP **Do not turn Piaget's age bands into milestone norms.** The cited texts do not label these bands as medians, normal limits or referral ages. They describe theoretical stages. Source variation, uneven performance and task demands make it incorrect to diagnose delay from a stage label or from one failed Piagetian task.

1.6 The classic tasks: what each task actually tests

A Piagetian task is valuable because the pattern of explanation reveals an underlying operation.

TASK	WHAT IT TESTS
Object-permanence task	The issue is whether the hidden object is represented despite absence from perception.
Perspective-taking task	The issue is coordination of viewpoints.
Conservation task	The examiner changes appearance while preserving quantity, then asks for both judgement and justification.
Class-inclusion task	The child must coordinate a subclass with the larger class.
Seriation and transitivity tasks	Relations must be ordered and mentally coordinated.
Formal-reasoning task	The examiner looks for generation of hypotheses and systematic control of variables.

Administration matters. Establish that the child understands the words, can see and manipulate the materials, and has not interpreted repetition of the question as a signal that the first answer was wrong. Ask "How do you know?" and record the reasoning rather than scoring only correct or incorrect. Repeating the same transformation with familiar objects can distinguish a conceptual limitation from confusion about the task. Do not coach the target operation and then claim to have measured spontaneous competence.

The best viva formulation is: *achievement, error, mechanism, task, limitation*. For preoperational thought, for example, the achievement is symbolic representation; the error is failure of conservation; the mechanism includes centration and irreversibility; the task is transformation of equal quantities; and the limitation is reliance on perceptual appearance. This structure prevents a recital of ages without psychology.

1.7 Strengths, limitations and contemporary reading

Piaget's enduring achievement was to show that children's errors are organised rather than random. He supplied testable constructs, linked knowledge to the child's own activity, and shifted developmental psychology from a catalogue of deficits to a study of changing cognitive structures. His tasks remain powerful teaching devices because they make abstract constructs visible in behaviour.

The limitations are equally examinable. Performance can improve when language is simplified, memory load is reduced or the situation is made familiar, suggesting that some classic tasks underestimate competence. Development is often gradual, overlapping and domain-specific rather than a clean step from one global structure to another. Social interaction, instruction, culture and the tools valued by a community receive less weight than in sociocultural theories. Formal reasoning is not consistently demonstrated across every person and every domain. The useful modern reading is therefore neither to discard Piaget nor to literalise him: retain the sequence as a model of increasingly coordinated representation and logic, while assessing the child's actual strategy in context.

1.8 Age alignment with Erikson, Freud, Kohlberg, Mahler and Vygotsky

The chapter's theory-alignment plate should be read horizontally: theories may discuss the same period of life while explaining different developmental work. Piaget explains the structure of knowing. Erikson's psychosocial stages explain successive tensions between the self and the social world. Berk places autonomy versus shame and doubt at 1 to 3 years, initiative versus guilt at 3 to 6 years, and industry versus inferiority at 6 to 11 years. Thus symbolic expansion, initiative and later school-age mastery overlap in time but are not interchangeable constructs.

Freud's psychosexual stages organise development around changing instinctual zones and conflicts. Berk lists the anal stage at 1 to 3 years, the phallic stage at 3 to 6 years, and latency at 6 to 11 years. Piaget's account does not explain libido or defence, and Freud's account does not test conservation or operations. Alignment helps recall; it does not imply that one theory validates another.

Kohlberg extended a structural approach to moral development, classifying the reasoning used to justify moral decisions rather than merely whether an answer was socially approved. Kaplan and Sadock describes preconventional morality before adolescence, conventional response levels during and later in adolescence, and a postconventional response level in late adolescence or early adulthood. Moral-stage reasoning and Piagetian cognition are related conceptually, but moral judgement also depends on social experience, values and context.

Mahler's separation-individuation theory concerns the child's emerging psychological separateness in relation to the caregiver. Kaplan and Sadock and Wolberg place the hatching period from about 4 or 5 months to 10 months; Wolberg places rapprochement onset between 15 and 18 months, describes the rapprochement crisis around 18 to 24 months, and places libidinal object constancy during the third year of life. These are the sources' own stage descriptions, not screening thresholds. Clinically, Mahler supplies relational language; Piaget supplies cognitive-structural language.

Vygotsky places greater weight on language, shared activity and culturally transmitted tools. The zone of proximal development is the gap between what a learner can do independently and what the learner can do with skilled support. Guided participation and scaffolding reveal emerging capacity that unsupported performance may conceal. Piaget asks what structure the child has constructed; Vygotsky asks what becomes possible in collaboration. The practical synthesis is dynamic: assess independent reasoning, then observe how performance changes with graduated help.

1.9 Piaget within the domains of child development

Piaget principally addresses cognition, although cognition is expressed through movement, language, play and social interaction. A child with a motor or language limitation may therefore perform poorly on a cognitive task for reasons other than the cognitive operation being tested.

1.10 Clinical use: developmental history, surveillance, red flags and Indian screening

Piaget calibrates the cognitive level of the interview; surveillance, red flags and screening are taught under the red-flags topic.

2 . Erikson psychosocial stages

Erik Erikson described personality development as a lifespan sequence of eight **psychosocial stages**. Each stage is organised around a **psychosocial crisis**, a tension between two necessary tendencies that arises from the interaction of biological maturation, the developing ego and the social world. A crisis is not a psychiatric emergency and it is not a choice in which one pole must be eliminated. It is a developmental turning point. A predominantly adaptive resolution strengthens the ego and yields a characteristic virtue; an unfavourable or markedly one-sided resolution leaves greater vulnerability when later tasks are encountered.

How to use this page. Learn the sequence as a chain of questions: *Can I rely on care? Can I act for myself? May I initiate? Can I master valued work? Who am I? Can I share myself without losing myself? What do I contribute? Can I accept the life I have lived?* Then attach the conflict, virtue, relational setting and common clinical distortion to each question. The age bands are textbook mappings whose normative construct was not specified by the sources. They are not medians, outer limits, screening cut-offs or referral thresholds. The theory-alignment plate may help compare Erikson with Piaget, Freud, Kohlberg, Mahler and Vygotsky, but temporal overlap never makes their constructs interchangeable.

Must memorise: trust gives hope, autonomy gives will, initiative gives purpose, industry gives competence, identity gives fidelity, intimacy gives love, generativity gives care, and integrity gives wisdom.

MNEMONIC

"Trust, autonomy, initiative, industry, identity, intimacy, generativity, integrity"

Trust gives hope, autonomy gives will, initiative gives purpose, industry gives competence, identity gives fidelity, intimacy gives love, generativity gives care, and integrity gives wisdom.

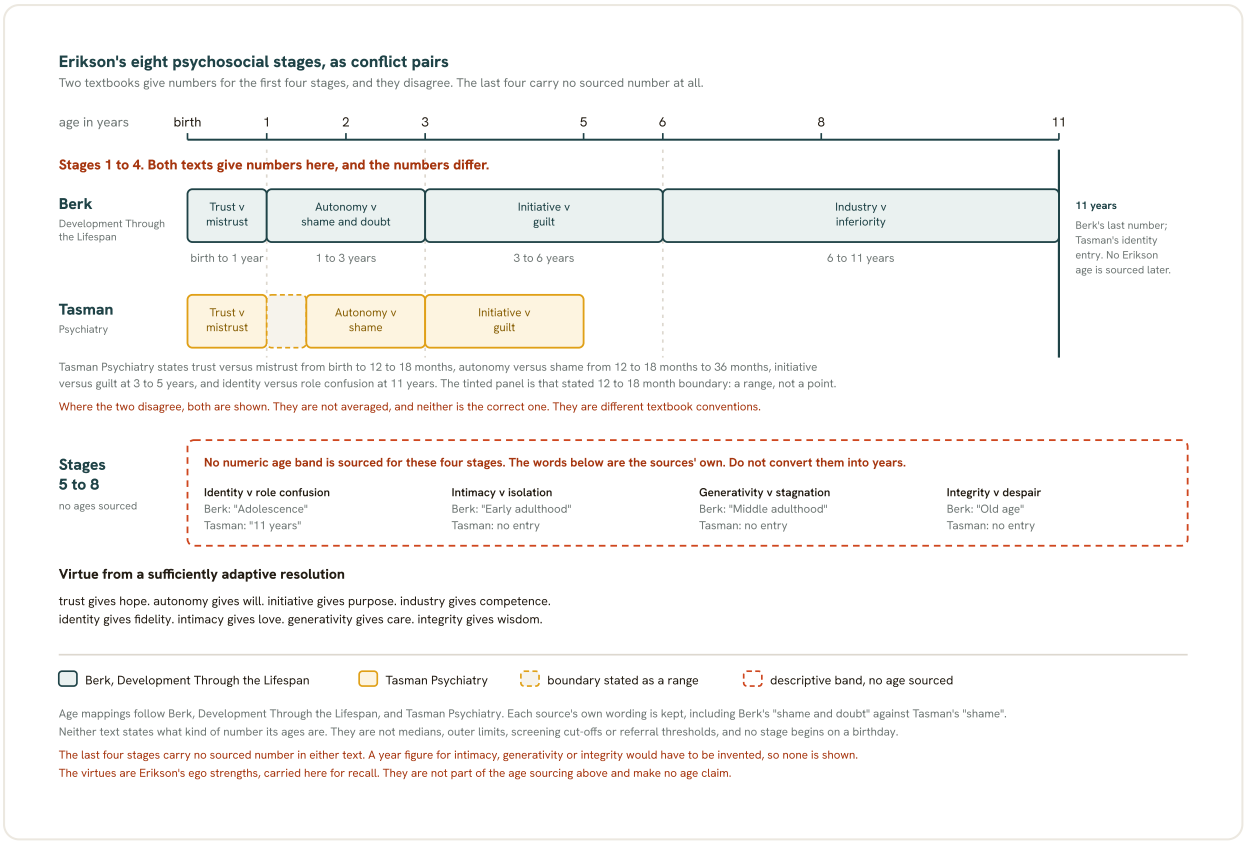

Fig 20.3 Erikson's eight psychosocial stages as conflict pairs. The first four sit on a sourced age axis, Berk's mapping above Tasman Psychiatry's; where the two disagree both are shown rather than averaged. The axis stops at 11 years because neither text gives an Erikson age past it, so the last four stages carry the sources' own life-period words instead of numbers. No boundary here is a referral threshold.

2.1 Architecture of the theory: epigenesis, crisis and ego strength

Erikson extended psychoanalytic development beyond childhood and beyond intrapsychic instinct. His **epigenetic principle** proposes that each psychosocial capacity has a period of relative ascendancy within an ordered sequence, while earlier themes remain active and can be revisited. Trust does not stop when autonomy begins; identity does not become irrelevant after intimacy. Later relationships, illness, migration, parenthood, loss and social change can reactivate earlier tensions and permit partial reworking. The model is therefore stage-like but not mechanically closed.

The two poles are sometimes called syntonic and dystonic tendencies. Healthy development does not mean total trust, autonomy or generativity. Some mistrust protects against exploitation, some shame supports social awareness, and some isolation preserves reflection and boundaries. The task is a workable ratio in which the adaptive tendency predominates without erasing the protective information carried by the other pole. The resulting **ego strength** is not a symptom score. It is a durable capacity, such as hope or fidelity, that supports later developmental work.

Erikson's distinctive contribution is the social location of the crisis.

- Caregiving relationships organise trust.
- Limits and bodily control organise autonomy.
- Family and play organise initiative.

- School and culturally valued work organise industry.
- Peers, ideals and social roles become increasingly important for identity.

Culture determines what counts as competence, legitimate independence, adulthood, contribution and a good life. The theory must therefore be used as a formulation scaffold, not as a culturally neutral measuring instrument.

RULE **Name four elements for every stage:** the conflict, the psychosocial task, the central relational or social field, and the virtue associated with a sufficiently adaptive resolution. Age alone is never an adequate answer.

2.2 Age alignment and how to state it safely

STAGE	BERK, *DEVELOPMENT THROUGH THE LIFESPAN*	TASMAN PSYCHIATRY
basic trust versus mistrust	**birth to 1 year**	trust versus mistrust, birth to 12 to 18 months
autonomy versus shame and doubt	**1 to 3 years**	autonomy versus shame, 12 to 18 months to 36 months
initiative versus guilt	**3 to 6 years**	initiative versus guilt, 3 to 5 years
industry versus inferiority	**6 to 11 years**	
identity versus role confusion	adolescence	11 years
intimacy versus isolation	early adulthood	
generativity versus stagnation	middle adulthood	
integrity versus despair	old age	

These are retained as each source states them. They must not be averaged into a new age boundary, treated as competing referral ages or presented as proof that a person has entered a stage on a birthday.

8 stages	Birth to 1 year	1 to 3 years	3 to 6 years
ONE LIFESPAN SEQUENCE	BERK TRUST MAPPING	BERK AUTONOMY MAPPING	BERK INITIATIVE MAPPING

2.3 Trust and autonomy: hope, will and the beginning of agency

Basic trust versus mistrust asks whether the world is sufficiently reliable for hope. The infant depends on caregivers for regulation, protection and the repeated relief of distress. Sensitive and reasonably predictable care supports a felt expectation that needs can be communicated and that another person may respond. The virtue is hope, the capacity to sustain expectation despite frustration. Mistrust is not produced by every delay or mismatch, and perfect gratification is neither possible nor desirable. The clinically important pattern is whether care is sufficiently coherent for the infant to tolerate absence and uncertainty without the world becoming wholly unsafe.

Trust is relational but not reducible to attachment classification. Attachment theory studies proximity, secure-base behaviour and reunion patterns in particular caregiver relationships; Erikson describes a broader ego expectation about self, others and the social world. Severe inconsistency, neglect or frightening care may compromise both, but a psychiatrist should not infer a specific attachment-pattern from the Eriksonian conflict or diagnose a caregiver from one observed interaction.

Autonomy versus shame and doubt asks whether emerging self-control can coexist with connectedness. Growing motor ability, language, choice, bodily regulation and the repeated use of "no" expand the child's sense of agency. Supportive adults offer bounded choices, tolerate safe attempts, set comprehensible limits and help after failure. The virtue is will, the capacity to choose and persist. Chronic overcontrol, humiliation, ridicule of accidents or demands far beyond capacity can make self-assertion feel dangerous and foster excessive shame or doubt. Permissiveness is not the opposite of shaming control: reliable limits help the child experience autonomy as organised and safe.

In a developmental history, ask how caregivers respond to distress, exploration, refusal, feeding, dressing and bodily-control struggles. Formulate the fit between the child's capacities, temperament and the caregiving environment. Do not attribute current anxiety, dependency or defiance to a single early-stage failure. Erikson supplies a hypothesis about meaning; history, observation and longitudinal evidence must test it.

2.4 Initiative and industry: purpose, competence and the social valuation of action

Initiative versus guilt asks whether the child may imagine, plan and act. Symbolic play, questions, fantasy, imitation of adult roles and self-started activity enlarge the field of action. Initiative is more than independence: it adds direction and purpose. Adults support it by taking ideas seriously, permitting safe experimentation and setting limits without treating curiosity or ambition as badness. The virtue is purpose. Guilt becomes excessive when wishes, questions, rivalry or ordinary attempts at action are repeatedly interpreted as harmful or unacceptable. Some guilt is developmentally useful because it permits concern for the effects of one's actions; incapacitating guilt suppresses initiative itself.

Industry versus inferiority asks whether effort can produce socially valued competence. Schooling, peer comparison, tasks, tools, rules and feedback move the child into a wider field of evaluation. The child learns to sustain attention, practise, cooperate, complete work and take justified pride in mastery. The virtue is competence. Repeated failure, unrecognised learning needs, exclusion, harsh comparison or praise detached from actual effort can undermine industry. Inferiority is not simply low self-esteem. It is the expectation that one's effort will not produce valued mastery.

In Indian clinical practice, marks and rank may dominate the family's account of competence, but industry is wider than examination performance. Practical skill, sport, art, caregiving, language, social contribution and persistence may all organise mastery. A child with ADHD, a specific learning disorder, chronic illness or sensory impairment may be industrious while producing

weak conventional outputs; those conditions themselves are developed in the ADHD and specific learning/communication disorders notes. Formulation should separate ability, opportunity, effort, accommodations and the social meaning attached to performance.

2.5 Identity versus role confusion: the central crisis of adolescence

Identity versus role confusion asks whether the adolescent can experience continuity while exploring possible selves. Identity formation integrates past identifications, bodily change, values, relationships, vocation, culture and imagined futures into a sufficiently coherent answer to "Who am I, and where am I going?" The virtue is fidelity, the capacity to commit to people and ideals while tolerating difference and remaining recognisably oneself. Role confusion may appear as unstable commitments, incompatible self-definitions, chronic diffusion or an identity chosen mainly to meet others' demands.

Erikson's **psychosocial moratorium** is a socially permitted interval for exploration before durable commitments are expected. It is not mere idleness. Marcia operationalised the identity theme along two dimensions, exploration and **commitment**, producing four identity statuses: diffusion, foreclosure, moratorium and achievement. These are statuses rather than an invariant stage sequence.

IDENTITY STATUS	DESCRIPTION
Foreclosure	describes commitment without meaningful exploration.
Moratorium	describes active exploration without settled commitment.
Achievement	combines exploration with commitment.
Diffusion	lacks both.

A person's status may differ across vocation, values and relationships.

Gender identity is a person's experienced sense of gender. It is distinct from gender expression, sexual orientation and sexual behaviour, and none of these should be treated as evidence of role confusion. Identity exploration can be developmentally normal. The clinical task is to assess distress, coercion, stigma, safety, family response, comorbidity and functioning without converting cultural nonconformity into psychopathology. Erikson's language can illuminate coherence and commitment, but it does not determine what a person's identity ought to be.

Psychosexual development is also broader than Freud's sequence of instinctual zones. In adolescence it includes bodily maturation, sexual feelings, relational boundaries, consent, values and the integration of sexuality into identity. The psychiatrist should distinguish normative exploration from exploitation, risky behaviour, compulsivity, trauma-related phenomena, mood-related disinhibition and distress driven by stigma.

The puberty reference plate should be read separately from Erikson's theory-alignment plate. The former describes bodily maturation; the latter aligns theoretical accounts of psychosocial, cognitive, psychosexual, moral and relational development. Physical maturation may alter the

social pressures surrounding identity, but no Tanner stage proves a level of identity formation, moral development or judgement.

2.6 Intimacy, generativity and integrity across adult life

Intimacy versus isolation asks whether identity can enter mutual commitment without dissolution. Berk places it in early adulthood. **Intimacy** includes emotional reciprocity, vulnerability, sexuality, friendship and durable commitment; it is not synonymous with marriage. Erikson's logic is that a sufficiently coherent identity makes it possible to share oneself without either fusion or defensive withdrawal. The virtue is love. Isolation may protect temporarily after loss or threat, but chronic avoidance of mutuality narrows the person's relational world.

Generativity versus stagnation asks what the adult creates, sustains and hands onward. Berk places it in middle adulthood. **Generativity** includes parenting but is not limited to biological parenthood. Teaching, mentoring, clinical service, productive work, institution-building, creativity and care for future generations can all express it. The virtue is care. Stagnation is an excessive narrowing toward self-absorption, repetition or the sense that one's activity does not nourish anything beyond the self.

Integrity versus despair asks whether the life course can be owned as a whole. Berk places it in old age. **Ego integrity** is not the belief that every decision was correct. It is the capacity to accept the singular life one has lived, integrate success with regret and face finitude without repudiating the self. The virtue is wisdom. Despair arises when time feels too short for repair and the life appears wasted, fragmented or intolerably unlike the life that should have been.

Adult developmental crises can organise the meaning of depression, caregiving burden, infertility, retirement, bereavement, migration or occupational disruption, but they do not replace diagnosis. A person without a partner is not necessarily isolated; a person without children is not necessarily stagnant; regret does not by itself mean despair. Ask what the person values, what social opportunities were available and how the present illness has altered the developmental task.

2.7 Alignment with Piaget, Freud, Kohlberg, Mahler and Vygotsky

The chapter's theory-alignment plate should be read horizontally, with one question attached to each theorist. Piaget asks how the structure of cognition changes. His sensorimotor account concerns knowledge through action and the emergence of representation; it does not explain trust. Freud asks how instinctual conflict is organised across the psychosexual stages; temporal overlap with an Eriksonian stage does not make autonomy equivalent to the anal stage or identity equivalent to the genital stage.

Kohlberg asks how reasons for moral decisions are structured. Kaplan and Sadock describe preconventional morality before adolescence, conventional response levels during and later in adolescence, and a postconventional response level in late adolescence or early adulthood. Moral development concerns the justification of right action, whereas Eriksonian identity concerns continuity, values and commitment. A sophisticated moral argument does not prove identity achievement, and social conformity does not by itself establish conventional moral reasoning.

Mahler asks how psychological separateness emerges within the caregiver relationship. Her separation-individuation theory includes a hatching period described by Kaplan and Sadock and Wolberg from about 4 or 5 months to 10 months. Wolberg places rapprochement onset between 15 and 18 months, the rapprochement crisis around 18 to 24 months, and libidinal object constancy during the third year of life. These are source descriptions, not screening thresholds. Mahler's individuation is not the same construct as Erikson's autonomy, although both attend to emerging separateness.

Vygotsky asks what development becomes possible through language, cultural tools and skilled collaboration. The zone of proximal development is the difference between independent performance and performance achieved with appropriate support. Erikson identifies the psychosocial meaning of mastery; Vygotsky helps the clinician observe how guided participation changes actual performance. A child who appears inferior in an unsupported task may reveal strong learning potential when the task is scaffolded.

The safest comparison formula in a viva is *same period, different explanatory target*. The theories can be placed beside one another for recall, but they cannot be added into a single universal clock. Their stage ages are descriptive conventions, their units of analysis differ, and none of the theoretical bands is a developmental referral threshold.

TRAP **Do not diagnose an "unresolved Erikson stage."** The conflicts are formulation constructs, not ICD diagnoses, psychometric scores or developmental-screening results. Avoid retrospective certainty, such as attributing adult symptoms to one caregiving event, and avoid reading age bands as deadlines.

2.8 Clinical formulation: strengths, limitations and cultural use

Erikson is clinically useful because he joins symptom, biography and social context. It prompts the psychiatrist to ask what developmental task the illness interrupts, what virtue remains available as a strength, and what social response is amplifying the conflict. Depression during vocational transition may be experienced through identity and competence; mania may destabilise commitments and intimacy; chronic psychosis may obstruct industry or generativity; caregiving and retirement may transform the meaning of contribution. These formulations enrich management when they remain hypotheses grounded in the person's narrative.

The model also has limits. Its broad concepts are difficult to operationalise, stage boundaries are not sharply defined, and development is more variable and recursive than a strict sequence suggests. The classical account can overprivilege individual autonomy, stable occupational identity and a linear adult life course. Collective identities, caste, class, gendered opportunity, disability, migration, chosen family and economic constraint may shape which resolutions are possible and valued. Indian family interdependence should not be mislabelled dependency merely because it differs from an individualist ideal.

Use **goodness-of-fit** to prevent moralising. **Temperament** refers to constitutionally influenced differences in reactivity and regulation; goodness-of-fit refers to the compatibility between those characteristics and environmental expectations. A cautious child in a patient environment may

develop competence, while the same child under ridicule and forced performance may experience inferiority. The temperament is not the Eriksonian crisis, but the fit can alter how the crisis is negotiated.

A sound formulation states the evidence and its limits: "The current transition appears to reactivate concerns about competence and identity" is defensible; "industry was not resolved, therefore this disorder developed" is not. Erikson should direct questions, identify strengths and organise meaning. It should not be used to blame parents, prescribe a culturally narrow life path or explain away neurodevelopmental, psychiatric and social causes.

2.9 Five worked cases: from recall to application

Worked case 1 - milestone-dating and red-flag reasoning. A child at 24 months of age is described as energetic, insistent on self-feeding and easily frustrated by adult help. The child does not use spontaneous two-word phrases. The Eriksonian reading is autonomy versus shame and doubt: the self-directed behaviour is developmentally meaningful and should be met with bounded choices rather than ridicule. The language finding is a separate red-flag: absence of spontaneous two-word phrases at 24 months of age warrants further developmental evaluation. Do not use "the autonomy stage" to normalise the language concern, and do not infer global delay from a single finding. Assess all developmental domains, hearing, regression and context.

Worked case 2 - attachment-pattern identification. In Ainsworth's Strange Situation, a young child explores while the caregiver is available, becomes distressed on separation, seeks contact on reunion and settles sufficiently to resume exploration. This pattern is most consistent with secure attachment because the caregiver functions as a secure base and haven. The Eriksonian link is supportive, not diagnostic: reliable care may contribute to basic trust, but secure attachment and trust are different constructs. One observation cannot establish the whole caregiving history or prove that an Eriksonian crisis is resolved.

Worked case 3 - temperament and goodness-of-fit. A child within Berk's 6 to 11 years industry-versus-inferiority mapping is slow to approach unfamiliar classroom tasks but works carefully after a demonstration. Repeated public comparison has led the child to say, "I am bad at everything." The theory-application is industry versus inferiority, but the mechanism is not laziness. A cautious temperament is meeting a poor goodness-of-fit. Assess learning, attention, sensory and emotional contributors; provide graduated demonstration, private feedback and tasks that permit observable mastery. The goal is evidence-based competence, not empty reassurance.

Worked case 4 - adolescent identity and risk-taking. An adolescent alternates between career plans, adopts different styles with different peers and takes a hazardous risk in a highly charged group setting, while reasoning thoughtfully about the same risk in clinic. Exploration without settled commitment may fit moratorium rather than pathology. The context shift is compatible with a dual-systems or maturational imbalance account of risk-taking, but it does not excuse harm or prove immaturity. Assess mood elevation, substance use, coercion, self-harm, sleep,

consequences and capacity. Explore identity formation and values without treating gender identity, appearance or nonconformity as role confusion.

Worked case 5 - adult theory-application. An older adult after bereavement reviews a life containing valued work, estrangement and choices now regretted, yet can hold gratitude and sorrow together and remains engaged in mentoring. The dominant Eriksonian formulation is integrity rather than despair, with generativity still active through mentoring. Integrity does not require a flawless or regret-free biography. If pervasive hopelessness, anhedonia, guilt or suicidal thinking is present, assess depressive illness directly; a developmental formulation must never replace risk assessment or diagnosis.

Exam synthesis. In any vignette, first identify the actual phenomenon: a developmental attainment, warning sign, relationship pattern, temperament-environment fit, physical pubertal stage, form of reasoning or psychosocial conflict. Then name the correct framework and state what it can and cannot infer. That separation prevents the commonest error in developmental psychiatry: using an elegant theory as if it were a measurement instrument.

3 . Freud psychosexual stages

Freud's psychosexual theory proposes that personality develops through a sequence in which **libido**, understood as psychic energy associated with the sexual drives, is organised predominantly around a different bodily zone and a different developmental conflict. In examination answers, "sexual" must be used in Freud's broad drive-theory sense rather than reduced to adult genital intercourse. The sequence is **oral, anal, phallic, latency and genital**. Each phase leaves residues in later personality, while excessive frustration or gratification may produce **fixation**; under stress, functioning may move back toward an earlier mode through **regression**. This is a historical psychoanalytic model of personality development, not a contemporary milestone schedule and not a method for diagnosing developmental delay.

How to use this page. First memorise the order, age brackets, principal zone and central conflict. Then add the characteristic mode of gratification, the proposed resolution and the classical fixation themes. Finally, separate three things that candidates commonly collapse: a psychosexual phase is not a developmental milestone, Freud's genital phase is not a Tanner stage, and a psychodynamic formulation is not proof that an early event caused the patient's current disorder.

> **Must memorise:** oral, anal, phallic, latency, genital; the drive focus moves from incorporation, through control and oedipal identification, to relative quiescence and then mature genital organisation.

3.1 The organising model and the five-stage sequence

A changing drive focus, a phase-specific conflict and a possible residue. Freud did not describe five watertight compartments. Earlier modes of pleasure and relating remain available after a later organisation becomes dominant. A stage is therefore best learnt through four linked questions:

1. *Where is gratification centred?*
2. *What conflict must be negotiated?*
3. *How is it resolved?*
4. *What pattern did Freud associate with fixation?*

The theory assumes that constitutional drives interact with caregiving and prohibition. The child's ego gradually develops ways of regulating these pressures, and identification contributes to internal structure, especially during the phallic phase.

Source-reported teaching brackets, not referral thresholds:

STAGE	BERK'S *DEVELOPMENT THROUGH THE LIFESPAN*	*TASMAN PSYCHIATRY*
Oral	Birth to 1 year	birth to 12-18 months
Anal	1-3 years	12-18 to 36 months
Phallic	3-6 years	3-5 years
Latency	6-11 years	
Genital	Adolescence	11 years plus for the adolescent genital phase

Birth to 1 year	1-3 years	3-6 years	6-11 years
ORAL - BERK	ANAL - BERK	PHALLIC - BERK	LATENCY - BERK

The sources state these ages without defining their normative construct. They should therefore be reproduced as the sources' approximate theoretical brackets, never converted into a median, an upper limit of normal or a when to refer threshold. Their overlap also warns against false precision. A child does not become abnormal because a psychodynamic theme appears outside its conventional bracket.

3.2 Oral stage: incorporation, dependence and the first relation to an object

The mouth is the principal zone, and feeding is both gratification and relationship. In the **oral stage**, sucking, swallowing and biting organise pleasure. The breast or feeding caregiver is not merely a source of nutrition in the theory; it is the first major **object**, meaning the person or representation toward whom a drive is directed. Satisfaction involves taking in, while delay and absence introduce frustration. The central developmental themes are receiving, incorporation, dependence and the beginnings of tolerating separation from immediate gratification.

Classical accounts distinguish an earlier *oral receptive* or incorporative mode from a later biting, aggressive mode. Freud and later psychoanalytic writers linked oral fixation with dependency, passivity, demandingness, gullibility or incorporative habits, and linked the biting mode with verbal aggression and hostility. These are theoretical associations, not validated one-to-one predictions. Feeding difficulty, smoking, overeating or dependency in an adult cannot by itself

demonstrate oral fixation, and a resident should never retrofit an infancy narrative merely because an adult symptom looks symbolically oral.

3.3 Anal stage: control, autonomy and the social demand for regulation

Pleasure in retention and expulsion meets the caregiver's demand for bowel control. In the **anal stage**, elimination becomes the principal bodily focus. Toilet training gives the child an arena in which bodily pleasure, autonomy, obedience, defiance, praise and shame can become linked. The theoretically important issue is not simply continence; it is the negotiation between the child's wish to control what is given or withheld and the environment's demand that discharge occur at an acceptable place and time.

Classical descriptions contrast anal-retentive themes, such as excessive orderliness, obstinacy, parsimony and control, with anal-expulsive themes, such as messiness, defiance and poorly regulated discharge. The familiar triad of orderliness, obstinacy and parsimony is a high-yield psychoanalytic association, but it is not a diagnostic triad. Contemporary formulation should ask how control, shame, autonomy and caregiver responses were experienced, while avoiding blame directed at toilet training or at the caregiver.

3.4 Phallic stage: oedipal conflict, identification and superego development

Genital awareness is organised around triangular attachment, rivalry and identification. The **phallic stage** centres on the phallus in Freud's theory and introduces the **Oedipus complex**: desire for the opposite-sex parent, rivalry with the same-sex parent and anxiety about the consequences of that rivalry. In Freud's account of the boy, castration anxiety promotes renunciation of the oedipal wish and identification with the father. This identification contributes to the consolidation of the superego and to the internalisation of prohibitions and ideals.

Freud's account of female development invoked penis envy and a different route through oedipal attachment. It has been criticised as androcentric, anatomically reductionist and based on male development as the norm. The term Electra complex is associated with Jung, not Freud's preferred terminology. In an examination, state the classical proposition accurately, then state the criticism. Resolution is described through relinquishment of the incestuous wish, identification and movement toward relationships outside the original triangle. Fixation has been associated with vanity, exhibitionism, rivalry, sexual inhibition or reckless assertion, but again these are hypotheses within a theory, not diagnostic findings.

TRAP **Phallic is not genital, and genital is not Tanner.** The phallic phase concerns oedipal organisation in early childhood. The later genital phase concerns the mature organisation of drives. Tanner staging describes observable pubertal anatomy and is a different construct altogether. Also remember that Jung, not Freud, popularised "Electra complex" as a label.

3.5 Latency: relative drive quiescence, sublimation and social learning

Latency is a relative reduction in overt psychosexual preoccupation, not the disappearance of libido. During the **latency stage**, oedipal wishes are held by repression and other defences, while energy is increasingly channelled into learning, peer relationships, play, competence and

culturally valued activity. **Sublimation** is the key mechanism: drive energy is redirected toward aims that are socially acceptable and psychologically productive.

Latency is sometimes described as an interval rather than a new erogenous-zone organisation, but it remains part of the five-part examination sequence. Its clinical themes include the capacity to learn, work with peers, follow rules and invest in interests outside the family triangle. It should not be mistaken for a period without sexuality, fantasy or conflict. The word *relative* protects the answer from that overstatement.

3.6 Genital stage: integration, reciprocity and mature object love

Adolescent drive reactivation is reorganised toward reciprocal relationships. In the **genital stage**, earlier partial drives are theoretically integrated under genital primacy. The developmental aim is not mere sexual activity. It is the capacity for reciprocal intimacy, concern for the other person, productive work and a balance between love and responsibility. Mature gratification now depends on recognising the object as a separate person rather than only as a source of need satisfaction.

Unresolved earlier conflicts may reappear when adolescent drives intensify, so the final phase includes both reworking and integration. The phrase *mature genital character* belongs to Freud's normative ideal and should not be treated as a contemporary measure of mental health. Sexual orientation, celibacy, disability, cultural restraint or absence of partnered sexual activity does not indicate failed genital development. This is another reason to keep the historical theory separate from moral judgement and from anatomical puberty.

3.7 Fixation and regression: the mechanisms that connect stages to adult formulation

Fixation is the persistence of a disproportionate libidinal investment in an earlier mode of gratification or conflict. Classical theory attributes it to marked frustration, excessive gratification or difficulty resolving the phase-specific conflict. Regression is a return, especially under stress, to a developmentally earlier organisation of wishes, defences, relationships or behaviour. Fixation describes a relatively enduring vulnerability; regression describes movement toward that point of vulnerability. They are related but not synonyms.

The clinically useful move is thematic and probabilistic. Dependency and taking-in may suggest an oral theme; control, withholding and shame may suggest an anal theme; rivalry, display and triangular relationships may suggest a phallic theme. The clinician then tests the hypothesis against the patient's history, current relationships, transference, defences and culture. The clinically unsafe move is deterministic: inferring a specific childhood event from an adult trait, or explaining a disorder solely by naming a stage.

RULE **A psychosexual formulation generates hypotheses; it does not establish causation.** Use stage language to organise recurring themes in gratification, control, rivalry, identification and intimacy. Do not use it as a developmental test, a diagnosis or proof of what happened in childhood.

3.8 Alignment with other developmental theories: same age axis, different constructs

The companion synthesis map aligns the major theories by age, but alignment means temporal overlap, not conceptual equivalence. Freud maps changing drive organisation through the psychosexual stages. Piaget maps cognitive structure, beginning with the sensorimotor period and moving through preoperational, concrete operational and formal operational thought. Erikson maps relational and social crises through the psychosocial stages. Thus an early-childhood conflict may simultaneously be described as anal in Freud, autonomy versus shame and doubt in Erikson, and sensorimotor or early preoperational in Piaget, without the terms meaning the same thing.

Kohlberg maps moral development from preconventional through conventional to postconventional reasoning. His sourced age relationships are descriptive bands such as before adolescence, during adolescence and later in adolescence, not numeric age ranges; adding numbers would manufacture precision. Mahler maps separation-individuation, including hatching, practising, rapprochement and movement toward object constancy. Vygotsky offers no stage sequence: the zone of proximal development, scaffolding, private speech and socially mediated learning are cross-cutting mechanisms. Vygotsky therefore belongs beside the age plate, not inside it as invented stages.

The clinical use of the alignment is to ask several different questions about the same child: how the child thinks, what social conflict is being negotiated, how drives and relationships are organised, how morality is reasoned, how separation is managed and what learning becomes possible with guidance. The plate prevents tunnel vision; it does not turn six theories into one grand developmental schedule.

3.9 Clinical value, cultural limits and contemporary critique

Freud's model remains important because it introduced developmental continuity, unconscious conflict, infantile sexuality, defence, symbolic meaning and the possibility that early relationship patterns recur in adult life. In psychodynamic assessment it can sharpen attention to how a patient receives care, manages dependency, uses control, enters triangles, responds to prohibition and negotiates intimacy. These themes can be observed in narrative, dreams, symptoms, transference and countertransference, then integrated with attachment, temperament, trauma, learning and the current social environment.

Its limitations are equally examinable. The theory was derived largely from retrospective clinical reconstruction rather than prospective developmental research; several central propositions are difficult to falsify; the account of female development is androcentric; the model can be heteronormative and overly centred on sexuality; and stage-to-trait links are vulnerable to circular explanation. Culture changes the meanings of feeding, sleeping, toilet training, bodily privacy, family hierarchy and adolescent intimacy. For Indian practice, joint-family structures and family-mediated caregiving may alter the relational expression of dependence or autonomy without indicating pathology. Use the theory as one formulation lens, not as a universal cultural ruler.

INDIA

The Freud brackets above come from general developmental and psychiatry texts and are not **Indian norms**. No verified India-specific psychosexual-stage age adaptation is supplied here, so none should be invented. Indian developmental instruments answer a different question: the **Trivandrum Development Screening Chart** screens development from **0 to 6 years** using 51 items, with one item delay constituting a positive screen, while **DASII** yields Motor DQ and Mental DQ, and a DQ below **85** is used as a delay marker in Indian follow-up practice. Neither instrument validates oral, anal or phallic fixation.

3.10 Spotting deviation from normal: developmental surveillance is a separate clinical task

Psychosexual stages do not define developmental red flags. Developmental surveillance is longitudinal observation of developmental progress, caregiver concerns and function, supported by milestone-based screening when indicated. It is the correct framework for spotting deviation, warning signs and deciding when to refer. Calling a child "fixated" does none of these jobs and may delay proper assessment.

High-yield developmental red flags include the following:

REFERRAL SIGNAL	AGE
Absent babbling	at **12 months**.
Absent single words	at **16 months**.
Absent spontaneous two-word phrases	at **24 months**.
Loss of language or social skills	at any age.

These are referral signals from *Developmental Psychopathology*, not Freud-derived ages. For gross motor development, the **WHO norms** are achievement windows bounded by the 1st and 99th centiles and are intended to signal the need for appropriate screening when a child appears late; they are screening signals, not diagnostic thresholds. India was one of the WHO study sites. Use the companion milestone plate for the individual windows rather than recreating it here.

The apparent Western-versus-Indian comparison must also be handled honestly. Freud's source brackets are theoretical ages, not **Western norms**, while the Trivandrum chart and DASII are Indian screening or assessment instruments, not psychosexual-stage adaptations. There is therefore no like-for-like set of **Indian norms** to place beside Freud's ages. Record genuine differences when two sources measure the same construct; when they do not, name the mismatch instead of forcing an alignment.

3.11 Consolidation: mnemonic, active recall and reconstruction

MNEMONIC

"Old Analysts Prefer Long Games"

O-A-P-L-G gives Oral, Anal, Phallic, Latency, Genital. Attach one organising word to each: *incorporation, control, identification, sublimation, reciprocity*. The mnemonic fixes order; the five organising words recover the theory.

Redraw from memory. Reconstruct the companion **synthesis map** with **theories by age** on separate horizontal lanes, place Freud's five stages on its lane, keep Kohlberg's bands descriptive, and draw Vygotsky as a cross-cutting mechanism. Then add the companion **milestone anchors** and developmental red flags on a separate clinical lane. Keeping the theory lanes separate from the surveillance lane is the final examination safeguard.

4 . Moral development (Kohlberg)

Lawrence Kohlberg's theory of moral development describes development in the *reasoning used to justify a moral decision*. It is not chiefly a theory of whether a person gives the examiner the approved answer, behaves well, obeys the law, or possesses a particular religious belief. Kohlberg extended Piaget's interest in the development of moral judgement and proposed an invariant sequence of increasingly differentiated ways of answering a central question: *why is an action right or wrong?* The sequence contains **three** levels, each containing **two** stages. The centre of moral authority shifts from externally imposed consequences, to interpersonal and social expectations, and finally to principles that can be used to evaluate the social order itself.

How to use this page. First fix the architecture: **preconventional**, **conventional**, and **postconventional**; then learn the contrast within each pair of stages. Stage 1 avoids punishment, stage 2 pursues exchange; stage 3 seeks interpersonal approval, stage 4 maintains the social system; stage 5 tests rules against rights and social contract, stage 6 reasons from universal ethical principles. In a dilemma, always identify the justification rather than the chosen act. Timing must remain descriptive: Kaplan and Sadock relates the stages to bands such as "school-aged children" and "during adolescence", but supplies no numeric ages for Kohlberg.

Must remember: Kohlberg stages the *reason for the judgement*, not the judgement itself.

MNEMONIC

"Punishment - Exchange - Approval - Law - Contract - Principle"

The sequence is punishment, exchange, approval, law, social contract, universal principle.

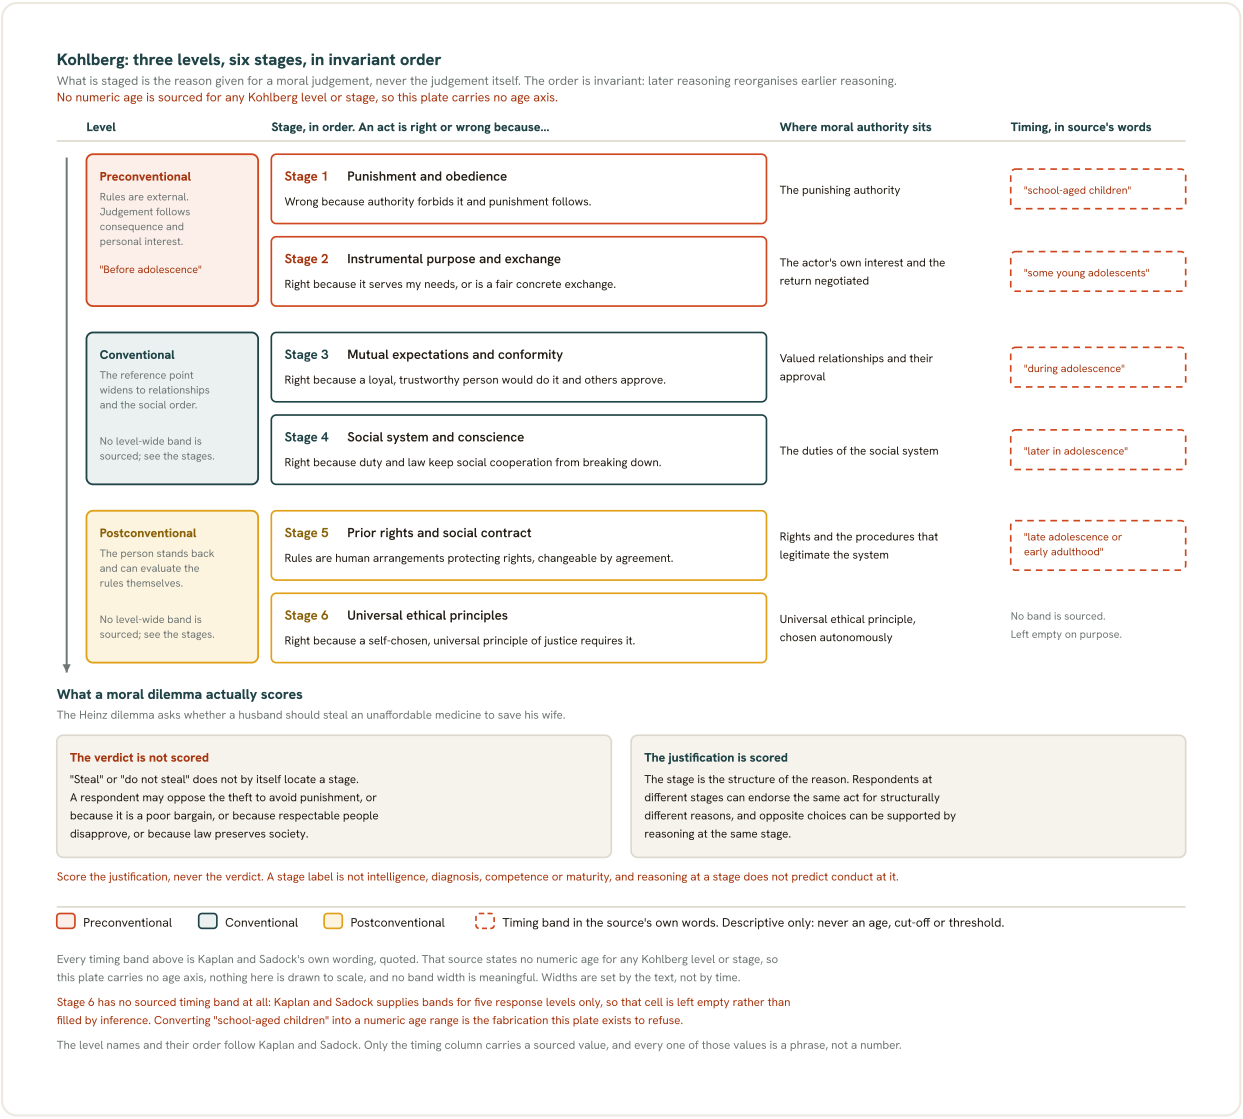

Fig 20.4 Kohlberg's three levels and six ordered stages, with what a moral dilemma scores. The timing column quotes Kaplan and Sadock's descriptive bands verbatim; that source gives no numeric age for any level or stage, so the plate has no age axis and nothing on it is drawn to scale. A level-wide band is sourced for the preconventional level only, and stage 6 has no band at all, so its cell is left empty rather than inferred.

4.1 Method and architecture: three levels, six ordered stages

A stage is a structure of reasoning, not a list of moral opinions. Kohlberg used hypothetical moral dilemmas, classically the Heinz dilemma, and questioned the respondent about the decision and its justification. In that dilemma, a person must consider whether a husband should steal an unaffordable medicine to save his wife. Saying "steal" or "do not steal" does not by itself locate a stage. A respondent might oppose theft because of punishment, because it is a poor bargain, because respectable people disapprove, because law preserves society, or because a law may be overridden by a more fundamental right. Conversely, respondents at different stages can endorse the same action for structurally different reasons.

3	6	2
LEVELS	ORDERED STAGES	STAGES PER LEVEL

The model is cognitive-developmental. Stages are proposed to occur in sequence, with later reasoning reorganising rather than merely adding to earlier reasoning. Movement depends on

cognitive development, perspective-taking and encounters with moral conflict. A person may show a dominant mode with adjacent-stage reasoning rather than perfectly pure performance in every situation. Developmental advance also does not guarantee moral conduct: behaviour is additionally shaped by emotion, impulse control, identification, attachment, reward, coercion, group norms and opportunity.

RULE **Score the justification, not the verdict.** Two people may make the same choice at different stages, and opposite choices may be supported by reasoning at the same stage.

4.2 Preconventional morality: consequences and personal interest

At the preconventional level, rules are experienced as external to the self. The child recognises authority and social rules, but moral judgement is organised around concrete consequences and personal advantage rather than around preserving a shared social system. Kaplan and Sadock describes this level as occurring **before adolescence**. This is a descriptive relationship, not a cutoff, expected range, or referral threshold.

Stage 1: punishment-and-obedience orientation. An act is wrong because authority prohibits it and punishment follows. Consequences are taken as evidence of wrongness, and the more severe the consequence, the worse the act may appear. Obedience is heteronomous: the rule comes from a powerful other, and the perspectives or intentions of those involved are poorly coordinated. Kaplan and Sadock associates this response level with **school-aged children**.

Stage 2: instrumental purpose, individualism and exchange. The person now recognises that different individuals have different interests. What is right serves one's needs and, where useful, the needs of others through a concrete exchange: "I will help you if you help me." Fairness is therefore understood as equal exchange or reciprocity, not yet as loyalty, social duty or impartial principle. Kaplan and Sadock notes this response level in **some young adolescents**. The phrase "some" matters: it must not be converted into a universal age norm.

4.3 Conventional morality: relationship approval and maintenance of society

At the conventional level, the reference point expands from the actor's immediate consequences to membership in relationships and society. The person values expectations, roles, rules and institutions because these sustain interpersonal trust and an ordered social world. "Conventional" here means conformity to a recognised social order, not shallow thinking.

Stage 3: mutual interpersonal expectations, relationships and conformity. The morally good person is kind, loyal, trustworthy and approved by significant others. Intentions become important, and the respondent can take the viewpoint of another person, but judgement remains tied to the expectations of close relationships and the wish to be seen as a "good" person. Kaplan and Sadock places this response level **during adolescence**.

Stage 4: social-system and conscience orientation. The frame widens from close relationships to society as an organised whole. Right conduct means performing one's duty, respecting legitimate authority and maintaining laws and institutions because social cooperation would otherwise break down. This is not simply fear of punishment: stage 1 obeys power to avoid

consequences, whereas stage 4 endorses law as necessary for the system. Kaplan and Sadock relates this response level to **later in adolescence**.

4.4 Postconventional morality: evaluating rules by principles

At the postconventional level, a person can stand back from a particular society's rules and ask whether they are justifiable. Laws remain important, but their legitimacy depends on values and principles that rational persons could endorse. The crucial move is from being governed by the social order to being able to evaluate it. Postconventional reasoning should not be confused with reflexive rebellion, personal preference, or disregard for law.

Stage 5: prior rights and social-contract orientation. Rules are understood as human arrangements designed to protect welfare, liberty and rights. Because arrangements are socially created, they may be changed by agreed procedures when they fail those purposes. Some values and rights retain priority even when a majority prefers otherwise. Kaplan and Sadock associates this response level with **late adolescence or early adulthood**; this wording is descriptive and does not imply that everyone reaches the stage.

Stage 6: universal ethical-principle orientation. Moral judgement is guided by self-chosen, generalisable principles of justice, equality and respect for human dignity. A valid principle applies consistently across persons, including oneself, and conscience follows the principle when ordinary law conflicts with it. Stage 6 differs from stage 5 in its source of obligation: stage 5 emphasises a fair social contract and basic rights, whereas stage 6 emphasises universal principles chosen through autonomous moral reasoning.

4.5 The sequence as a set of contrasts

The fastest way to retrieve the stages in an examination is to ask where moral authority sits. At stage 1 it sits with the punishing authority; at stage 2 with the individual's concrete interest and negotiated return; at stage 3 with valued relationships and approval; at stage 4 with the duties of the social system; at stage 5 with rights and procedures that legitimate the system; and at stage 6 with universal ethical principle. Three contrasts prevent most errors.

CONTRAST	DISTINCTION
Punishment versus law:	both may support obedience, but one avoids a consequence while the other preserves social order.
Approval versus contract:	one asks what a good person in the relationship would do, while the other asks what free and equal persons could justify.
Contract versus principle:	one revises law through shared procedures, while the other tests every law and procedure against a generalisable ethical commitment.

TRAP **Do not turn descriptive bands into numeric ages.** "School-aged children", "some young adolescents", "during adolescence", "later in adolescence", and "late adolescence or early adulthood" are Kaplan and Sadock's formulations. Kohlberg has no sourced numeric age row for the theory-alignment plate.

4.6 What the theory explains, and what it does not

Kohlberg explains the organisation of moral judgement. It does not provide a complete psychology of morality. Knowing what is right does not ensure doing it, and sophisticated reasoning can be used after the fact to rationalise conduct. Empathy, guilt, shame, temperament, attachment, modelling, cultural learning, power, material constraint and the immediate social context can all influence behaviour without being reducible to a reasoning stage. Nor should a stage label be mistaken for intelligence, diagnosis, legal competence, criminal responsibility or overall maturity.

The approach nevertheless made important contributions. It treated children as active constructors of moral meaning rather than passive recipients of rules; separated the structure of a reason from its surface content; and supplied a developmental account of perspective-taking, authority, reciprocity, obligation and justice. Its structured dilemmas also made moral reasoning open to systematic interview and longitudinal study.

4.7 Criticisms and later refinements

Justice is not the whole of morality. Carol Gilligan argued that an emphasis on rights, rules and abstract justice can undervalue an ethic of care centred on relationship, responsibility and response to need. The useful examination answer is not that one sex reasons by justice and another by care as a fixed biological divide. The stronger criticism is that the scoring framework privileged one moral voice and that care and justice may both be available across persons and contexts.

Culture shapes the meaning of mature reasoning. The proposed order has received support across settings, but the claim that abstract individual rights represent the highest endpoint can favour liberal, individualistic assumptions. Community, sacred obligation, family duty and relational responsibility may be morally elaborated rather than merely conventional. **Dilemma performance is also context-sensitive.** Hypothetical answers may not predict action under fear, loyalty, intoxication, peer pressure or personal loss; education and verbal ability influence how reasons are expressed; and the same person may reason differently across dilemmas. Finally, stage boundaries may be less discrete than a strict staircase suggests, with mixed and adjacent-stage responses occurring in practice.

4.8 Clinical use and relation to the other developmental theories

Use the framework to formulate reasoning, never to stamp a child with a stage. In a child or adolescent assessment, a clinician can ask how the patient understood a conflict involving rules, peers, harm or fairness, then explore intentions, consequences, perspective-taking and the perceived source of obligation. A shift from "I will be punished" to "people will be harmed" or "the rule protects everyone" adds clinically useful information about social cognition and judgement. Interpretation must remain contextual and should be integrated with cognitive ability, language, family values, school experience, neurodevelopment, affect regulation and actual behaviour. It is not a diagnostic test and should not be used alone for a forensic conclusion.

CLINICAL USE

After a recurrent rule-breaking episode, ask the patient to explain why the act was acceptable or unacceptable, what each person believed, and whether the rule would remain fair if roles were reversed. The purpose is to sample perspective-taking and the structure of moral reasoning, not to demand a socially approved answer. A rehearsed answer without corresponding conduct is still clinically informative: it shows the gap between moral cognition and moral action.

Use the accompanying theory-alignment plate as a map of different questions, not as proof that the theories describe the same process.

- Piaget, from the sensorimotor period onward, maps changes in cognitive structure.
- Erikson maps psychosocial stages and their central conflicts.
- Freud maps psychosexual stages.
- Mahler describes separation-individuation.
- Kohlberg maps moral reasoning.

Vygotsky should sit beside, not inside, that stage sequence: sociocultural mediation, private speech and the zone of proximal development are cross-cutting mechanisms, not age-bound stages. Kohlberg likewise appears on the plate only in Kaplan and Sadock's descriptive bands, never on an invented numeric age axis.

5 . Mahler separation-individuation theory

Margaret Mahler's separation-individuation theory is a psychoanalytic account of how the infant moves from an experienced psychological unity with the mother toward a stable sense of being a separate person who can remain emotionally connected to her. Its subject is the ***psychological birth*** of the individual, not biological birth and not the attainment of a motor milestone. **Two** developmental lines proceed together but are not identical: **separation** is the emergence from symbiotic fusion and the differentiation of self from object, while **individuation** is the acquisition of a distinctive identity, autonomous ego functions and an enduring inner sense of self.

Fig 20.5 Mahler's account of psychological birth. Separation and individuation proceed together through differentiation, practising and rapprochement toward a stable inner representation of the caregiver and a distinct sense of self.

How to use this page. Fix the distinction between separation and individuation, then learn the sequence: the historical precursor phases of normal autism and normal symbiosis, followed by differentiation or hatching, practising, rapprochement, and consolidation toward libidinal object constancy. For each phase, ask what changes in self-object boundaries, exploration, use of the caregiver and mental representation. Finally, retain the limits: this is an object-relations formulation, not a developmental screening schedule, and its age brackets must not be converted into referral thresholds.

Must memorise: separation means "I am not you"; individuation means "I am me"; their sequence is hatching, practising, rapprochement and consolidation toward object constancy.

MNEMONIC

"Hatching - practising - rapprochement - consolidation"

separation means "I am not you"; individuation means "I am me"; their sequence is hatching, practising, rapprochement and consolidation toward object constancy.

5.1 The organising model: psychological birth through two intertwined lines

The child becomes separate without becoming unrelated. Mahler's model belongs to object-relations theory, where an ***object*** is a significant person as experienced and mentally represented, not an inanimate thing. Development requires a gradual reorganisation of the infant-mother relationship. Perceptual differentiation, locomotion and autonomous ego capacities support separation; the consolidation of identity and internal representations supports individuation. The endpoint is therefore neither fusion nor detachment. It is the capacity to function as a distinct self while maintaining a dependable emotional bond with a whole caregiver.

Mahler developed the theory through observations of young children and their mothers. In the classical vocabulary, *mother* denotes the central maternal object. In contemporary clinical use, *primary caregiver* is often the more accurate functional term, while the original terminology should still be named in an examination answer. The theory focuses on intrapsychic organisation inferred from behaviour within a relationship; it does not claim that visible independence alone proves psychological individuation.

Source-reported theoretical timings, not normative cut-offs:

TIMING	STAGE	SOURCE
The first weeks of the infant's life	normal autistic phase	in Wolberg's *Technique of Psychotherapy*
Three to four weeks	normal symbiotic phase	as reported by Wolberg
About 4 or 5 months to 10 months	hatching phase	in Wolberg
Between 15 and 18 months	onset of rapprochement	in Wolberg
15-24 months	is the rapprochement phase	in *Cognitive Therapy of Personality Disorders*
Around 18 to 24 months of age	rapprochement crisis	in Wolberg
During the third year of life	libidinal object constancy	in Wolberg

The first weeks of the infant's life	About 4 or 5 months to 10 months	15-24 months	During the third year of life
NORMAL AUTISTIC PHASE	HATCHING PHASE	RAPPROCHEMENT PHASE	LIBIDINAL OBJECT CONSTANCY

These sources state theoretical ages without identifying them as medians, expected ranges, upper limits or red-flag thresholds. They must therefore be repeated only as source-reported stage

timings. Overlap or variation between texts is not evidence of abnormal development, and none of these values tells a clinician when to refer a child.

RULE **Mahler's ages locate concepts within a theory; they do not define developmental normality.** Use developmental surveillance and validated screening instruments to detect delay. Do not diagnose a failed phase, fixation or developmental disorder from a child's calendar age.

5.2 Precursor phases: normal autism and normal symbiosis

Mahler begins with states in which self and other are not yet represented as clearly separate. In the historical **normal autistic phase**, the infant was described as predominantly invested in physiological regulation and protected from external stimulation by a relatively closed psychological barrier. The term *autistic* here belongs to Mahler's early psychoanalytic vocabulary. It does not mean autism spectrum disorder, does not predict it and should never be entered into a modern case record as though it were a diagnosis.

In the **normal symbiotic phase**, the infant is increasingly responsive to the mothering environment but is theorised to experience infant and mother as a dual unity within a common boundary. Symbiosis in this model is an intrapsychic state of undifferentiation, not merely closeness, dependence or frequent physical contact. The caregiver regulates tension and supplies gratification, while repeated experiences begin to organise an expectation of relief and relationship. Normal symbiosis is a precursor to differentiation; persistent adult dependency cannot simply be labelled proof that the person is "stuck" in it.

5.3 Differentiation or hatching: the beginning of separation

Attention turns outward and the infant begins to inspect the boundary between familiar self-object unity and the wider world. The **differentiation subphase**, also called hatching, marks the proper beginning of separation-individuation. The metaphor is psychological, not anatomical. The infant becomes more alert to the environment, studies the mother's face and body, compares familiar and unfamiliar people, and begins to move physically away while checking back perceptually. These behaviours are read as signs of emerging differentiation rather than complete selfhood.

The clinical emphasis is on discrimination and boundary formation. Familiarity becomes more organised, the external world acquires greater salience and the mother is increasingly apprehended as a particular object rather than merely part of a need-satisfying unit. Yet separation remains supported by the caregiver's availability. Hatching is therefore not abrupt detachment. It is a gradual opening of a relationship in which difference can be noticed without the bond disappearing.

5.4 Practising: locomotion, exploration and the exhilaration of autonomy

New autonomous capacities widen the child's psychological and physical world. In the **practising subphase**, locomotion and other developing ego functions permit active exploration away from the caregiver. Mahler described an exuberant investment in the wider world, with the child appearing temporarily absorbed in newly acquired competence and relative independence.

The caregiver remains the secure emotional centre. The child returns for brief contact or emotional refuelling, then ventures outward again.

The high-yield paradox is that apparent independence still rests on dependable availability. Exploration does not prove that the object is no longer needed; it shows that connection can support movement away. Clinically, this helps the resident observe how autonomy and dependence coexist rather than forcing behaviour into either "independent" or "dependent". Motor progress may facilitate practising, but Mahler's phase is a relational and intrapsychic construct, not a motor-development category.

5.5 Rapprochement: separateness becomes emotionally costly

The child now recognises separateness more fully and seeks renewed emotional closeness without surrendering autonomy. In the **rapprochement subphase**, the earlier exhilaration of practising gives way to a sharper awareness that the caregiver is a separate person who cannot be controlled by omnipotent wish. The child brings discoveries back to share, follows the caregiver, demands participation and alternates between bids for help and assertions of independence. Mahler described this push-pull as **ambitendency**: a simultaneous wish to move away and to be close.

The rapprochement crisis is the intensification of that conflict. Dependence may feel necessary, while closeness may threaten the new autonomy. Frustration exposes the fact that the loved object also disappoints, so affectionate and angry experiences must increasingly be held together rather than kept apart. A sufficiently available caregiver neither abandons the child nor erases every frustration. She permits approach, tolerates rejection and survives ambivalence, helping the child discover that separateness need not mean loss.

5.6 Consolidation and libidinal object constancy

A stable inner representation permits connection across absence, frustration and mixed feeling. During consolidation, individuation advances and self-other boundaries become more durable. **Libidinal object constancy** means that a predominantly positive, emotionally invested representation of the caregiver can be maintained when she is absent, unavailable or temporarily experienced as frustrating. Love and anger can be directed toward the same whole person without that person having to become entirely good or entirely bad.

Object constancy depends on integrating affectively contrasting representations of self and object. It supports tolerance of delay, separation and ordinary ambivalence, while stabilising identity and relationships. It is an achievement with degrees, not an all-or-none certificate permanently acquired at a single moment. Stress can still strain the capacity to hold a complex view of self and others.

TRAP **Object constancy is not Piagetian object permanence.** Object permanence is the cognitive understanding that an object continues to exist when not perceived. Mahler's object constancy is affective and representational: the relationship to a whole loved person remains internally available across absence and frustration. Also, Mahler's "normal autistic phase" is not autism spectrum disorder.

5.7 Clinical formulation: useful relational questions, not developmental verdicts

Mahler gives the psychiatrist a vocabulary for recurrent tensions between closeness and autonomy. In assessment, ask:

- whether separation evokes abandonment;
- whether intimacy evokes engulfment;
- whether the patient alternates between clinging and withdrawal;
- whether disappointment rapidly converts an admired person into a hated one;
- whether an absent attachment figure can remain emotionally real.

Similar patterns may appear in relationships, the therapeutic frame, transference and countertransference.

The model has been influential in psychodynamic formulations of borderline personality organisation, particularly accounts of unstable self-image, splitting, fear of abandonment and rapprochement-like oscillation. The safe formulation is analogical and probabilistic: a present pattern resembles a conflict described by the theory. The unsafe formulation is causal and retrospective: the patient has a disorder because a named Mahler phase failed. Adult symptoms cannot reconstruct infancy with that certainty, and no single relational pattern is specific to one developmental history.

Its limitations are examinable. The earliest phases rely on inferences about infant subjectivity; later infant research challenges the idea of an originally closed or wholly undifferentiated infant; the word *autistic* is now misleading; and the original mother-infant dyad may understate fathers, grandparents, siblings, multiple caregivers, temperament and the wider social environment. The theory may also invite caregiver blame if used crudely. Its continuing value lies in organising clinical questions about boundaries, ambivalence and internal representations, not in serving as a literal developmental test.

5.8 Alignment with the major developmental theories

The companion theory-alignment map places the models on a shared age axis, but temporal overlap does not make their constructs interchangeable. Mahler explains separation-individuation and self-object differentiation. Piaget explains changing structures of thought from the sensorimotor stage onward. Erikson organises development through psychosocial stages such as trust versus mistrust and autonomy versus shame and doubt. Freud organises drive and conflict through the psychosexual stages. The map supplies the source-reported age bands; the text must not turn lateral alignment into theoretical equivalence.

Kohlberg describes moral development in the ordered levels preconventional, conventional and postconventional. Kaplan and Sadock relate these to descriptive bands such as before adolescence, during adolescence, later in adolescence, and late adolescence or early adulthood; no sourced numeric ages should be invented. Vygotsky is not a stage theorist. His zone of proximal development, scaffolding, private speech and socially mediated learning are mechanisms that

operate across development, so he belongs beside the age-aligned stage theories rather than inside the plate as a fabricated sequence.

Clinically, each theory asks a different question of the same presentation: Piaget asks how the child represents and reasons; Erikson asks what social conflict is being negotiated; Freud asks how drive and defence are organised; Kohlberg asks how a moral judgement is reasoned; Mahler asks how separateness and connection are managed; Vygotsky asks what learning becomes possible with guided participation. A strong examination answer preserves those levels instead of blending them into a single omnibus theory.

5.9 Nearby relational constructs: theory of mind, language and parenting

Theory of mind is the capacity to attribute mental states to oneself and others and to understand that another person's belief may differ from reality and from one's own belief. *Psychotherapy for Borderline Personality Disorders* reports that passing a false-belief task is expected at **four or five years**. This is not Mahler's object constancy: theory of mind concerns representing another mind, whereas object constancy concerns sustaining an affective representation of a whole attachment object.

The major language acquisition theories also answer a different question.

THEORY	EMPHASIS
Chomsky	emphasises an innate biological preparedness for language and rule formation.
Skinner	emphasises operant learning, reinforcement, shaping and imitation.
Vygotsky	emphasises social mediation, shared activity and the transformation of interpersonal speech into private speech and self-regulation.

Contemporary understanding is not served by making any one of these a subphase of separation-individuation. Language can express emerging self-other distinction, but language development and Mahler's relational sequence are not the same construct.

Baumrind parenting styles classify patterns of warmth and behavioural demand. The classic styles are authoritative, authoritarian and permissive; the later two-dimensional extension adds uninvolved or neglectful parenting. They describe caregiving climate rather than the child's intrapsychic phase. In a clinical interview they help characterise limits, responsiveness and autonomy support, but they neither diagnose a Mahlerian disturbance nor prove how the child experiences the caregiver.

5.10 Indian clinical use and examination reconstruction

INDIA

Mahler's source-reported timings are not Indian developmental norms, and no verified India-specific age adaptation of the theory is supplied here. In Indian families, caregiving may be distributed across parents, grandparents, siblings and other relatives; proximity and interdependence may be valued without implying failed individuation. Formulate the child's actual pattern of boundaries, exploration, availability and emotional representation within that family and culture. Do not mistake a Western ideal of early behavioural independence for psychological health, and do not use Mahler in place of Indian developmental screening or formal assessment.

How to write the long answer. Begin with psychological birth and define separation and individuation separately. Name the precursor phases, then describe hatching, practising, rapprochement and consolidation in order. Attach one organising idea to each: *differentiation, exploration, ambivalence, integration*. Distinguish object constancy from object permanence, give one psychodynamic formulation use, and close with the empirical, cultural and caregiver-blame limitations.

6 . Vygotsky sociocultural theory and zone of proximal development

Lev Vygotsky's sociocultural theory explains cognitive development as a socially mediated process. The child does not develop as an isolated thinker who later enters society. Learning begins in shared activity with more knowledgeable people, is organised by culturally supplied tools and signs, especially language, and is gradually transformed into the child's own psychological functioning. The best-known construct is the **zone of proximal development** (ZPD): the region between what a learner can accomplish independently and what the learner can accomplish through effective guidance or collaboration. The theory is developmental, but it is **not stage-based**. It supplies no Vygotskian sequence of age-linked stages.

How to use this page. Build the answer around one movement: **from shared regulation to self-regulation**. First define social mediation and internalisation, then define the ZPD by its **two** boundaries, explain contingent support and its withdrawal, and connect private speech with the development of self-guidance. End with educational and clinical use, followed by the limits of inferring learning potential from a brief interaction. Schunk's *Learning Theories: An Educational Perspective*, Berk's *Development Through the Lifespan* and Ciccarelli's account support the conceptual treatment; none supplies age stages for Vygotsky.

Must memorise: Development moves from the social plane to the psychological plane: what the learner first does with guidance is gradually internalised and done independently.

6.1 The sociocultural proposition: mind develops through mediated participation

Higher mental functions have social origins and are culturally organised. Vygotsky distinguished elementary capacities with a biological basis from **higher mental functions**, such as deliberate attention, strategic memory, planning and conceptual thought. Higher functions do

not simply unfold from maturation. They are reorganised through participation in culturally structured activity. A caregiver labels objects, directs attention, breaks a task into parts, models a strategy and helps the child remember what to do next. In time, the child takes over these regulatory operations.

This account is dialectical: the social world shapes the child, but the child is not passive. The learner acts, responds, selects tools, alters the interaction and gradually becomes a participant with greater responsibility. Development is therefore neither the direct transmission of adult knowledge nor solitary discovery alone. It is the transformation of activity conducted between people into activity organised within the person.

6.2 Cultural tools, signs and internalisation

Human beings change cognition by using culturally inherited means. **Mediation** occurs when action is organised through a tool or sign rather than by a direct stimulus-response link. Material tools change the external environment; psychological tools and signs change how attention, memory and problem-solving are organised. Language, writing, counting systems, diagrams, mnemonics, maps and culturally taught problem-solving routines are examples. Because cultures provide different tools and practices, the form and priorities of cognition cannot be understood apart from the learner's social setting.

Internalisation is not the copying of an external act into an unchanged inner space. It is a transformation. An instruction first spoken by another person may later be spoken by the child to guide action, then become abbreviated as inner speech. The original interaction is reconstructed as a means of self-regulation. The common summary is that a higher function appears first on the *interpsychological* plane, between people, and later on the *intrapsychological* plane, within the person.

RULE **Social origin does not mean passive absorption.** Internalisation is an active reorganisation of shared activity into self-directed psychological functioning.

6.3 The zone of proximal development: actual and potential performance

The ZPD is defined by the difference that appropriate assistance makes. The learner's lower boundary is the level of **independent performance**, often called the actual developmental level. The upper boundary is the level of **assisted performance** that becomes possible with adult guidance or collaboration with a more capable peer. The ZPD is the region between these boundaries. It is not everything a child cannot do, and it is not a fixed store of hidden intelligence. A task lies beyond the useful zone when even well-matched assistance does not make performance possible.

Three

INSTRUCTIONAL LOCATIONS

INSTRUCTIONAL LOCATION	DESCRIPTION
Below the ZPD	already mastered independently, so extensive help adds little developmental value.
Within the ZPD	not yet independent, but achievable with responsive guidance, making it the principal teaching zone.
Beyond the ZPD	not achievable even with suitable support at that point, so prompting alone becomes unproductive.

The ZPD shifts attention from a static question, *What can this learner do now?*, to a developmental question, *What can this learner do with help, and how much help is required?* Two learners with the same unaided score may differ in responsiveness to modelling, prompts, feedback and transfer. Conversely, assisted success must not be counted as independent mastery. The quality of the support, the learner's familiarity with the language and task, motivation, anxiety, fatigue and the relationship with the examiner can all affect the observed zone.

6.4 Scaffolding: contingent support, fading and transfer of responsibility

Scaffolding is the instructional process most commonly used to operationalise the ZPD. The more knowledgeable participant recruits attention, simplifies the task, models a step, asks a leading question, supplies a cue, highlights an error or maintains motivation. Support is *contingent*: it increases when the learner is stuck and decreases when competence appears. The aim is not permanent assistance but a transfer of responsibility to the learner through fading.

The term *scaffolding* was introduced later by Wood, Bruner and Ross rather than coined by Vygotsky. It is compatible with his account, but the **two** terms are not synonyms. The ZPD describes a relation between present independent performance and assisted possibility; scaffolding describes one way of supporting activity within that relation. Good scaffolding is calibrated and temporary. Giving the answer, overprompting every step or withdrawing help abruptly can all obscure what the learner understands.

TRAP **ZPD is not the task itself, and scaffolding is not unlimited help.** The zone is defined by the learner's change in performance under appropriate assistance. Support must be adjusted and then faded until the learner regulates the task independently.

6.5 Language, private speech and the growth of self-regulation

Speech changes from a means of coordinating with others into a means of coordinating oneself. In shared activity, **social speech** allows a caregiver and child to direct attention, label a goal and organise action. The child later uses **private speech**, audible speech addressed to the self, to plan, inhibit an impulsive response, sequence steps and correct errors. With increasing internalisation, this becomes condensed **inner speech**. Inner speech is not merely ordinary conversation moved silently into the head; it becomes abbreviated and shaped for self-guidance.

Private speech is therefore functional rather than simply immature. It is especially likely when a task is difficult, novel or requires control, and overt self-talk may reappear when an older learner is challenged. The classic contrast is with Piaget, who treated egocentric speech mainly as

evidence that the young child had not yet fully accommodated the listener's perspective. Vygotsky instead emphasised its transition from interpersonal communication to intrapersonal regulation. The views address different features of children's self-directed talk and should not be reduced to a slogan that one theorist found it useless and the other useful.

6.6 Learning leads development: teaching within the emerging competence

Vygotsky rejected teaching that merely waits for fully formed capacities. Instruction is most developmentally productive when it engages functions that are emerging and supports performance within the ZPD. In this sense, appropriately organised learning leads development: guided participation creates opportunities for the learner to practise forms of attention, reasoning and self-regulation that later become independent. This does not mean that any teaching can override readiness, neurodevelopmental constraints or prior knowledge. The learner must be able to participate meaningfully in the supported activity.

Applications include modelling with gradual withdrawal, guided questioning, cooperative learning, peer tutoring, reciprocal teaching, cognitive apprenticeship and worked examples that become progressively incomplete. A more capable peer may support learning, but peer status alone does not guarantee effective mediation. The peer must understand the task, communicate accessibly, notice the learner's response and adjust help. Collaboration is valuable when responsibility and explanation are shared, not when one student completes the work for another.

6.7 Dynamic assessment and clinical use

Dynamic assessment extends the ZPD into assessment by embedding teaching within the evaluation. A test-teach-retest format, graduated prompts or mediated learning can show which cues unlock performance, how rapidly a strategy is acquired, whether improvement transfers to a related task and how much assistance remains necessary. This complements a static score by sampling learning processes and modifiability. It does not make standardised assessment redundant, and assisted performance should be reported separately from unaided performance.

> **CLINICAL USE**
>
> When a child cannot organise a multistep task, first observe independent performance. Then offer the least intrusive useful support, such as restating the goal, modelling the first step or giving a visual sequence, and record the response. Improvement with modest, transferable support suggests an accessible learning pathway; persistent difficulty despite well-matched help suggests the need to examine language comprehension, attention, memory, intellectual functioning, anxiety, sensory factors and the suitability of the task. This is formulation evidence, not a diagnosis.

In psychiatry, the same logic can guide cognitive remediation, executive-function support, psychoeducation and rehabilitation. The clinician identifies what the patient can manage alone, co-constructs the next step and withdraws prompts as self-management improves. The goal is agency, not dependence on the therapist. A person's need for scaffolding may vary across tasks and states, so the ZPD should not be treated as a single stable trait or converted into a global intelligence label.

6.8 Alignment with stage theories: a cross-cutting mechanism, not another row

The accompanying theory-alignment plate places different developmental questions beside one another. Piaget describes changes in cognitive structure from the sensorimotor period onward. Erikson organises development through psychosocial stages and their central conflicts. Freud proposes psychosexual stages organised around drive, bodily focus and conflict. Kohlberg describes ordered forms of moral development, but his sourced age relationships are descriptive bands rather than numeric ranges. Mahler describes separation-individuation and the development of psychological separateness in relationship.

Vygotsky differs structurally from all five: sociocultural theory and the zone of proximal development specify mechanisms through which learning and self-regulation can occur across development. There are no Vygotskian stages to align by age. The plate should therefore show Vygotsky beside the stage sequences as a cross-cutting mechanism, never as an invented age row. Temporal overlap between theories also does not make their constructs equivalent: cognitive structure, psychosocial conflict, psychosexual organisation, moral reasoning, separation and supported learning answer different questions.

6.9 Culture, Indian clinical interpretation and limitations

Culture is constitutive in the theory, not decorative context added after cognition develops. Languages, scripts, number systems, schooling practices, work routines, narratives and patterns of adult-child participation influence which skills are practised and how they are organised. This is a major strength of the framework. It also creates a methodological challenge: performance in an unfamiliar testing interaction may underestimate competence acquired through everyday participation, while familiarity with school-like dialogue may advantage another learner.

> **INDIA**
>
> In Indian practice, mediation may be distributed across parents, grandparents, siblings, teachers and peers, and learning may occur through observation, participation, recitation, demonstration or direct questioning. These forms should be described rather than ranked against a single classroom ideal. Language of testing matters in a multilingual child, as does familiarity with the examiner's style. No verified India-specific numeric ZPD norm or Vygotskian age-stage adaptation is supplied here, and none should be invented. The absence of an age table is expected because the ZPD is relational and task-specific, not an age stage.

The principal criticisms are equally examinable.

- The theory gives powerful concepts but less precise specification of how broad cultural processes produce particular individual cognitive changes.
- The boundaries of a ZPD can be difficult to measure reliably because assistance is interactive and examiner-dependent.
- A more capable partner may transmit error, prejudice or conformity as well as skill.
- Social mediation can be overstated at the expense of biological maturation, temperament, spontaneous exploration and individual construction.

- Successful performance with help does not prove durable learning unless support can be faded and the strategy transfers beyond the teaching episode.

6.10 Examination reconstruction

Long-answer sequence. Define sociocultural theory, state the social origin of higher mental functions, explain cultural tools and internalisation, define both boundaries of the ZPD, distinguish the ZPD from scaffolding, trace social speech to private and inner speech, then add dynamic assessment, one clinical use and the principal criticisms. Close by stating that Vygotsky proposed no age-linked stages.

MNEMONIC

Social activity - mediation - internalisation - ZPD - contingent support - fading - self-regulation.

It traces the movement from shared regulation to self-regulation. If that chain is intact, the rest of the answer can be rebuilt rather than recited.

7 . Bowlby and Ainsworth attachment theory and Strange Situation

Attachment is an enduring, selective emotional bond in which a child seeks proximity to a familiar caregiver, especially when frightened, tired, ill or uncertain. John Bowlby supplied the evolutionary and developmental theory; Mary Ainsworth converted that theory into naturalistic observation and a standardised laboratory assessment, the Strange Situation. The central idea is functional rather than sentimental: the caregiver becomes a **safe haven** under threat and a **secure base** from which the child can explore. The examiner usually wants **three** distinctions. Attachment is not simply feeding or dependency, an attachment pattern is not a fixed personality trait, and insecure attachment is not in itself a psychiatric disorder.

How to use this page. First learn Bowlby's attachment behavioural system and internal working model. Then learn why Ainsworth treated exploration, separation and reunion as one organised system. Finally, identify the **four** patterns from reunion behaviour: secure, avoidant, ambivalent or resistant, and disorganised. The final section connects attachment with normal adolescent development, because adolescence reorganises rather than abolishes the secure-base relationship.

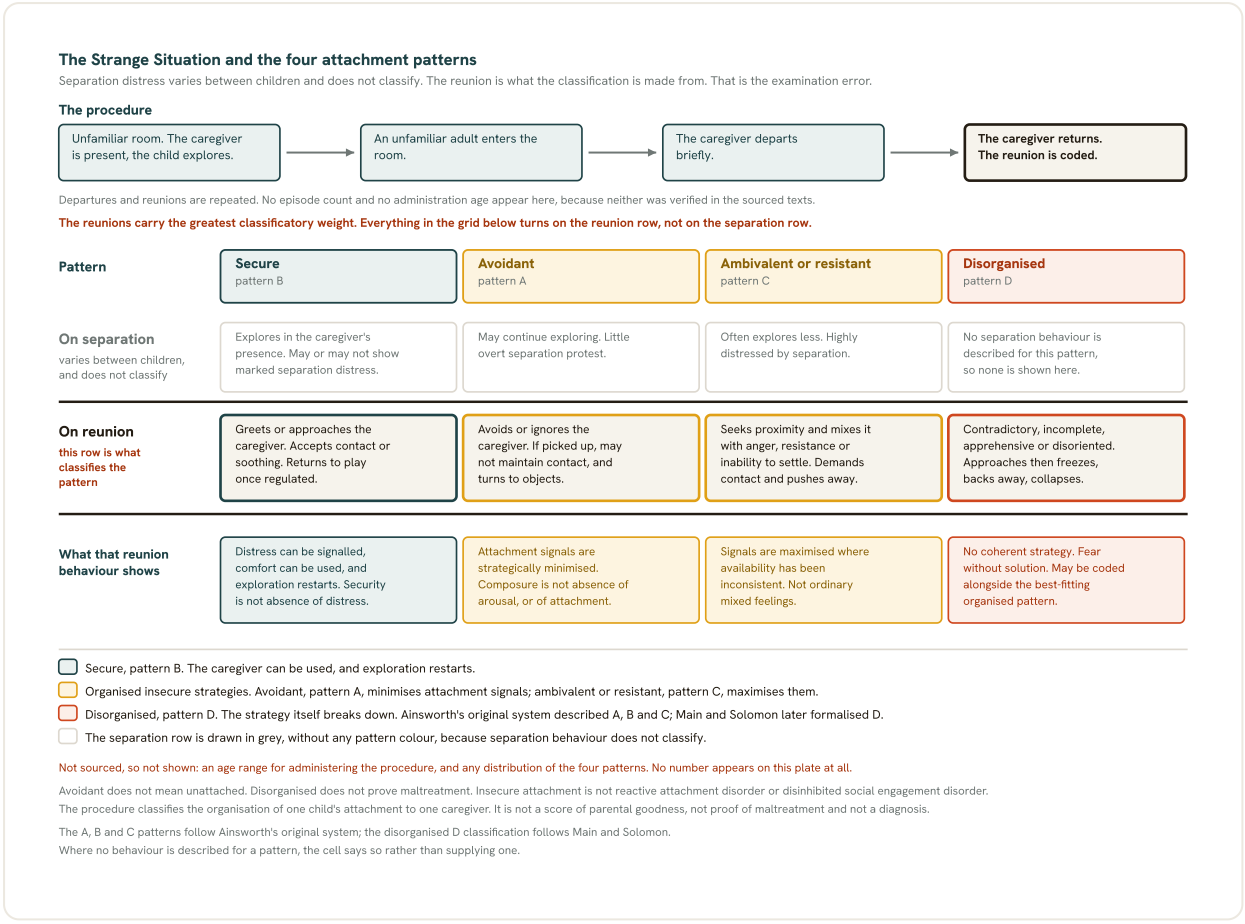

Fig 20.6 The Strange Situation and the four attachment patterns, keyed to behaviour on separation and on reunion. The separation row is drawn grey and undifferentiated because separation distress varies and does not classify; the reunion row carries the classification. The organised A, B and C patterns follow Ainsworth's original system, the disorganised D classification follows Main and Solomon. No age, episode count or pattern distribution appears, because none was verified in the sourced texts.

7.1 Bowlby: attachment as an evolved behavioural system

Proximity to a protective caregiver is the set goal. Bowlby rejected the drive-reduction claim that the infant becomes attached merely because the caregiver supplies food. He drew on psychoanalysis, ethology, control-systems thinking and observations of separation to propose an innate **attachment behavioural system**. Signals such as crying, smiling, calling, clinging and following increase caregiver proximity. The system is activated by threat, pain, fatigue, unfamiliarity or separation; it is relatively quiet when the child feels safe, allowing exploration and play. Attachment and exploration are therefore complementary systems. A securely based child is not continuously close to the caregiver. The child moves away to explore and returns when safety must be restored.

Bowlby's term monotropy described a tendency for one attachment figure to acquire special importance, not a biological rule that a child can form only one bond. Children can develop a hierarchy of attachments to several consistent caregivers. What matters clinically is not whether care matches a narrow family form, but whether available caregivers are familiar, responsive and sufficiently predictable. Bowlby's early writing on maternal deprivation was historically influential, but a modern reading separates the effects of prolonged loss, disrupted continuity,

insensitive care and the wider adversity that often accompanies them. The theory predicts risk, not destiny.

RULE **Attachment is a safety-regulation system, not a measure of how much a child loves a parent.** Read proximity-seeking, exploration and reunion as organised behaviour serving protection.

7.2 Internal working models and developmental organisation

Repeated interactions become expectations about self, others and help. Through recurrent caregiver responses, the child constructs **internal working models**: expectations about whether distress will be noticed, whether another person will be available, and whether the self is worthy and effective in eliciting care. These models guide attention, affect regulation, memory, help-seeking and later relationships. A history of responsive care favours open signalling and confidence in comfort; recurrent rejection may favour suppression of attachment signals; inconsistent response may amplify them. These are adaptive strategies in a particular relationship, not conscious decisions and not immutable templates.

Bowlby's developmental account is commonly organised as a phase sequence, and the qualitative progression runs as follows:

PHASE	QUALITATIVE PROGRESSION
Pre-attachment	broadly directed social signals.
Attachment-in-the-making	preference for familiar caregivers.
Clear-cut attachment	active proximity regulation.
Goal-corrected partnership	an increasing ability to represent the caregiver's goals and negotiate separation.

Working models are carried forward through continuity of expectations and relationships, but they remain open to revision through later caregiving, reflective capacity, psychotherapy and corrective relationships. Stability is therefore probabilistic, with both continuity and change expected.

7.3 Ainsworth: sensitivity, secure base and observational method

Ainsworth made caregiver-child organisation observable. Her naturalistic work in Uganda and later longitudinal observations in Baltimore refined Bowlby's theory. She described the infant's use of the caregiver as a secure base and emphasised **caregiver sensitivity**: noticing the child's signals, interpreting them accurately, and responding promptly and appropriately. Sensitivity is associated with security, but neither one interaction nor one caregiver characteristic mechanically produces a classification. Child temperament, caregiver state, cumulative experience, culture and the immediate context all contribute to observed behaviour.

Ainsworth's major methodological advance was to judge the organisation of behaviour rather than count isolated acts. Crying alone does not define insecurity, and a child who does not cry is not automatically secure. The question is whether the child can use the caregiver to regulate arousal and then resume exploration. This shift from single behaviours to the pattern linking

separation, proximity-seeking, contact, soothing and renewed play is the conceptual bridge to the Strange Situation.

7.4 Strange Situation: procedure, observations and scoring logic

A standardised, progressively stressful observation of attachment and exploration. The **Strange Situation Procedure** places a young child and caregiver in an unfamiliar room, introduces an unfamiliar adult, and includes brief caregiver departures and reunions. These manipulations activate the attachment system while leaving opportunities for play. Observers code exploration, distress on separation, response to the unfamiliar adult, proximity-seeking, contact maintenance, resistance, avoidance and the child's capacity to settle. The reunions carry the greatest classificatory weight because they show what the child does when the attachment figure becomes available after stress.

The procedure does not provide a global score of parental goodness, prove maltreatment, measure the total strength of the bond or diagnose a disorder. It samples behaviour in a structured context and classifies the organisation of one child's attachment to one caregiver. The original Ainsworth system described the organised A, B and C patterns. Mary Main and Judith Solomon later formalised the disorganised or D classification for behaviour that lacks a coherent approach to the attachment dilemma.

Must memorise: In the Strange Situation, reunion behaviour is decisive: secure children seek and use comfort, avoidant children minimise contact, resistant or ambivalent children seek yet resist it, and disorganised children show no coherent strategy.

MNEMONIC

"Seek, minimise, seek yet resist, no coherent strategy"

In the Strange Situation, reunion behaviour is decisive: secure children seek and use comfort, avoidant children minimise contact, resistant or ambivalent children seek yet resist it, and disorganised children show no coherent strategy.

7.5 Secure and avoidant attachment patterns

Secure, pattern B: distress can be signalled, comfort can be used, exploration can restart. A **secure** child generally explores in the caregiver's presence, may or may not show marked separation distress, greets or approaches the caregiver on reunion, accepts contact or soothing, and returns to play once regulated. Security is therefore not absence of distress. It is the flexible and effective use of the caregiver when distressed. The associated caregiving history is commonly sensitive, available and reasonably predictable, but the classification remains descriptive and probabilistic rather than a retrospective proof of caregiving quality.

Avoidant, pattern A: attachment signals are minimised. An **avoidant** child may continue exploring, show little overt separation protest, and avoid or ignore the caregiver on reunion. If picked up, the child may not actively maintain contact and may turn attention toward objects. The crucial interpretation is strategic minimisation of visible attachment behaviour in that

relationship, often associated with expected rejection or discomfort around bids for closeness. Apparent composure must not be equated with absence of arousal, absence of attachment or superior independence.

7.6 Resistant or ambivalent and disorganised attachment patterns

Resistant or ambivalent, pattern C: attachment signals are intensified but do not readily achieve settling. The **ambivalent** or resistant child often explores less, becomes highly distressed by separation, and on reunion combines proximity-seeking with anger, resistance or inability to settle. The child may demand contact and simultaneously push away, arch or remain preoccupied with the caregiver. This pattern is understood as maximising attachment signals when caregiver availability has been experienced as inconsistent. The word ambivalent refers to the observed mixture of approach and resistance, not to ordinary mixed feelings.

Disorganised, pattern D: the attachment strategy breaks down. A **disorganised** child shows contradictory, incomplete, apprehensive or markedly disoriented behaviour in the caregiver's presence, such as approaching and then freezing, backing away, collapsing, or displaying incompatible sequences without a stable strategy. The caregiver may be simultaneously the expected source of safety and a source of alarm, creating fear without solution. Disorganisation is associated with frightening or frightened caregiving, unresolved caregiver trauma, maltreatment and severe family stress, but it is not specific to any one cause. It may be coded alongside the best-fitting organised pattern and must never be treated as proof that abuse occurred.

TRAP **Do not convert attachment classifications into diagnoses.** Avoidant does not mean unattached, disorganised does not prove maltreatment, and insecure attachment is not synonymous with reactive attachment disorder or disinhibited social engagement disorder. RAD and DSED are separate clinical disorders linked to a history of severely insufficient care, and they are developed in the Child behavioural, emotional and other disorders notes.

7.7 Interpretation, cultural caution and clinical use

Classify the relationship in context, not the child's essence. Attachment security may differ across caregivers because each relationship has a different history. Classifications show moderate continuity at group level when care and context remain stable, but individual change is possible. Temperament can affect the intensity and style of distress without by itself determining security. Cultural practices also shape baseline separation experience, proximity, stranger familiarity and the social meaning of independence. Cross-cultural differences in pattern distribution therefore require ecological interpretation rather than a hierarchy of cultures.

Clinically, attachment theory helps formulate emotion regulation, help-seeking, interpersonal expectations and the meaning of separation. It does not justify diagnosing an attachment style from an adult's brief self-report, reading childhood causation directly from a current relationship, or blaming one caregiver. Adult attachment interviews and romantic-attachment questionnaires examine related but non-identical constructs and are not interchangeable with the Strange Situation. In a psychiatric assessment, ask:

- Who actually provided care.

- How the child sought comfort.
- How caregivers responded.
- Whether separations or changes in placement occurred.
- How the relationship functions now.

Use these observations to build a developmental formulation, not a label masquerading as explanation.

7.8 Attachment in adolescence: the secure base at a distance

Adolescence changes the regulation of closeness; it does not end attachment. In normal adolescent development, the secure-base function becomes less dependent on immediate physical proximity and more dependent on the expectation that support is available. Autonomy and attachment are not opposites. Security permits exploration of education, peers, values and intimate relationships, while caregivers remain a refuge under significant stress. Peers and romantic partners acquire attachment functions, but this redistribution is gradual and relationship-specific.

EXAM DISTINCTIONS	REUNION PATTERNS

8 . Temperament and goodness of fit (Thomas and Chess)

Temperament is the characteristic style with which a child responds to the world: the tempo, intensity, regularity and flexibility of behaviour rather than its particular content. Thomas and Chess captured the distinction neatly by asking *how* a child behaves, not *what* the child does or *why* the child does it. Temperament appears early, has a constitutional contribution and shows some continuity, but it is neither an immutable biological destiny nor a diagnosis. Its expression changes with development, relationships, learning, culture and context.

How to use this page. First learn the **nine dimensions**, then the **three types** derived from recurring combinations of those dimensions. Finally, understand **goodness of fit**, because that is the clinically important part of Thomas and Chess: adaptation depends not on a supposedly good or bad child, but on the match between the child's temperament and the demands, expectations and supports of the environment. In a theory answer, define temperament, list the nine dimensions, describe the three types with their classic proportions, explain goodness of fit and finish with clinical application and limitations.

> **The must-memorise line:** Thomas and Chess described nine dimensions and three temperamental constellations, but outcome depends chiefly on goodness of fit between the child and the environment.

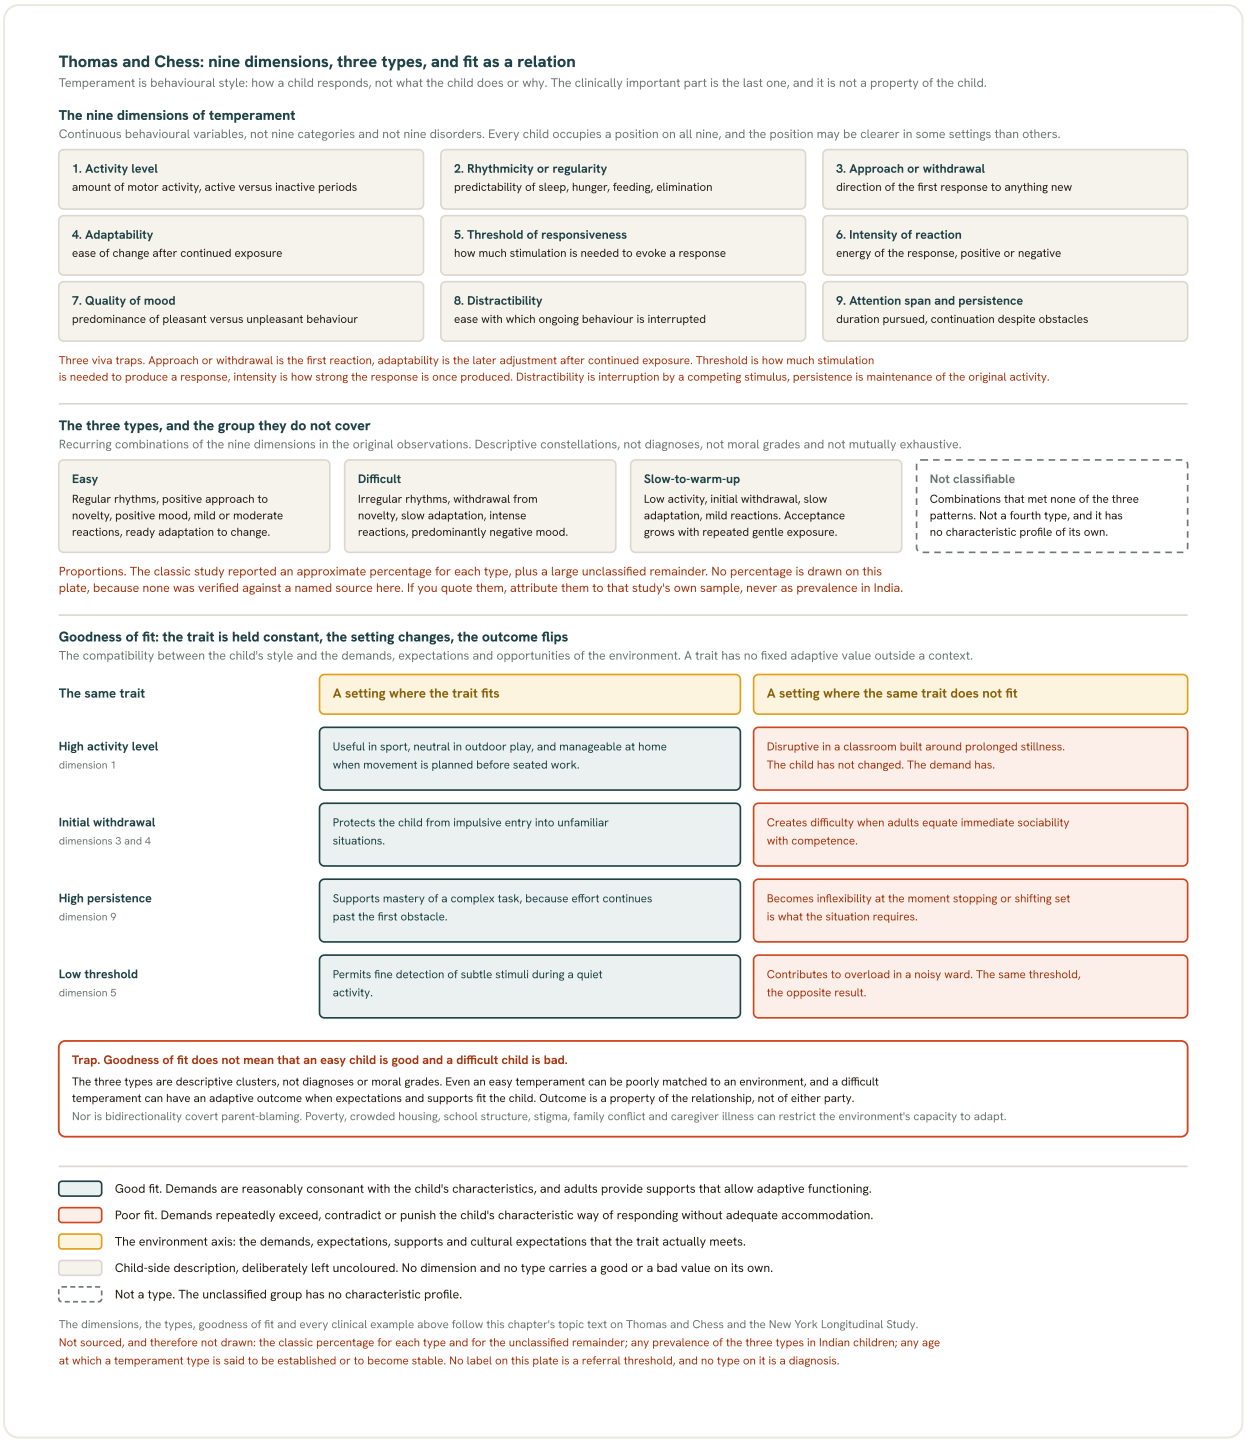

Fig 20.7 Thomas and Chess drawn as an interaction. The nine dimensions and the three types are the child side and are left uncoloured, because no dimension and no type carries a value on its own; a fourth box marks the group the three types did not cover, which is not a fourth type. Colour appears only in the fit table, where one trait is held constant and meets two settings, and the outcome reverses without the child changing. Content follows this chapter's topic text on Thomas and Chess and the New York Longitudinal Study. The classic proportions for each type are named on the plate but not drawn, because no percentage for them was verified against a named source here.

8.1 Thomas and Chess: the interactional view of temperament

Temperament is behavioural style, and development is transactional. In the New York Longitudinal Study, Alexander Thomas, Stella Chess and colleagues followed children and their families to examine early individual differences and later adjustment. Their work challenged explanations that attributed children's behavioural problems either entirely to innate defect or

entirely to parental handling. Children differ from the outset in how readily they become aroused, approach novelty, adapt to change, sustain activity and express mood. These differences alter how caregivers respond; caregiver responses then shape how the child's style is expressed and regulated. Child and environment therefore influence one another over time.

This is a **transactional model**, not a one-way causal model. A highly active child may invite more prohibition from an exhausted caregiver, while the resulting conflict may further amplify restless behaviour. The same child in a setting with safe movement, brief instructions and predictable transitions may function well. Conversely, an initially easy interaction can deteriorate when environmental demands change. Temperament contributes to the probability and form of an interaction; it does not independently dictate psychopathology.

RULE **Describe the child, the environment and the match.** A Thomas-and-Chess formulation is incomplete if it lists traits but does not show how environmental demands, caregiver responses and cultural expectations convert those traits into adaptation or difficulty.

8.2 The nine dimensions of temperament

The nine dimensions are continuous behavioural variables, not nine separate disorders. Each child occupies a position on every dimension, and the position may be more evident in some settings than in others. The examiner usually expects the complete list with a one-line meaning:

DIMENSION	MEANING
Activity level	the amount of motor activity and the relative proportion of active to inactive periods. Ask how much the child moves during play, meals, travel, learning and sleep-related routines.
Rhythmicity or regularity	the predictability of biological functions and routines, including sleep, hunger, feeding and elimination.
Approach or withdrawal	the direction of the initial response to a new person, place, food, activity or other stimulus. Approach means initial acceptance or engagement; withdrawal means initial hesitation, avoidance or distress.
Adaptability	the ease and speed with which behaviour changes after continued exposure to novelty or altered circumstances. It is distinct from the first response: a child may initially withdraw yet adapt well after familiarisation.
Threshold of responsiveness	the intensity of stimulation required to evoke a response. A low threshold means that weak light, sound, texture, temperature or social stimulation is sufficient; a high threshold means that stronger stimulation is needed.
Intensity of reaction	the energy level of the response, whether positive or negative. It concerns how strongly emotion or behaviour is expressed, not which emotion is expressed.
Quality of mood	the relative predominance of pleasant, friendly and joyful behaviour versus unpleasant, distressed or unfriendly behaviour.
Distractibility	the ease with which an ongoing behaviour is interrupted or altered by extraneous stimulation. It is not synonymous with a disorder of attention.
Attention span and persistence	the duration for which an activity is pursued and the tendency to continue despite obstacles. Attention span concerns sustained engagement; persistence concerns continuation when continuation becomes difficult.

Three distinctions prevent common viva errors. **Approach-withdrawal** is the initial reaction, whereas **adaptability** is the later adjustment. **Threshold** is the amount of stimulation needed to produce a response, whereas **intensity** is the strength of the response once produced. **Distractibility** is interruption by competing stimuli, whereas **attention span and persistence** describe maintenance of the original activity.

8.3 The three types: easy, difficult and slow-to-warm-up

The three types are clusters of dimensions found repeatedly in the original observations. They are descriptive constellations, not mutually exhaustive categories. A child's profile may resemble one constellation, contain features of several, or fit none. The labels are historically important and highly examinable, but the word *difficult* must be handled carefully because it describes a pattern of interactional challenge rather than a defective child.

TEMPERAMENTAL CONSTELLATION	CHARACTERISTIC PATTERN	LIKELY INTERACTIONAL ISSUE
Easy temperament	Regular biological rhythms, positive approach to novelty, relatively positive mood, mild or moderate reactions and ready adaptation to change	Usually elicits confident and rewarding caregiving, but genuine distress may be overlooked because the child is usually manageable
Difficult temperament	Irregular rhythms, withdrawal from novelty, slow adaptation, intense reactions and predominantly negative mood	May evoke coercion, criticism or inconsistent responses, producing escalating conflict when expectations are rigid
Slow-to-warm-up temperament	Low activity, initial withdrawal, slow adaptation and relatively mild reactions; acceptance increases gradually with repeated non-threatening exposure	May be misread as stubborn, uninterested or incapable if adults demand rapid participation

9	40%	10%	15%
DIMENSIONS IN THE THOMAS AND CHESS FRAMEWORK	APPROXIMATELY EASY IN THE CLASSIC CLASSIFICATION	APPROXIMATELY DIFFICULT IN THE CLASSIC CLASSIFICATION	APPROXIMATELY SLOW-TO-WARM-UP IN THE CLASSIC CLASSIFICATION

The proportions belong to the classic study classification and should not be presented as universal prevalence estimates for contemporary Indian children. Their examination value lies in showing that the three types never covered the entire population. The unclassified group is not a fourth type. In the classic study classification, **35%** were approximately mixed or not classifiable into the three types; their combinations did not meet one of the three characteristic patterns.

8.4 Goodness of fit: the central clinical proposition

Goodness of fit is the compatibility between the child's temperamental capacities and style, and the demands, expectations and opportunities of the environment. A good fit occurs when environmental demands are reasonably consonant with the child's characteristics and when adults provide supports that allow adaptive functioning. A poor fit occurs when demands repeatedly exceed, contradict or punish the child's characteristic way of responding without adequate accommodation or skill-building. The outcome is a property of the relationship between child and context, not a moral property located inside either one.

Consider high activity. It may be disruptive in a classroom built around prolonged stillness, useful in sport, neutral during outdoor play and manageable at home when movement is planned before seated work. Initial withdrawal may protect a child from impulsive entry into unfamiliar

situations, yet create difficulty when adults equate immediate sociability with competence. High persistence may support mastery of a complex task but become inflexibility when stopping or shifting is required. A low sensory threshold may contribute to overload in a noisy ward yet permit fine detection of subtle stimuli in a quiet activity. The trait has no fixed adaptive value outside a context.

Goodness of fit also includes culture. Families and schools differ in the value placed on quietness, assertiveness, emotional expressiveness, regularity, rapid sociability and obedience. A style praised in one setting may be discouraged in another. Cultural formulation does not mean accepting severe impairment or harmful caregiving. It means identifying whose expectation is being used, what the setting actually requires and whether that requirement can be modified without compromising the child's development or safety.

TRAP **Goodness of fit does not mean that an easy child is good and a difficult child is bad.** The three types are descriptive clusters, not diagnoses or moral grades. Even an easy temperament can be poorly matched to an environment, and a difficult temperament can have an adaptive outcome when expectations and supports fit the child.

8.5 From temperament to outcome: risk, protection and bidirectional effects

Temperament affects outcome through repeated transactions rather than direct determinism. A temperamental feature can influence exposure to situations, the responses elicited from other people, the child's interpretation of those responses and opportunities to practise regulation. When a mismatch is chronic, child and adult may enter a self-reinforcing sequence. Intense protest evokes harsh control; harsh control increases arousal and protest; both participants then anticipate conflict. When fit improves, the sequence can reverse: predictable preparation reduces arousal, calmer participation evokes more supportive responses, and successful experiences expand the child's tolerance.

Temperament can therefore function as a risk factor, a protective factor or a modifier of how other risks are expressed. It may influence the form of a symptom without being its cause. Inhibited approach can resemble anxiety, high activity can resemble hyperactivity, negative mood can resemble depression, irregularity can complicate sleep and feeding, and low persistence can look like defiance or inattention. The resident must establish pervasiveness, developmental change, subjective distress, functional impairment and the full syndrome before moving from style to disorder.

Parent and child effects are bidirectional, but bidirectionality must not become covert parent-blaming. Caregivers bring their own temperament, health, stress, beliefs, resources and expectations. A mismatch may occur between a highly intense child and a highly intense caregiver, or between an active child and a caregiver whose circumstances allow little safe movement. Poverty, crowded housing, school structure, stigma, family conflict and caregiver illness can restrict the environment's capacity to adapt even when the caregiver understands the child well.

8.6 Clinical assessment of temperament and fit

Assess a pattern across time and settings, not a single performance in the clinic. Begin with concrete examples rather than labels. Instead of asking whether the child is difficult, ask what happens with an unfamiliar person, an unexpected change, waiting, loud sound, a missed meal, a challenging task or a transition away from preferred play. Establish the trigger, initial response, intensity, duration, adaptability after continued exposure, recovery and effect on function. Map the answers onto the nine dimensions only after hearing the behaviour.

Take accounts from the child where developmentally appropriate, caregivers and teachers, because temperament is expressed differently across contexts and each observer has a relationship-specific view. Direct observation should sample free activity, structured demands, novelty, transition, frustration and recovery. The clinic itself is an unfamiliar and stimulating environment, so withdrawal, silence or high activity there cannot be assumed to represent the child's usual style. Look for both stable tendencies and situational exceptions; exceptions reveal environments in which fit is already better.

A useful formulation has four parts:

1. **Child profile:** identify the prominent dimensions and strengths using neutral behavioural language.
2. **Environmental profile:** identify family, school and cultural demands, available supports and the temperaments of important caregivers.
3. **Fit and transaction:** specify where mismatch occurs, how each participant responds and what cycle maintains the difficulty.
4. **Clinical boundary:** assess impairment and alternatives, including neurodevelopmental disorder, anxiety, mood disturbance, sleep or medical problems, trauma, attachment disturbance, sensory impairment and adverse environment.

Temperament is not a diagnosis of exclusion, but neither should it be used to explain away a disorder. The key question is whether the nine-dimension profile adequately describes a stable style or whether there is an additional syndrome with distress, impairment, developmental deviation or episodic change. A previously characteristic style that changes markedly should prompt assessment for state-related causes rather than being relabelled as temperament.

8.7 Management: change the fit, support regulation and preserve strengths

The intervention target is usually the transaction, not eradication of the trait. The clinician first reframes the behaviour in non-moral language, helps caregivers anticipate predictable points of mismatch and designs the environment so that the child can succeed while gradually building capacity. This is sometimes called temperamental guidance. It validates the child's style without allowing harmful behaviour and supports the caregiver without implying that every difficulty results from parenting.

Management follows the functional profile. An irregular child benefits from external predictability and consistent cues without punitive battles over perfect regularity. A child who

withdraws from novelty benefits from preparation, observation from a safe distance, gradual entry and repeated low-pressure exposure rather than forced sociability. A highly active child needs planned movement, brief achievable seated tasks and safe outlets. A child with intense reactions needs calm adult responses, simple limits and help labelling early arousal before escalation. A child with a low threshold may need reduction of avoidable sensory load and graded coping with unavoidable stimulation. Low persistence calls for task chunking, visible completion points and reinforcement of effort, whereas very high persistence may require supported transitions and practice shifting set.

The environment must adapt, but accommodation is not capitulation. A good fit both accepts the child's starting style and teaches the skills needed for wider participation. Expectations should be realistic, explicit and gradually increased. School collaboration is often decisive because the child may spend much of the waking routine under group demands. Review whether the change reduces conflict, improves participation and preserves the child's strengths; if impairment persists, reassess the formulation and comorbidity.

8.8 Strengths, limitations and later extensions

The model's enduring strength is that it moved child psychiatry from blame toward person-environment interaction. It offered an observable vocabulary for early behavioural individuality, recognised the child's active contribution to relationships and generated the clinically useful concept of goodness of fit. It also anticipated contemporary developmental psychopathology by treating outcome as the product of transactions over time rather than a simple line from one early trait to one later disorder.

Its limitations are equally examinable. The three types compress continuous traits and leave a substantial group unclassified. Several dimensions overlap conceptually, and ratings can be influenced by the observer's expectations, mood and relationship with the child. Stability is relative rather than absolute because the expression of temperament changes with maturation and context. The classic proportions arose from a particular sample and should not be universalised across socioeconomic and cultural settings. Finally, later temperament models organise traits differently and give greater attention to reactivity, self-regulation and biological mechanisms, so Thomas and Chess should be presented as a foundational framework rather than the final taxonomy of temperament.

The historical labels also require ethical translation. *Difficult* is useful in an examination when explicitly attributed to the Thomas-and-Chess classification, but clinical communication should describe the actual profile: irregular, initially withdrawing, slowly adaptive, intensely reactive or predominantly negative in mood. Precise description reduces shame and leads directly to intervention. A global label does neither.

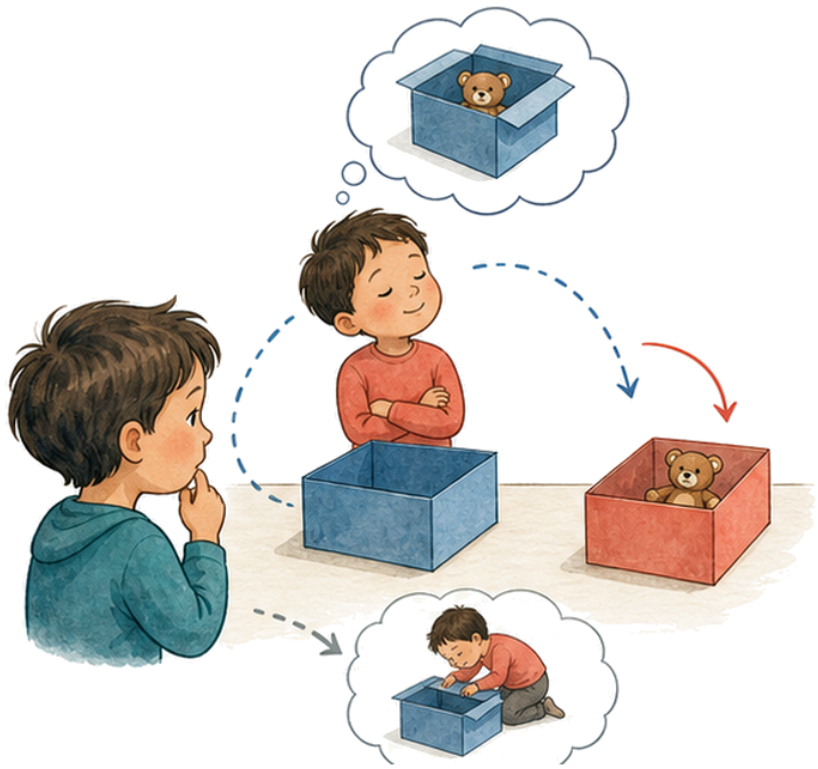
8.9 Examination synthesis and retrieval

A complete short note can be built in five moves. Define temperament as behavioural style; name Thomas and Chess and the New York Longitudinal Study; list all nine dimensions; describe easy, difficult and slow-to-warm-up temperaments with the classic proportions and the

unclassified remainder; then explain goodness of fit with one clinical example, bidirectionality, management and limitations. If time is short, marks are lost most often by omitting threshold, confusing adaptability with approach, or listing the three types without explaining fit.

MNEMONIC

"move, clock, meet, change, notice, react, feel, shift, stay"



Move recalls activity level; clock, rhythmicity; meet, approach or withdrawal; change, adaptability; notice, threshold; react, intensity; feel, quality of mood; shift, distractibility; and stay, attention span and persistence. The sequence is only a retrieval aid. In the answer, use the formal terms.

Worked viva formulation: A child initially refuses unfamiliar classroom activities, reacts mildly and joins after repeated observation. This is closer to a slow-to-warm-up pattern than a difficult pattern because intensity is low and adaptation occurs gradually. If the teacher permits observation and phased entry, participation improves: that is better goodness of fit. If the child is forced to perform immediately and is repeatedly criticised, withdrawal may increase: that is poorer fit. Neither response alone establishes an anxiety disorder; distress, pervasiveness, persistence and impairment still require assessment.

Final clinical synthesis. Thomas and Chess supplied a vocabulary for the child's characteristic style, but their larger contribution was relational. Temperament describes how the child enters an interaction; goodness of fit explains why the same style can lead to competence in one environment and conflict in another. The mature answer neither blames the child nor idealises accommodation. It identifies the profile, maps the environment, changes the transaction and assesses separately for disorder.

9 . Theory of mind development

Theory of mind is the capacity to attribute mental states to oneself and to other people, and to use those attributions to explain and predict behaviour. The attributed states include intentions, desires, knowledge, beliefs, emotions and pretence. The decisive idea is representational: another person acts on how the world is represented in that person's mind, not necessarily on how the world really is or on what the observer knows. Theory of mind therefore permits the child to understand deception, surprise, misunderstanding, secrecy, irony and the fact that two people can interpret the same event differently. It is often called **mentalizing**, although clinical literature sometimes uses mentalizing more broadly for the imaginative interpretation of self and others in terms of intentional mental states.

- Joint attention
- Pretence
- First-order belief
- Second-order belief
- Mental-state inference

Fig 20.8 Theory of mind develops through interacting social, representational, linguistic and executive capacities. False-belief understanding is the central test: another person acts on what they believe, even when that belief conflicts with reality.

This is not a single switch and not a synonym for sociability. Its development rests on an interacting set of capacities: social attention, joint attention, symbolic representation, language, executive control, autobiographical memory and experience of conversation. A child may be affectionate yet fail a formal false-belief task because the language is too difficult; another may pass a structured task yet misunderstand rapidly changing intentions in ordinary interaction. For an examination answer, define the construct, describe its precursors, explain the false-belief test, compare the major explanatory models, and finish with clinical interpretation rather than treating one task as a diagnostic instrument.

Must remember: False belief is the examination pivot: the child must predict action from another person's belief even when that belief conflicts with reality and with the child's own knowledge.

9.1 What theory of mind includes, and what it does not

A representational account of minds, not merely a response to behaviour. At the simplest level, the child recognises that people are agents whose actions are directed toward goals. Development then involves distinguishing *desire* from *belief*: two people can want different outcomes, and two people can hold different representations of the same reality. Mature social understanding further requires recognising that access to information determines knowledge, that beliefs may be false, and that outward expression can differ from inner emotion. These strands do not have to develop at identical rates, which is why theory of mind is better considered a family of related abilities than a unitary faculty.

Cognitive theory of mind concerns beliefs, intentions and knowledge. **Affective theory of mind** concerns inference about another person's feelings. **Empathy** overlaps with the second but is not identical to it: affective resonance, concern and the motivation to help are separable from the ability to identify what someone feels. **Joint attention** is also distinct. It is the shared coordination of attention between a person and an object or event, and is a developmental foundation for learning what another person is attending to; it does not by itself demonstrate understanding of false belief. Likewise, mirror self-recognition concerns representation of the self, not direct proof that the child represents another person's mind.

RULE **Do not equate precursor, correlate and criterion.** Joint attention, pointing, pretend play, language and executive control support theory of mind. The classic explicit test is false-belief reasoning. None of these observations alone diagnoses or excludes a neurodevelopmental disorder.

9.2 Developmental sequence: from shared attention to represented belief

The sequence is more reliable than a rigid age ladder.

1. Early face-to-face reciprocity and turn-taking make interaction predictable.
2. The infant then coordinates gaze and attention with another person, follows what the other person is attending to, and uses gestures such as pointing to request or share interest.
3. Symbolic and pretend play show that one object or action can stand for another, an essential representational step.
4. The child subsequently reasons about desires, perception and access to knowledge, then understands that belief can diverge from reality.

MNEMONIC

"Share - Symbolise - Believe"

Shared attention follows what another person is attending to; symbolic and pretend play show that one object or action can stand for another; then the child understands that belief can diverge from reality.

Conversation with caregivers and peers supplies repeated evidence that different people know, want, remember and feel different things.

8 to 12 months	Around 12 months	18 months of age	Four or five years
JOINT ATTENTION ACCURACY	JOINT ATTENTION AND POINTING	SYMBOLIC PLAY	EXPLICIT FALSE-BELIEF TASK PERFORMANCE

Berk describes joint attention as becoming more accurate across 8 to 12 months. This is a developmental description, not a referral cutoff. The *New Oxford Textbook of Psychiatry* describes joint attention and pointing as expected in most typically developing children around 12 months. Dulcan describes symbolic play as expected at 18 months of age. *Developmental Psychopathology* places its expected appearance at approximately **20 months of age**. These are source-specific descriptions, not interchangeable thresholds. *Psychotherapy for Borderline Personality* describes explicit false-belief task performance as expected at four or five years. Berk also reports performance after **three and a half years** and describes a span between **four and six years**, but those statements do not establish referral thresholds.

The source language matters clinically. An expected attainment age describes what usually occurs; it is not an upper limit and it is not a red-flag threshold. The range reported by Berk is also not permission to refer every child outside an average-looking point. Development must be interpreted longitudinally and in context, especially when task language, hearing, schooling or cultural familiarity may alter performance.

9.3 False-belief tasks: the classic demonstration

The test asks whether the child can suppress reality and answer from another mind. In the classic change-of-location task, a protagonist puts an object in one location and leaves. In the protagonist's absence, the object is moved. The child is asked where the protagonist will look on returning. The reality-based answer is the new location; the belief-based answer is the original location, because that is where the protagonist falsely believes the object remains. A correct response therefore requires the child to represent the protagonist's informational access separately from the child's own knowledge.

The unexpected-contents task uses a familiar container whose actual contents violate its appearance. After discovering the contents, the child is asked what another, uninformed person will think is inside. Related paradigms test appearance versus reality, knowledge from seeing, hidden emotion, deception, irony and social faux pas. **First-order false belief** has the form, "She thinks X." **Second-order false belief** embeds one mind within another, "He thinks that she thinks X." No verified numeric attainment age for the second-order form is supplied here, so it should not be placed on an age axis.

Good testing includes control questions. The examiner checks whether the child remembers the object's original and current locations, follows the story, identifies who saw the transfer, and understands the question. Failure can arise from receptive-language load, working-memory demand, inattention or difficulty inhibiting the true location. Success can also be achieved through learned verbal rules rather than flexible social understanding. Spontaneous behaviour in natural interaction and performance across several tasks are therefore more informative than a single pass or fail.

TRAP **"The child knows where the object really is" is not the target answer.** False-belief tasks deliberately pit the child's true knowledge against the protagonist's outdated belief. Also avoid converting expected performance at four or five years into a diagnostic or referral cutoff.

9.4 Competing explanations of theory of mind development

No single account explains every finding.

ACCOUNT	EXPLANATION	QUALIFICATION
Theory-theory account	Proposes that children build and revise an informal causal theory of mind, much as they revise explanations in other knowledge domains. Observed action, testimony and conversational correction provide evidence; conceptual change moves the child from desire-based explanations toward representational belief.	Its strength is developmental change, but the metaphor of a child scientist can understate embodied and relational learning.
Simulation account	Proposes that the child predicts another person's action by using their own mind as a model, imaginatively placing themselves in the other's situation and adjusting for differences. It captures perspective-taking and the intimate relation between self-knowledge and understanding others.	It struggles when the other person's beliefs, motives or emotional responses are very unlike the child's own.
Modular or domain-specific accounts	Propose a specialised mechanism for representing propositional attitudes such as belief. They explain the apparently distinctive problem posed by mental representations and the characteristic social-cognitive profile seen in some neurodevelopmental conditions.	However, a strongly encapsulated module can underplay the effects of language, executive function, teaching and social experience.
Executive-function accounts	Emphasise working memory, cognitive flexibility and inhibitory control. The child must hold two representations in mind and inhibit the salient true state of affairs.	
Language and sociocultural accounts	Emphasise mental-state vocabulary, complement syntax, narrative, sibling and peer discourse, and conversation about reasons for behaviour. Complement constructions such as "She thinks that..." permit one proposition to be represented inside another, mirroring the representational structure demanded by false-belief reasoning.	Association does not establish that language alone causes theory of mind: linguistic competence, executive control and social understanding remain partly dissociable. The most defensible synthesis is interactive: representational competence, executive control, language and social experience constrain one another across development.

Applied to theory of mind, the sociocultural frame directs attention to joint activity, conversation about feelings and reasons.

Responsive mental-state conversation supports theory of mind.

9.5 Psychopathology: delayed, reduced and excessive mentalizing

Clinical interpretation. Theory of mind disturbance is clinically important but diagnostically non-specific. In autism spectrum disorder, whose fuller treatment is in the Intellectual disability and autism spectrum disorder notes, difficulties may involve spontaneous joint attention, integrating contextual cues, inferring intentions or applying explicit knowledge rapidly in everyday interaction. Some verbally able individuals pass standard false-belief tasks through language or learned strategies while continuing to find unstructured social inference effortful. A failed task is not sufficient for diagnosis, and a passed task does not exclude autism.

In schizophrenia and other psychotic states, difficulty may involve both under-attribution and distorted attribution of intention, especially under ambiguity. In personality pathology, particularly borderline presentations, the problem may be unstable or excessive inference about mental states, sometimes termed hypermentalizing, rather than a simple absence of theory of mind. Mood, arousal, trauma, attachment insecurity and interpersonal threat can transiently reduce the accuracy of mentalizing. The useful clinical contrast is therefore hypomentalizing, too little or overly concrete inference; hypermentalizing, elaborate inference unsupported by evidence; and reasonably calibrated mentalizing, which remains tentative and revisable.

Performance is also affected by intellectual functioning, language disorder, attention, executive dysfunction, hearing impairment and limited familiarity with the test format. Deficits can be trait-like, state-dependent or secondary to another cognitive limitation. Theory of mind should therefore contribute to formulation, never substitute for the full developmental and mental-state assessment.

9.6 Clinical assessment and examination synthesis

Assess development, task performance and real-world use separately. Begin with caregiver history of early reciprocity, gesture, joint attention, pretend play, language development, peer relationships, understanding of deception and humour, and any loss of language or social skills. Observe gaze coordination, sharing of interest, response to another person's distress, flexibility during misunderstanding and the person's tendency to check uncertain interpretations. In a formal task, simplify the language without changing the logic, establish that the person understood and remembered the story, and include reality, memory and information-access controls.

Interpret the result against receptive and expressive language, attention, working memory, inhibition, general cognitive level, hearing, educational exposure and cultural-linguistic context. Repeating the same task with translated words is not automatically a valid cultural adaptation. In multilingual Indian settings, establish the language in which the child normally discusses intentions and emotions, and use collateral examples from home and school. When developmental concern is broader than theory of mind, use an appropriate validated developmental screening or assessment pathway, developed in the Child psychiatry: assessment, treatment, services and protection notes, rather than inventing a false-belief referral age.

The short-answer synthesis is compact. Theory of mind is the capacity to represent one's own and others' mental states and predict behaviour from them. Joint attention and symbolic play are precursors; explicit false-belief reasoning is the classic test. Development reflects interacting domain-specific, simulation, executive, language and sociocultural processes. Clinically, failure is non-specific, success can be scaffolded, and the valid unit of assessment is the developing person in context rather than a single task score.

10 . Language acquisition theories (Chomsky, Skinner, Vygotsky)

Language acquisition asks how a child moves from hearing speech in social interaction to understanding and producing a rule-governed, productive language. **Three** classic answers emphasise different causal levels. B. F. Skinner treats verbal behaviour as behaviour shaped by its consequences and controlling context. Noam Chomsky argues that the speed, uniformity and generativity of acquisition require an innate, species-typical capacity for grammar. Lev Vygotsky places language within socially mediated development: speech first coordinates activity between people and is then internalised as a tool for thought and self-regulation. The most defensible contemporary answer is not to declare one winner. Biological preparedness, learning mechanisms and communicative participation operate at different levels and answer different parts of the problem.

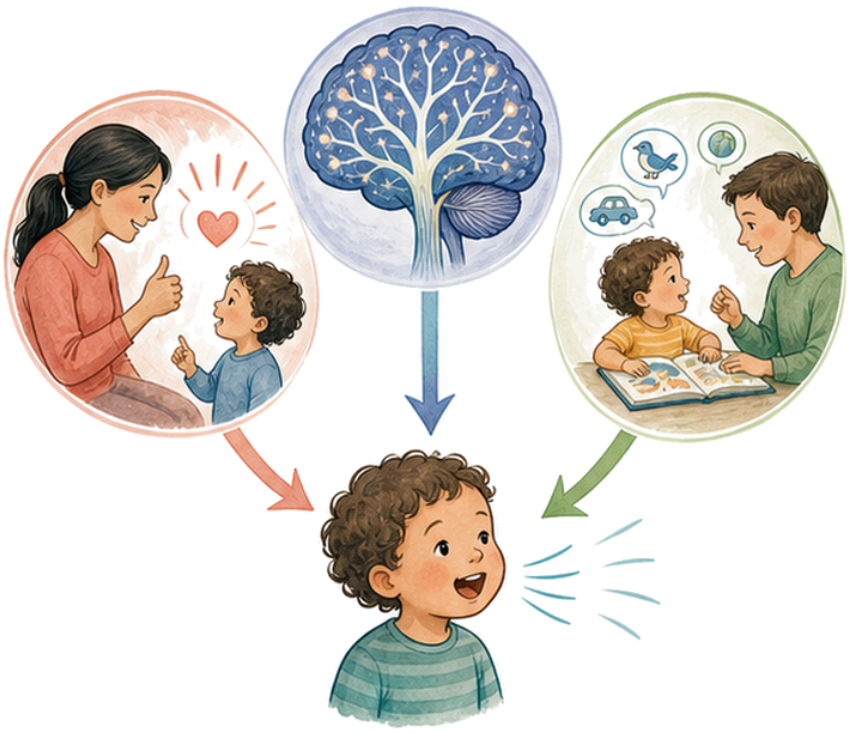


Fig 20.9 Classic accounts of language acquisition work at different causal levels: Skinner emphasises learning contingencies, Chomsky innate grammatical preparedness, and Vygotsky socially mediated speech that becomes internalised.

How to use this page. Learn each theory through **four** questions: *what is acquired, what drives acquisition, what evidence supports it, and what does it fail to explain?* For Skinner, the unit is a functional verbal response and the driver is its learning history. For Chomsky, the central object is grammatical competence and the driver is an innate language faculty constrained by universal principles. For Vygotsky, the unit is mediated social activity and the developmental movement is from shared speech to inner regulation. In a long answer, compare mechanisms rather than writing three disconnected biographies.

Must memorise: Skinner explains language through learning contingencies, Chomsky through innate grammatical preparedness, and Vygotsky through social mediation and internalisation.

10.1 The problem every theory must solve

Children acquire more than a stock of copied words. They learn a sound system, a lexicon, rules for combining words, meanings, conversational intentions and the social conditions under which an utterance is appropriate. They also produce sentences they have never heard, understand that the same form can serve different functions, and make systematic errors that reveal an active rule rather than random failure. Any adequate theory must therefore explain productivity, generativity, comprehension, social use, variation across languages and the transition from assisted participation to increasingly independent communication.

The theories differ partly because they choose different explananda. Skinner asks what environmental variables control a verbal act. Chomsky asks what internal system makes grammatical knowledge possible. Vygotsky asks how culturally organised interaction becomes a psychological tool. A behavioural account can explain why a request occurs in one context without specifying the child's abstract grammar. A grammatical account can explain structural knowledge without explaining why the child chooses a tact, request or reassurance in a particular relationship. A sociocultural account can explain guided participation without, by itself, providing a formal grammar. Apparent contradiction often falls once the level of explanation is named.

3	1	0
CAUSAL EMPHASES	DEVELOPMENTAL PROBLEM	THEORIES SUFFICIENT ALONE

10.2 Skinner: language as learned verbal behaviour

Speech is behaviour whose form and probability are shaped by antecedents and consequences. In Skinner's operant account, the child emits vocal behaviour; caregivers and the wider verbal community selectively respond; useful forms become more likely in relevant contexts. Positive reinforcement, shaping of closer approximations, imitation, prompting, stimulus discrimination and generalisation all contribute. Reinforcement need not mean sweets or praise. Receiving the requested object, attracting attention, continuing a pleasurable exchange or obtaining information can itself strengthen a verbal response.

Skinner classified verbal behaviour by its controlling relation rather than by conventional grammar.

VERBAL OPERANT	CONTROLLING RELATION
A mand	is controlled by a motivating condition and specifies its characteristic consequence, as when a thirsty child requests water.
A tact	is evoked by an object, event or property and maintained by socially generalised consequences, as when the child names a dog.
An echoic response	has point-to-point similarity with heard speech.
An intraverbal	is occasioned by other verbal behaviour without simply reproducing it, as in answering a question or completing a familiar phrase.
Autoclitic behaviour	qualifies or organises other verbal responses, indicating relations such as certainty, negation or attribution.

The same spoken word can therefore belong to different operants depending on what controls it and what consequence follows.

The account is strongest where the learning history is visible: vocabulary taught through joint activity, requests shaped by successful communication, pronunciation altered by feedback, and context-specific use acquired through modelling and consequences. It also gave language research an insistence on observable function. Its central weakness is explanatory reach. Children generate novel utterances, acquire complex structure without explicit reinforcement of every form, and produce rule-based overgeneralisation rather than merely imitating adult speech. Caregivers also respond to meaning, truth and conversational success, not consistently to grammatical form. Conditioning is therefore relevant, but a complete language theory cannot be a catalogue of reinforced sentences.

10.3 Chomsky: an innate capacity for generative grammar

Finite exposure yields knowledge capable of generating indefinitely many sentences.

Chomsky's nativist theory begins from the mismatch between the linguistic input available to the child and the structured grammatical knowledge eventually acquired. The input is variable, incomplete and not organised as a formal lesson, yet children converge on complex rules and recognise relations that cannot be reduced to adjacent word associations. This is the classic **poverty-of-the-stimulus argument**: experience is necessary to select and develop a language, but experience alone appears insufficient to specify every constraint the learner comes to respect.

The traditional examination formulation is an innate **language acquisition device**, a theoretical language-learning capacity that allows the child to extract grammatical structure from speech. In later generative accounts, the more important idea is **universal grammar**: species-typical initial constraints or principles that delimit the kinds of grammar a human learner can acquire. The child is not born knowing English, Hindi, Kannada or any other particular language. The claim is that human biology supplies a structured readiness, while exposure determines which language-specific system develops.

Chomsky also distinguished **competence**, the speaker-hearer's internal knowledge of language, from **performance**, actual language use under limits of attention, memory, motivation and context. A hesitant or incomplete utterance does not necessarily reveal an absent rule. The theory explains productivity, rapid rule extraction and patterned errors more convincingly than simple imitation does. Its limitations are equally important: the proposed innate content is difficult to specify and test independently; formal grammar does not by itself explain vocabulary learning, communicative intention, caregiver-child interaction or cultural variation; and usage-based evidence shows that distributional learning and repeated constructions carry more information than a stark poverty account sometimes assumes.

RULE **Innate capacity is not innate vocabulary.** Chomsky proposes biological preparedness for acquiring grammatical structure. The particular language, its words and its conventional uses still require exposure and participation.

10.4 Vygotsky: language is socially mediated and then internalised

Language develops in joint activity before it becomes a means of organising the self. Vygotsky's sociocultural theory treats language as both a cultural sign system and a psychological tool. A more knowledgeable participant directs attention, labels experience, interprets the child's attempts, models a form, asks questions and structures the activity. Through such mediated participation, the child gains not only words but culturally patterned ways of remembering, planning, categorising and solving problems. Acquisition is therefore inseparable from the purposes for which people communicate.

The **zone of proximal development** (ZPD) is the region between what the learner can perform independently and what becomes possible with responsive guidance or collaboration. Language supports learning within this zone through modelling, prompts, recasts, expansion of the child's utterance, shared attention and dialogue. Scaffolding is the later term commonly used for contingent support that is adjusted and gradually withdrawn. It is compatible with Vygotsky, but was not his own term and is not synonymous with the ZPD.

Development proceeds through the following sequence.

1. Social speech, used to coordinate with another person.
2. Private speech, audible self-directed language used to guide action.
3. Condensed inner speech.

Private speech is therefore a transitional instrument of self-regulation rather than meaningless immaturity. Vygotsky's theory is developmental but **not stage-based**. It provides no sequence of Vygotskian stages and no age row for the accompanying theory-alignment plate. Its major strengths are the integration of language, culture, teaching and self-regulation. Its limitations include imprecise measurement of the ZPD, dependence on the skill of the assisting partner, and less specification of biological constraints and formal linguistic structure.

10.5 Direct comparison: what changes the child's language?

Skinner locates change in contingencies. The child repeats and differentiates verbal acts because their consequences vary across situations. The adult is a source of models, prompts and reinforcement. Error is a response not yet adequately shaped or brought under the relevant stimulus control. **Chomsky locates change in the growth of an internally constrained grammar.** Input triggers and informs a biologically prepared system. The adult provides linguistic data, but need not explicitly teach every rule. Error can reveal a productive rule that has been extended too widely. **Vygotsky locates change in participation and internalisation.** The adult or capable peer co-regulates attention and meaning within activity, then transfers responsibility as the child appropriates language for communication and thought.

Their signature predictions also differ. A Skinnerian analysis asks whether changing antecedents and consequences changes the target utterance. A Chomskyan analysis asks whether the child's output displays rule-governed structure not directly copied from the input. A Vygotskian analysis asks how performance changes under calibrated assistance and whether socially organised speech becomes independent self-guidance. These predictions can coexist in one episode. A caregiver may reinforce a request, supply grammatically structured input, and scaffold the child's participation at the same time.

TRAP **Do not write "Skinner equals nurture, Chomsky equals nature, Vygotsky equals both" and stop.** A scoring answer names the mechanism: operant contingencies, innate grammatical constraints, and socially mediated internalisation.

10.6 What later evidence adds: interaction, statistics and use

Later approaches weaken the idea that acquisition must be assigned to a single mechanism. Social-interactionist accounts emphasise joint attention, turn-taking, communicative intention and responsive caregiver speech. Usage-based accounts propose that children learn recurring constructions from meaningful use and gradually abstract patterns across exemplars. Statistical learning shows that learners can extract distributional regularities from sequences, while connectionist models demonstrate how graded patterns may emerge without an explicitly represented rule for every construction. These approaches challenge a rigid version of both imitation-only behaviourism and richly pre-specified grammar.

They do not erase the classic theories. Reinforcement and modelling demonstrably alter language behaviour; human neurobiology constrains which communication systems can be acquired and how readily; and language develops in relationships structured by culture. The useful synthesis is biopsychosocial and developmental: biologically prepared learning systems detect structure in socially meaningful input, while interaction supplies motives, feedback, shared reference and opportunities for practice. The relative contribution of each process varies across phonology, grammar, vocabulary, pragmatics and inner speech.

10.7 Clinical and Indian interpretation

A theory is not a milestone chart and cannot diagnose delay. Chomsky, Skinner and Vygotsky explain proposed mechanisms of acquisition; developmental surveillance asks whether

communication skills are emerging as expected and whether a sourced referral signal is present. The accompanying language-milestone plate should be read according to the construct attached to each value: expected attainment, expected range, median, upper limit and red flag are not interchangeable. A child outside an expected description is not automatically disordered, while a sourced red flag warrants further evaluation rather than a theory-based label.

INDIA

Assessment in India must establish the child's exposure and competence across all languages used at home, school and the wider community. Code-switching, language mixing and unequal vocabulary across languages can reflect ordinary multilingual use rather than deficient grammar. Ask who speaks which language with the child, for what purpose, with what consistency, and whether the concern appears across languages. Skinner directs attention to opportunities and consequences for communication; Chomsky prevents low exposure from being mistaken for absent human language capacity; Vygotsky directs attention to family dialogue, siblings, teachers, cultural tools and the child's response to support. None justifies judging competence from performance in the examiner's preferred language alone.

Clinically, use the theories to generate questions, not conclusions. Does the child initiate communication when it produces a meaningful consequence? Can a model, prompt or expansion elicit a more advanced form? Does the child produce novel combinations rather than echoes alone? How does performance change with a familiar communication partner? Is language being used for joint attention, requests, comment, play and self-guidance? Hearing, oral-motor function, cognition, social communication, the language environment and regression must be assessed separately. Loss of language or social skill is a red flag at any age and is never explained away as a preferred theoretical pathway.

10.8 Examination reconstruction

Long-answer sequence. Define language acquisition, state the problem of productivity, then write Skinner as operant learning with verbal operants, Chomsky as innate grammatical preparedness with universal grammar and competence-performance, and Vygotsky as social mediation with the ZPD, private speech and internalisation. Compare the role of input, adult, child and error; add one strength and one limitation of each; end with an interactionist synthesis and the statement that Vygotsky has no age-linked stages.

MNEMONIC

"Consequence - grammar - mediation"

Skinner shapes use, Chomsky constrains structure, Vygotsky transforms shared speech into self-regulation.

11 . Parenting styles (Baumrind) and family influences on development

Parenting style is the relatively stable emotional climate in which caregivers exercise authority, express warmth, communicate expectations and respond to the child. It is broader than a single

parenting practice. A practice is a specific act, such as praising effort, supervising internet use or imposing a consequence; a style is the recurring relational pattern within which such acts acquire meaning. Baumrind's work made this pattern examinable by distinguishing authoritative, authoritarian and permissive parenting. Maccoby and Martin later organised the framework along two dimensions, **responsiveness** and **demandingness**, and separated an uninvolved pattern from permissiveness.

How to use this page. Learn the two dimensions before the four labels. Then connect parenting with development through modelling, reinforcement, attachment, language, emotion socialisation and family systems. In a long answer, define style, draw the two-by-two classification, distinguish each pattern, discuss associated outcomes without claiming causation, and finish with bidirectionality, culture, socioeconomic context and clinical assessment. The central correction is simple: families influence development powerfully, but neither parenting style nor family structure mechanically determines a child's outcome.

The must-memorise line: authoritative parenting combines high responsiveness with high demandingness: warmth without structure is permissive, and structure without responsiveness is authoritarian.

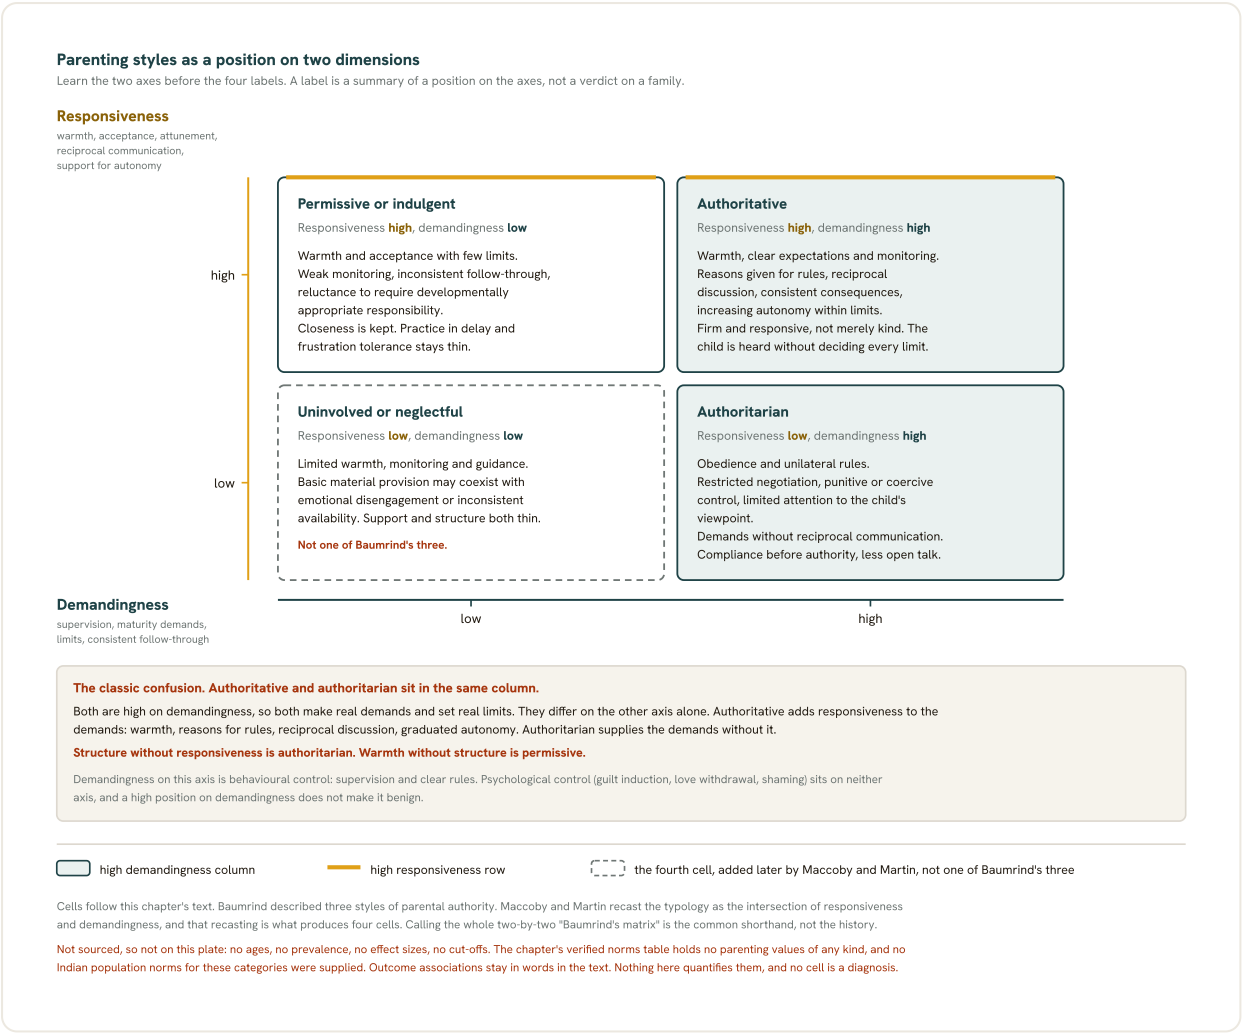

Fig 20.10 The parenting styles placed on responsiveness and demandingness. Fill marks the high-demandingness column and the saffron edge marks the high-responsiveness row, so authoritative and authoritarian are visibly the same column and a different row: they differ on responsiveness alone. The low-low cell is drawn dashed because it is Maccoby and Martin's addition, not one of Baumrind's original three styles. No ages, prevalence figures or effect sizes appear because none were sourced for this chapter.

11.1 From Baumrind's three styles to the two-dimensional model

Baumrind described patterns of parental authority; the familiar four-cell matrix is a later extension. Diana Baumrind distinguished three broad parenting styles from observations of parent-child interaction. **Authoritative parenting** combined firm standards with warmth and communication. **Authoritarian parenting** emphasised obedience and control with relatively little reciprocal discussion. **Permissive parenting** was accepting and non-punitive but placed few consistent demands on the child. Maccoby and Martin subsequently recast the typology as the intersection of responsiveness and demandingness, producing four cells and adding the low-low pattern commonly called **uninvolved** or neglectful parenting.

Responsiveness refers to warmth, acceptance, attunement, reciprocal communication and support for age-appropriate autonomy. It asks whether the caregiver notices and responds to the child's needs while recognising the child as a separate person. Demandingness refers to supervision, maturity demands, behavioural expectations, limit-setting and consistent follow-through. It asks whether the caregiver provides an organised structure and expects the child to participate in it. Neither dimension is intrinsically good at its maximum. Responsiveness without

boundaries can fail to contain behaviour, while demandingness that becomes rigid, humiliating or coercive is not healthy structure.

2	3	4
CLASSIFICATION DIMENSIONS: RESPONSIVENESS AND DEMANDINGNESS	STYLES IN BAUMRIND'S ORIGINAL TYPOLOGY	CELLS IN THE LATER MACCOBY-MARTIN FORMULATION

MNEMONIC

"High responsiveness + high demandingness = authoritative"

Authoritative parenting combines high responsiveness with high demandingness: warmth without structure is permissive, and structure without responsiveness is authoritarian.

11.2 The four parenting styles

Classify the observed pattern on both dimensions, then describe what the caregiver actually does. The labels are useful summaries, but behavioural description prevents them from becoming moral verdicts.

STYLE	RESPONSIVENESS	DEMANDINGNESS	CHARACTERISTIC FAMILY CLIMATE
Authoritative	High	High	Warmth, clear expectations, monitoring, reasons for rules, reciprocal discussion, consistent consequences and increasing autonomy within limits
Authoritarian	Low	High	Obedience, unilateral rules, restricted negotiation, punitive or coercive control, and limited attention to the child's viewpoint
Permissive or indulgent	High	Low	Warmth and acceptance with few limits, weak monitoring, inconsistent follow-through or reluctance to require developmentally appropriate responsibility
Uninvolved	Low	Low	Limited warmth, monitoring and guidance; basic material provision may coexist with emotional disengagement or inconsistent availability

RULE **Authoritative means firm and responsive, not merely kind.** It preserves parental authority while making rules predictable, proportionate and open to explanation. The child may be heard without being allowed to decide every limit.

Three distinctions carry marks:

Authoritative and authoritarian parenting
are not synonyms: both contain demands, but only the former combines them with responsiveness and reciprocal communication.

Permissive and uninvolved parenting
both have low demandingness, but permissive parenting retains warmth and engagement.

behavioural control from psychological control
Behavioural control, such as supervision and clear rules, differs from psychological control, such as guilt induction, love withdrawal, shaming or intrusion into the child's emotional world. The former can be protective; the latter constrains autonomy and can be harmful even when the household appears orderly.

11.3 Developmental correlates and the problem of causal overclaim

Parenting styles are associated with developmental outcomes, but the associations are probabilistic and context-dependent. Across much of the literature, authoritative parenting is associated with stronger self-regulation, social competence, academic engagement and psychological adjustment. Its proposed advantage is not leniency. Predictable limits reduce uncertainty, warmth preserves connection, explanations help the child internalise rules, and graduated autonomy gives repeated practice in decision-making. These processes can support both competence and relatedness.

Authoritarian parenting is commonly associated with compliant behaviour in the immediate presence of authority but less spontaneous autonomy, lower open communication and, in some settings, more internalising or externalising difficulty. Permissive parenting may preserve closeness but provide insufficient practice in delay, frustration tolerance and responsibility. Uninvolved parenting is associated with broad developmental risk because both relational support and behavioural organisation are reduced. None of these statements diagnoses an individual child or proves that a parenting style caused an outcome. Effects vary with temperament, developmental capacity, caregiver consistency, neighbourhood safety, peer context, culture and the meaning the child assigns to control.

TRAP **Do not turn an association into parent-blaming.** Child temperament and behaviour alter parenting, caregiver stress and illness constrain responsiveness, and social adversity can make consistency difficult. A style label describes a pattern in a system; it does not identify a single cause or assign guilt.

11.4 Why parenting has effects: six developmental pathways

Parenting influences development through repeated transactions, not through the label itself. Six pathways organise the answer:

DEVELOPMENTAL PATHWAY	HOW IT INFLUENCES DEVELOPMENT
Attachment and co-regulation:	sensitive, predictable responses help the child use the caregiver as a source of safety and regulation. Repeated co-regulation contributes to later self-regulation, although attachment is relationship-specific and should not be inferred from a global style label alone.
Modelling:	children observe how adults manage anger, disagreement, affection, work, substances, gender roles and help-seeking. What caregivers enact may teach more strongly than what they instruct.
Reinforcement and discipline:	attention, praise, withdrawal of attention and consequences alter the probability of behaviour. Harsh or inconsistent discipline can create a coercive cycle in which escalating child behaviour and escalating adult control reinforce one another.
Emotion socialisation:	caregivers label emotions, validate or dismiss them, model regulation and teach which expressions are acceptable. Emotion coaching can build recognition and modulation; ridicule or punishment of emotion may produce concealment without regulation.
Cognitive and language stimulation:	conversation, shared attention, play, explanation and responsive expansion of the child's communication provide material for language, executive control and social understanding.
Opportunity and monitoring:	families shape exposure to peers, education, sleep routines, media, risk, responsibility and supportive adults. Monitoring is protective when it is informed and proportionate, but becomes intrusive when it denies developmentally appropriate privacy and autonomy.

These pathways interact. A caregiver who calmly labels distress, maintains a clear limit and helps the child recover is simultaneously providing co-regulation, modelling, language, reinforcement and emotion socialisation. Conversely, chronic conflict can occupy attention, disturb sleep, reduce exploration and make even ordinary demands feel threatening. The developmental effect lies in the recurring pattern and its meaning, not in one isolated exchange.

11.5 The family as a system: bidirectionality, relationships and context

A child develops within a network of relationships whose members continually influence one another. A transactional model rejects a one-way arrow from parent to child. The child's temperament, neurodevelopmental profile, health and behaviour evoke responses from caregivers; those responses alter the child's subsequent behaviour; the new behaviour then changes the caregiver again. An irritable child may meet an exhausted caregiver, escalating both distress and control, whereas the same child may settle with predictable routines and a caregiver who has support. This is an interaction, not proof that either participant is intrinsically difficult.

Family systems theory adds that each dyad is affected by the larger system. The quality of the couple or co-parenting relationship can increase consistency or draw the child into conflict. Triangulation occurs when tension between adults is displaced through the child or the child is recruited into an alliance. Boundaries can become excessively diffuse or rigid, roles can reverse through parentification, and one member can be designated as the problem-bearer for a wider family difficulty. These concepts are hypotheses for assessment, not labels to impose after a single interview.

Family influence extends beyond parents. Siblings provide companionship, conflict, imitation, comparison and practice in negotiation; differential parenting may be as important as average parenting. Grandparents and other caregivers can supply continuity and protection, or create conflicting rules when caregiving authority is unclear. The developmental importance of family structure depends largely on relationship quality, stability, resources and conflict. A single-parent, joint, blended, adoptive or same-sex-parent family is not inherently pathogenic. Structure tells the clinician who is present; process tells the clinician what happens between them.

11.6 Language acquisition: what the family supplies and what it cannot explain alone

The family creates the language-learning environment, but no single language acquisition theory is sufficient. Skinner emphasised learning through imitation, shaping and reinforcement. Caregivers do reinforce communicative success, model words and expand incomplete utterances, but children generate novel sentences and acquire grammar too rapidly for direct reinforcement to be the whole account. Chomsky emphasised an innate biological preparedness for language and the child's capacity to infer an underlying grammar from limited input. This explains productive rule learning but does not make social interaction dispensable.

Vygotsky treated higher mental functions as socially mediated and later internalised. In the zone of proximal development, a child performs with guidance beyond what can yet be done independently; scaffolding is the temporary support that is adjusted and withdrawn as competence grows. Dialogue with caregivers becomes increasingly internalised, including through private speech, and supports planning and self-regulation. Vygotsky proposed a cross-cutting developmental mechanism, not a sequence of age-defined stages, so he should not be forced onto a numeric stage axis.

The useful synthesis is interactionist. Biological preparedness makes language possible; exposure supplies a linguistic system; attention and memory extract regularities; reinforcement shapes communicative effectiveness; and responsive interaction gives words shared reference and social purpose. Family practices matter through turn-taking, joint attention, contingent response, elaboration, mental-state talk and opportunities to speak. Parenting style changes the climate of these exchanges. Authoritative dialogue invites explanation within structure, authoritarian exchanges may privilege commands and obedience, permissive interaction may be rich but inconsistently organised, and uninvolved parenting may provide less contingent communication. These are tendencies, not fixed predictions about any family or language community.

11.7 Theory of mind, false belief and family conversation

Social understanding develops through representing minds as well as observing behaviour. Theory of mind is the capacity to attribute beliefs, desires, intentions and emotions to oneself and others, and to understand that another person's mental state may differ from one's own and from reality. A standard false-belief task tests whether the child predicts behaviour from an actor's mistaken belief rather than from the child's own knowledge. The cited developmental source describes success on such a task as expected at **four or five years**. This is an expected attainment statement, not a diagnostic or referral threshold.

Family interaction can support theory of mind through conversation about feelings, motives, mistakes, deception and different viewpoints; shared reading and sibling disputes also provide occasions to explain why people act as they do. Language is both a medium for discussing mental states and a cognitive resource for holding competing representations in mind. Performance also depends on comprehension, attention, memory, inhibition, task wording, familiarity and culture. Failure on one false-belief task therefore does not establish a global absence of theory of mind, identify a parenting style or diagnose a disorder.

11.8 Broader family influences on development

Parenting occurs inside social conditions that can protect or constrain the family. Development is influenced by caregiver mental and physical health, substance use, marital and intergenerational conflict, domestic violence, bereavement, migration, discrimination, poverty, housing, nutrition, educational access, neighbourhood safety and social support. These factors may act directly on the child and indirectly by altering caregiver availability, predictability and emotional reserve. Treating a resource-constrained family as simply inconsistent confuses a social determinant with a character judgement.

Risk is cumulative but not destiny. Stable relationships, a caregiver who can repair after conflict, supportive kin, school connection, safe routines and access to treatment can buffer adversity. Family conflict is particularly harmful when it is intense, chronic, unresolved or draws the child into adult disputes. In contrast, observing disagreement followed by negotiation and repair can teach that relationships survive conflict. The clinically relevant variables are exposure, meaning, persistence, protection and recovery.

Family transmission is also not purely environmental. Parents and children share genetic liabilities, and genetically influenced child characteristics can shape both the environments selected by the family and the responses evoked from others. This does not reduce development to heredity. It explains why an observed association between parenting and child outcome may contain inherited, evocative and environmental pathways at the same time. Developmental formulation should keep all three visible.

11.9 Culture and the Indian family context

The two dimensions travel better across cultures than stereotypes about the four labels. Responsiveness and demandingness can be described behaviourally in any family, but the meaning of obedience, autonomy, proximity, privacy and interdependence varies. Firm control

may be interpreted differently when it is embedded in warmth, shared obligation and credible concern for safety. This cultural moderation does not make humiliation, violence, terror or coercive psychological control benign. Culture explains meaning; it does not excuse harm.

INDIA

Assessment should identify the actual caregiving unit rather than assuming a nuclear household. Grandparents, older siblings and other relatives may share authority, care and financial responsibility. Educational pressure, respect for elders, family interdependence and collective decision-making may be valued, while autonomy may be expressed through negotiated responsibility rather than early separation. Ask who sets rules, who comforts, who supervises, whether caregivers agree, and how the child understands these practices. Do not label joint-family involvement, close parent-child proximity or deference to elders as pathology without evidence of distress, coercion or impairment. Equally, do not hide abuse or severe restriction behind the phrase "Indian culture." No verified Indian population norms for Baumrind-style prevalence or comparative effect sizes are supplied here, so Western associations must not be relabelled as Indian norms.

11.10 Clinical assessment, formulation and intervention

Translate labels into observable sequences and modifiable processes. Ask each caregiver and the child, when developmentally appropriate, for concrete recent examples of praise, rules, refusal, anger, affection, supervision, privacy, conflict and repair. Establish what happened before the interaction, what each person did, what followed immediately and what happened the next time. Observe tone, turn-taking, intrusiveness, warmth, limit-setting and the child's bids for help or autonomy. Obtain information across home, school and other caregiving settings because a family may be structured in one domain and overwhelmed in another.

A useful formulation has **five** layers:

1. The child's temperament and developmental capacities.
2. The caregiver's style, health and history.
3. Specific parenting practices.
4. Relationships and alliances across the family.
5. The wider cultural, socioeconomic and safety context.

Then identify the feedback loop maintaining the difficulty and the protective processes already present. Screen directly for violence, maltreatment, caregiver mental illness, substance problems and risk to the child rather than allowing a benign style label to obscure safeguarding concerns.

Intervention targets the process that can change. Core elements include predictable routines, developmentally appropriate expectations, clear brief instructions, positive attention for desired behaviour, consistent non-violent consequences, emotion coaching, collaborative problem-solving, graduated autonomy and repair after conflict. Parent-management approaches are especially useful for coercive cycles and inconsistent reinforcement; family work is useful when conflict, alliances or contradictory caregiving maintain the problem; treatment of caregiver

illness and practical social support may be prerequisites for change. The aim is not to manufacture an idealised parent. It is to increase safety, responsiveness, effective structure and the family's capacity to adapt as the child develops.

Final synthesis. Baumrind's framework is a map of the caregiving climate, not a verdict on a family. The strongest answer begins with responsiveness and demandingness, distinguishes the original three styles from the later fourth, explains developmental pathways, and then qualifies every outcome claim with bidirectionality, temperament, culture and social context. Family relationships provide the setting in which language, emotion regulation, theory of mind and autonomy are practised. Their influence is profound precisely because it is repeated, relational and modifiable, not because it is deterministic.

The domains and the milestones

12 . Domains of child development (motor, language, cognitive, social, emotional)

Child development is an ordered but variable acquisition of function across five interacting domains: **gross motor**, **fine motor**, **language and speech**, **cognitive development**, and **social and emotional development**. The domains are separated for examination and screening, not because they develop independently. A child who cannot explore because of a motor impairment receives a different stream of cognitive and social experience; a child with impaired hearing may appear delayed in language, play and social reciprocity; a child exposed to chronic adversity may show effects across attention, learning, affect regulation and relationships. The clinically useful question is therefore not merely, "Has the child acquired the milestone?" It is, "What is the pattern across domains, what is the trajectory, and is there loss, asymmetry or a qualitative abnormality?"

How to use this page. First learn the architecture: the five domains, the principles of developmental progression, and the distinction between a typical age, a normal window and a referral threshold. Then use the milestone, stage-alignment and primitive-reflex plates as reference tools rather than as lists of isolated dates. Finally, learn how normal variation becomes a clinical signal: developmental surveillance detects a trajectory, screening estimates risk, assessment characterises the profile, and diagnosis explains it. The central exam skill is to move from a remembered milestone to a domain-specific interpretation without turning a screening cut into a diagnosis.

Development is a trajectory across domains: loss at any age, marked asymmetry, or a milestone outside a construct-explicit window demands explanation, not a reflex label.

MNEMONIC

"G F L C S: five interacting domains"

Gross motor, **F**ine motor, **L**anguage and speech, **C**ognitive development, and **S**ocial and emotional development are the five interacting domains.

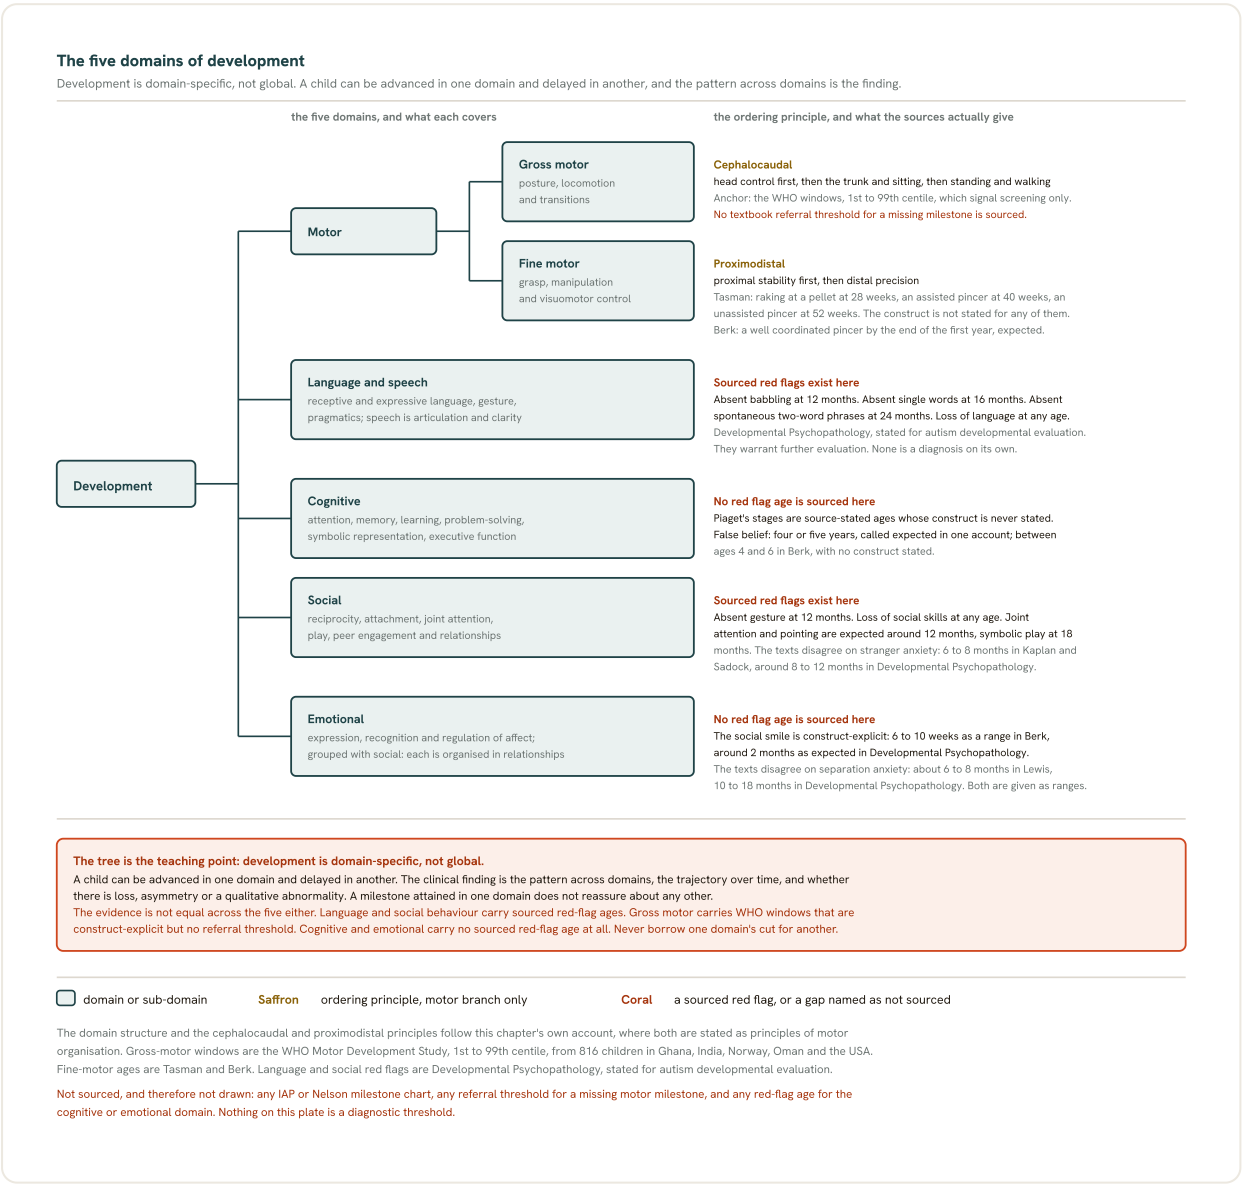

Fig 20.11 The five domains as a classification tree, with the two ordering principles that govern the motor branch only. Gross-motor windows are the WHO Motor Development Study, 1st to 99th centile; fine-motor ages are Tasman and Berk; language and social red flags are Developmental Psychopathology, stated for autism developmental evaluation. Cognitive and emotional development carry no sourced red-flag age, and that absence is drawn rather than filled in.

12.1 Organising development: domains, direction and developmental constructs

Development is orderly, cumulative and uneven. The sequence is usually more stable than the precise timing. Motor control proceeds broadly cephalocaudal, from head control towards control of the trunk and lower limbs, and proximodistal, from central and proximal stability towards distal precision. General movements become differentiated skills; reflex-dominated behaviour gives way to voluntary control; receptive capacities commonly precede expressive performance; and regulation is first shared with a caregiver before it becomes increasingly internal. Earlier

skills constrain later ones, but a child need not advance at the same rate in every domain. A jagged profile may be more informative than a uniformly low profile.

The five-domain formulation prevents two common errors. First, *motor* must be divided into gross motor posture and locomotion, and fine motor grasp, manipulation and visuomotor integration. Second, *language* is not synonymous with speech: language includes receptive and expressive symbolic communication, pragmatics and gesture, whereas speech concerns the motor production and intelligibility of sounds. Cognition includes attention, memory, learning, problem-solving, symbolic representation and executive functions. The social domain concerns reciprocity, attachment, joint attention, play and relationships; the emotional domain concerns expression, recognition and regulation of affect. These last two are often combined as social and emotional development because each is organised within relationships.

RULE **Always attach an age to its construct.** "Half of children by" states a median; "usually by" states an expected attainment; "normally between" states an expected range; "still normal up to" states an upper limit; and "refer if absent by" states a red flag. One cannot be substituted for another.

A milestone is a conveniently observable marker, not the whole developmental process. Milestones by age are useful only when the source and normative meaning are retained. Many textbook milestone ages are presented without saying whether they are averages, typical attainments or outer limits. Such values can be repeated as the source states them, but they cannot honestly be converted into "when to refer" thresholds. The reference plates therefore distinguish construct-explicit ranges from source-stated ages whose statistical role is unclear.

12.2 Motor development: posture, locomotion, grasp and visuomotor control

Gross motor development builds an antigravity platform; fine motor development uses that platform for exploration. Gross motor examination follows head control, rolling, sitting, transitional movements, standing, gait, running, jumping and stairs. Fine motor examination follows visual regard and reach, grasp pattern, transfer, release, pincer control, block construction, scribbling and copying. Quality matters as much as attainment: persistent fisting, early fixed hand preference, asymmetry, abnormal tone, unusual movement strategies or loss of a skill cannot be reassured away by the presence of another milestone.

The most defensible infancy anchor is the WHO Motor Development Study, which followed children in Ghana, India, Norway, Oman and the USA. Its windows run from the 1st to the 99th centile and are explicitly screening signals, not diagnostic thresholds. The gross-motor milestone plate gives all six windows, from sitting without support through walking alone, with the centile construct visible beside each value. Their breadth is a corrective to the false precision of a single milestone date. They signal the need for screening when a child appears late; they do not by themselves diagnose developmental delay.

4.3%	90%	5 sites
OF CHILDREN IN THE WHO STUDY DID NOT EXHIBIT HANDS-AND-KNEES CRAWLING AT ALL	APPROXIMATELY ACHIEVED FIVE GROSS MOTOR MILESTONES IN A COMMON SEQUENCE	INCLUDED INDIA, MAKING THE WHO WINDOWS DIRECTLY RELEVANT TO INDIAN TEACHING

Crawling is the classic trap. It is common but not universal, so absence of crawling alone is not a developmental red flag. Look instead at the child's overall locomotor strategy, tone, symmetry, transitions and progression towards supported and independent mobility. The full gross-motor milestone plate should be read as a set of windows, not a railway timetable.

Fine motor progression illustrates proximodistal organisation. An early palmar or raking approach becomes increasingly radial and then finger-thumb controlled; voluntary release and construction follow. The fine-motor milestone plate preserves Berk's expected ranges alongside the source-stated ages from Indian and international clinical references whose normative construct is unclear. It carries the longer sequence from grasp and transfer through block construction, scribbling and copying forms. At examination, link a failure to vision, tone, coordination, opportunity and comprehension before calling it an isolated fine-motor delay.

12.3 Language and speech: receptive, expressive, pragmatic and phonological development

Communication begins before words and comprehension generally outruns production. The sequence runs through social attention, reciprocal vocalisation, cooing, babbling, gesture, understanding of familiar words and commands, meaningful single words, word combinations, increasingly grammatical sentences, narrative and conversational competence. **Receptive language** is what the child understands; **expressive language** is what the child communicates through gesture, words and sentences; **pragmatics** is the social use of communication; and speech is the articulation, fluency, voice and motor realisation of language. A child may therefore have normal language with a speech-sound problem, or intact speech production with impaired social communication.

Source-stated expectations provide useful anchors without pretending to be universal deadlines. The language milestone plate separates cooing and babbling, receptive language, gesture, meaningful words, word combinations, vocabulary growth, grammar and intelligibility, and labels whether a value is expected, a range, a median or merely source-stated. One especially examinable construct error concerns Tasman's median expressive vocabulary of **50 words at 18 months** in US toddlers: this means half had reached that number, not that every child below it has delay. Expected intelligibility values in Kaplan and Sadock and DSM-5-TR are likewise not automatic referral thresholds.

The Indian Psychiatric Society clinical reference places babbling at 4 to 5 months, picking up familiar objects on request at 1 year, and two- to three-word sentences at **2 years**, but does not state the normative construct for these ages. Berk, in contrast, gives **18 to 24 months** as an expected range for combining two words. These statements should remain side by side rather than being collapsed into one falsely exact Indian or Western cut-off.

Language assessment begins with hearing and the communication environment, then separates comprehension, expression, gesture, reciprocity, speech clarity and oral-motor function. Ask about the languages used with the child and judge competence across the entire linguistic repertoire. Multilingual exposure does not justify loss of language, absent gesture or poor

reciprocity. Conversely, a smaller vocabulary in each individual language can mislead if the child's total conceptual vocabulary and communicative effectiveness are ignored.

12.4 Cognitive development, language acquisition and theory of mind

Cognition develops through action, representation, language and increasingly organised reasoning. Piaget's account remains the standard examination scaffold.

1. The sensorimotor stage emphasises knowledge through perception and action and the emergence of object permanence.
2. The preoperational stage brings symbolic representation but reasoning remains intuitive and vulnerable to centration and egocentrism.
3. Concrete operations bring conservation, reversibility and logical operations on tangible material.
4. Formal operations permit systematic abstraction and hypothetical reasoning.

The stage-alignment plate gives the source-stated age ranges. The clinical use is not to "diagnose a Piaget stage" but to pitch questions, explanations and testing tasks at the child's representational capacity.

Vygotsky offers a complementary, non-stage account. Cognitive development is socially and culturally mediated; skills first occur between people and are then internalised. The zone of proximal development is the distance between what a learner can do independently and what becomes possible with competent assistance. Scaffolding supplies temporary structure and is withdrawn as mastery grows; private speech helps organise behaviour and becomes internal speech. In assessment, compare unsupported performance with the child's response to graded prompts. The amount and kind of help that unlocks performance may reveal learning potential that a static score misses.

Three broad families explain language acquisition. Skinner's learning account emphasises imitation, shaping and reinforcement of communicative behaviour. Chomsky's nativist account argues that the speed and generativity of grammar require an evolved language capacity rather than reinforcement alone. Social-interactionist accounts, including Vygotsky's, emphasise joint activity, caregiver responsiveness, shared attention and language used within the zone of proximal development. Contemporary clinical reasoning is integrative: biological preparedness, auditory and cognitive capacities, social motivation, exposure and contingent interaction all matter. The practical use is causal restraint. Delayed language is not automatically poor parenting, and a rich language environment does not exclude hearing impairment, neurodevelopmental disorder or oral-motor difficulty.

Theory of mind is the capacity to represent mental states as mental states and to understand that another person may hold a belief different from reality and from one's own. Passing a false-belief task is expected at about **4 or 5 years** in the cited account. Failure on one task is not synonymous with autism: performance also depends on language comprehension, working memory, attention and the exact task demands. Clinically, theory of mind is examined through

pretend play, perspective-taking, deception, humour, social inference and the child's explanation of other people's actions, not through one laboratory item alone.

12.5 Social and emotional development: attachment, play, temperament and parenting

Social-emotional development is regulation within relationships. Early reciprocal attention and the social smile are followed by selective attachment behaviour, wariness of unfamiliar people, separation protest, joint attention, imitation, symbolic play, peer engagement and increasingly reflective emotion regulation. The social-emotional milestone plate sets out the source-stated windows and expected attainments for these behaviours. Observe whether they are spontaneous, shared for enjoyment and integrated with eye gaze, affect and gesture, rather than merely present on command.

The literature gives different expected windows for the normal anxieties of attachment. The plate therefore keeps Lewis, Kaplan and Sadock, and Developmental Psychopathology side by side instead of collapsing them into one cut-off. The examinable principle is qualitative: separation and stranger anxiety reflect discrimination of familiar caregivers and attachment, and become concerning when intensity, persistence or developmental context causes marked impairment.

Thomas and Chess describe **temperament** through nine dimensions: activity level, rhythmicity, approach or withdrawal, adaptability, threshold of responsiveness, intensity of reaction, quality of mood, distractibility, and attention span or persistence. Their three types are easy, difficult, and slow-to-warm-up. These are descriptive constellations, not diagnoses, and many children do not fit a pure type. **Goodness of fit** is the match between the child's temperamental characteristics and the demands, expectations and supports of the environment. A highly active child may function well where movement is permitted and poorly where prolonged stillness is demanded. Clinical intervention can therefore alter the fit without pathologising the child.

Baumrind parenting styles organise caregiving by responsiveness and demandingness.

PARENTING STYLE	PATTERN
Authoritative parenting	Combines warmth with clear, developmentally appropriate limits.
Authoritarian parenting	Is controlling with lower responsiveness.
Permissive parenting	Is responsive with few consistent demands.
The later uninvolved category	Describes low responsiveness and low demandingness.

These patterns are associations, not deterministic labels, and must be interpreted in cultural, socioeconomic and safety context. The clinical use is to translate a style label into modifiable behaviour: predictability, contingent warmth, supervision, repair after conflict and limits that match the child's developmental capacity.

12.6 Stage theories on one axis: psychosocial, psychosexual, moral and relational development

Stage theories ask different questions and should be aligned, not blended. The alignment plate places the source-stated numeric stages on a shared axis while leaving genuinely non-

numeric theories non-numeric.

12.7 Primitive reflexes: emergence, integration and neurological meaning

Primitive reflexes are expected early patterns whose interpretation depends on the specific reflex, the method and the neurological context. The primitive-reflex plate shows appearance, how each reflex is elicited, and the source-stated disappearance. At the bedside assess symmetry, vigour, habituation where relevant, and persistence alongside tone, posture and voluntary movement. Absence when expected, marked asymmetry, or persistence that interferes with voluntary control may indicate central or peripheral dysfunction, but gestational age, illness and state of arousal matter.

The sources do not always give one disappearance age. Berk, Hutchison and Tasman differ for Moro and palmar grasp, while Babinski has separate expected, upper-limit and red-flag statements. The primitive-reflex plate displays these source-specific claims without forcing them into one value. Hutchison also gives a general warning about persistence of primitive reflexes, yet its reflex-specific entries show why the honest answer must name the reflex and construct rather than manufacture a universal cut-off.

TRAP **A disappearance age is not automatically a referral age.** Textbooks may report different expected ages for the same reflex. State the source, preserve whether it is expected, an upper limit or a red flag, and interpret the reflex within the neurological examination.

Reflexes should not be recited in isolation from developmental organisation. Their integration permits increasingly selective voluntary movement, but development is not a simple switch from "reflex present" to "reflex absent". The reflex table is a reference for examination; the clinical task is to decide whether the entire motor pattern is coherent.

12.8 Developmental surveillance, red flags and Indian assessment pathways

A concise clinical synthesis. Name the affected and preserved domains; describe onset, sequence, rate, plateau or regression; compare performance with construct-appropriate norms; examine hearing, vision, growth, neurology and dysmorphism; document the relational and learning environment; and choose screening or assessment deliberately. The diagnostic question comes last. Developmental competence is not the accumulation of dates but the organisation of increasingly adaptive function across motor, language, cognitive, social and emotional systems.

13 . Gross motor and fine motor milestones by age

Developmental milestones are landmarks in an unfolding process, not deadlines stamped onto a child. The exam task is therefore twofold: know the age-linked sequence well enough to recognise a delay, and know what kind of age each source is giving you. An **expected range** describes variation in attainment; an **expected age** describes what a typical child usually does; an **upper limit** marks the outer boundary of normal; and a **red-flag threshold** triggers further assessment. Most textbook ages do not identify which of these constructs they represent. Those ages may be repeated in the source's own terms, but they must never be promoted into referral rules.

How to use this page. Begin with the two orienting maps: the **developmental-theory alignment** and the **domains-and-milestones framework**. Then use the accompanying milestone plates to learn sequence and age together. Read gross motor against the construct-explicit WHO windows, read fine motor as source-labelled examination anchors, and finish by asking whether the child is following the expected sequence, whether skills have been lost, and whether screening rather than diagnosis is the next step.

The must-memorise line: an age is not a referral threshold until the source identifies it as an upper limit or a red flag.

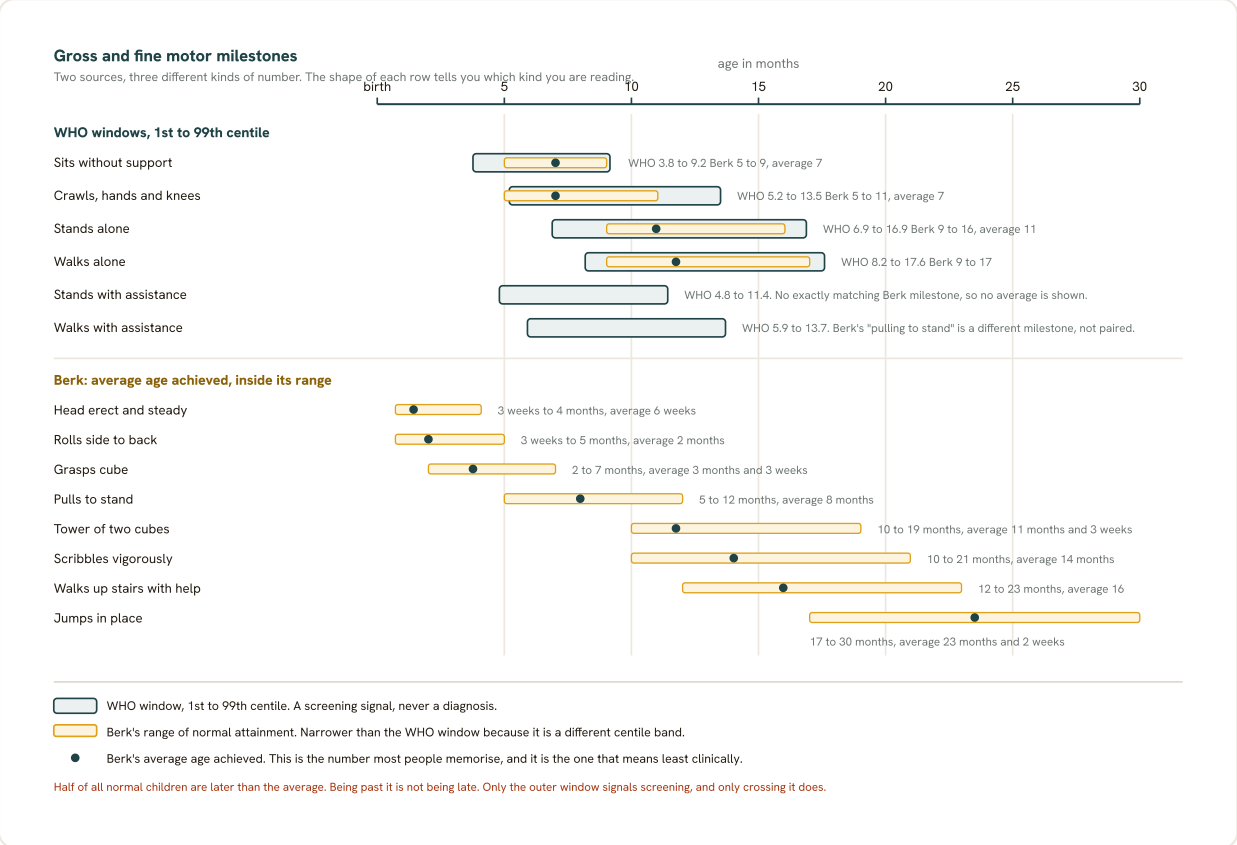

Fig 20.12 Motor milestones from two sources, drawn so the kind of number is visible. Outer bars are the WHO Motor Development Study windows between the 1st and 99th centiles, from 816 children in Ghana, India, Norway, Oman and the USA. Inner bars and dots are Berk's ranges and average ages. Where no Berk milestone matches a WHO one exactly, no average is shown rather than pairing an approximate equivalent.

13.1 The twin orienting maps: theories by age and domains and milestones

One map explains the child; the other describes the child's observable development. The developmental-theory alignment places the stage theories beside one another so that the resident can compare what each theory foregrounds at the same period: cognition in Piaget, psychosocial conflict in Erikson, drive organisation in Freud, separation-individuation in Mahler and moral reasoning in Kohlberg. Vygotsky belongs beside, not inside, this age axis because his sociocultural account is not a stage sequence. The second map is the domains-and-milestones framework: gross motor, fine motor, language and speech, social and emotional development, and cognitive or adaptive functioning. Together they prevent a common error, which is to confuse a theory about development with a milestone used to observe it.

The maps also operate at different levels. A **stage theory** supplies a broad organising idea, while a **milestone** is a directly elicited or observed behaviour. Neither is a diagnosis. A child may attain motor skills within a wide normal window while showing difficulty in another domain, and apparent delay may reflect opportunity, illness, sensory impairment or cultural variation rather than a unitary disorder. The developmental framework is therefore always domain-specific before it becomes global.

RULE **Separate sequence, age and construct.** First ask whether the skill appears in the expected developmental order; then identify the source's age; finally decide whether that age is an expected range, an upper limit, a red flag or an age whose normative role is unclear.

MNEMONIC

"SAC: Sequence, Age, Construct"

First ask whether the skill appears in the expected developmental order (Sequence), then identify the source's age (Age), and finally decide whether that age is an expected range, an upper limit, a red flag or an age whose normative role is unclear (Construct).

13.2 Band A: the stage-theory alignment

The theories by age plate is an alignment device, not a claim that the theories are interchangeable. Read its source-specific age bands horizontally, but keep each theory's question distinct. Piaget's sequence of sensorimotor, preoperational, concrete operational and formal operational stages helps the clinician pitch explanations and tasks to the child's mode of reasoning. Erikson's psychosocial stages, from trust through autonomy, initiative, industry and identity, organise the age-salient relational conflict. Freud's psychosexual stages, oral, anal, phallic, latency and genital, remain historically important for formulation and examination theory. The age bands on the plate are source descriptions whose normative construct is unclear; none defines a clinical threshold.

Mahler's separation-individuation model follows differentiation, practising, rapprochement and object constancy, and is clinically useful when thinking about autonomy in relation to a caregiver. Kohlberg's moral development must not be assigned invented numerical ages: Kaplan and Sadock uses descriptive bands such as before adolescence, during adolescence and late adolescence or early adulthood. Vygotsky proposed no age stages. His zone of proximal development, scaffolding, private speech and socially mediated learning are cross-cutting mechanisms that guide how much support permits the child's next level of performance. The plate therefore shows Kohlberg as descriptive bands and Vygotsky beside the age axis, never as fabricated numeric rows.

13.3 Band B: the five domains and the organisation of motor development

The domains of child development are related but not reducible to one another. **Gross motor** development concerns posture, balance and large antigravity movements; **fine motor** development concerns reach, grasp, release, manipulation and visuomotor construction. The remaining domains are language and speech, social and emotional development, and cognitive or

adaptive functioning. Examination should therefore be domain-specific: delayed independent walking is not equivalent to delayed pincer grasp, and either may occur with preserved language and social reciprocity.

Motor control generally becomes organised in a **cephalocaudal** direction, with control of the head and upper trunk preceding control needed for standing and walking, and in a **proximodistal** direction, with shoulder and arm control preceding refined finger use. These are organising gradients, not clocks. The milestones by age plates convert the gradients into observable behaviours, while the clinician tests quality as well as attainment: symmetry, tone, postural control, movement strategy, persistence of primitive patterns and spontaneous use of both hands.

13.4 Gross motor milestones by age: use WHO windows as screening signals

The WHO Motor Development Study gives the most defensible construct-explicit gross motor framework. It followed 816 children from Ghana, India, Norway, Oman and the USA and derived windows bounded by the 1st and 99th centiles. These are *windows of achievement*, intended to support descriptive population comparisons and to signal the need for screening when a child appears late. They are not diagnostic boundaries. The gross motor plate therefore owns the complete sequence, while the prose here teaches how to interpret it:

1. sitting without support;
2. standing with assistance;
3. hands-and-knees crawling;
4. walking with assistance;
5. standing alone;
6. walking alone.

3.8 to 9.2 months	8.2 to 17.6 months	4.3 percent
WHO 1ST-TO-99TH-CENTILE WINDOW FOR SITTING WITHOUT SUPPORT	WHO 1ST-TO-99TH-CENTILE WINDOW FOR WALKING ALONE	CHILDREN DID NOT SHOW HANDS-AND-KNEES CRAWLING AT ALL

The span between the two anchors matters. Standing alone has the widest WHO window, from 6.9 to 16.9 months, while sitting without support has the narrowest. About **90 percent** of children achieved five of the milestones in a common sequence, but crawling was not universal. India was one of the WHO study sites, so the WHO norms are not simply Western norms imported into Indian practice, although they are still multinational rather than an Indian-only reference.

Source-specific differences must remain visible. For Western norms, Berk reports a U.S. expected range of 5 to 9 months for sitting alone and 9 to 17 months for walking alone. WHO gives **3.8 to 9.2 months** and **8.2 to 17.6 months** respectively. Kaplan and Sadock gives 9 to 15 months as an expected range for independent walking. These figures answer different source questions and should not be averaged into a new norm.

TRAP **Failure to crawl is not, by itself, a red flag.** WHO found that 4.3 percent of children never exhibited hands-and-knees crawling. The examination error is to convert a non-universal milestone into a compulsory gateway to walking.

13.5 Fine motor milestones by age: grasp, transfer, pincer and construction

Fine motor development is a progression from whole-hand contact to precise opposition and planned construction. The fine motor plate should be learned as a sequence:

SEQUENCE	FINE MOTOR MILESTONE
1	early grasp;
2	purposeful transfer between hands;
3	radial hand use;
4	pincer opposition;
5	spontaneous scribbling;
6	block construction;
7	copying forms.

The child's posture and vision matter throughout; a poor reach may arise from proximal instability, and an apparent manipulation problem may reflect visual or asymmetric motor difficulty.

The source labels must be preserved. The IPS child and adolescent psychiatry guideline lists bidextrous grasp at 3 months, monodextrous grasp and object transfer at 6 months, and pincer grasp at 9 months, but does not state whether these are expected ages, averages or limits. Kaplan and Sadock says the pincer grasp is first seen at about 9 months, again without converting the statement into a threshold. Berk makes the stronger construct-explicit claim that a well-coordinated pincer grasp is expected by the end of the first year. For a U.S. reference range, Berk places vigorous scribbling between 10 and 21 months and building a tower of two cubes between 10 and 19 months.

Tasman supplies the familiar examination sequence for block towers and copied forms, but those entries have an unclear normative construct. They belong on the milestone plate as source-listed anchors, not in a referral algorithm. The same caution applies when different books disagree: Tasman lists copying a cross and a square at 48 months, while the IPS guideline lists copying a cross at 3 years. Record both source claims; do not collapse them, choose a hidden average or describe either as an upper limit.

13.6 Primitive reflexes: appearance, disappearance and the meaning of persistence

Primitive reflexes are normal early motor phenomena whose later persistence may indicate impaired cortical maturation or neurological dysfunction. The accompanying reflex table owns the verified appearance and disappearance ages and should be used during revision to pair each reflex with how it is elicited. In prose, the high-yield principle is that a reflex age remains

source-specific: Moro disappearance is expected at 12 weeks in Tasman but at 6 months in Berk and Hutchison, while asymmetric tonic neck reflex disappearance is expected at 4 months in Berk. The disagreement must be shown rather than silently harmonised.

Hutchison treats persistence of primitive reflexes beyond the fourth month of life as a general red flag, but its individual-reflex statements must still be respected. The extensor plantar response may remain within the upper limit up to 18 months, whereas Babinski persistence beyond 2 years is a red flag. Thus, primitive reflexes are interpreted by reflex, context and source, not by applying one disappearance age indiscriminately to all.

13.7 Step 5: developmental history, screening and Indian clinical use

A milestone concern becomes clinically meaningful only after a developmental history and direct observation. The developmental history establishes pregnancy and birth context, illness, opportunity for movement, the sequence and quality of attainment across all five domains, asymmetry or early hand preference, functional impact, family observations and any loss of previously acquired skills. Loss of language or social skills at any age requires assessment. Developmental screening then identifies children who need fuller evaluation; it does not itself provide an aetiological diagnosis.

WHO norms contribute a multinational motor reference that included an Indian site.

14 . Language and speech developmental milestones

Language development is not a list of words tied to birthdays. It is the progressive organisation of attention, comprehension, symbolic representation, vocabulary, grammar, speech-sound production and social communication. The examination task is to recognise the sequence, separate receptive language from expressive language and speech, preserve the normative meaning of every age, and identify the few absences that are genuine developmental red flags. An expected age describes what a typical child usually does; a median means that half of the reference group has attained the skill; an upper limit marks the outer boundary of normal; and a red-flag threshold warrants further assessment. A textbook age whose construct is unclear must never be converted into a referral rule.

How to use this page. Start with the twin orienting maps, the **developmental-theory alignment** and the **domains-and-milestones framework**. Then follow communication from prelinguistic vocalisation to words, combinations, grammar and intelligibility. Read the accompanying milestones by age plate for the full source-labelled sequence, not as a set of deadlines. Finish with worked cases and retrieval prompts. Throughout, ask four questions:

- what domain is being tested;
- whether the skill is understood or produced;
- what construct the stated age carries; and
- whether the finding requires observation, screening or referral.

The must-memorise line: refer for absent babbling or gestures at **12 months**, absent single words at **16 months**, absent spontaneous two-word phrases at **24 months**, or loss of language or social skills at any age.

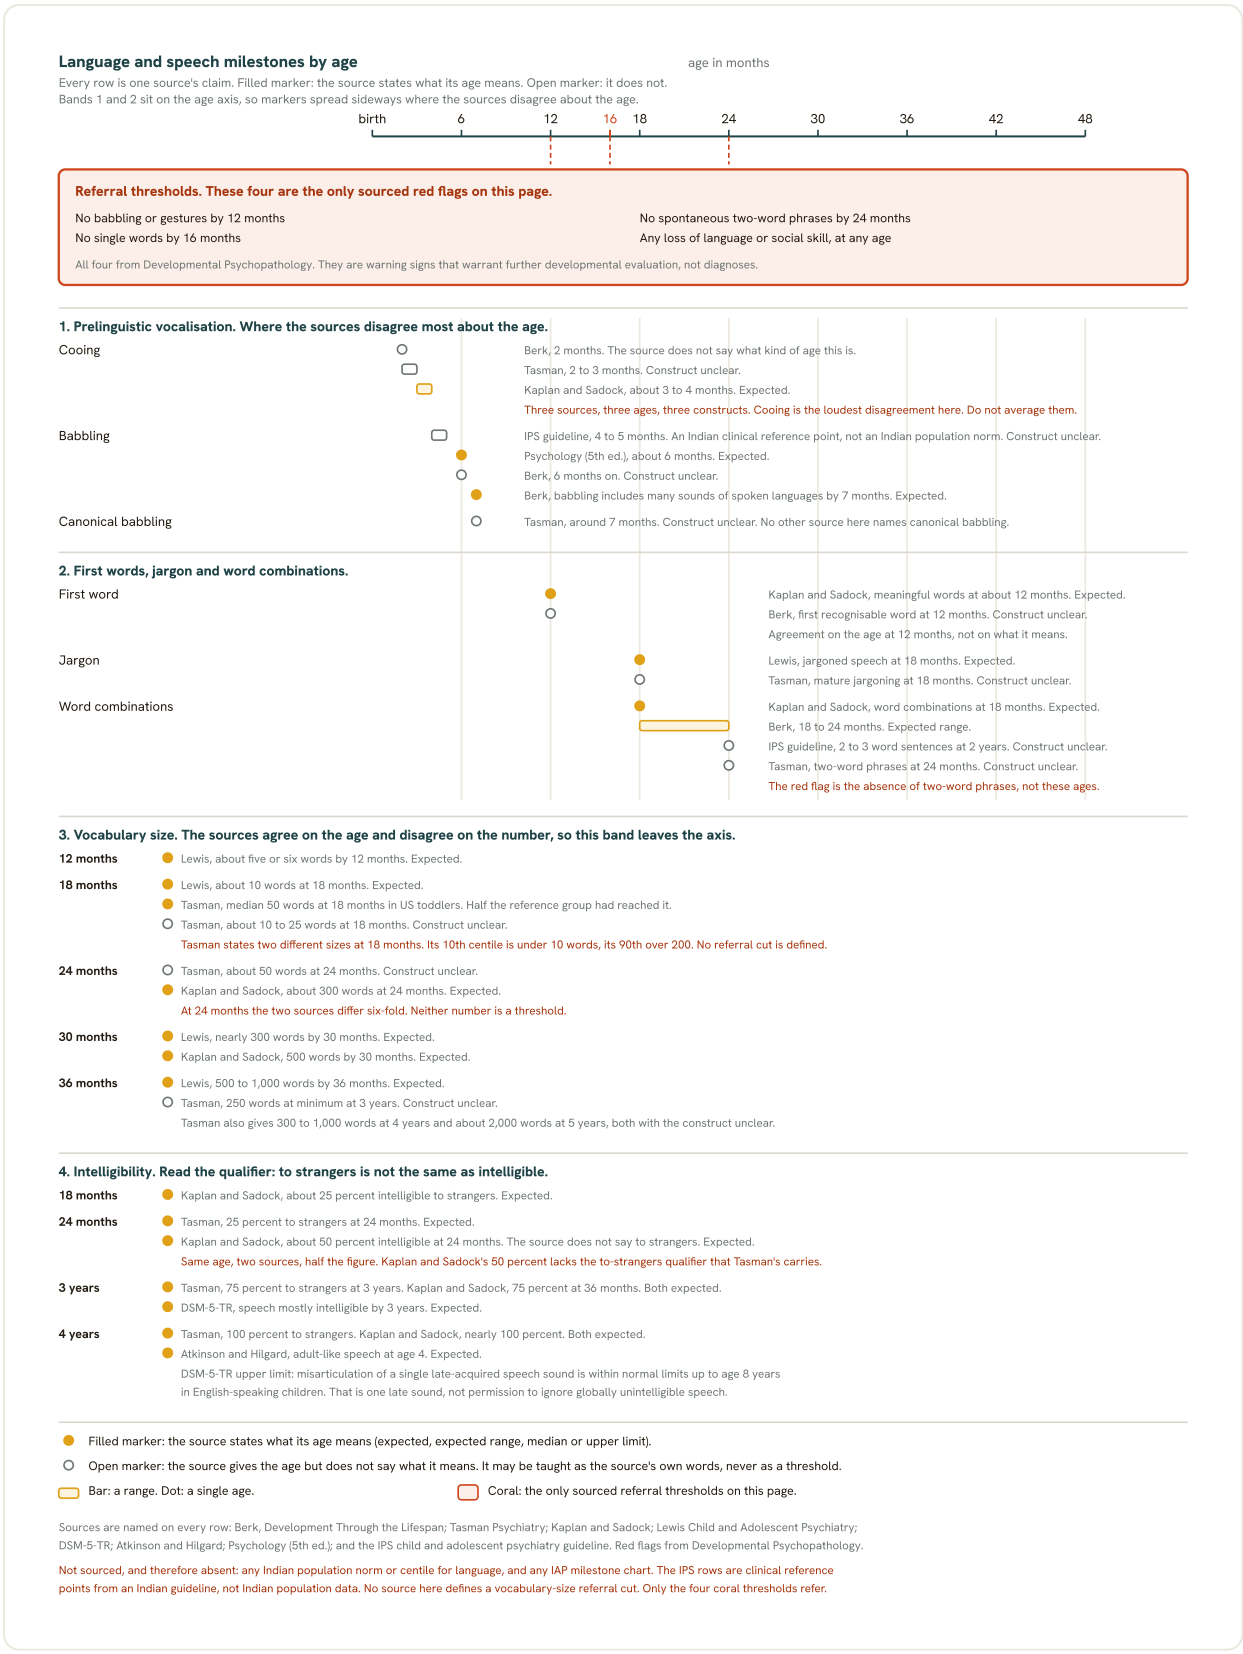

Fig 20.13 Language and speech milestones, drawn so that source and construct stay visible. Each row is one source's stated claim: Berk (Development Through the Lifespan), Tasman, Kaplan and Sadock, Lewis, DSM-5-TR, Atkinson and Hilgard, Psychology (5th ed.) and the IPS child and adolescent psychiatry guideline. Filled markers are ages whose normative construct the source states; open markers are ages it leaves unclear. Cooing, babbling and vocabulary size are shown as disagreements rather than averaged, because no source reports an average. The coral band carries the four red flags from Developmental Psychopathology, which are the only referral thresholds here.

14.1 The twin orienting maps: developmental theories and observable milestones

One map explains development; the other records what the child can do. The developmental-theory alignment places major theories by age on a shared axis without pretending that they describe the same process. Piaget's sensorimotor, preoperational, concrete operational and formal operational stages concern the organisation of thought and help the clinician pitch explanations and tasks. Erikson's psychosocial stages concern trust, autonomy, initiative, industry and identity and help frame the child's age-salient relational task. Freud's psychosexual stages, oral, anal, phallic, latency and genital, remain historically important in examination theory and psychodynamic formulation. The accompanying alignment plate owns the source-specific age bands. Their normative construct is unclear, so none is a clinical threshold.

Mahler's separation-individuation theory follows differentiation, practising, rapprochement and object constancy and is useful when formulating autonomy in relation to the caregiver. Its sourced ages remain on the alignment plate because their normative construct is unclear. Kohlberg's moral development must remain in Kaplan and Sadock's descriptive bands: before adolescence, school-aged children, some young adolescents, during adolescence, later in adolescence, and late adolescence or early adulthood. These bands help the clinician examine the structure of moral reasoning, but no numeric age may be manufactured from them. Vygotsky did not propose age stages. His zone of proximal development, scaffolding, private speech and socially mediated learning sit beside the age axis as mechanisms that explain how supported performance can exceed independent performance.

The second orienting map is the domains-and-milestones framework. It divides observable development into gross motor, fine motor, language and speech, social and emotional, and cognitive or adaptive domains. A theory is an explanatory lens; a milestone is an observed or elicited behaviour. The distinction matters clinically: a child may have age-appropriate gross motor and fine motor skills but delayed language, or may speak little because hearing, opportunity or social reciprocity is impaired. The developmental framework is therefore domain-specific before it becomes a global judgement.

RULE **Name the construct before using the age.** Say "expected" only when the source says typical attainment, "median" only when it identifies the 50th percentile, "upper limit" only for an outer normal boundary, and "red flag" only for a stated referral threshold. Otherwise attribute the age to its source and leave its normative role unclear.

14.2 Band A relational and constitutional frameworks

Attachment, temperament, theory of mind, language-acquisition theory and parenting style influence the communicative environment. In practice, biology, learning and responsive interaction work together.

14.3 Band B: the five domains and the architecture of communication

Language is one developmental domain, but it recruits all the others. The five domains of child development are gross motor, fine motor, language and speech, social and emotional, and cognitive or adaptive functioning. Gross motor development concerns posture and large

movement; fine motor development concerns reach, grasp, manipulation and visuomotor construction. Motor control is commonly organised along cephalocaudal and proximodistal gradients. Language and speech concerns comprehension, symbolic communication, words and grammar, plus the motor production of intelligible sounds. Social and emotional development supplies reciprocity and joint engagement, while cognition supports representation, memory and rule learning.

Within communication, keep four components separate.

COMPONENT	FUNCTION
Receptive language	is what the child understands.
Expressive language	is what the child communicates.
Speech	is the motor and acoustic production of sounds.
Pragmatics	is the socially appropriate use of communication.

Infants understand more than they can produce, so the absence of spoken words does not by itself define the level of comprehension. Assessment must sample response to name, words and commands, gestures and joint attention, spontaneous communication, vocabulary, sentence structure, articulation, voice, fluency and intelligibility. Hearing must be examined because a sensory limitation can mimic or compound language delay.

The milestone framework is sequential rather than rigidly universal. Prelinguistic vocalisation precedes meaningful words; single words precede productive combinations; vocabulary and grammar expand; and speech becomes increasingly intelligible. The accompanying domain-specific plates own the full motor, language and social and emotional milestone reference tables. They should be read horizontally across age and vertically within each domain, without duplicating them into a second prose table.

14.4 From cooing and babbling to words and combinations

Early communication moves from vocal play to symbols shared with another person. Kaplan and Sadock describes cooing as expected at about 3 to 4 months and meaningful words as expected at about 12 months. *Psychology* (5th ed.) describes babbling as expected at about 6 months, while Berk states that babbling includes many sounds of spoken languages by 7 months. These expected claims should be distinguished from source-listed ages whose construct is unclear, such as cooing at 2 months in Berk, canonical babbling around 7 months in Tasman, and first recognisable word at 12 months in Berk.

The Indian clinical reference in the IPS child and adolescent psychiatry guideline lists babbling at 4 to 5 months, understanding "no" at 9 months and picking up familiar objects when asked at 1 year. The source does not say whether these are expected ages, averages or limits. They should therefore be retained as IPS clinical reference points, not labelled Indian population centiles and not converted into referral thresholds. Western and Indian-source statements stay visible side by side because silently averaging them creates a norm that no source reported.

Kaplan and Sadock describes word combinations as expected at 18 months. Berk gives an expected range of 18 to 24 months for combining two words, while the IPS guideline lists 2- to 3-word sentences at 2 years without specifying the normative construct. Lewis describes one-word sentences as expected at 18 months, jargoned speech at 18 months, and three- to four-word sentences by 3 years. The correct examination answer names the behaviour, the source and the construct, then uses the explicit red-flag thresholds for referral rather than treating any one textbook anchor as a deadline.

14.5 Vocabulary, grammar and intelligibility

Vocabulary size varies widely; communicative organisation and intelligibility provide the more useful sequence. Lewis gives expected expressive vocabulary anchors of about five or six words by 12 months, about 10 words at 18 months, nearly 300 words by 30 months, and 500 to 1,000 words by 36 months. Tasman reports a median of 50 words at 18 months among US toddlers, meaning half had attained that vocabulary size by that age. It also reports fewer than 10 words at the 10th percentile and more than 200 at the 90th percentile at 18 months, but does not define a referral cut. These values demonstrate variability and must not be collapsed into a single universal minimum.

about 25 percent	about 50 percent	about 75 percent	nearly 100 percent
SPEECH INTELLIGIBLE TO STRANGERS AT 18 MONTHS	EXPECTED SPEECH INTELLIGIBILITY AT 24 MONTHS	KAPLAN AND SADOCK EXPECTS INTELLIGIBILITY TO STRANGERS AT 36 MONTHS	EXPECTED SPEECH INTELLIGIBILITY AND ADULT-LIKE AT 4 YEARS

DSM-5-TR says speech is mostly intelligible by 3 years.

Grammar changes alongside vocabulary. **Telegraphic speech**, in which content words carry meaning while smaller grammatical elements are sparse, is expected around a year and a half in *Psychology* (5th ed.). Two- and three-word sentences are expected at about 2 years in Atkinson and Hilgard, and sentences become progressively more grammatical. By about 6 years, children are expected to be nearly as fluent as adults. Fluency, grammar and articulation are related but separable, so a child may have age-appropriate ideas and sentence structure yet remain difficult to understand.

Speech-sound expectations must also preserve their construct. DSM-5-TR states that most speech sounds and words become clear with development, while misarticulation of a single late-acquired English speech sound can remain within normal limits up to 8 years. That is an upper-limit statement for a specific late-acquired sound in English-speaking children, not permission to ignore globally unintelligible speech or impairment in another linguistic context.

TRAP **Do not turn a vocabulary count into a universal referral threshold.** At 18 months, Lewis expects about 10 words, while Tasman reports a US median of 50 words and a very wide percentile spread. The four explicit communication red flags, functional impairment, trajectory, comprehension, hearing and social communication decide escalation.

14.6 Primitive reflexes, adolescence and the wider developmental axis

Communication must be interpreted within neurological and maturational development. **Primitive reflexes** are expected early neurological responses. The accompanying reflex table owns their verified appearance, method by which each is elicited, and source-specific disappearance. The high-yield lesson is not to harmonise disagreement: Tasman expects Moro disappearance at 12 weeks, whereas Berk and Hutchison give 6 months; Berk expects asymmetric tonic neck reflex disappearance at 4 months. Hutchison treats persistence of primitive reflexes beyond the fourth month of life as a general red flag, but allows an extensor plantar response up to 18 months as an upper limit and treats Babinski persistence beyond 2 years as a red flag. Each reflex must therefore be interpreted individually.

Adolescent development extends the same developmental method beyond childhood. Its tasks include identity formation, autonomy, peer and intimate relationships, values, gender identity and continuing psychosexual development. Puberty describes biological maturation, while Tanner staging records morphology rather than assigning a fixed age. Girls are staged separately for breast and pubic-hair development; boys for genital and pubic-hair development. Stage I is preadolescent and stage V is mature or adult distribution. The verified puberty plate retains sex-specific ranges without inventing Indian timing data.

The neurodevelopment of adolescence is often framed through a dual-systems or maturational imbalance account, in which reward and socioemotional salience can exert strong influence while cognitive control continues to consolidate. This helps explain peer-sensitive risk-taking without treating normal exploration as pathology. Clinically, the resident asks about persistence, context, impairment, mood, substance use, trauma and coercion rather than applying a moral label.

14.7 Step 5: developmental red flags, surveillance and Indian screening

Screen and refer. The practical question is when to refer, and these explicit thresholds answer it more safely than an unlabelled textbook milestone. Arrange comprehensive developmental, hearing and communication assessment when concern persists or a red flag is present.

14.8 Step 6: five worked cases

Worked case 1, milestone-dating: An 18-month-old uses about 10 words, understands familiar requests and has started combining words. Lewis treats about 10 expressive words as expected at this age, Kaplan and Sadock expects word combinations, and Tasman reports a much higher US median of 50 words. The correct conclusion is that the sources describe different constructs and populations. Assess trajectory, comprehension, hearing and function; do not diagnose delay from the median.

Worked case 2, red-flag: A child has no single words at 16 months. This meets a verified red-flag threshold for further developmental evaluation. Take a full developmental history, test hearing, observe gestures, joint attention and reciprocity, screen development, and refer. Waiting for an unlabelled later textbook anchor would misuse the evidence.

Worked case 3, attachment-pattern: In a Strange Situation vignette, a child explores with the caregiver present, is distressed by separation, seeks comfort on reunion and then returns to play.

The pattern is secure attachment because the caregiver functions as a secure base and reunion restores regulation. The answer describes the observed strategy, not the worth of the parent.

Worked case 4, temperament and goodness-of-fit: A slow-to-warm-up child speaks freely at home but becomes silent when repeatedly pressed to perform before unfamiliar adults. Thomas and Chess directs attention to approach or withdrawal, adaptability and intensity. A slower, predictable introduction improves goodness of fit. The theory explains context-sensitive performance without assuming a fixed language deficit.

Worked case 5, theory-application: A child can complete a verbal classification task with graduated prompts but not independently. Vygotsky locates this performance in the zone of proximal development and supports scaffolding followed by withdrawal of help. Piaget asks what kind of reasoning the task demands, while Erikson asks how the encounter supports initiative or industry. The theories illuminate different aspects of one observation and do not replace direct assessment.

14.9 Step 7: consolidation, retrieval and synthesis

MNEMONIC

"Hear, Share, Say, String, Clear."

Hear stands for receptive language and hearing; *Share* for gesture, joint attention and pragmatics; *Say* for meaningful words and vocabulary; *String* for word combinations and grammar; *Clear* for articulation and intelligibility. Run the mnemonic in that order during a developmental history. Add the red-flag ladder separately: 12 for babbling or gestures, 16 for a single word, 24 for a spontaneous pair, and any age for loss.

Synthesis map: redraw from memory two parallel lines. On the first, place the sourced theories by age, keeping Kohlberg as descriptive bands and Vygotsky as a cross-cutting mechanism. On the second, place milestone anchors from cooing and babbling through words, combinations, grammar and intelligibility. Beneath both, write the five domains and the four red flags. This makes the theory-alignment map explain the child while the milestone map records the child's observable function.

Final clinical synthesis. Language assessment is developmental reasoning in miniature: identify the domain, distinguish understanding from production, describe the sequence and trajectory, preserve the source's normative construct, look for regression and social-communication change, examine hearing and the caregiving environment, and use screening to decide who needs formal assessment. The safest resident is not the one who recites the most ages, but the one who knows exactly what each age is allowed to mean.

15 . Social and emotional developmental milestones

Social and emotional development is the progressive organisation of reciprocal engagement, attachment behaviour, shared attention, play, self-awareness, understanding of other minds and regulation of affect within relationships. It is not a single skill and it cannot be judged from eye

contact alone. A child may produce a behaviour on request yet rarely use it spontaneously to share interest; another may show an age-listed behaviour but with poor reciprocity, little affective integration or loss of previously acquired skills. For the psychiatry resident, the decisive task is therefore to combine milestone timing with quality, context, trajectory and function.

How to use this page. Begin with the five domains of child development, then learn the social and emotional sequence from social reciprocity through joint attention, symbolic play, peer engagement and theory of mind. Use the accompanying social and emotional milestone plate for the domain-specific reference table. This page explains what the entries mean, why normal anxiety windows differ across sources, and how to move from milestones by age to developmental surveillance and referral without converting an expected age into a red-flag threshold.

In social and emotional development, timing starts the assessment; spontaneity, reciprocity, integration, trajectory and loss decide its clinical meaning.

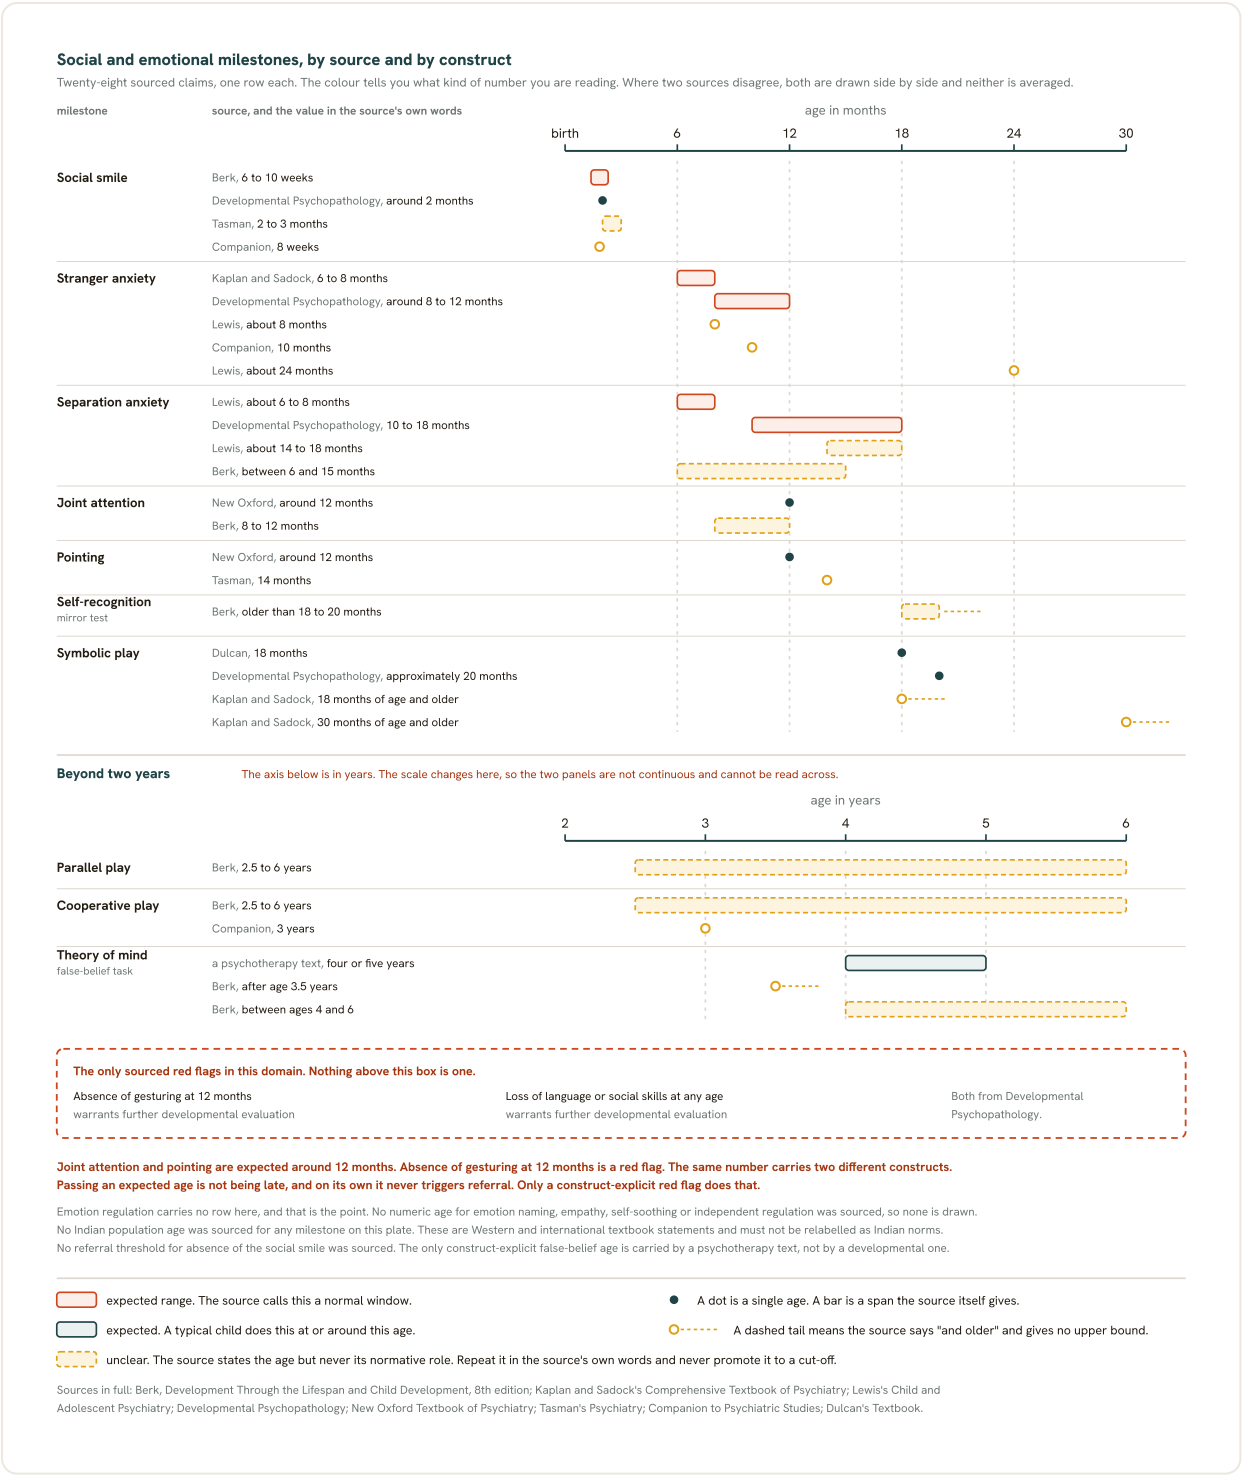

Fig 20.14 Social and emotional milestones, drawn one row per sourced claim so that disagreement between texts stays visible. Colour encodes the normative construct each source states for itself: an expected range, an expected age, or an age whose role the source never states. Stranger anxiety is 6 to 8 months in Kaplan and Sadock and around 8 to 12 months in Developmental Psychopathology; separation anxiety is about 6 to 8 months in Lewis and 10 to 18 months in Developmental Psychopathology. Both windows are kept side by side and neither is averaged. No milestone on this plate is a referral threshold; the only two sourced red flags for this domain are boxed separately. The lower panel is on a years axis, not months.

15.1 The domain within the five-domain developmental map

The domains are examined separately but develop as one system. The five domains are gross motor, fine motor, language and speech, cognitive or adaptive development, and social and emotional development.

DOMAIN	CONTRIBUTION
Gross motor development	supplies posture and mobility.
Fine motor development	supplies reach, grasp and manipulation.
Language and speech	supplies comprehension, expression and verbal communication.
Cognition	supplies representation, learning and problem-solving.
Social and emotional development	supplies reciprocity, relationships, play and regulation.

Social behaviour therefore recruits every other domain. A child must be able to perceive a social cue, orient and act on it, understand its meaning, and regulate the resulting arousal.

The general motor principles of cephalocaudal and proximodistal progression explain why early postural control and proximal stability support later exploration and gesture, but they are not laws for dating social milestones. Social-emotional progression is better understood as widening organisation: regulation is initially supported by a caregiver, dyadic engagement becomes shared engagement around an object or event, symbolic play permits representation, peer interaction becomes more coordinated, and the child increasingly understands mental states. These are linked developmental achievements, not isolated party tricks.

RULE **Name the construct whenever you name an age.** An expected age says what usually occurs; an expected range describes a normal window; a source-stated age with an unclear construct must remain source-stated; and a red flag says when absence warrants further evaluation. None can silently substitute for another.

The accompanying plate owns the full domain-specific social and emotional milestone reference table. Read it horizontally to see the child's profile across functions and vertically to follow one function over time. Where two sources give different windows, retain both. Where a source does not identify its value as expected, median, upper limit or red flag, do not promote that value into a clinical cut-off.

15.2 Early reciprocity and the social smile

The earliest useful observation is not whether the infant smiles, but whether the smile is socially organised. A **social smile** is elicited in reciprocal interaction and is integrated with orientation, facial affect and the other person's behaviour. Berk gives an expected range of **6 to 10 weeks**; *Developmental Psychopathology* describes it as expected at around 2 months in typically developing infants. These are compatible expected statements, not referral thresholds. Tasman lists 2 to 3 months and *Companion to Psychiatric Studies* lists 8 weeks, but neither source states the normative construct, so those values should be repeated only in the source's own descriptive role.

During examination, create an opportunity for mutual engagement rather than commanding a performance. Observe orientation to the caregiver's face and voice, change in affect with

interaction, reciprocal vocal or facial response, ease of soothing and recovery after arousal. A single smile is weak evidence if it is not socially directed; limited eye contact is also nonspecific when considered alone. Vision, hearing, illness, fatigue, temperament, unfamiliar surroundings and the caregiver-child interaction can all change what appears in the room. The correct mental status description is behavioural and present tense, while the developmental history establishes whether the pattern is typical, delayed, inconsistent or lost.

15.3 Selective relationships: stranger anxiety and separation anxiety

Wariness and protest can be normal signs that the infant now discriminates familiar relationships. **Stranger anxiety** refers to wariness or distress in response to an unfamiliar person. Kaplan and Sadock gives an expected range of 6 to 8 months, whereas *Developmental Psychopathology* gives an expected range of 8 to 12 months. Lewis describes about 8 months and about 24 months, and *Companion to Psychiatric Studies* lists 10 months, but those source statements have an unclear normative construct. The expected ranges must remain side by side; averaging them would create a norm reported by neither source.

Separation anxiety is distress associated with separation from a familiar caregiver. Lewis gives an expected range of about 6 to 8 months, while *Developmental Psychopathology* gives an expected range of 10 to 18 months. Lewis also describes about 14 to 18 months and Berk describes 6 to 15 months, but those two statements do not specify their normative role. This source variation is itself examinable: the behaviour is developmentally intelligible, but the literature does not provide one universal date that separates normal from abnormal.

TRAP **Normal anxiety is not defined by one birthday.** Do not diagnose from the mere presence or absence of stranger or separation anxiety at one visit, and do not merge differing source windows. Judge intensity, persistence, context, recovery with the caregiver, functional impairment and the wider developmental profile.

Clinically, observe whether the caregiver functions as a source of regulation and whether distress settles sufficiently for exploration to resume. The form of the response matters more than its theatrical intensity. A tired infant in an unfamiliar clinic may protest strongly; a quiet infant may freeze rather than cry. The resident should document the trigger, proximity-seeking, consolability, recovery, exploration and consistency across settings before inferring a relational pattern.

15.4 Joint attention and pointing: from dyadic to shared engagement

Joint attention turns a two-person exchange into a shared mental focus on something in the world. **Joint attention** requires coordinated attention between child, another person and an object or event. It includes following another person's gaze or point and actively directing another person's attention for sharing, not merely to obtain an object. The *New Oxford Textbook of Psychiatry* states that joint attention is expected around **12 months** in most typically developing children. Berk describes increasing accuracy between 8 and 12 months, but does not specify the normative construct for that age band.

Pointing is likewise expected around 12 months in most typically developing children according to the *New Oxford Textbook of Psychiatry*; Tasman lists 14 months without defining whether that is an expected age, average or limit. The important distinction is functional. Imperative pointing requests something; declarative pointing shares interest for its own social value. Assessment should therefore sample gaze-following, showing, giving, pointing, shifting gaze between object and person, and checking the adult's response. A hand movement without coordinated gaze or shared affect is not equivalent to spontaneous declarative communication.

Because social communication and language develop together, ask how the child communicates wants, enjoyment and surprise before relying on spoken vocabulary. Hearing and vision must be considered. So must opportunity: the meaning of a behaviour depends on whether it appears spontaneously across familiar settings, not merely after repeated prompting in a clinic. Around 12 months is an expected attainment statement for joint attention and pointing, whereas absence of gesturing at 12 months is the separately sourced red-flag statement. The identical number does not make the constructs interchangeable.

15.5 Symbolic play, self-recognition and peer sociability

Play reveals representation, social reciprocity and flexibility in a natural behavioural sample.

Symbolic play, also called pretend play, uses an action or object to stand for something else. Dulcan describes symbolic play as expected at **18 months**; *Developmental Psychopathology* describes it as expected at approximately 20 months in most children. Kaplan and Sadock lists symbolic play at 18 months and older and at 30 months and older in clinical play descriptions, but those statements do not identify a normative construct. The expected values belong on the milestone plate as separate source claims, not as a new averaged deadline.

Examine play for initiation, imitation, shared enjoyment, symbolic substitution, sequencing, flexibility and inclusion of another person. Functional use of an object is not yet symbolic use; repetitive manipulation is not equivalent to pretend play; and reproducing a prompted action once is weaker evidence than spontaneous flexible play. The play sample should be interpreted with fine motor ability, language comprehension, cognitive level, sensory profile, familiarity with the materials and prior opportunity.

Self-recognition in the mirror test is reported by Berk in children older than 18 to 20 months, but the source does not say whether this is an average, range or limit. Keep it as a source-stated observation. For peer sociability, *Companion to Psychiatric Studies* lists cooperative play at 3 years, while Berk describes both parallel play and cooperative play across 2.5 to 6 years. Their normative constructs are unclear. These figures describe patterns in the cited sources and must not be treated as referral deadlines.

Parallel and cooperative play are also not mutually exclusive stages through which every child marches on a fixed timetable. Ask what the child actually does with peers: watches, imitates, plays alongside, exchanges objects, negotiates roles, sustains a shared theme, tolerates frustration and repairs conflict. Context matters. Solitary play in a new clinic cannot establish the child's usual

peer competence, while school reports and direct observation in familiar settings may reveal a very different profile.

15.6 Understanding minds and regulating emotion

Later social competence depends increasingly on representing internal states rather than responding only to visible behaviour. **Theory of mind** is the capacity to understand that another person can have thoughts, intentions, desires and beliefs different from one's own. Success on a standard false-belief task is expected at **4 or 5 years** in the cited source. Berk reports performance after 3.5 years and between 4 and 6 years but does not identify the normative construct of those values. Failure on a single task is not a diagnosis because language comprehension, attention, working memory and task demands contribute to performance.

Emotional development includes recognition and expression of affect, use of another person's signals, tolerance of arousal, recovery after frustration and an increasing capacity to regulate behaviour in context. The clinically useful sequence is qualitative: regulation begins in interaction with a caregiver and becomes progressively internalised, flexible and responsive to social rules. No verified numeric ages for specific emotion-labelling or self-regulation milestones were supplied, so none should be invented. Assessment instead compares behaviour across home, school and clinic, noting triggers, strategies, recovery, caregiver support and impairment.

Social cognition and emotion regulation must be interpreted culturally. Eye gaze, proximity, independence, deference, emotional display and adult-child conversation vary with family and community expectations. Culture does not explain away regression, marked functional impairment or absence of basic communicative gesture, but it changes the form in which competence is expressed. A sound answer describes the observed behaviour first, then considers developmental level, language, sensory capacity, temperament, context and culture before drawing a clinical inference.

15.7 Step 5: spotting deviation from normal and deciding when to refer

Developmental red flags are construct-explicit escalation signals, not retrospective labels. The verified social-communication warning signs are absence of gesturing at **12 months** and loss of language or social skills at any age. Both warrant further developmental evaluation. Because language and social communication are tightly coupled, absence of babbling at 12 months, absence of single words at 16 months and absence of spontaneous two-word phrases at 24 months are additional communication red flags that should be checked in the same assessment. A red flag indicates when to refer; it does not establish aetiology or diagnosis.

Spotting deviation requires more than threshold checking. Look for regression, plateau, marked unevenness across domains, lack of spontaneous reciprocity, poor integration of gaze, gesture and affect, unusual rigidity or repetitive play, weak generalisation across settings, and functional impact on learning or relationships. Only those two social-communication findings above are verified referral thresholds in the supplied evidence. Expected ages for the social smile, joint attention, pointing or symbolic play must not be relabelled as red flags merely because the child has passed them.

A focused developmental history records pregnancy and birth context, health, hearing and vision, opportunities for interaction, caregiver concerns, the sequence of attainment across gross motor, fine motor, language and speech, cognition, and social and emotional development, plus any loss of skills. Observe the child with the caregiver and during free play. Sample response to social bids, shared enjoyment, gesture, joint attention, imitation, symbolic play, flexibility, regulation and recovery. Seek reports across settings because a short clinic encounter can under-sample both strengths and difficulties.

Developmental surveillance is the longitudinal clinical process of eliciting concerns, observing development and following trajectory. **Developmental screening** uses a standardised tool to identify children who need comprehensive assessment. Screening is not diagnosis. Refer promptly for comprehensive developmental assessment when a verified red flag is present, when skills are lost, or when persistent concern and functional impairment remain despite an apparently reassuring single observation. Hearing and vision assessment are integral where communication or social response is in question.

15.8 Indian screening context without invented Indian milestones

Indian practice has validated screening instruments, but the available evidence does not supply an Indian social-emotional milestone table. The Trivandrum Development Screening Chart, developed at the Child Development Centre in Kerala, covers 0 to 6 years and contains 51 items. In the validation study by Nair and colleagues, one item delay was the operational positive result called TDSC delay, with DDST as the reference standard. This is a screening rule for the instrument as a whole, not permission to reconstruct individual item ages or to convert a textbook social milestone into a TDSC cut.

1,183 CHILDREN IN THE TDSC VALIDATION SAMPLE	**84.62%** SENSITIVITY, WITH A 95 PERCENT CONFIDENCE INTERVAL FROM 71.92 TO 93.12	**90.8%** SPECIFICITY, WITH A 95 PERCENT CONFIDENCE INTERVAL FROM 88.97 TO 92.43	**99.23%** NEGATIVE PREDICTIVE VALUE, WITH A 95 PERCENT CONFIDENCE INTERVAL FROM 98.48 TO 99.67

The DASII yields separate Motor DQ and Mental DQ values, and Indian follow-up practice uses a DQ below 85 as a delay marker. That marker is instrument-level evidence, not a milestone age. The Baroda Development Screening Test was India's first developmental screening tool, introduced in 1991. These instruments help organise referral after developmental surveillance raises concern; they do not replace a social history, direct observation, sensory assessment or a fuller developmental evaluation.

No verified Indian population ages for the social smile, stranger anxiety, separation anxiety, joint attention, pointing, symbolic play, peer play or false-belief performance were supplied. The Western and international textbook statements on the milestone plate therefore remain labelled by source and population where known. They must not be relabelled as Indian norms. This is especially important in viva answers: name the source construct, describe the behaviour and use the validated Indian screening pathway without claiming an Indian centile that has not been published in the material available here.

15.9 Clinical application and retrieval

- **Worked vignette 1, expected age versus red flag:** A caregiver reports no communicative gestures, including no pointing, showing or giving, at 12 months. Pointing itself is expected around 12 months in the *New Oxford Textbook of Psychiatry*, while absence of gesturing at 12 months is separately sourced as a warning sign. Clarify gaze shifts and shared enjoyment as part of the wider social-communication profile. Because the red-flag construct is met, arrange further developmental evaluation; do not diagnose from that finding alone.
- **Worked vignette 2, source variation:** An infant becomes wary of an unfamiliar examiner. Kaplan and Sadock gives a stranger-anxiety range of 6 to 8 months, while *Developmental Psychopathology* gives 8 to 12 months. The correct answer preserves both expected ranges and interprets the behaviour through familiarity, intensity, consolability and recovery. It does not average the ranges and does not call ordinary wariness pathological.
- **Worked vignette 3, play quality:** A child reproduces feeding a doll after repeated demonstration but does not initiate pretend actions, share enjoyment or vary the play. The observed imitation is real, but it does not by itself establish spontaneous flexible symbolic play. Sample familiar materials and caregiver interaction, assess language, cognition and fine motor ability, and obtain behaviour across settings before interpreting the finding.

MNEMONIC

"smile, selective relationships, share, symbol, self and minds"

Smile recalls early reciprocity. Selective relationships recalls stranger and separation anxiety. Share recalls joint attention and pointing. Symbol recalls pretend and peer play. Self recalls self-recognition. Minds recalls false-belief understanding.

Then add the clinical spine: five domains, spontaneous quality, trajectory, loss, developmental surveillance, screening and referral.

Final clinical synthesis. Social and emotional milestones are best understood as an expanding capacity to engage, share, represent, relate and regulate. The safe examination answer names the behaviour, gives the source's normative construct, preserves population and source differences, describes quality and context, looks for loss and functional impairment, and uses construct-explicit warning signs to decide when to refer. Recitation earns a mark; disciplined interpretation prevents harm.

16 . Primitive reflexes and their disappearance

Primitive reflexes are stereotyped, involuntary motor responses elicited by a defined sensory or positional stimulus in the immature nervous system. Their orderly appearance in the newborn and subsequent disappearance reflect intact lower neural pathways followed by increasing supraspinal control. They are therefore neither ordinary voluntary milestones nor isolated curiosities. In an examination, each reflex must be judged by four questions:

1. Is it present when it should be?

2. Is it elicited correctly?
3. Is it symmetrical?
4. Has it been inhibited when expected?

The accompanying reflex table is the visual reference for appearance and disappearance ages. Use it as a source-labelled map, because several respected textbooks give different disappearance points for the same reflex. The safe clinical answer is not to average discrepant ages. State the reflex, demonstrate how it is elicited, quote the named source or range, and distinguish an expected disappearance from an upper limit or a red-flag threshold.

Must memorise: A primitive reflex is interpreted by expected presence, adequate elicitation, symmetry and timely disappearance, never by presence or absence alone.

MNEMONIC

"Present, elicit, symmetry, disappear"

Interpret a primitive reflex by whether it is present when it should be, elicited correctly, symmetrical and inhibited when expected.

Primitive reflexes: elicitation, appearance, disappearance

Persistence beyond the disappearance age is the sign, not the reflex itself. Read one reflex across its row. Do not collapse the table into a single disappearance rule.

Reflex	How it is elicited, and the response	Appears	Disappears, by named source
Rooting	Stroke the cheek or corner of the mouth. The neonate turns toward it, opens the mouth.	● neonate Morgan	● Berk: 3 weeks, becomes voluntary turning ● Neuroanatomy atlas: about 1 year of age
Sucking	Contact with the lips or palate produces rhythmic sucking.	● neonate Kaplan and Sadock	● Berk: after 4 months ● Neuroanatomy atlas: about 1 year of age
Moro	Infant fully supported, a brief controlled head-position change. Never an actual drop.	● Neonatal period, first 4 weeks Tasman	● Tasman: 12 weeks ● Berk and Hutchison: 6 months
Asymmetric tonic neck	Turn the supine infant's head to one side. Face side extends, occiput side flexes: fencer.	○ 4 weeks Tasman	● Berk: 4 months
Palmar grasp	A finger laid across the palm, gentle pressure. The fingers flex around it.	● neonate Kaplan and Sadock	● Hutchison: 2 months ● Berk: 3 to 4 months
Plantar grasp	Pressure at the base of the toes produces toe flexion.	Not sourced No age in the cited texts.	● Hutchison: 2 months
Stepping	Held upright, soles on a firm surface, the body inclined forward. Alternating steps.	● Neonatal period, first 4 weeks Tasman	● Hutchison: 2 months ○ Berk: 2 months, in relation to weight gain
Babinski extensor plantar	Stroke the lateral sole, heel to forefoot, then medially. Great toe extends, toes fan.	● newborns New Oxford	● Berk: 8 to 12 months ● New Oxford: during the first 2 years of life ● Hutchison: extensor plantar up to 18 months

Five of the eight reflexes carry more than one disappearance age. Both claims are shown. Never average them into a false consensus.

Rooting, sucking, Moro and palmar grasp genuinely disagree between texts. Babinski's four boundaries are complementary: a range, a broader range, an upper limit, a red flag.

Red flags. These three are the only ones sourced in this chapter, and all three come from Hutchison's Clinical Methods.

Sucking reflex absent beyond the 36th week of gestation.
Primitive reflexes persisting beyond the fourth month of life.
Babinski reflex persisting beyond the age of 2 years.

The fourth-month statement is a general screening prompt. It does not override the later reflex-specific expectations above for Moro, sucking and the extensor plantar response.

● expected: a typical infant, per the source ● expected range: the normal window ● upper limit: the outer bound of normal
○ construct not stated by the source: teach its own words, never convert it into a referral threshold

Every age is quoted from a named text and stays attached to it. Sources: Hutchison's Clinical Methods, Berk's Development Through the Lifespan, Tasman, Kaplan and Sadock, the New Oxford Textbook of Psychiatry, an atlas of neuroanatomy, and Morgan's Introduction to Psychology. Elicitation follows this chapter's text.

Not sourced and therefore not shown: an appearance age for plantar grasp, and any Indian normative reflex schedule. No Western age is relabelled as an Indian norm.

Fig 20.15 The primitive reflexes, with each age kept attached to the text that states it. Disappearance ages come from Hutchison's Clinical Methods, Berk's Development Through the Lifespan, Tasman, and the New Oxford Textbook of Psychiatry; appearance ages from Kaplan and Sadock, Tasman, the New Oxford Textbook of Psychiatry and Morgan. Dots mark what kind of number each age is, because an expected age, an upper limit and a red flag are not interchangeable. Where texts disagree, both claims are shown rather than averaged. The three red flags are the only ones sourced.

16.1 What primitive reflexes signify

They test maturation as well as pathway integrity. A primitive reflex is produced by a relatively fixed sensorimotor circuit that is clinically visible while **descending inhibition** is immature. With maturation, the response is inhibited, incorporated into voluntary movement or replaced by a more purposeful response. Thus, normal development has two examinable directions: an early reflex should be obtainable at the relevant stage, and it should later recede. Persistence, asymmetry, failure to elicit an expected response, or re-emergence after it has disappeared can each be abnormal, but they point to different problems.

Presence alone does not certify a normal nervous system. A response may be weak because the infant is drowsy, recently fed, unwell or poorly positioned; it may be absent because the stimulus was inadequate; and it may be asymmetric because of a peripheral injury even when central maturation is otherwise appropriate. Conversely, persistence suggests deficient inhibition only after the reflex-specific expectation and the rest of the neurologic examination are considered.

16.2 Examination technique: make the response interpretable

Standardise the infant's state before interpreting the movement. Examine in a warm, safe setting, preferably when the infant is awake and settled. Observe spontaneous posture and

movement first. Then apply one clear stimulus, support the head and trunk throughout, compare the two sides where the response permits, and describe the actual movement rather than merely writing “reflex present”. Repeat only when necessary, because habituation, crying and repeated stimulation can alter the response. Record gestational context and the infant's behavioural state.

RULE **First prove that the test was valid.** Name the stimulus, the motor response, its symmetry and the infant's state. Only then compare the finding with the expected disappearance age.

The usual bedside sequence is efficient: test the orofacial responses, then upper-limb grasp, the startle and postural responses, stepping, plantar grasp and the plantar response. This reduces unnecessary repositioning and makes side-to-side comparison easier.

16.3 Disappearance ages are source-specific constructs

Do not convert a textbook age into a referral threshold.

CONSTRUCT	MEANING
An “expected” disappearance	describes what the source presents as usual.
An “expected range”	describes a window.
An “upper limit”	marks the outer boundary of normal.
A “red flag”	is the point at which persistence or absence warrants concern.

These constructs are not interchangeable. If two books differ, retain both claims with attribution rather than creating a false consensus.

TRAP **“All primitive reflexes must disappear by the fourth month” is unsafe.** *Hutchison's Clinical Methods* gives persistence beyond the fourth month of life as a general red flag, but the same source and other textbooks give later reflex-specific expectations for Moro, sucking and the extensor plantar response. Use the general statement as a screening prompt, not as a universal cut-off that overrides the named reflex.

the fourth month of life	36th week of gestation	18 months of age	2 years
GENERAL RED FLAG	ABSENCE RED FLAG	UPPER LIMIT	RED FLAG

The disagreement often reflects differences in elicitation, the strength counted as “present”, whether a response has become voluntary, and the population or edition being described. The accompanying plate therefore keeps each age attached to its source. It should be read horizontally, one reflex at a time, not collapsed into a single disappearance rule.

16.4 Rooting and sucking: feeding-related primitive responses

Rooting is elicited by stroking the cheek or the corner of the mouth; the neonate turns toward the stimulus and opens the mouth. Its appearance is described in the neonate. Berk and a neuroanatomy atlas give markedly different disappearance points, shown with their attributions in the accompanying reflex table. These values should not be averaged. The difference may reflect

distinct operational boundaries between a reflexive turn and a residual feeding response, so the source must travel with the age.

Sucking is elicited by contact with the lips or palate and produces rhythmic sucking. Kaplan and Sadock describe its appearance in the neonate. *Hutchison's Clinical Methods* treats absence beyond the **36th week of gestation** as a red flag. Berk and the neuroanatomy atlas again give different expected disappearance points; retain both as source-specific values from the plate. The clinically important distinction is between an absent feeding response when it should be established and persistence of a reflexive pattern after voluntary feeding control develops.

16.5 Moro and asymmetric tonic neck reflex

Moro reflex is tested with the infant fully supported: a brief, controlled change in head position produces abduction and extension of the upper limbs, followed by adduction and flexion. The manoeuvre is a **supported head-extension stimulus**, never an actual drop. Tasman describes Moro as present in the neonatal period and gives an earlier disappearance point than Berk and *Hutchison's Clinical Methods*. The plate preserves both claims. Quote the source rather than turning either value into an unsupported universal limit.

For the asymmetric tonic neck reflex, turn the supine infant's head gently to one side. The limbs on the face side extend and those on the occipital side flex, producing the “fencer” posture. Tasman records its early presence without defining the normative construct; this must not be restated as a referral threshold. Berk supplies an expected disappearance point in the plate. Marked obligatory persistence can interfere with midline hand use and rolling, while asymmetry requires a broader neurologic and musculoskeletal assessment.

16.6 Grasp and stepping responses

Palmar grasp is elicited by placing a finger across the palm and applying gentle pressure; the fingers flex around it. Kaplan and Sadock describe appearance in the neonate. Berk gives an expected disappearance range, whereas *Hutchison's Clinical Methods* gives a different expected point; both remain source-labelled in the plate. For plantar grasp, pressure at the base of the toes produces toe flexion. Hutchison supplies its expected disappearance point, but no appearance age was available from the cited sources.

Stepping is elicited by supporting the infant upright, allowing the soles to contact a firm surface and inclining the body slightly forward; alternating step-like movements follow. Tasman describes it as expected in the neonatal period. Hutchison gives an expected disappearance point. Berk also describes disappearance in relation to weight gain but does not define the normative role of that statement, so it should not be converted into an upper limit or referral threshold. The exact source-specific entries belong to the accompanying plate.

16.7 Babinski response: expected early, concerning when persistent

The Babinski reflex, or **extensor plantar response**, is elicited by stroking the lateral sole from heel toward the forefoot and then medially. Extension of the great toe, often with fanning of the other toes, is expected in newborns according to the *New Oxford Textbook of Psychiatry*. It is

commonly taught beside the primitive reflexes because its interpretation changes with nervous-system maturation.

The sources offer complementary, not identical, boundaries, and the plate keeps them separate. Berk supplies an expected disappearance range, the *New Oxford Textbook of Psychiatry* gives a broader expected range, and Hutchison states that an extensor plantar response may occur up to **18 months of age**, an upper limit, while persistence beyond **2 years** is a red flag. Therefore an extensor response at the end of infancy is not automatically an upper motor neuron sign, whereas persistence beyond the sourced red-flag boundary requires neurologic assessment.

16.8 Clinical interpretation: pattern before label

Abnormality lies in the pattern. Bilateral absence of a response expected in a newborn raises questions about gestational maturity, arousal, systemic illness, medication effect or diffuse neurologic dysfunction. A consistently asymmetric Moro or grasp response raises a different set of possibilities, including a focal central lesion, peripheral nerve injury or painful limb movement. Persistence of several primitive responses, particularly with abnormal tone, posture or delayed voluntary motor control, is more concerning for impaired **central inhibition** than a single borderline response.

Re-emergence later in life is described as a frontal release sign. Grasping, rooting, snout and palmomental responses may appear with frontal or diffuse cerebral dysfunction, including neurocognitive disorders, but one isolated sign has limited specificity. In psychiatry, these signs strengthen a neurologic formulation only when they fit the cognitive examination, functional decline and the rest of the neurologic findings.

> **INDIA**
>
> The cited disappearance values are textbook schedules, not Indian normative percentiles. Do not manufacture an India-specific age conversion. In an Indian infant, retain the named source and interpret the response with gestational context, longitudinal development and the complete neurologic examination.

In a short case or viva, the highest-scoring formulation is compact: “I elicited the reflex with the appropriate stimulus; the response was present or absent, graded by quality and symmetry; I compared it with the source-specific disappearance expectation; and I interpreted it with tone, posture, voluntary movement and the rest of development.” That answer demonstrates technique, developmental reasoning and restraint. It avoids the two common errors: treating every age as a hard cut-off and diagnosing neurologic disease from one reflex in isolation.

17 . Adolescent development and identity formation

Adolescence is the developmental transition from childhood dependence toward adult roles, marked by pubertal change, reorganisation of cognition and emotion, increasing importance of peers and intimate relationships, and the construction of a more coherent identity. It is neither a prolonged childhood nor an incomplete adulthood. Development is asynchronous: physical

maturation, reward sensitivity, abstract reasoning, self-regulation, autonomy and social opportunity do not move in lockstep. The psychiatrist therefore judges the adolescent against developmental trajectory, pubertal status, context and functioning, not against a single stereotype of maturity.

How to use this page. Build the answer in **four** layers. Begin with puberty and Tanner staging, then explain the neurodevelopmental basis of context-sensitive risk-taking, then describe identity formation through Erikson and Marcia, and finally integrate gender, sexuality, peers, family and culture. Keep **three** distinctions intact: Tanner stage is based on physical characteristics rather than chronological age; exploration is not itself pathology; and gender identity, gender expression and sexual orientation are separate constructs.

The must-memorise line: Adolescence is an asynchronous transition in body, brain and social role, while identity is formed through exploration and commitment within family, peer and cultural relationships.

RULE **The psychiatrist therefore judges the adolescent against developmental trajectory, pubertal status, context and functioning, not against a single stereotype of maturity.** Development is asynchronous: physical maturation, reward sensitivity, abstract reasoning, self-regulation, autonomy and social opportunity do not move in lockstep.

TRAP **Exploration is not itself pathology.** Normal diversity in tempo and expression is expected, but marked distress, sustained impairment, coercion, regression or a clear episodic change requires assessment rather than automatic attribution to adolescence.

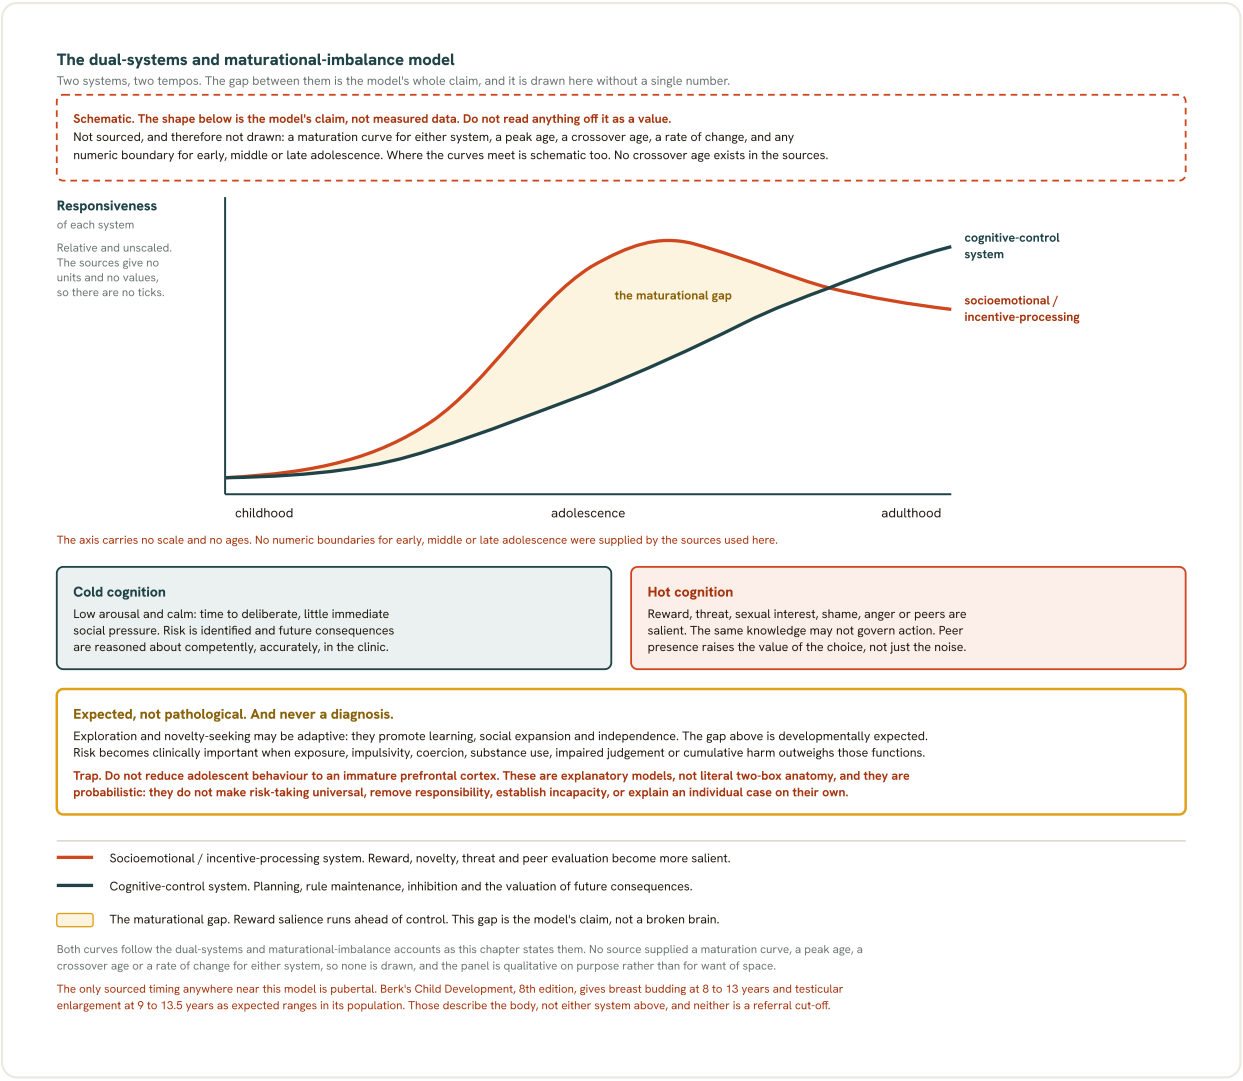

Fig 20.16 The adolescent dual-systems and maturational-imbalance model, drawn qualitatively. The curves carry the model's claim, that a fast-changing socioemotional system runs ahead of a more slowly stabilising cognitive-control system, and that the gap between them is the window in which risk-taking is developmentally expected rather than pathological. The shape is schematic: no source supplied a maturation curve, peak age, crossover age or rate for either system, so none is drawn and the axis carries no ages. The only sourced timing shown is pubertal, from Berk's Child Development, 8th edition, as expected ranges.

17.1 A developmental frame: simultaneous change across interacting systems

The central principle is uneven but coordinated development. Puberty changes the body, sleep, affective salience and how other people respond to the young person. Cognitive development expands hypothetical, future-oriented and self-reflective thought. Social development shifts toward greater privacy, peer affiliation, reciprocal intimacy and negotiation of authority. Identity development integrates bodily experience, values, relationships, education, work, culture, gender and sexuality into an account of who the person is and where life is going. Change in one system alters every other system: earlier or later pubertal change can affect body image and peer position, while family response can amplify or buffer its psychological impact.

Developmental tasks are therefore better treated as linked processes than as a checklist. The adolescent must:

- incorporate a changing body; become more autonomous without losing secure relatedness;

- form increasingly mutual peer relationships; develop values and future goals; regulate strong affect;
- make decisions under social pressure; establish a workable sense of self.

Progress is non-linear. A person may reason abstractly in a calm classroom yet decide impulsively in an emotionally charged group, appear independent with peers yet seek parental regulation during illness, or explore one identity domain while remaining committed in another.

The useful clinical model is **transactional**. Biological changes alter behaviour and social signalling; family, school, peers, media and culture shape the opportunities and meanings attached to those changes; repeated experiences then modify self-concept and regulation. Neither biology nor environment alone explains the outcome. Normal diversity in tempo and expression is expected, but marked distress, sustained impairment, coercion, regression or a clear episodic change requires assessment rather than automatic attribution to adolescence.

17.2 Puberty: biological maturation, variable timing and psychological meaning

Puberty is the biological process of sexual maturation, whereas adolescence is the broader psychological and social transition. Gonadal maturation produces secondary sexual characteristics and reproductive capacity; adrenarche is a related but distinct process involving adrenal androgen effects. The order and tempo of visible changes matter more clinically than a single calendar age. Pubertal events also acquire personal and social meaning through comparison with peers, cultural expectations, gender experience, body ideals, family communication and the adolescent's readiness for change.

Psychological effects depend on timing relative to peers and on context, not merely on whether a value falls inside a range. Ask about the adolescent's understanding of changes, body satisfaction, teasing, sexualisation, sports or school consequences, privacy, menstrual experience where relevant, and whether physical development is congruent with gender experience. Puberty may increase visibility and social expectations before cognitive or emotional capacities have developed to the same degree.

17.3 Cognitive and moral development: expanding capacity with uneven performance

Adolescent thought increasingly permits abstraction, hypothesis, metacognition and projection into possible futures. In Piaget's scheme this is **formal operational thought**: reasoning about propositions and possibilities rather than only concrete events. It supports scientific reasoning, ideological debate, imagining alternative selves and considering long-term consequences. It also enables heightened self-consciousness because the adolescent can represent how others might be evaluating them. Formal reasoning is not used uniformly; familiarity, education, emotion and task demands strongly influence performance.

Two classic descriptions help explain adolescent egocentrism. The **imaginary audience** is the sense of being continuously observed or judged, which can intensify concern about appearance and embarrassment. The **personal fable** is a felt uniqueness of one's experience and, at times, a sense that ordinary consequences do not fully apply. Neither construct should be used to

caricature all adolescents. Both are hypotheses about self-focused social cognition and must be distinguished from delusional conviction.

Kohlberg's moral development should be taught in sequence without invented numeric ages. Kaplan and Sadock describes:

LEVEL	KAPLAN AND SADOCK DESCRIPTION
Preconventional morality	before adolescence
Some second-level reasoning	in young adolescents
Third-level conventional reasoning	during adolescence
Fourth-level conventional reasoning	later in adolescence
Fifth-level postconventional reasoning	in late adolescence or early adulthood.

Moral reasoning on a dilemma is not identical to moral conduct: emotion, relationships, incentives, culture and power affect what a person actually does.

17.4 Erikson and Marcia: identity as exploration and commitment

Erikson locates the central psychosocial task of adolescence in identity versus role confusion. Identity is a workable sense of continuity and sameness across time, combined with a social recognition that one is the person one understands oneself to be. It integrates earlier identifications with present capacities and future roles. Role confusion refers to difficulty organising these elements into a sufficiently coherent direction, not ordinary uncertainty during exploration. Successful development yields fidelity, the capacity to sustain commitments while recognising ideological and interpersonal difference.

James Marcia operationalised identity through two processes: **exploration**, the active consideration of alternatives, and **commitment**, an investment in chosen goals, values or roles. Their combinations produce four **identity statuses**:

IDENTITY STATUS	DESCRIPTION
Identity diffusion	neither active exploration nor stable commitment.
Foreclosure	commitment adopted without meaningful exploration, often from family or authority expectations.
Moratorium	active exploration without a settled commitment.
Identity achievement	commitment formed after meaningful exploration.

four
IDENTITY STATUSES

These are statuses, not fixed personality types and not an irreversible staircase. The same adolescent may be achieved in religion, foreclosed in vocation, in moratorium regarding relationships and diffuse about politics. Status can change when education, migration, conflict, discrimination, illness or new relationships reopen a domain. Moratorium can be

developmentally productive, while commitment itself is not proof of maturity if it was coerced or cannot be revised in response to experience.

17.5 Identity develops in relationships, culture and digital spaces

Healthy individuation changes the form of attachment rather than requiring emotional separation from the family. The adolescent seeks greater privacy, agency and reciprocal negotiation while still using caregivers as sources of security, values and practical support. Conflict may increase around boundaries, education, relationships, technology and appearance, but conflict alone does not demonstrate dysfunction. The clinically useful questions are whether disagreement can be negotiated, whether the adolescent has a voice, whether caregivers remain available, and whether autonomy is expanding in a way that is safe and culturally intelligible.

Peers provide comparison, belonging, rehearsal of adult-like intimacy and feedback about possible selves. Close friendships become more reciprocal and self-disclosing; peer groups can support exploration but can also enforce conformity. Social exclusion, bullying and minority stress can become incorporated into self-concept. Digital spaces extend these processes through persistent audiences, curated self-presentation, rapid feedback and access to identity communities. Online identity is not necessarily false; it may be experimental, aspirational, fragmented or more authentic than the identity permitted offline.

INDIA

In Indian practice, identity may be negotiated within strong family interdependence, educational competition, linguistic and religious communities, caste and class location, migration, gendered expectations and collective decisions about work or relationships. Do not equate autonomy with Western-style separation or assume that family commitment means foreclosure. Ask what the commitment means to this adolescent, whether alternatives were thinkable, how much choice was available and what consequences followed dissent. Assess the young person privately as well as in the family context, while explaining confidentiality and its safety limits.

17.6 Gender identity and psychosexual development

Gender identity, gender expression and sexual orientation answer different questions.

Gender identity
is the person's internal sense of gender.

Gender expression
is how gender is communicated through appearance, behaviour, name or social role.

Sexual orientation
concerns patterns of romantic or sexual attraction.

None can be inferred reliably from the others, from Tanner stage, from play or clothing, or from a single sexual experience. Exploration or nonconformity is not in itself a disorder.

Psychosexual development during adolescence includes integration of the sexually maturing body, desire, fantasy, attraction, values, consent, boundaries, behaviour, intimacy and relationship expectations. Pubertal capacity does not equal emotional readiness, informed decision-making or

consent. History-taking should separate attraction, identity, behaviour and distress because they may not align, particularly where stigma or safety concerns limit disclosure. Ask neutrally about relationships, coercion, online contact, contraception and infection protection where clinically relevant, without assuming heterosexuality or sexual activity.

In Freud's historical stage scheme, the genital stage is placed in adolescence. This remains examinable as theory but is not a contemporary developmental norm and does not provide a clinical threshold. Current assessment focuses on the adolescent's lived development, bodily experience, relationships, safety and functioning. Distress associated with gender incongruence must be distinguished from distress produced by rejection, bullying, family conflict or discrimination. A respectful interview uses the adolescent's stated name and pronouns, establishes what can safely be shared with caregivers, and assesses mood, self-harm risk and support without treating identity diversity as pathology.

17.7 Clinical assessment: normal exploration, developmental vulnerability and disorder

The assessment unit is the adolescent in a developmental system. Interview the adolescent privately for at least part of the assessment, interview caregivers, and obtain school or other collateral information when indicated. Explain confidentiality at the outset and state the circumstances in which safety requires disclosure. Establish pubertal trajectory and body experience, sleep, nutrition, cognition and school function, family relationships, peers, romantic and sexual development, gender experience, online life, substances, risk-taking, values, future plans and identity commitments.

For any concerning behaviour, reconstruct the sequence: developmental baseline, onset, triggers, context, frequency, persistence, degree of control, consequences and recovery. Ask whether it occurs mainly in hot peer contexts or also in calm solitary settings; whether it is exploratory, compulsive, coerced, intoxication-related or driven by elevated mood, depression, anxiety, trauma or neurodevelopmental difficulty; and whether it produces sustained impairment. Episodicity, loss of previously stable functioning, pervasive impairment, dangerous consequences, marked distress or a pattern grossly discordant with context weighs against a purely normative explanation.

Pubertal assessment requires the same construct discipline. Record Tanner morphology and source-stated expected ranges, but do not diagnose from an endpoint that was not validated as a clinical cut-off. When timing, sequence or physical findings raise concern, undertake appropriate paediatric or endocrine evaluation rather than converting an expected range into a referral rule. Identity assessment likewise avoids premature closure: uncertainty may be normal exploration, a stable commitment may be healthy or coerced, and apparent confusion may reflect unsafe disclosure conditions rather than lack of identity.

17.8 Examination synthesis and retrieval spine

A complete long answer moves from maturation to meaning. Define adolescence as a broad biological, psychological and social transition. Describe puberty and Tanner staging, making clear that stages are morphological and components are scored separately. Explain dual systems and

maturational imbalance as context-sensitive accounts of risk-taking. Add cognitive and moral development, then make identity formation the centre of the answer through Erikson's identity versus role confusion and Marcia's exploration-commitment statuses. Finish with family, peers, culture, gender, psychosexual development and clinical differentiation from disorder.

MNEMONIC

"body, brain, bond, belief and becoming"

Body recalls puberty and Tanner morphology. Brain recalls control, reward and hot-context decisions. Bond recalls family, peers and intimacy. Belief recalls abstract thought, values and moral reasoning. Becoming recalls identity exploration, commitment, gender and future roles.

Final clinical synthesis. Normal adolescent development is organised variability, not uniform instability. The safe psychiatric formulation links bodily maturation, neurodevelopment, relationships and culture to the adolescent's pattern of exploration and commitment. It respects diversity, preserves confidentiality, identifies coercion and impairment, and avoids turning either an expected age range or an identity difference into a diagnosis.

18 . Puberty, neurodevelopment of adolescence and risk-taking behaviour

Adolescence is a developmental transition, not merely an age band. Three processes run together but are not interchangeable: **puberty**, the biological maturation of the reproductive system and secondary sexual characteristics; **adolescent neurodevelopment**, the continuing reorganisation of brain structure, connectivity and function; and psychosocial development, in which the young person negotiates autonomy, identity, sexuality, peer belonging and adult roles. Their partial mismatch explains much of normal adolescent behaviour. Reward, emotion and social evaluation can acquire unusual motivational force while cognitive control is still becoming more consistent across situations. The result is not global irrationality. It is a context-sensitive period in which judgement may be good in calm conditions and less reliable under arousal, peer observation, immediate reward or threat.

How to use this page. Keep five distinctions clean. Puberty is not the whole of adolescence. Gonadarche is not adrenarche. Tanner stage describes physical maturation and does not assign a chronological age. Capacity for abstract reasoning does not guarantee self-regulation under emotional load. Finally, risk-taking is neither inevitable nor uniformly pathological: some exploration is developmentally useful, but its probability and consequences depend on the person, the peer group, the family, the opportunity and the behaviour involved.

MNEMONIC

"Body, brain, context"

Puberty is the biological maturation of the reproductive system and secondary sexual characteristics; adolescent neurodevelopment is the continuing reorganisation of brain structure, connectivity and function; and psychosocial development is the negotiation of autonomy, identity, sexuality, peer belonging and adult roles. Their partial mismatch explains much of normal adolescent behaviour.

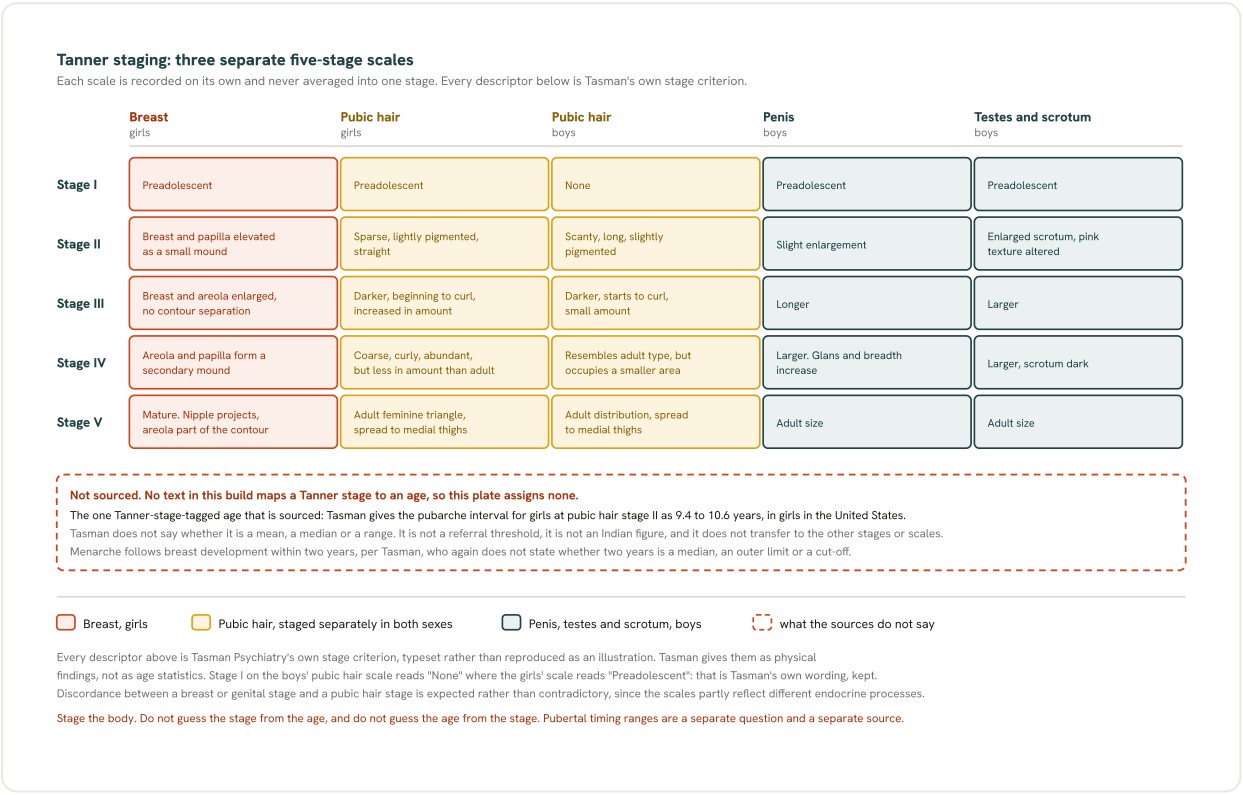

Fig 20.17 Tanner staging as three separate five-stage scales, after Tasman Psychiatry. The descriptors are typeset from Tasman's own stage criteria rather than reproduced as an illustration. No age is attached to any stage, because no source in this build maps one; the single Tanner-stage-tagged age that is sourced is named in the band below the grid, with the source's silence about what kind of number it is.

18.1 Puberty: endocrine activation and physical maturation

Puberty is driven by coordinated endocrine change, with gonadal and adrenal maturation proceeding through related but distinct pathways. Reactivation of the hypothalamic-pituitary-gonadal axis produces pulsatile gonadotropin-releasing hormone secretion, pituitary luteinising hormone and follicle-stimulating hormone release, and increasing gonadal steroid production. This **gonadarche** produces maturation of the testes or ovaries, the growth spurt and the development of secondary sexual characteristics. **Adrenarche** is the increase in adrenal androgen production; it contributes particularly to pubic and axillary hair, body odour and skin changes, but it is not evidence by itself that the gonadal axis has matured. Lewis describes adrenarche as beginning at **6 to 8 years**; because that source does not define the value as a normal limit or a referral threshold, it must not be used as either.

The observable sequence matters more than a single calendar age. In girls, breast development, pubic hair, acceleration in linear growth and menarche are related markers but need not advance in exact synchrony. In boys, enlargement of the scrotal-genital complex, pubic hair, penile growth, change in body composition, the growth spurt and spermarche similarly form a sequence rather than one event. Sex steroids also act on bone, muscle, adipose distribution, skin, sleep, sexual motivation and the brain. These biological effects interact with the meaning assigned to bodily change by the adolescent, family and peer culture. Thus an identical physical event can be experienced as welcome maturation, embarrassment, loss of control, gender incongruence or social advantage.

RULE **Stage the body; do not guess the stage from age.** Tanner stage is a physical examination description. Chronological age, menarche, height and the adolescent's own report may support the history, but none substitutes for the relevant stage criteria.

18.2 Tanner staging: what the five stages actually describe

Tanner staging uses separate five-stage scales for breast development, male genital development and pubic hair. Stage I is preadolescent. In girls, breast stage II is elevation of the breast and papilla as a small mound; stage III adds enlargement of the breast and areola without separation of their contours; stage IV produces a secondary mound of areola and papilla; and stage V is the mature contour, with a projecting nipple and the areola returning to the general breast contour. In boys, genital stage II is marked by scrotal enlargement with altered pink texture; stage III is characterised particularly by penile lengthening; stage IV adds increasing breadth and glans development with darker scrotal skin; and stage V is adult size. These are morphological descriptions, not age labels.

Pubic hair is staged separately in both sexes. Stage I has no pubic hair. Stage II is sparse and lightly or slightly pigmented hair, initially relatively straight. Stage III hair is darker, begins to curl and increases in amount. Stage IV is coarse, curly and adult-like but occupies a smaller area. Stage V has adult distribution, extending to the medial thighs; in girls it forms the adult feminine triangle. Discordance between genital or breast stage and pubic-hair stage is therefore not a contradiction: the scales partly reflect different endocrine processes. The examiner records each component separately rather than averaging them into a synthetic stage.

Use the Tanner reference plate for the visual sequence. Do not attach ages to its rows. Tasman states that menarche occurs within **2 years** after breast development, but the source does not identify that interval as a median, outer limit or referral cut-off; it should be repeated only as Tasman's descriptive statement. Menarche also does not mean that all physical maturation is complete.

Tanner stage is a clinical descriptor, not a judgement of psychological maturity, consent capacity, sexual experience or gender identity. Examination requires explanation, assent or consent as applicable, privacy, respectful exposure limited to what is necessary, and a chaperone according to clinical policy and the adolescent's needs. Self-assessment may support history-taking when

examination is not appropriate, but it is less reliable than a properly conducted clinical examination.

18.3 Pubertal timing: expected ranges, sequence and tempo

Normal timing is broad, and a range is not a diagnosis. Berk's *Child Development*, 8th edition, reports expected ranges for major pubertal events. These values describe windows in the cited population and must not be converted into medians, guarantees or stand-alone referral thresholds.

8 to 13 years
GIRLS: BREAST BUDDING AND ONSET OF THE HEIGHT SPURT

10.5 to 14 years
GIRLS: MENARCHE

9 to 13.5 years
BOYS: TESTICULAR ENLARGEMENT

12 to 16 years
BOYS: SPERMARCHE

SEX	PUBERTAL EVENT	EXPECTED RANGE
Girls	Breast budding and onset of the height spurt	8 to 13 years
Girls	Peak height spurt	10 to 13.5 years
Girls	Appearance of pubic hair	8 to 14 years
Girls	Breast-growth completion	10 to 17 years
Girls	Menarche	10.5 to 14 years
Boys	Testicular enlargement	9 to 13.5 years
Boys	Penile enlargement	10.5 to 14.5 years
Boys	Onset of the height spurt	10.5 to 16 years
Boys	Peak height spurt	12.5 to 15.5 years
Boys	Appearance of pubic hair	10 to 15 years
Boys	Spermarche	12 to 16 years
Boys	Completion of penile and testicular growth	12.5 to 16 years

Interpretation requires **timing**, **sequence** and **tempo**. Timing asks when change begins relative to the reference population; sequence asks whether expected components are appearing in a coherent order; tempo asks how the changes progress over time. A young person at one edge of a wide expected range may still be developing normally. Conversely, an unusual sequence, arrest or very rapid progression can warrant assessment even when one observed event happens within an expected range. Evaluation should integrate growth trajectory, nutrition and chronic illness, medication and substance exposure, neurological and endocrine symptoms, family pattern, psychosocial distress and examination findings. The ranges above are reference information, not permission to dismiss a concerning trajectory.

INDIA

No Indian population-specific pubertal timing ranges were available in the supplied sources. Do not silently relabel the ranges from Berk as Indian norms. In an Indian examination answer, state the source and population limitation, use the physical sequence and longitudinal growth record, and seek locally validated paediatric or endocrine guidance for clinical thresholds.

18.4 The adolescent brain: remodelling, connectivity and context

Adolescent neurodevelopment is network reorganisation, not simple growth of an unfinished brain. Experience-dependent synaptic stabilisation and pruning make frequently used circuits more efficient while reducing redundant connections. Progressive myelination improves the speed and reliability of long-range communication. White-matter organisation, cortical specialisation and integration among prefrontal, striatal, limbic and temporoparietal regions support gains in working memory, planning, response inhibition, error monitoring, future simulation, social cognition and emotion regulation. These processes do not mature in lockstep, and performance varies with task demands and emotional state.

The prefrontal cortex contributes to planning, rule maintenance, inhibition and valuation of future consequences. The ventral striatum and related dopaminergic circuits participate in reward anticipation, reinforcement learning, novelty and action selection. The amygdala and broader limbic circuitry help assign emotional salience, while medial prefrontal and temporoparietal systems contribute to self-referential and social inference. Development changes the balance and connectivity among these systems. Pubertal hormones can influence motivational and affective processing, but puberty and neural maturation are neither identical processes nor reducible to one hormone level.

A crucial distinction is between **cold cognition** and **hot cognition**. Cold cognition is reasoning under low arousal, with time to deliberate and little immediate social pressure. Hot cognition occurs when reward, threat, sexual interest, shame, anger or peers are salient. An adolescent may explain consequences accurately in the clinic and still choose differently in the heat of the real situation. The discrepancy does not prove deceit or incapacity. It shows that knowledge of risk and regulation of behaviour are separable functions.

TRAP **Do not teach adolescence as a defective-adult brain with a single completion age.** The examinable account is uneven, experience-sensitive network maturation. Adolescents can reason competently, especially in calm settings; vulnerability rises when immediate reward, emotion and peer evaluation load the system.

18.5 Dual-systems and maturational-imbalance models

The dual-systems family of models explains risk as a temporary imbalance between motivational drive and regulatory control. One system is often described as socioemotional or incentive-processing, involving reward-sensitive striatal and limbic circuits that become highly responsive to novelty, immediate gain and social evaluation. The other is a cognitive-control system, relying substantially on prefrontal and frontoparietal networks that support inhibition, planning and resistance to distraction. When incentive salience is high and control is not

consistently recruited, behaviour can shift toward immediate reward despite an intact verbal understanding of later costs.

The **maturational-imbalance model** makes the same broad point while emphasising developmental differences in the timing and coordination of subcortical affective systems and cortical control systems. Peer presence matters because it can increase the subjective value of reward and social approval rather than merely "pressure" the adolescent through explicit persuasion. A choice that looks reckless to an adult may therefore be locally rational within the adolescent's current valuation: the social reward is immediate, visible and identity-relevant, while the harm is delayed and probabilistic.

These models are useful, but they are not complete theories of every adolescent. They do not imply that all adolescents take more risks, that the brain mechanically causes misconduct, or that control always loses to reward. Risk depends on trait impulsivity and sensation seeking, prior adversity, mood and substance use, sleep and arousal, family monitoring, peer norms, opportunity, expected benefit and the severity and reversibility of possible harm. Nor do the models erase agency. They identify situations in which scaffolding, delay, environmental design and supportive adults can make self-control easier to deploy.

> **Must remember:** adolescent risk-taking is best understood as *context-sensitive motivational imbalance*, not absence of knowledge, absence of control or inevitable recklessness.

18.6 Gender identity and psychosexual development

Sex characteristics, gender identity, gender expression and sexual orientation are distinct constructs.

- Sex characteristics include chromosomal, gonadal, hormonal and anatomical features.
- Gender identity is the person's internal sense of gender.
- Gender expression is how gender is communicated through appearance, behaviour and social role.
- Sexual orientation concerns patterns of romantic or sexual attraction.

None can be inferred reliably from the others, and gender-nonconforming expression is not by itself psychopathology.

Puberty can make these domains more salient because the body changes visibly, sexual interest may intensify, peers classify one another more sharply and future relational roles become imaginable. For some adolescents, bodily change is congruent with identity; for others it produces or intensifies distress. The psychiatrist's task is not to force an identity conclusion. It is to clarify the adolescent's own experience over time, the degree of distress and impairment, body-related discomfort, family and peer response, bullying or violence, mood and self-harm risk, and the presence of coexisting neurodevelopmental or psychiatric needs without treating those needs as explanations that invalidate gender experience.

Psychosexual development includes integration of the sexually maturing body, attraction, fantasy, intimacy, values, consent, boundaries and responsibility. Freud's genital stage is historically examinable and is placed in adolescence, but it is not an adequate contemporary account of sexuality. A clinical formulation should instead be developmental, non-judgemental and safeguarding-aware. Ask in private, use the adolescent's terms, distinguish consensual exploration from coercion or exploitation, assess digital as well as in-person contexts, and explain confidentiality and its safety limits before eliciting sensitive information.

18.7 Risk-taking: adaptive exploration, hazardous exposure and individual difference

Risk-taking is any choice made under uncertainty in which an outcome of value is accompanied by a meaningful possibility of harm. It is broader than impulsivity. Impulsivity is poorly controlled action with insufficient forethought; sensation seeking is preference for novel, intense experience; risk-taking may be planned or spontaneous and may involve social, physical, sexual, financial, academic or legal consequences. Substance use, dangerous driving, unsafe sexual behaviour, aggression, self-harm challenges and online exposure are clinically important examples, but so are positive risks such as trying a difficult skill, leaving a familiar peer group or speaking publicly. Development requires exploration; prevention should reduce catastrophic and irreversible harm without attempting to abolish autonomy.

Risk rises when several layers converge. At the individual level consider reward sensitivity, impulsivity, attention and executive function, mood elevation or depression, trauma responses, substance intoxication, sleep loss and beliefs about invulnerability. At the interpersonal level consider peer norms, desire for status, romantic context, family conflict, supervision and modelling. At the environmental level consider access, anonymity, commercial persuasion, unsafe roads, weapons or substances, and online algorithms that amplify novelty and social comparison. Protective factors include a warm relationship with at least one dependable adult, clear and proportionate limits, prosocial peers, school connection, meaningful roles, future goals, emotion-regulation skills and practical barriers to the most dangerous opportunities.

The intervention follows the mechanism. Information alone is weak when the adolescent already knows the hazard. Use collaborative motivational interviewing, identify the reward the behaviour provides, rehearse implementation intentions, reduce access to lethal or irreversible means, create an exit plan for peer situations, move decisions out of high-arousal contexts and enlist supportive adults with the adolescent's participation whenever safety permits. Harm reduction and autonomy-supportive boundaries are often more developmentally effective than shame, surveillance without relationship or an abstract lecture about consequences.

18.8 Clinical assessment and the examination answer

Assess the adolescent confidentially, developmentally and systemically. Begin with the adolescent and caregiver together, then interview the adolescent alone for part of the consultation. Explain confidentiality and its limits in plain language before asking about risk. A HEEADSSS-style review keeps the field broad: home; education or employment; eating; activities and peers; drugs; sexuality; suicide, self-harm and mood; and safety. Add sleep, online

behaviour, bullying, violence, legal exposure, strengths and future goals. Obtain collateral information where necessary, but preserve a private space so disclosure is possible.

The formulation should connect the behaviour to development rather than merely name it. Describe pubertal status and trajectory, cognitive and neurodevelopmental strengths or vulnerabilities, identity tasks, emotional state, the immediate reward, peer and family context, access to means, previous consequences, protective factors and readiness to change. Separate experimentation from a persistent syndrome, and separate chronological age from decision-specific capacity. Capacity is functional: the young person must understand, retain, use or weigh relevant information and communicate a choice in the actual context being assessed.

For a long-answer question, use a disciplined sequence: define adolescence and puberty; describe gonadarche, adrenarche and Tanner staging; state the sourced timing ranges with their population limitation; explain pruning, myelination and changing frontostriatal-limbic connectivity; compare dual-systems and maturational-imbalance accounts; integrate identity, gender and psychosexual development; then finish with determinants, protective factors and clinical management of risk-taking. The highest-scoring conclusion is balanced: adolescence brings increased opportunity for hazardous behaviour, but also exceptional learning, flexibility, social sensitivity and capacity for growth. Developmental vulnerability is real without being destiny.

19 . Gender identity and psychosexual development in childhood

Gender identity and psychosexual development emerge through the continuing interaction of bodily maturation, cognition, attachment, learning, family relationships, peers and culture. They are not single milestones reached on a fixed birthday. The child gradually makes sense of bodily sex characteristics and social categories, develops an internal sense of gender, learns how gender is expressed and regulated in the surrounding culture, acquires privacy and interpersonal boundaries, and later integrates puberty, attraction, values, intimacy and consent into a more coherent identity. Variation is expected. The clinical task is to distinguish diversity and exploration from distress, impairment, coercion, trauma and disorder without making any one form of play, dress, friendship or attraction carry more meaning than it can support.

How to use this page. Begin by separating the constructs that examination questions often collapse. Then describe the major explanatory models, give Freud as a historical stage theory, outline expected sexual learning and boundary acquisition, and connect puberty and Tanner staging to adolescent identity. Finish with adolescent neurodevelopment, risk-taking and a developmentally informed clinical assessment. Throughout, hold **two** disciplines: Tanner stage is morphological rather than chronological, and gender expression or sexual behaviour cannot by itself establish gender identity, sexual orientation, abuse or psychopathology.

The must-memorise line: Separate body, identity, expression, attraction and behaviour, then interpret each against developmental context, consent, distress, impairment and safety.

19.1 The conceptual map: related domains that must not be collapsed

A high-scoring answer defines the constructs before explaining their development.

TERM	MEANING
Sex characteristics	include chromosomal, gonadal, hormonal and anatomical features; sex assignment at birth is a social and clinical classification usually made from observed anatomy.
Gender identity	is the person's internal sense of gender.
Gender expression	is the outward communication of gender through appearance, behaviour, name, language and social role.
gender role	is the culturally organised set of expectations attached to gender categories.

These domains interact, but none is a simple read-out of another.

Sexual orientation concerns patterns of romantic or sexual attraction. **Sexual behaviour** describes what a person does, while **sexual identity** is the label or self-understanding a person adopts. Attraction, behaviour and identity may not align, especially during development or where disclosure is unsafe. **Psychosexual development** is broader than genital maturation: it includes bodily awareness, pleasure, attachment, fantasy, attraction, gender, privacy, boundaries, consent, intimacy, values and the meaning assigned to relationships.

RULE **Ask five separate questions: body, identity, expression, attraction and behaviour.** Do not infer one from another. Tanner morphology does not determine psychological maturity; gender expression does not establish orientation; and a single behaviour does not establish a stable identity.

5
SEPARATE QUESTIONS

19.2 Development is transactional: biology, relationships and culture continually modify one another

No single-cause theory adequately explains gender identity or psychosexual development. Biological organisation supplies a sexed body and contributes hormonal and neurodevelopmental influences. The child experiences that body through touch, caregiving, language and other people's responses. Cognitive development permits classification, perspective-taking and an increasingly stable autobiographical self. Social learning supplies models, reinforcement and sanctions. Family, peers, school, religion, media and wider culture specify which expressions are encouraged, tolerated or punished. The child is active within this system, attending selectively, interpreting feedback and shaping the responses received from others.

A transactional model therefore replaces the false choice between nature and nurture. Bodily characteristics affect how others classify and treat a child; those responses influence opportunities and self-description; the child's preferences evoke further responses; and puberty

later changes both the body and its social meaning. Temperament, cognitive capacity, neurodevelopmental differences, family flexibility, peer acceptance and exposure to stigma alter the pathway. The same observable expression can consequently have different meanings in different children and settings.

Development also occurs within a hierarchy of contexts. Caregiver language and discipline operate at the immediate level; school rules and peer cultures organise daily belonging; media and institutions circulate ideals of masculinity, femininity and attractiveness; and legal, religious and economic conditions influence safety and disclosure. Culture is not an ornamental final paragraph. It helps determine which possibilities can be imagined, named and enacted.

19.3 Cognitive-developmental, social-learning and gender-schema accounts

The major theories differ in what they treat as the engine of development. In the cognitive-developmental account, the child actively constructs gender categories. The conceptual sequence is gender labelling, recognition that gender is stable across time, and gender constancy despite superficial changes in clothing, activity or appearance. Once the child regards a category as self-relevant, behaviour is organised toward consistency with it. This account explains active self-socialisation but may understate biological influence, early learning and the flexibility of real gender experience.

Social-learning theory emphasises observation, imitation, reinforcement and punishment. Children see which behaviours are rewarded in caregivers, siblings, peers and media figures; direct praise or ridicule then increases or suppresses expression. Social-cognitive theory adds expectations, self-efficacy and reciprocal influence, so the child is not merely a passive recipient of conditioning. These models explain how local gender conventions are acquired and why expression can change across settings, but learning a convention does not prove that the convention determines the child's internal identity.

Gender-schema theory links cognition and culture. Repeated cultural distinctions form organised schemas that guide attention, memory, interpretation and behaviour. Information marked as relevant to the self is noticed and remembered more readily, while schema-inconsistent examples may be overlooked or distorted. Schemas are efficient but revisable. Exposure to broader roles, flexible caregivers and counter-stereotypic models can enlarge the child's map of what is possible without dictating identity.

19.4 Freud's psychosexual theory: historically examinable, not a contemporary milestone schedule

Freud remains important for the history of developmental psychiatry and for examination essays, particularly his emphasis on early experience, conflict and unconscious meaning. His account is not a modern developmental surveillance tool. It gives neither a valid way to infer gender identity nor a clinical rule for deciding whether childhood sexual behaviour is expected. Contemporary formulation places the theory beside cognitive, learning, attachment, biological and sociocultural accounts rather than allowing it to stand as the sole explanation.

19.5 Sexual development in childhood: curiosity, privacy, boundaries and relationship learning

Childhood sexual development is broader than overt sexual behaviour. It includes learning the names and functions of body parts, recognising bodily differences, experiencing comfort and pleasure, asking questions, developing modesty, understanding private and public conduct, rehearsing family and relationship roles in play, and learning that bodies belong to their owners. Self-touch, curiosity and exploratory play can occur in development, but their meaning depends on context rather than on the behaviour label alone.

Assess behaviour along several dimensions: spontaneity, frequency, flexibility, mutuality, developmental similarity of the children involved, power difference, secrecy, coercion, emotional tone, explicitness, intrusiveness, response to calm redirection and effect on functioning. Developmentally understandable exploration is generally flexible, non-coercive and not organised around fear or a marked power imbalance. Concern rises with force, threats, injury, persistent distress, compulsive repetition, a substantial asymmetry in power or developmental capacity, explicit imitation beyond the child's likely experience, or behaviour that remains intrusive despite appropriate limits. No single sign proves abuse, but a concerning pattern requires careful safeguarding assessment.

Adults teach psychosexual safety through accurate language, matter-of-fact answers, respect for privacy, permission to refuse unwanted touch, distinction between safe privacy and unsafe secrecy, and consistent boundaries that do not shame the body. Excessive alarm can attach fear and guilt to ordinary curiosity; dismissiveness can leave the child without language for disclosure. The developmental aim is neither sexualisation nor silence, but embodied autonomy, appropriate privacy and the capacity to seek help.

19.6 Puberty and Tanner staging: physical maturation changes the developmental task

Secondary sexual characteristics make gender experience more immediate. See the Puberty topic.

19.7 Adolescence: identity formation, neurodevelopment and context-sensitive risk-taking

Normal adolescent development is asynchronous across body, brain and social role. Pubertal maturation increases the salience of body image, attraction, peer evaluation and belonging, while autonomy, intimacy, values and future roles are being renegotiated. In Erikson's account, the central conflict is identity versus role confusion. Identity integrates continuity across time with commitments in education, work, values, relationships, gender and sexuality. Ordinary uncertainty and exploration are not equivalent to role confusion.

19.8 Gender diversity, distress and contemporary classification

Variation in gender identity or expression is not itself evidence of mental disorder. A child may prefer activities, clothing, roles or companions that do not fit local stereotypes without experiencing incongruence or distress. Conversely, a child may experience a persistent difference between assigned sex and experienced gender even when expression is constrained. The clinician should explore the child's own account, consistency across contexts, bodily experience, family response, peer safety and functional impact without interrogating the child toward a predetermined conclusion.

WHO's ICD-11 places **gender incongruence** under conditions related to sexual health rather than mental and behavioural disorders, reflecting that transgender and gender-diverse identities are not conditions of mental ill-health. WHO also states that gender-variant behaviour and preferences alone are not a basis for assigning the diagnosis. The examinable distinction is therefore between identity diversity, incongruence and the presence of distress or clinical need. Distress may arise from bodily incongruence, but it may also arise from bullying, rejection, violence, shame or forced concealment; formulation must identify the source rather than attributing every symptom to identity.

TRAP **Do not diagnose from gender nonconformity.** Toys, clothing, mannerisms, friendships, fantasy play or one sexual experience do not by themselves establish gender identity, sexual orientation, abuse or disorder. The same rule prevents both pathologising diversity and missing genuine distress.

A developmentally competent interview uses the child's stated language where possible, avoids assumptions about heterosexuality or binary identity, and separates the young person's wishes from caregiver fears. Support does not mean forcing an identity label or predicting an adult outcome. It means maintaining safety, permitting honest exploration, reducing shame, treating co-occurring symptoms on their own merits and preserving access to appropriate specialist assessment when needed.

19.9 Clinical assessment, safeguarding and the Indian context

The assessment unit is the child within a developmental and relational system. Interview caregivers and the child, including time with the child separately when developmentally appropriate. Explain confidentiality and its safety limits. Establish the child's language for body and gender, pubertal status, body comfort, play and interests, attraction and relationships where relevant, family beliefs, peer response, school functioning, online exposure, privacy practices and sources of support. Ask what changed, when it changed, in which settings, what preceded it, how persistent and flexible it is, what meaning the child gives it, and whether distress belongs to the child, the family or both.

For sexual behaviour, reconstruct the event without repeated suggestive questioning. Assess the developmental capacities and power relationship of everyone involved, mutuality, coercion, threats, secrecy, explicitness, injury, emotional response, access to sexual material and the child's subsequent behaviour. Safeguarding concern requires a calm, child-centred response, careful documentation in the child's own words, attention to immediate safety and use of the appropriate multidisciplinary and statutory pathway. A behavioural sign neither proves nor excludes abuse.

INDIA

Gender and psychosexual development may be negotiated within joint or extended families, strong educational expectations, religious and linguistic communities, gendered household roles and unequal permission for autonomy. Ask who actually provides care, who controls disclosure and what consequences the child anticipates. Interviewing only the accompanying adult can erase the child's account; interviewing only the child can miss dependence and safety constraints. Use clear language in the family's preferred language, separate cultural meaning from coercion, and do not use "Indian culture" either to pathologise family interdependence or to excuse humiliation, violence or forced conformity. No Indian population-specific age sequence for gender labelling or identity consolidation is supplied, so none should be inferred.

Formulation should distinguish predisposing factors, current developmental tasks, precipitating events, maintaining responses and protective relationships. Screen for mood and anxiety symptoms, self-harm, trauma, bullying, family violence, neurodevelopmental differences, substance use and online exploitation when indicated. A sudden or episodic change, regression, pervasive impairment, marked distress, coercion, dangerous exposure or loss of previously stable functioning weighs against a purely normative explanation. Treatment targets the actual source of difficulty rather than trying to make identity or expression conform to a stereotype.

19.10 Examination synthesis: move from definitions to development, then to clinical discrimination

A complete long answer has a clear spine.

- Define sex characteristics, gender identity, gender expression, gender role, sexual orientation and psychosexual development.
- Explain transactional development through biological, cognitive, learning, family and cultural influences.
- Contrast cognitive-developmental, social-learning and gender-schema theories.
- Present Freud as a historical stage account with source-stated mappings, not as a milestone schedule. Describe childhood curiosity, privacy and boundary learning, then connect puberty and Tanner morphology to adolescent identity formation, dual systems, maturational imbalance and risk-taking. Finish by distinguishing diversity and exploration from distress, impairment, coercion, trauma and disorder.

MNEMONIC

"Body, self, signal, attraction, behaviour and safety"

Retrieval spine: *body, self, signal, attraction, behaviour and safety*. Body recalls sex characteristics, puberty and Tanner staging. Self recalls gender identity and identity formation. Signal recalls expression and gender roles. Attraction recalls orientation. Behaviour recalls what is enacted rather than assumed. Safety recalls consent, power, distress, impairment and safeguarding.

Final clinical synthesis. Gender identity and psychosexual development are developmental processes, not conclusions drawn from a single behaviour. Good psychiatry keeps constructs separate, respects bodily and identity diversity, reads puberty through morphology and source-stated ranges, and places every concern within relationships, culture, consent, distress, functioning and safety.

Development in context and clinical use

20 . Developmental red flags and warning signs

A developmental red flag is not simply a child who is slower than a remembered textbook average. It is a finding that raises the probability of a developmental disorder sufficiently to require prompt evaluation, or a pattern so biologically atypical that ordinary variation is an unsafe explanation. The examiner expects the resident to distinguish *variation* from *delay*, and delay from *deviance*, *dissociation*, *plateau* and *regression*. The central clinical question is therefore not, "Has the child crossed one age line?" but, "What is the trajectory, which domains are affected, and is the pattern compatible with normal variation?"

How to use this page. First learn the few findings that demand further evaluation, especially loss of acquired skills and the language-social warning signs. Then learn to recognise abnormal trajectories across gross motor, fine motor, language, social-adaptive and cognitive domains. Finally, separate **surveillance**, which is longitudinal and continuous, from **screening**, which applies a standardised tool, and from **diagnostic assessment**, which determines the developmental profile and cause. The milestone and primitive-reflex plates are memory maps; this page owns the clinical act of spotting deviation and deciding what happens next.

Loss of previously acquired language or social skills at any age is a red flag and requires prompt developmental evaluation.

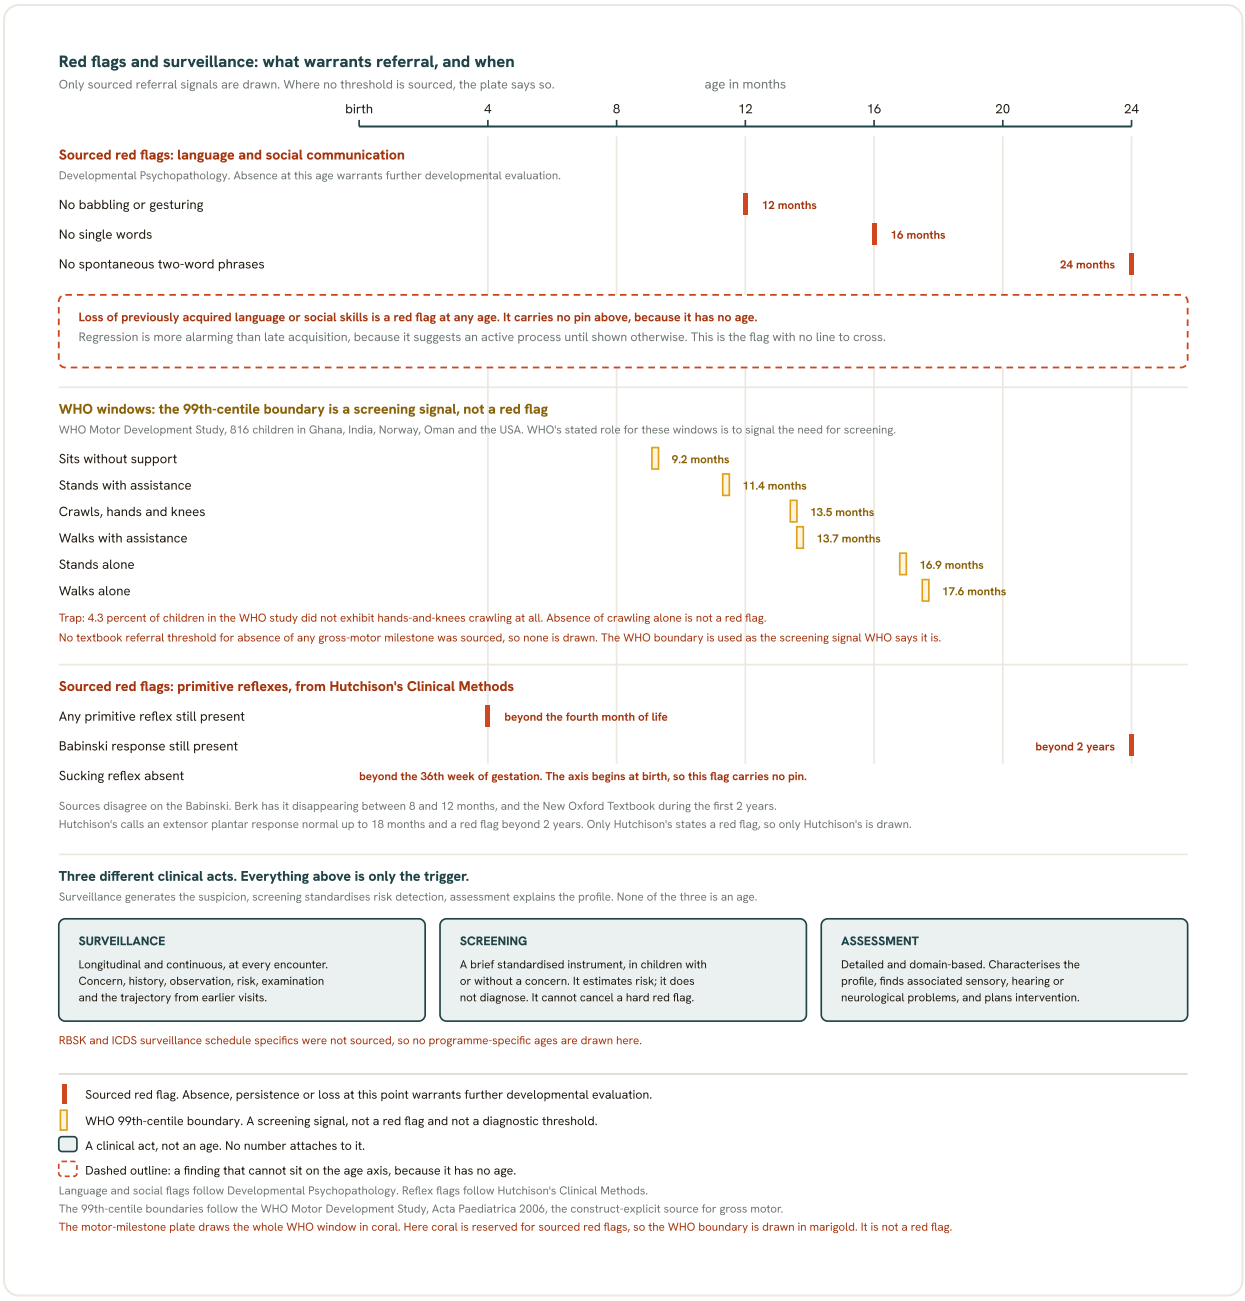

Fig 20.18 Red flags and surveillance, drawn so that only sourced referral signals appear. Coral pins are the language and social red flags from Developmental Psychopathology and the primitive-reflex red flags from Hutchison's Clinical Methods. Marigold markers are the 99th-centile boundaries of the WHO Motor Development Study windows, which WHO itself states are a signal to screen rather than a diagnostic threshold. No textbook referral threshold for absence of a gross-motor milestone was sourced, so none is drawn, and no surveillance schedule appears because RBSK and ICDS specifics were not sourced.

Developmental screening and assessment instruments: what is sourced, and what is not

One row carries real psychometrics. Three are almost empty. The empty cells are the finding, not an oversight: each property was searched for and no source states it.

Instrument	Age range	Items	Output and cut-off	Accuracy	Reliability
Trivandrum Development Screening Chart TDSC. A screening tool. Child Development Centre, Kerala.	Birth to 6 years	51	One item delay is a positive screen, called TDSC delay.	Sensitivity 84.62 percent Specificity 90.8 percent Negative predictive value 99.23 percent Negative likelihood ratio 0.17	Test-retest, intraclass correlation 0.77 Inter-rater, intraclass correlation 0.97
Developmental Assessment Scales for Indian Infants DASII. An assessment measure, not a screening test.	not sourced	not sourced	Two developmental quotients, Motor DQ and Mental DQ. A DQ below 85 is used as a delay marker.	not sourced	not sourced
Denver Developmental Screening Test II DDST-II. A screening test.	Birth to 72 months	not sourced	not sourced	not sourced	not sourced
Baroda Development Screening Test BDST. Introduced in 1991. India's first screening tool.	not sourced	not sourced	not sourced	not sourced	not sourced

The accuracy and reliability figures come from the chart's validation against the Denver Developmental Screening Test. The age range in the Denver row is sourced for the DDST-II.
No source states whether the version used as that reference standard and the DDST-II are the same. They are shown as two separate sourced facts rather than joined into one.

Named rather than hidden: what was searched for and is not sourced

DASII manual specifics. Administration age range, item count, norming sample, centiles, every cut-off other than the delay marker below 85, and all reliability and validity values.
TDSC item lines. The individual milestone items and their ages are not sourced. The psychometrics are; the contents are not, so the chart is described here and never reproduced.
The Denver test beyond its age range, and the Baroda test beyond its year and its primacy. Neither has a sourced item count, cut-off or accuracy figure.

not sourced. The property was searched for and no source states it. Nothing is supplied from memory to fill the cell.

Every other cell carries a value that appears in one of the sources named below. No instrument form is reproduced on this plate.

TDSC properties follow Nair and colleagues, Development and validation of the Trivandrum Development Screening Chart for children aged 0 to 6 years, Indian Journal of Pediatrics 2013.
The two DASII quotients follow Kadam and colleagues. The delay marker below 85 follows Shukla and colleagues. The Baroda test's year and primacy follow Shekhawat and colleagues.
The Denver age range follows Lewis, Child and Adolescent Psychiatry.

Screening estimates risk and does not diagnose. A negative screen does not overrule regression, an abnormal examination or persistent caregiver concern.

Fig 20.19 The developmental screening and assessment instruments compared by what is sourced. Only the Trivandrum chart carries validated psychometrics, from Nair and colleagues, and its accuracy is against the Denver Developmental Screening Test. The DASII contributes its two quotients and the delay marker below 85; the Denver test contributes only an age range; the Baroda test contributes only its year and its primacy. Dashed cells are properties that were searched for and are not sourced, left empty rather than filled from memory. No instrument form is reproduced.

20.1 Normal variation, delay and abnormal developmental trajectories

Development is a trajectory, not a checklist. A milestone age has meaning only when its construct is known.

MILESTONE CONSTRUCT	MEANING
A median	means that half of children have attained the skill by that age.
An expected range	describes a normal window.
An upper limit	is the outer bound regarded as normal.
A red-flag threshold	is an operational point at which further evaluation is warranted.

Converting an average or median into a referral threshold is a clinical error. Equally, being within an age window does not neutralise abnormal quality, asymmetry, regression or a concerning neurological examination.

Developmental delay is slower acquisition of skills in one or more domains while the usual sequence is broadly preserved. Global developmental delay describes substantial delay across multiple developmental domains in a young child, but the label does not state the cause.

Dissociation is unequal development between domains, such as relatively preserved motor ability with marked language-social delay. Deviance is an unusual sequence or quality of development rather than mere lateness. A plateau is failure to acquire new skills over time. Regression is loss of a skill that was convincingly acquired, and is more alarming than isolated late acquisition because it suggests an active or progressive process until shown otherwise.

RULE **Judge the child by trajectory, pattern and quality, not by one remembered average age.** A red flag can arise from absence, loss, asymmetry, abnormal sequence, abnormal movement quality or a widening gap between domains.

MNEMONIC

"Trajectory, pattern and quality"

Judge the child by trajectory, pattern and quality, not by one remembered average age. A red flag can arise from absence, loss, asymmetry, abnormal sequence, abnormal movement quality or a widening gap between domains.

20.2 Developmental surveillance, screening and assessment are different clinical acts

Developmental surveillance is the repeated, flexible clinical process conducted across encounters. It integrates parental concerns, developmental history, observation of the child, risk factors, physical and neurological examination, and the trajectory recorded at previous visits. Ask what the child can do spontaneously in daily life, not merely whether the child once performed a prompted task. Clarify onset, consistency, context, quality and whether any skill has been lost. Observe communication, play, reciprocity, posture, movement, hand use and problem-solving before directing the child, because spontaneous behaviour often contains the most valid developmental information.

Developmental screening is the use of a brief standardised instrument in children who may or may not already have an identified concern. It estimates risk; it does not diagnose. A negative screen does not overrule convincing regression, abnormal examination or persistent caregiver concern. Developmental assessment is the more detailed, domain-based evaluation used to characterise strengths and impairments, quantify development where appropriate, identify associated sensory or neurological problems, formulate differentials and plan intervention. Surveillance generates suspicion, screening standardises risk detection, and assessment explains the profile.

20.3 Spotting deviation: read the pattern before the individual milestone

Use five questions whenever development appears atypical.

1. Is this *absence* of a skill, *loss* of a skill, or merely inconsistent performance?
2. Is one domain affected or are multiple domains involved?
3. Is the sequence recognisable but slow, or qualitatively unusual?
4. Are there associated neurological signs, abnormal head growth, dysmorphism, feeding difficulty, poor vision or hearing, seizures, altered tone, weakness or asymmetry?

5. What is the functional consequence in communication, play, self-care, mobility, learning and participation?

Patterns narrow the differential. Predominantly motor delay with abnormal tone or reflexes points toward a motor-system disorder; language delay requires separation of hearing impairment, developmental language disorder, broader cognitive delay and autism-related social-communication difficulty; social-communication deviation with restricted or repetitive behaviour raises concern for autism; and global delay requires a broad biological and environmental assessment. In every pattern, check pregnancy and birth history, neonatal illness, seizures, infections, nutrition, medication or toxin exposure, family history, consanguinity, psychosocial deprivation and opportunities for learning. These factors modify interpretation but do not justify watchful waiting when a hard red flag is present.

Asymmetry is a warning sign even when an age threshold has not been crossed. Persistent one-sided hand use in infancy, unequal movement, early fixed hand preference, scissoring, persistent fisting, abnormal posturing or an abnormal gait directs attention to focal or motor-pathway pathology. Likewise, the manner of a skill matters: sitting with marked truncal instability and walking with an abnormal pattern are not made normal by timely onset.

20.4 Language and social-communication red flags: the hard thresholds

The most examinable age-linked warning signs are absence of early communication behaviours and loss of acquired social-communication skills. Developmental Psychopathology identifies the findings in the strip below as warranting further developmental evaluation. These are referral signals, not median attainment ages.

12 months	16 months	24 months	Any age
NO BABBLING OR GESTURING	NO SINGLE WORDS	NO SPONTANEOUS TWO-WORD PHRASES	LOSS OF LANGUAGE OR SOCIAL SKILLS

Interpret these against the quality of communication. Joint attention and pointing are expected around 12 months in most typically developing children according to the New Oxford Textbook of Psychiatry, and symbolic play is expected at 18 months in Dulcan's Textbook of Child and Adolescent Psychiatry. Concern rises when limited eye contact, poor response to name, absent sharing of interest, lack of communicative gesture, poor reciprocity or repetitive behaviour forms a coherent pattern. Do not diagnose autism from a single missed behaviour, but do not dismiss a convergent social-communication pattern because vocabulary appears adequate. The disorder itself, with its criteria and management, is developed in the Intellectual disability and autism spectrum disorder notes; this page owns only the act of noticing the pattern and referring.

Speech clarity must also be interpreted by construct. Kaplan and Sadock describes speech as about **50 percent** intelligible at 24 months, about **75 percent** intelligible to strangers at 36 months, and nearly **100 percent** intelligible to strangers by 4 years. These are expected values, not automatic referral thresholds. A child who is difficult to understand requires assessment of hearing, oral-motor function, speech-sound production, receptive and expressive language, and the effect on participation.

20.5 Gross-motor warning signs: use WHO windows as screening signals

The WHO Motor Development Study provides construct-explicit windows of achievement bounded by the 1st and 99th centiles. It followed children in Ghana, India, Norway, Oman and the USA, so India was part of the source population. Sitting without support occurred from 3.8 to 9.2 months, standing alone from 6.9 to 16.9 months, and walking alone from 8.2 to 17.6 months. A child beyond the upper boundary signals the need for appropriate screening, which is the role WHO itself states for these windows. They are screening signals, not diagnostic cut-offs and not independently sourced referral thresholds.

Gross-motor concern is strengthened by an abnormal neurological examination, loss of motor skills, persistent asymmetry, abnormal tone, weakness, poor antigravity movement, abnormal movement quality, feeding or respiratory difficulty, or delay in other domains. Conversely, an isolated variation in sequence can be benign. The gross-motor plate should be read as a set of windows rather than as a ladder of compulsory achievements.

TRAP **Hands-and-knees crawling is not universal.** In the WHO study, 4.3 percent of children did not exhibit it at all. Absence of crawling alone is therefore not a developmental red flag; judge the overall trajectory, movement quality and neurological findings.

20.6 Primitive reflexes: persistence, asymmetry and re-emergence matter

Primitive reflexes are expected in the newborn period and are progressively integrated as cortical control matures. Their interpretation is not a memory contest about disappearance ages alone. A reflex that is unusually persistent, strongly asymmetric, absent when it should be present, or re-emerges after integration may indicate neurological dysfunction. The primitive-reflex plate provides the expected sequence; the clinical examination must compare the reflex response with tone, posture, spontaneous movement, symmetry and the child's functional motor repertoire.

Hutchison's Clinical Methods treats persistence of primitive reflexes beyond the fourth month of life as a general warning sign, persistence of the Babinski response beyond 2 years as a red flag, and absence of the sucking reflex beyond the 36th week of gestation as a red flag. These sourced warning signs should not be replaced by conflicting remembered averages. A reflex abnormality warrants a neurological and developmental assessment rather than an isolated label.

20.7 Indian screening instruments: TDSC and DASII

The Trivandrum Development Screening Chart (TDSC), developed at the Child Development Centre, Thiruvananthapuram Medical College, is an Indian screening instrument for children from birth to 6 years. The validated chart contains 51 items, and **one item delay** constitutes a positive screen termed "TDSC delay". In its validation against the Denver Developmental Screening Test, sensitivity was 84.62 percent, specificity 90.8 percent, negative predictive value 99.23 percent, test-retest reliability 0.77, and inter-rater reliability 0.97. These properties make it useful for screening, but a positive result is not a diagnosis and a negative result cannot cancel a hard clinical red flag; the underlying theory of sensitivity, specificity, predictive value and reliability belongs to the Psychometry, Assessment and Descriptive Psychopathology notes.

The Developmental Assessment Scales for Indian Infants (DASII) yields separate **Motor DQ** and **Mental DQ**. Indian follow-up studies use a DQ below 85 as a marker of delay. DASII is an assessment measure rather than a substitute for surveillance, and the two quotients help display dissociation between motor and mental development. The Baroda Development Screening Test, introduced in 1991, was India's first developmental screening tool according to Shekhawat and colleagues. Keep the categories clear in an answer: TDSC and the Baroda instrument are screening tools; DASII provides domain-based developmental quotients.

20.8 When to refer and what the first evaluation must contain

Refer promptly when there is regression, a hard red flag, abnormal neurological findings, marked asymmetry, a deviant developmental sequence, multi-domain delay, or persistent concern despite a reassuring screen. Do not use "wait and watch" as a substitute for surveillance. If observation is appropriate for a borderline concern, it requires a documented baseline, an explicit review plan and instructions to return earlier if skills are lost or new warning signs appear. Early referral is not overdiagnosis: it opens the route to hearing and vision assessment, developmental and neurological evaluation, aetiological investigation where indicated, and early intervention while diagnostic clarification continues.

The initial doctor-facing work-up begins by verifying the concern with caregiver examples and direct observation, mapping skills across all domains, and establishing whether the course is delayed, dissociated, deviant, plateauing or regressive. Examine growth, head size and trajectory, dysmorphic features, skin markers, vision, hearing, oral-motor function, tone, power, reflexes, coordination, gait and asymmetry. Review antenatal, perinatal, neonatal, medical, seizure, nutritional, family and psychosocial history. Select investigations from the phenotype rather than ordering an indiscriminate panel, and refer to the appropriate developmental paediatric, paediatric neurological, audiological, ophthalmological, speech-language, occupational or mental-health service.

The viva answer. Define the warning sign, state whether the quoted age is an expected value, a range, an upper limit or a red-flag threshold, describe the whole developmental pattern, and finish with action. The safest closing line is: *I would not diagnose from a missed milestone alone, but I would not delay evaluation when there is regression, a sourced red flag, abnormal quality or a convergent multi-domain concern.*

21 . Effects of deprivation, institutionalization and early adversity on development

Early development depends not only on freedom from injury, but on the reliable presence of expected experience: responsive caregiving, language, touch, play, nutrition, safety and opportunities to explore. **Deprivation** is the absence or marked reduction of these expected inputs. **Threat** is the presence of experiences that signal actual or possible harm, such as violence or abuse. **Early adversity** is the broader term, covering deprivation, threat, loss, instability, discrimination, displacement, severe family stress and other conditions that exceed the child's available supports. These exposures often co-occur, but they are not interchangeable. The

distinction matters because a child lacking cognitive and social input may follow a different developmental pathway from a child repeatedly learning that the environment is dangerous.

Fig 20.20 Early adversity is not one exposure. Deprivation and threat can follow different developmental pathways, while the nature, timing, duration and severity of exposure and the availability of responsive caregiving shape both persistence and recovery.

How to use this page. Build the answer around **five** propositions.

1. Effects depend on the nature, timing, duration and severity of the adversity, not merely its presence.
2. **Institutionalization** is not a single exposure: it may combine rotating caregivers, low responsiveness, sensory monotony, crowding, malnutrition, illness and repeated loss.
3. The classical studies by Spitz and Harlow established the developmental importance of relationship and contact, but have major methodological and ethical limits.
4. The Romanian natural experiments show both persistent deprivation-related difficulties and substantial recovery after family placement.

5. **Resilience** is an outcome produced by interacting systems, not a fixed trait that makes a child invulnerable.

MNEMONIC

"NTDS"

Effects depend on the **N**ature, **T**iming, **D**uration and **S**everity of the adversity, not merely its presence.

five
PROPOSITIONS

21.1 Concepts and causal framework: deprivation is not the same as separation, poverty or threat

Define the exposure before attributing an effect. **Neglect** is a failure to meet a child's physical, medical, educational, emotional or supervisory needs. **Psychosocial deprivation** refers particularly to insufficient responsive interaction, stable attachment opportunities, language and cognitive stimulation. **Maternal deprivation** is the older historical label, but it is too narrow when it implies that only a biological mother can provide the necessary relationship. The developmentally relevant issue is the availability of a small number of stable, sensitive and committed caregivers. **Separation** is an event; its effect depends on what relationship is lost, what care replaces it, how predictable the transition is and whether reunion and continuity are possible. **Privation**, used in older literature, means that a selective attachment relationship was never adequately established, whereas deprivation may refer to loss of, or insufficient access to, an expected input.

Poverty increases exposure to nutritional compromise, environmental hazards, caregiver stress, disrupted schooling and reduced access to care, but poverty itself is not proof of neglect or deficient attachment. Likewise, institutional residence does not make every child's experience identical. Quality varies with caregiver continuity, responsiveness, group size, opportunities for play and language, health care and contact with family. The causal formulation therefore asks: *what input was absent, what threat was present, when and for how long, through which mediators, and what protective relationships remained?*

Sheridan and McLaughlin's dimensional model separates deprivation from threat.

DIMENSION	DEFINITION	DEVELOPMENTAL RELEVANCE
deprivation	the absence of expected social and cognitive inputs	Deprivation is especially relevant to language, executive function and higher-order cognitive development because the relevant circuits receive less patterned experience.
threat	experience involving harm or danger	Threat more directly calibrates fear learning, attention to danger and emotion-processing systems.

The model is not a claim of **one** exposure to one brain region. Real children commonly experience both dimensions, and development reflects their interaction with genes, prenatal conditions, nutrition, illness, relationships and later environments.

RULE **Exposure is not outcome.** Early adversity changes probabilities across several developmental domains; it does not establish inevitable damage, a particular diagnosis or poor parenting by inference.

21.2 Mechanisms: how early adversity becomes biologically and psychologically embedded

Adversity acts through repeated transactions between the child and the environment. A responsive caregiver ordinarily provides co-regulation: detecting the infant's state, reducing distress, organising sleep and feeding, sharing attention, naming experience and making exploration safe. When care is inconsistent or impersonal, arousal may remain poorly regulated and the child receives fewer contingent exchanges from which language, social prediction and self-regulation are learned. A threatening environment adds repeated detection of danger, narrowing attention toward immediate survival cues. The adaptations may be useful in the adverse setting while carrying costs in a safer one.

The stress-response system is one mediator. Repeated or uncontrollable stress can alter hypothalamic-pituitary-adrenal regulation, autonomic balance, immune and inflammatory signalling, sleep and metabolic function. The expected pattern is not simply "more cortisol": chronic exposure may produce elevation, flattening or blunted reactivity depending on timing, measurement and adaptation. At the neural level, studies report group differences in cortical and white-matter development, frontolimbic connectivity, reward learning and executive-control systems after severe deprivation. These are probabilistic associations, not a diagnostic brain signature. Prenatal risk, malnutrition, infection, genetic liability, placement selection and later experience can confound observed differences.

Learning mechanisms are equally important. Sparse language and play reduce opportunities to acquire vocabulary, causal models and executive strategies. Unpredictable care makes sustained attention and delayed reward less useful than rapid switching. Repeated caregiver loss can make adults unreliable sources of safety. Harsh or frightening care may produce hypervigilance, avoidance, dissociation, aggression or compulsive compliance. Epigenetic findings offer plausible

pathways by which experience can influence gene expression, but they do not justify claims that adversity permanently "rewrites" a child's genes. Biological embedding remains open to modification because the developing system continues to transact with later care.

21.3 Developmental phenotype: broad effects with marked individual variation

Severe deprivation can affect growth, cognition, language, motor development, attachment, emotion and behaviour at the same time. Physical findings include poor weight or linear growth, feeding and sleep disturbance, recurrent illness and stereotyped self-stimulation. Developmental effects may include delayed motor coordination, reduced language exposure and vocabulary, lower general cognitive performance, weak working memory, impaired sustained attention and executive dysfunction. School-age manifestations may include learning difficulty, inattention, impulsivity and problems with planning rather than a uniform global deficit.

Socioemotional development can follow more than one pattern. Some children are withdrawn, wary, emotionally constricted and do not reliably seek or accept comfort. Others show indiscriminate approach, reduced reticence with unfamiliar adults and poor checking back with a caregiver. In current classification these patterns are distinguished as reactive attachment disorder and disinhibited social engagement disorder, which are developed in the Child behavioural, emotional and other disorders notes. Both require a history of grossly insufficient care, but neither is diagnosed from that history alone. Assessment requires the child's actual pattern of behaviour, direct observation with current caregivers and exclusion of better explanations. Indiscriminate friendliness is not equivalent to secure attachment, and a child may develop a selective attachment to a new caregiver while disinhibited social behaviour persists.

Emotional and behavioural outcomes include anxiety, depressive symptoms, irritability, aggression, emotional dysregulation, dissociation, self-harm risk and later interpersonal difficulty. Early institutional deprivation has also been associated with a characteristic cluster involving inattention or overactivity, autistic-like social-communication features, disinhibited social behaviour and cognitive impairment. These are group-level patterns, not proof that every previously institutionalized child has a deprivation-specific syndrome. Development may show multifinality, in which the same adversity leads to different outcomes, and equifinality, in which a similar clinical presentation arises from different developmental routes.

21.4 Spitz: anaclitic depression and hospitalism

Spitz's observations made emotionally responsive care visible as a developmental necessity. René Spitz compared infants reared in different institutional settings and described deterioration after loss of a familiar caregiver despite provision of basic physical care. He used anaclitic depression for the syndrome following prolonged separation from an attachment figure: protest and weeping gave way to withdrawal, reduced responsiveness, disturbed feeding and sleep, developmental slowing and physical decline. Hospitalism described the more pervasive developmental deterioration seen with prolonged impersonal institutional care, including passivity, failure to thrive, susceptibility to illness and high mortality in the historical settings he observed.

The enduring inference is not that separation from the biological mother mechanically causes depression. It is that food, cleanliness and medical custody are insufficient without stable, contingent and affectionate human interaction. Spitz also helped shift hospital and residential practice toward caregiver access and relational continuity. His terms are historically examinable, but anaclitic depression is not simply the infant form of a current major depressive episode, and hospitalism is not a modern diagnostic category.

The limitations are substantial. The studies were observational, the institutional groups differed in more than caregiver contact, physical illness and nutrition were incompletely controlled, assessment was not blinded, and the interpretation was shaped by contemporary psychoanalytic theory. These weaknesses prevent precise causal estimates. The observations remain influential because later attachment research, adoption studies and intervention trials converge on the importance of stable, responsive care.

21.5 Harlow: contact comfort, fear regulation and the limits of animal evidence

Harlow showed that feeding alone does not explain attachment behaviour. Infant rhesus macaques were reared with inanimate surrogate mothers, one made of bare wire and another covered with soft cloth. Even when the wire surrogate supplied milk, the infants spent much more time clinging to the cloth surrogate. Under fear, they sought the cloth surrogate, and its presence supported exploration of an unfamiliar setting. Harlow called the relevant property contact comfort. The experiment directly challenged drive-reduction accounts in which attachment was merely learned because the caregiver relieved hunger.

Later social-isolation work showed disturbed social interaction, fear, repetitive behaviour and impaired mating and parenting in monkeys deprived of normal peer and maternal experience. Partial improvement after later social contact demonstrated both the cost of early deprivation and some capacity for recovery. The broader lesson is that attachment is supported by comfort, safety, reciprocal interaction and species-typical social experience, not by calories alone.

The evidence cannot be translated literally from macaques to children. Human caregiving includes language, culture, symbolic meaning, multiple attachment figures and institutions that vary widely. Rearing conditions were artificial, outcomes were partly species-specific, and the procedures caused severe suffering that would not meet contemporary ethical standards. Harlow's work therefore supports a mechanism, the motivational importance of comfort and relationship, but does not define a human sensitive-period cutoff or prove a deterministic human outcome.

TRAP **Spitz did not prove that only mothers matter, and Harlow did not prove that feeding does not matter.** Both challenged custodial models of care by showing that stable, responsive relationship and comfort are independent developmental needs.

21.6 Romanian natural experiments: ERA and the Bucharest intervention

The Romanian studies provide the clearest human evidence that severe institutional deprivation has causal developmental effects and that family care can produce substantial recovery. After the fall of the Romanian regime, many children who had experienced profoundly

understaffed, socially and cognitively sparse institutions entered adoptive families. The English and Romanian Adoptees study, or ERA study, followed Romanian adoptees placed in the United Kingdom and compared their development with adoptees who had not experienced the same severe deprivation. Because nutrition, prenatal risk and deprivation still varied, it was not a randomized experiment. Its strength was the unusual, time-limited exposure followed by generally well-resourced adoptive care and prolonged follow-up.

Many children showed striking catch-up in physical growth and cognitive performance after adoption, demonstrating that early effects were not fixed. A subgroup with more prolonged severe deprivation showed persistent or emerging difficulties in cognition, inattention or overactivity, disinhibited social engagement and autistic-like social communication. The ERA investigators described this as a deprivation-specific pattern. Some difficulties persisted into adult life even after years in supportive families, while emotional symptoms could become more apparent later. **Two** conclusions must be held together: recovery can be large, and residual vulnerability can remain.

The Bucharest Early Intervention Project added stronger causal evidence by randomly assigning institutionalized children to high-quality foster care or care as usual, with a never-institutionalized comparison group. Assignment to foster care produced better cognitive and physical outcomes and fewer attachment or social-relatedness difficulties and other psychopathology across follow-up. Studies also found more favourable trajectories in brain electrical activity and aspects of white-matter development. Placement timing and the subsequent quality and stability of care influenced some outcomes, but not every domain showed the same timing effect. It is therefore inaccurate to teach one universal age after which recovery is impossible.

The projects are complementary rather than interchangeable. ERA is an adoption-based longitudinal natural experiment with strong evidence of long-term developmental patterning. The Bucharest project is a randomized foster-care intervention that strengthens causal inference about the benefit of family placement. Ethical debate remains because the trial occurred in a setting where institutional care was still the prevailing care pathway, and researchers did not remove children assigned to care as usual. Its central clinical result is nevertheless clear: high-quality family care is an active developmental treatment, not merely a change of address.

21.7 Sensitive periods, cumulative risk and developmental timing

A sensitive period is a time of heightened plasticity, not an expiry date for recovery. During periods when attachment, language, sensory systems and stress regulation are being rapidly organised, expected input can have unusually strong effects. Earlier onset, greater severity, longer duration and involvement of multiple developmental systems generally increase risk. Yet the timing gradient differs by outcome: language, attachment behaviour, executive function, growth and emotional symptoms do not share one timetable. A single global cutoff converts a graded and domain-specific finding into a false rule.

The cumulative-risk model predicts increasing difficulty as adversities accumulate. It is useful for public-health stratification but an unweighted count hides whether the exposures were deprivation, threat or instability, their severity and duration, and the protective systems surrounding the child. Adverse childhood experience scores similarly describe population-level dose-response associations; they are not diagnostic tests, causal explanations or individual prognoses. Two children with the same count may have very different exposures, meanings and outcomes.

Development also involves experience-expectant plasticity, in which the brain anticipates common inputs such as patterned language and responsive interaction, and experience-dependent plasticity, in which individual learning modifies circuits throughout life. Early deprivation can therefore constrain the architecture on which later learning builds, while later relationships, education and treatment can still reorganise function. Recovery may be domain-specific: physical catch-up can coexist with executive or relational difficulty, and secure attachment to a new caregiver can coexist with persistent social disinhibition.

Must remember: early adversity is probabilistic, timing is domain-specific, and stable responsive caregiving is both the principal protective factor and the core intervention.

21.8 Clinical assessment, prevention and management

The clinical task is to reconstruct the developmental ecology, identify current needs and change the caregiving environment. Establish immediate safety first. Take a chronological account of prenatal and birth risk, nutrition, illness, developmental opportunities, separations, caregiver changes, institutional conditions, abuse or threat, schooling and current placement. Record the source and certainty of each claim because records may be incomplete and narratives may conflict. Assess growth, hearing, vision, sleep, feeding, neurological status, language, cognition, adaptive function, attachment behaviour, attention, mood, trauma symptoms, self-harm and social functioning. Observe the child with the present caregiver and obtain collateral information from school and previous services when appropriate.

Do not repeatedly elicit graphic trauma details when they are not required for care. Ask what happened, what continues, what triggers current difficulty and what helps. Separate a child's adaptations from moral judgement: food hoarding, watchfulness, indiscriminate friendliness, lying, emotional shutdown or controlling behaviour may have been functional in an unpredictable setting. Also avoid diagnostic overshadowing. Developmental disability, autism, attention-deficit/hyperactivity disorder, post-traumatic symptoms, depression, anxiety, malnutrition and sensory impairment may coexist with, resemble or occur independently of deprivation-related problems.

Management begins with a safe, stable, responsive family environment and the smallest feasible number of consistent caregivers. Prevent further placement disruption, support the caregiver-child relationship, coach caregivers in contingent responding and co-regulation, and establish predictable routines without punitive rigidity. Provide nutritional, medical, sensory,

developmental, speech-language and educational interventions according to need. Use trauma-focused treatment for clinically significant trauma symptoms, not simply because adversity occurred. Parent-child and attachment-focused work must be evidence-based and non-coercive; forced holding, induced regression and "rebirthing" practices are unsafe.

INDIA

In Indian practice, distinguish poverty and family stress from wilful neglect, and assess the wider caregiving network rather than assuming a nuclear-family model. Kinship care may preserve language, culture and continuity, but safety and caregiver capacity still require direct assessment. When residential care cannot be avoided, the developmental targets are caregiver continuity, responsive interaction, play and language, schooling, nutrition, health care, sibling and safe family contact, and an active plan toward stable family-based care. Coordination among paediatrics, psychiatry, clinical psychology, social work, speech and language services, education and child-protection systems is usually more important than any single test.

For an examination answer, define deprivation and distinguish it from threat; describe the multi-domain phenotype and mechanisms; present Spitz and Harlow with their limitations; compare the ERA natural experiment with the Bucharest randomized foster-care intervention; explain sensitive periods without a rigid cutoff; and finish with resilience, protective systems and family-based intervention. The mature conclusion is neither pessimistic nor sentimental: early severe deprivation can leave enduring developmental effects, but the developing child remains plastic, and timely, stable, high-quality relationships materially alter the trajectory.

22 · Resilience and protective factors in child development

Resilience is positive adaptation despite exposure to significant adversity. It is not invulnerability, a fixed temperament, or proof that adversity was harmless. It is a **dynamic developmental process** produced by transactions between the child and changing caregiving, family, school, peer, cultural and social systems. The same child may function well in one domain and struggle in another, and may show competence at one point but difficulty after a later developmental demand. The useful clinical question is therefore not, "Is this child resilient?" but, "What risks, resources and adaptive processes are operating now, in which domain, and what can be changed?"

How to use this page. Build the answer in **three** moves. First, establish both sides of the definition: meaningful adversity and demonstrable adaptation. Second, distinguish a factor that generally promotes development from one that specifically buffers the effect of risk. Third, move across ecological levels, from child capacities to at least one stable caring adult, family organisation, school belonging and community resources. The classic deprivation literature supplies causal clues, but its most defensible lesson is neither determinism nor romantic recovery: early relationships and stimulation matter greatly, developmental plasticity remains real, and earlier restoration of family care generally permits broader recovery.

3	5	4	3
RESILIENCE MODELS	ECOLOGICAL LEVELS	INTERVENTION TASKS	PREVENTION LEVELS

Resilience is not a trait inside the child: it is positive adaptation arising from dynamic child-context processes despite significant adversity.

22.1 Core concepts: risk, promotive factors, protective factors and vulnerability

The work of Norman Garmezy, Michael Rutter and Emmy Werner redirected research from cataloguing damage toward studying variation in outcome and the processes that alter risk pathways. Ann Masten's phrase *ordinary magic* captures the mature position: resilience usually arises from ordinary adaptive systems, not rare heroic qualities. It also differs from post-traumatic growth, which denotes perceived or demonstrable positive change after struggle; a child can be resilient without reporting growth, and claimed growth does not exclude distress.

A **risk factor** raises the probability of an adverse outcome; it does not make that outcome inevitable. Risks may be biological, psychological or social, and their meaning depends on timing, duration, severity and developmental context. **Cumulative risk** is often more informative than a single exposure because poverty, caregiver illness, violence, maltreatment, discrimination, disrupted schooling and unsafe neighbourhoods cluster and transact. **Equifinality** means that different developmental pathways can lead to a similar outcome, whereas **multifinality** means that the same early adversity can lead to different outcomes.

A **promotive factor** predicts better functioning across levels of risk. A **protective factor**, in the stricter research sense, modifies the effect of adversity: its benefit is especially evident when risk is present. A **vulnerability factor** amplifies the effect of risk. A resource such as good schooling may be promotive in most children and protective under family adversity, depending on the hypothesis and data. This distinction matters in an examination answer because merely listing desirable characteristics does not explain resilience.

RULE **Demonstrate adversity and adaptation separately.** Resilience can be inferred only when significant risk has occurred and the child shows adequate functioning in a specified domain, judged against developmentally and culturally appropriate expectations.

22.2 Models of resilience: how protection changes a developmental pathway

MODEL	HOW PROTECTION CHANGES THE PATHWAY
compensatory model	A positive influence has a beneficial effect independent of risk, partly offsetting its burden.
protective or buffering model	An interaction: the association between adversity and poor outcome is weaker when the protective process is present.
challenge, steeling or inoculation model	Manageable stress, successfully negotiated with adequate support, may strengthen later coping. It must not be used to justify preventable adversity; overwhelming or uncontrollable stress is not therapeutic.

Differential susceptibility and biological-sensitivity models add a further correction. A highly reactive child may fare worse in an adverse environment yet gain more from a supportive one. The same characteristic is therefore not always a vulnerability. Contemporary developmental psychopathology treats resilience as a changing trajectory generated by person-context transactions, developmental cascades and feedback loops. Improved caregiver responsiveness may strengthen regulation, which improves school participation, which then enlarges peer support and competence. Conversely, one failure can spread across domains if no system interrupts it.

22.3 Early adversity: threat, deprivation and biological embedding

Early adversity is heterogeneous. Experiences dominated by threat, such as violence or abuse, make harm salient and may bias fear learning, vigilance and emotion processing. Experiences dominated by deprivation, such as severe neglect or understimulation, remove expected cognitive, linguistic and relational input and may particularly affect learning and executive development. Most real children experience mixtures of both, so the distinction is a formulation aid rather than a diagnostic partition.

Repeated activation of stress-response systems without adequate co-regulation can produce toxic stress and allostatic load. Candidate pathways include altered hypothalamic-pituitary-adrenal regulation, autonomic reactivity, sleep disturbance, inflammatory signalling and experience-dependent changes in neural networks supporting attention, reward, memory and affect regulation. These are probabilistic mechanisms, not permanent lesions. Genes influence sensitivity to environments; environments influence gene expression and neural development; later caregiving and learning can alter the trajectory. This is the biological basis for holding risk and plasticity together.

22.4 Romanian orphan studies: the abstracted lesson

Developmental plasticity is real. Timing and the quality and stability of placement matter. Catch-up is domain-specific: catch-up in height or IQ does not prove recovery in attachment, attention, social functioning or later mental health.

TRAP **Do not turn deprivation research into either determinism or "complete recovery".** Group-level persistence does not fix an individual child's destiny, and catch-up in height or IQ does not prove recovery in attachment, attention, social functioning or later mental health.

22.5 Sensitive periods, developmental timing and recovery

A **sensitive period** is a phase during which experience has an unusually strong influence on a developing system; learning may remain possible later, but often requires more input or follows a different route. A **critical period** is a narrower claim in which an experience is required within a restricted window for typical development. Human psychosocial development usually warrants the more cautious term *sensitive period*. The institutional studies support timing effects, but they do not justify one universal cut-off for every function.

Different systems have different windows and recovery curves. Attachment organisation, language, executive function, growth, peer reciprocity and stress regulation need not recover together. Outcome depends on the nature of deprivation, its duration and severity, the child's prior condition, biological susceptibility, the timing and stability of placement, and the quality of later caregiving and education. Developmental cascades explain why early intervention has broad value: restoring caregiver regulation can improve attention and exploration, which expands learning, competence and relationships. The converse is also true, so later transitions can reveal difficulties that seemed absent earlier.

22.6 Protective processes across the child's ecology

- **Child level.** Cognitive ability, language, flexible problem-solving, self-regulation, sociability, realistic self-efficacy and the capacity to seek help can support adaptation. These are partly shaped by experience and should not be moralized as willpower.
- **Caregiver level.** The most consistently useful process is at least one stable, committed and emotionally available adult who notices the child, provides co-regulation, sets predictable limits and repairs relational ruptures.
- **Family level.** Warmth, routines, low conflict, safe housing, adequate material resources, shared meaning and support for caregivers reduce chaos and preserve developmental opportunity.
- **School and peer level.** A safe school, teacher attunement, academic support, opportunities for mastery, inclusive peer relationships and protection from bullying create competence and belonging.
- **Community and cultural level.** Accessible health and social services, safe neighbourhoods, social cohesion, mentors, recreation, faith or cultural networks, and policies that reduce poverty and discrimination operate upstream. Culture shapes which outcomes count as competent adaptation and which supports are acceptable.

A protective process is strongest when it is developmentally matched, available in ordinary settings and sustained across transitions.

INDIA

Formulate the ecology, not merely the child. Ask about caregiver mental illness and substance use, domestic violence, migration, caste or minority stress, gendered restriction, disability, school exclusion, examination pressure, digital and peer environments, and material insecurity. Then map usable protection: an extended-family adult, teacher, peer, Anganwadi or school support, paediatric and mental-health services, child-protection mechanisms and local community networks. Extended family can be protective, neutral or harmful; do not assume that family presence equals emotional safety. When abuse, exploitation or neglect is ongoing, safeguarding and reduction of exposure come before teaching the child coping skills.

22.7 Assessment: a strengths-based formulation without minimizing harm

Assessment begins with a timeline of exposures, developmental transitions and changes in functioning. Specify the adversity by type, severity, duration, proximity and current status; separate threat from deprivation where useful; and identify mediators such as sleep, caregiver responsiveness, school attendance and peer exclusion. Examine adaptation in multiple domains: symptoms, attachment and relationships, learning, behaviour, physical health, self-care and age-appropriate participation. Obtain accounts from the child, caregivers and school because competence and distress are context-dependent.

Then construct a resilience map: risks and vulnerabilities; existing resources; mechanisms through which they help; inaccessible or unstable supports; and leverage points that can change the trajectory. A resilience questionnaire may organize information but cannot certify a resilient personality. Cross-sectional good functioning may conceal effort, dissociation, parentification or a later cost, while symptoms in one domain can coexist with genuine competence in another. Trauma-informed assessment therefore combines safety, curiosity and developmental formulation without forcing disclosure or demanding a narrative of growth.

22.8 Intervention: reduce adversity, restore relationships and build adaptive systems

Intervention is not "resilience training" alone. The **first** task is to stop or reduce the active adversity: ensure safety, treat caregiver illness, address violence and substance use, secure nutrition, housing and schooling, and prevent repeated placement disruption. The **second** is to strengthen caregiving through responsive parent work, co-regulation, predictable routines and support for caregiver stress. The **third** is to build the child's skills in a developmentally fitted way, including emotion identification, problem-solving, executive supports, social competence, mastery and help-seeking. The **fourth** is to enlarge the ecology through school accommodations, mentoring, peer connection and coordinated health, education and social care.

MNEMONIC

"Reduce - Restore - Build - Enlarge"

Reduce the active adversity; restore relationships through responsive parent work, co-regulation, predictable routines and support for caregiver stress; build the child's skills; enlarge the ecology through school accommodations, mentoring, peer connection and coordinated health, education and social care.

Effective prevention combines universal supports for all children, selective interventions for groups exposed to elevated risk and indicated treatment for children already showing difficulty. Review outcomes over time and across domains, especially at transitions. The ethical endpoint is not to make children tolerate unsafe systems. It is to reduce preventable exposure, increase dependable protection and restore the ordinary relationships and opportunities through which development proceeds.

22.9 Exam synthesis

A complete long answer opens with resilience as a dynamic process, distinguishes promotive from protective effects, and gives compensatory, buffering and challenge models. It then explains cumulative risk, equifinality, multifinality and developmental cascades; uses Spitz, Harlow and the Romanian orphan natural experiments with their limitations; and links the ERA findings to sensitive periods without claiming a universal cut-off. Finish with child, caregiver, family, school and community protective processes, followed by assessment and intervention. The single sentence that rescues the answer from a list is this: **resilience emerges when ordinary adaptive systems, especially stable caregiving, regulation, learning, belonging and social protection, remain available or are restored under adversity.**

Apply and consolidate

23 . Apply: worked cases

These cases close the developmental arc by making the resident perform the decisions that lists of theories and milestones are meant to support. The sequence is deliberate: date a milestone without turning a typical age into a deadline, recognise a genuine referral signal, identify an attachment strategy from reunion behaviour, formulate temperament as a person-environment fit, and apply a developmental theory without pretending that it is a screening instrument.

MNEMONIC

"Phenomenon - construct - comparison - clinical action"

Identify the phenomenon actually being tested, name the relevant construct, compare it only with an age or pattern that measures the same construct, and state what follows clinically.

How to use this page. In each case, take the steps in this order.

WHAT TO ESTABLISH	TASK
Phenomenon	Identify the phenomenon actually being tested.
Construct	Name the relevant construct.
Comparison	Compare it only with an age or pattern that measures the same construct.
Clinical implication	State what follows clinically.

The answer comes last. A correct label without the intervening reasoning is fragile in a viva and unsafe in practice.

23.1 Milestone dating: late against a typical age, still within the WHO window

Presentation. A child at 15 months of age pulls to stand, cruises along furniture, stands briefly without support and communicates socially, but has not yet walked alone. There has been steady acquisition of skills, no loss, no asymmetry and no abnormality of tone or movement quality. The caregiver has read that children usually walk independently by **12 months** and asks whether this proves **developmental delay**.

Reasoning. The first task is to name what the two ages mean. Kaplan and Sadock describes independent walking as expected at 12 months and gives an expected range of 9 to 15 months. An **expected age** describes typical attainment; it is not a **referral threshold**. The WHO Motor Development Study gives a different and more construct-explicit measure: its 1st-to-99th-centile window for walking alone is **8.2 to 17.6 months**. WHO states that its upper boundary is a signal for appropriate screening when a child appears late, not a diagnostic cut-off.

The child is later than the typical 12-month anchor but remains within the WHO achievement window and at the end of Kaplan and Sadock's expected range. The preserved progression toward independent gait and the absence of regression, asymmetry or abnormal motor quality further reduce the force of a single late-looking date. This does not mean that development is ignored. Surveillance continues, and examination still covers all domains, hearing, vision and neurology. It means only that the typical age cannot be promoted into a referral rule.

Answer. This is a late-normal gross-motor attainment on the information given, not developmental delay established by the 12-month expected age. Continue developmental surveillance and reassess the trajectory. Crossing the WHO **17.6-month** boundary would be a screening signal, while regression or abnormal neurological findings would change the action immediately.

23.2 Deviation call: a sourced communication red flag

Presentation. A child at 24 months of age uses several meaningful single words and obtains desired objects by pointing, but never produces spontaneous two-word phrases. Motor development has progressed, and the caregiver reports no loss of previously acquired skills.

Reasoning. The finding is not judged from vocabulary size alone. Berk gives 18 to 24 months as an expected range for combining two words, but the clinically decisive statement is separate:

Developmental Psychopathology identifies absence of spontaneous two-word phrases at **24 months** as a **red flag** warranting further developmental evaluation. Here the age is explicitly a referral signal, not merely an expected attainment or median.

The threshold does not diagnose a language disorder or autism. The next step is to define the profile.

- Confirm whether phrases are truly spontaneous rather than imitated.
- Assess receptive language, gesture, joint attention, reciprocity and symbolic play.
- Establish language exposure across all languages used by the child.
- Examine hearing and oral-motor function.

Map gross motor, fine motor, cognitive or adaptive, and social-emotional development rather than inferring global delay from one communication finding. The absence of regression is reassuring about the course but does not cancel the hard red flag.

Answer. This is a developmental red flag requiring prompt hearing and developmental evaluation. It is a referral decision, not a diagnosis, and a reassuring motor history or a negative brief screen would not overrule it.

23.3 Attachment-pattern identification: contact sought but not used effectively

Presentation. During a Strange Situation observation, a young child explores little, becomes intensely distressed when the caregiver leaves, and hurries toward the caregiver on reunion. Once picked up, the child arches away, pushes against the caregiver, continues crying and does not settle sufficiently to return to play.

Reasoning. Separation distress alone cannot classify attachment. The reunion is more informative because it shows whether renewed access to the caregiver restores regulation. A secure child can seek and use comfort, then resume exploration. An avoidant child minimises overt proximity-seeking and may turn away or ignore the caregiver. This child instead maximises attachment signals: proximity is urgently sought, yet contact is mixed with anger or resistance and does not readily produce settling.

The simultaneous approach and resistance form a coherent strategy and therefore differ from **disorganisation**, where behaviour lacks a stable strategy and may include contradictory, apprehensive, frozen or disoriented sequences. The observed pattern describes this child's relationship with this caregiver in this procedure. It is not a diagnosis, a fixed personality trait or proof of inconsistent caregiving.

Answer. The pattern is ambivalent or resistant attachment, pattern C. The decisive clues are intensified proximity-seeking, resistance during contact and failure to use reunion effectively for soothing and renewed exploration.

23.4 Temperament and goodness of fit: the setting creates the difficulty

Presentation. A child watches an unfamiliar classroom activity from the edge, declines the teacher's first invitation and speaks little while everyone is watching. With advance warning, time

to observe and a quiet invitation from a familiar teacher, the child joins, completes the task and later participates comfortably. At home and with familiar peers, communication and play are fluent. The school has responded by calling the child stubborn and demanding immediate public participation.

Reasoning. Thomas and Chess directs attention to behavioural style before disorder. The initial response to novelty is withdrawal; the later capacity to join after familiarisation concerns adaptability. Because the response is cautious, improves gradually and is not described as an intense, persistently negative or globally dysregulated pattern, it is closer to a slow-to-warm-up temperament than to the classic difficult constellation.

The impairment is transactional. Immediate public performance and criticism create a poor **goodness of fit** by punishing the child's characteristic entry into novelty. Preparation, observation, phased entry and a familiar adult improve the fit without declaring that the child can avoid every demand. The cross-setting strengths argue against treating silence in the unfamiliar classroom as proof of a fixed language deficit, but persistent distress or impairment would still require assessment for anxiety, communication difficulty and other alternatives.

Answer. This is a **slow-to-warm-up temperamental pattern** made problematic by poor goodness of fit. Management should alter the transaction through predictable preparation and graduated participation while separately assessing any sustained impairment.

23.5 Theory application: supported performance is not a new Vygotskian stage

Presentation. A child cannot independently sort a mixed set of objects by a changing rule. The examiner first restates the goal, then models the opening move and finally uses a visual cue. With that graduated help, the child completes the remaining items and applies the same strategy to a related task. A static score records only the initial failure.

Reasoning. Vygotsky asks how performance changes through social mediation. The lower boundary is what the child can do independently; the upper boundary is what becomes possible with appropriate assistance. The distance between them is the zone of proximal development. The examiner's calibrated prompts are scaffolding: support is increased only as needed, then should be faded as responsibility transfers to the learner. Improvement that generalises to a related task is stronger evidence of an emerging strategy than completion achieved by simply giving the answer.

Piaget would ask what structure of classification or rule use the task requires, and a static assessment would describe unaided performance. Those are different questions. The assisted success must not be reported as independent mastery, but neither should the unaided failure be treated as the child's full learning capacity. Most importantly, Vygotsky proposed no age-linked stages, so the case cannot be labelled as entry into a new Vygotskian stage.

Answer. The case demonstrates performance within the **zone of proximal development**, revealed through **scaffolding** and dynamic assessment. Record independent and assisted

performance separately, fade help, test transfer and investigate language, attention, memory or task mismatch if well-calibrated support does not unlock performance.

RULE **An expected age describes typical attainment; it is not a referral threshold.** A typical age cannot be promoted into a referral rule.

TRAP **Do not report assisted success as independent mastery.** The assisted success must not be reported as independent mastery, but neither should the unaided failure be treated as the child's full learning capacity.

12 months	9 to 15 months	8.2 to 17.6 months	24 months
TYPICAL INDEPENDENT WALKING AGE	KAPLAN AND SADOCK EXPECTED RANGE	WHO WALKING WINDOW (1ST TO 99TH CENTILE)	TWO-WORD-PHRASE RED FLAG

HOLD THIS

A correct label without the intervening reasoning is fragile in a viva and unsafe in practice.

24 . Consolidation

This closing topic turns developmental psychiatry into a retrievable clinical map. The aim is not to recite every date in isolation. It is to recover **three** linked structures under examination pressure: which question each **developmental theory** asks, which observable functions belong to each **developmental domain**, and how the meaning of an age determines whether the doctor continues surveillance, screens or refers.

How to use this page. Learn the master mnemonic, cover the page and work through the answer-free prompts, then redraw the theory and milestone tracks from memory. On checking the redraw, be strict about construct.

TRAP **A typical age is not a deadline.** A WHO **99th-centile** boundary is a screening signal rather than a diagnosis, and only an explicitly sourced red flag supports an age-linked referral call.

three	five	1st-to-99th-centile
LINKED STRUCTURES	DEVELOPMENTAL DOMAINS	WHO GROSS-MOTOR CONSTRUCT

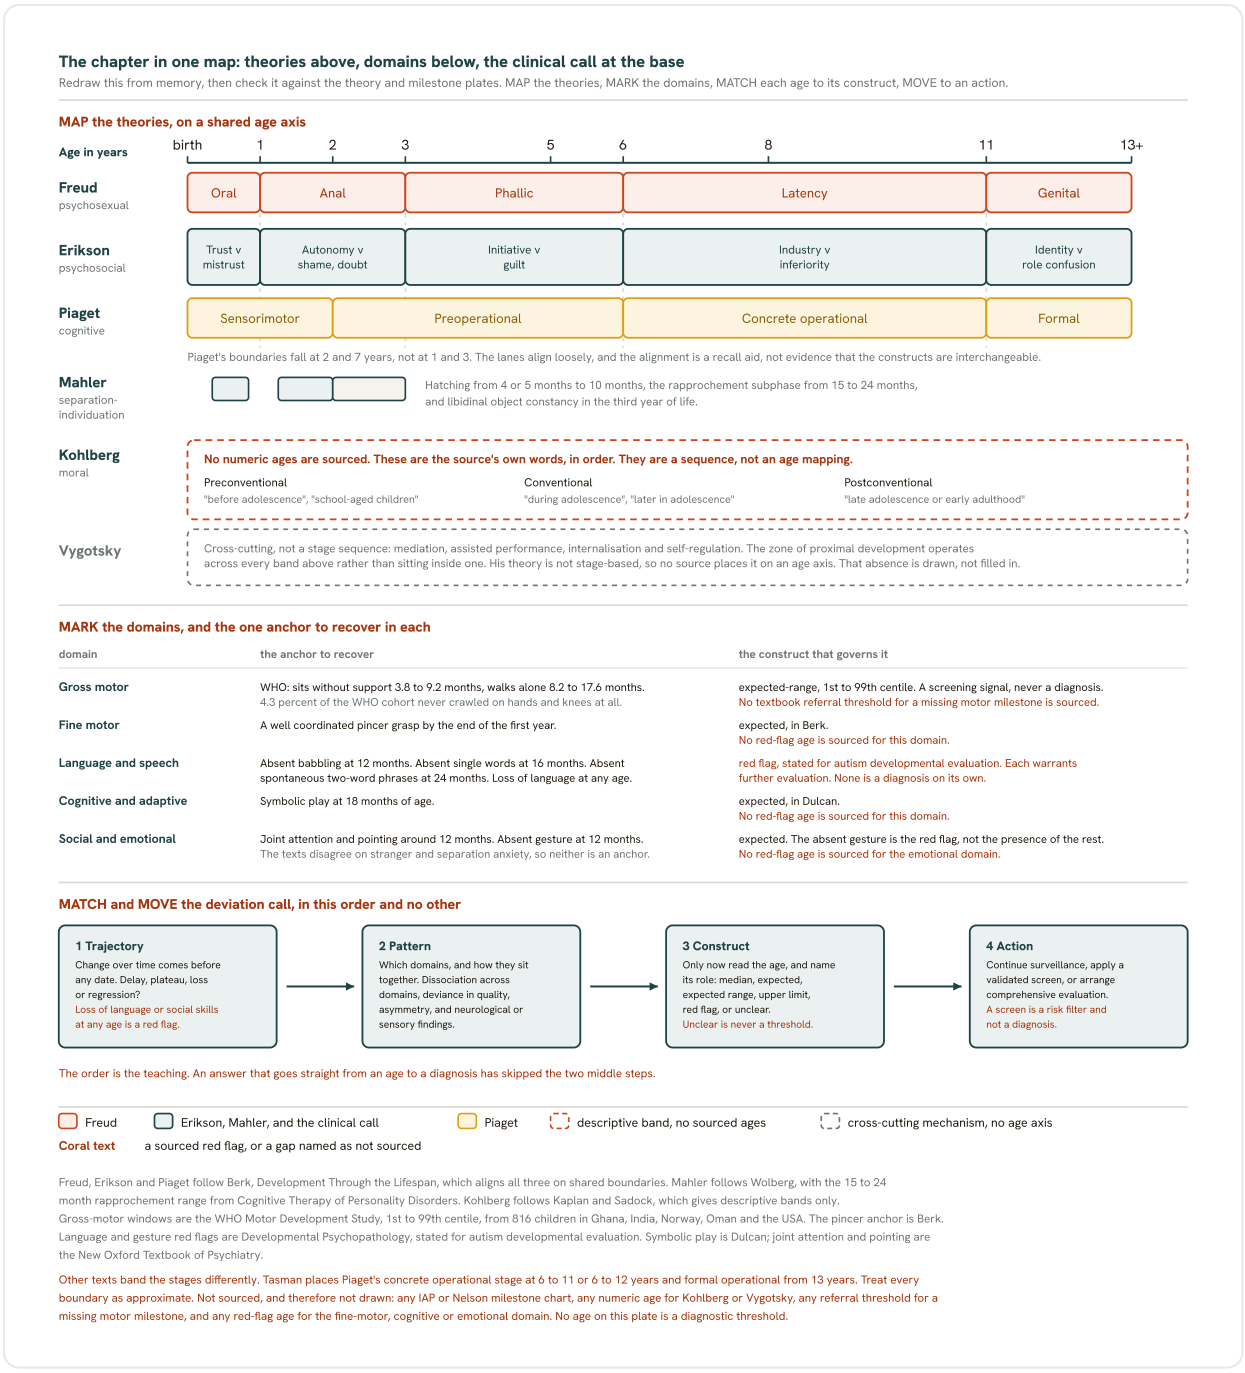

Fig 20.21 The whole-chapter synthesis map, drawn to be redrawn from memory. Theory lanes follow Berk, Mahler follows Wolberg, and Kohlberg sits in descriptive bands because no numeric ages are sourced for him. Vygotsky is drawn across the axis rather than on it, since his theory is not stage-based. Gross-motor windows are the WHO Motor Development Study, 1st to 99th centile; the language and gesture red flags are Developmental Psychopathology, stated for autism developmental evaluation. The plate carries one anchor per domain rather than the milestone tables, and names the domains for which no red-flag age is sourced.

24.1 The retrieval method: rebuild relationships, not isolated lists

Retrieve the map in a fixed clinical order. Start with the explanatory theories, move to observable development across domains, attach every age to its normative construct, and finish with the clinical action. This order prevents three common collapses: a theory stage becoming a milestone, an expected attainment becoming a referral threshold, and a positive screen becoming a diagnosis.

The theories answer different questions about the same developing person.

THEORY	QUESTION
Piaget	how cognition is organised
Erikson	which psychosocial conflict is foregrounded
Freud	how drive and conflict are organised
Mahler	how psychological separateness develops within relationship
Kohlberg	how moral decisions are justified
Vygotsky	what learning becomes possible through social mediation

HOLD THIS

Their temporal alignment is a recall aid, not evidence that the constructs are interchangeable.

24.2 Master mnemonic: MAP, MARK, MATCH, MOVE

MNEMONIC

MAP - MARK - MATCH - MOVE

MAP the theory lanes: cognition, psychosocial conflict, psychosexual organisation, separation-individuation and moral reasoning, with sociocultural mediation running across them. **MARK** observable development in the **five** domains: gross motor, fine motor, language and speech, cognitive or adaptive, and social and emotional. **MATCH** each age to its **normative construct**: median, expected attainment, expected range, upper limit, red flag or a source-stated age whose normative role remains unclear. **MOVE** from observation to action: describe the trajectory and quality, look for loss, asymmetry and multi-domain involvement, use screening as a risk filter, and refer for regression, a sourced red flag or a concerning neurological or sensory pattern.

The mnemonic contains the chapter's division of labour. The theory map explains; the milestone map describes; the construct check interprets; and the final verb commits the doctor to an action. If the answer jumps directly from an age to a diagnosis, one of the middle steps has been skipped.

24.3 Answer-free active recall

Cover the rest of the page and answer each prompt aloud or on paper. Check only after completing the retrieval attempt.

1. What distinct developmental question is asked by Piaget, Erikson, Freud, Mahler, Kohlberg and Vygotsky?
   How would you reconstruct the source-stated age lanes for Piaget, Erikson and Freud without turning theoretical brackets into clinical thresholds?
   What is the sequence of Mahler's separation-individuation account, and which two similarly named cognitive and relational constructs must not be confused?
   How are Kohlberg's levels and stages ordered, and what exactly is scored in a moral dilemma?

Where should Kohlberg and Vygotsky sit on a theories-by-age map, and why must neither be given an invented numeric row?

2. Name the five developmental domains and describe how a limitation in one can alter performance in the others.
   What do cephalocaudal and proximodistal organisation explain, and what do they not date?
   Reproduce the WHO gross-motor achievement windows from the milestone plate and state the clinical meaning of the upper boundary.
   Why is absence of hands-and-knees crawling alone an unsafe referral rule?
   Trace the communication sequence from prelinguistic exchange through words, combinations, grammar and intelligibility, preserving the construct attached to each anchor.
   Which communication findings are explicit age-linked red flags, and how would you evaluate a child who meets one?
3. How do **developmental delay**, **dissociation**, **deviance**, **plateau** and **regression** differ?
   How do **surveillance**, **screening** and **formal developmental assessment** differ in purpose and output?
   Which reunion behaviours distinguish secure, avoidant, ambivalent or resistant, and disorganised attachment?
   Name the Thomas-and-Chess dimensions, distinguish their three constellations, and formulate one example of goodness of fit.
   How do responsiveness and demandingness generate the parenting-style patterns, and why are outcome associations not deterministic?
4. How would you separate gender identity, gender expression, sexual orientation and sexual behaviour in a developmental assessment?
   Why must Tanner stage be assigned from morphology rather than chronological age or psychological maturity?
   How do dual-systems and maturational-imbalance accounts explain a difference between calm reasoning and behaviour in a highly charged peer context?
   Which features of deprivation, later care and protective relationships determine whether risk becomes persistent impairment or recovery?

24.4 The synthesis redraw: theories above, milestones below, action at the base

Redraw the synthesis as aligned horizontal tracks. Across the top, place the age axis from infancy through adulthood. Give Piaget, Erikson and Freud separate lanes using the source-stated stage bands, and give Mahler a shorter early relational lane using only its sourced phase timings. Place Kohlberg in ordered descriptive bands rather than numeric ages. Draw Vygotsky beside the entire axis as a cross-cutting process of mediation, assisted performance, internalisation and self-regulation. The alignment should make temporal overlap visible while keeping each theory's explanatory target separate.

Below the theory lanes, draw the five developmental domains. In the gross-motor lane, reconstruct the WHO windows from sitting without support through walking alone and label the **1st-to-99th-centile** construct. In the fine-motor lane, recover the sequence from grasp and

transfer through pincer control, construction, scribbling and copied forms. In the language lane, move from vocalisation and gesture through meaningful words, combinations, grammar and intelligibility. In the cognitive or adaptive lane, place symbolic representation, problem-solving and theory-of-mind anchors. In the social and emotional lane, move from reciprocity and selective attachment through shared attention, symbolic play, peer engagement and regulation. Use the existing milestone and reflex plates to check the redraw rather than recreating their source-labelled tables in prose.

Add a separate pubertal branch rather than forcing it onto the childhood milestone ladder. Record Tanner morphology by component, not by age, and place identity formation, relationships, gender and psychosexual development beside the adolescent body and brain changes. This preserves the central distinction: physical maturation, cognitive capacity, moral reasoning, identity and consent are related but are not interchangeable measures.

Finally, draw the clinical action rail beneath every domain. Its sequence is *trajectory, pattern, construct, action*. Mark regression, plateau, asymmetry, abnormal quality, sensory or neurological findings and unevenness across domains before checking a date. Then label the date honestly as expected, a range, an upper limit, a red flag or unclear. End with the appropriate move:

- continue surveillance or apply a validated screen
- arrange comprehensive developmental evaluation

RULE **Developmental psychiatry is not the memorisation of ages, but the disciplined interpretation of change over time.** The completed redraw should make one principle unavoidable.

Previously asked

This chapter is the one place in the series where the honest answer about past questions is that the examiner has not asked them here. Normal development is examined, and examined often, but it is examined as *psychology* under Paper I rather than as child psychiatry under Paper III. Every developmental question on record in the catalogue sits in the basic sciences and psychology section: Erikson's psychosocial stages has appeared four times, most recently in 2021 and before that in 2017 and twice in 2012, always as a ten-mark question; Jean Piaget was asked in 2011; and psychological development in adolescence, paired with its relation to psychiatric disorders in adolescence, came up in 2018 and again in 2020. Those questions and their model answers live where they were asked, in the General and Developmental Psychology notes, and they are not repeated here.

That distribution is worth reading rather than shrugging at, because it tells you how the material is tested. The theories are examined as theories, on their own terms, in a psychology paper: name the stages, get the order right, get the count right, say what each stage is *for*. What this chapter adds is the part the examiner does not ask directly and the clinic asks constantly, which is the deviation call. No question on record asks for a milestone table. Plenty of clinical practice asks

whether this particular child, at this particular age, is outside the normal window, and that judgement rests on knowing which of the ages you memorised is a typical attainment and which is a screening boundary. A candidate who can recite Piaget's four stages and still cannot say whether a fourteen-month-old who is not walking needs referring has learned the examinable half and missed the useful half.

ON THE THEORIES, EXAMINED UNDER PAPER I PSYCHOLOGY

Erikson and his psychosocial stages is the highest-yield developmental question in the catalogue, at four appearances for ten marks. Piaget follows. Both reward the same discipline: the stages in order, at their exact count, each with its central conflict or operation and its one clinical use. The age bands are the least reliable part of both answers and should be given as the approximate, source-dependent ranges they are. MUHS 2011, 2012, 2017, 2021

ON ADOLESCENCE, EXAMINED UNDER PAPER I PSYCHOLOGY

Psychological development in adolescence is asked with its psychiatric relation attached, which is the examiner signalling that normal adolescent development is the setup and the disorders are the payoff. The normal half is owned here: identity formation, the neurodevelopment of adolescence, the imbalance between a fast-maturing reward system and a slow-maturing control system, and why risk-taking is developmentally expected rather than pathological. The disorder half belongs to the disorder chapters. MUHS 2018, 2020

WHAT HAS NEVER BEEN ASKED, AND WHAT TO DO ABOUT IT

There is no question on record on the milestone tables, on the primitive reflexes, on attachment classification, on temperament, or on the developmental screening instruments. Two readings are available and both are worth holding. The first is that these are low-yield for the written paper and should be learned to a clinical rather than an examination standard. The second is that they are exactly the material a viva or a clinical case can turn on without warning, because they are what a child psychiatrist is assumed to know rather than asked to prove. Prepare the theories for the paper. Prepare the deviation call for the patient.

Quick review

DEVELOPMENTAL PSYCHIATRY: THEORIES, MILESTONES AND THE DEVIATION CALL	
THE INTERPRETIVE RULE	
CONSTRUCT BEFORE ACTION	**Median** means half have attained the skill; **expected** means usually attained; **expected range** is a normal window; **upper limit** is the outer normal bound; and **red flag** warrants further evaluation. If the source leaves the construct unclear, repeat only its own wording. Never turn it into a referral threshold.
WHAT EACH THEORY ASKS	
PIAGET	**How is cognition organised?** Sensorimotor action becomes preoperational representation, concrete operations bring reversible logic for tangible material, and formal operations extend reasoning to propositions and possibilities. The stage bands are theoretical descriptions, not milestone norms or referral ages.
ERIKSON	**Which psychosocial conflict is foregrounded?** Trust versus mistrust, autonomy versus shame and doubt, initiative versus guilt, industry versus inferiority, identity versus role confusion, intimacy versus isolation, generativity versus stagnation, and integrity versus despair. Use the conflict and strength for formulation, not diagnosis.
FREUD	**How are drive, bodily focus and conflict organised?** Oral, anal, phallic, latency and genital. Fixation is an enduring investment in an earlier mode; regression is movement back toward it under stress. These are historical psychosexual mappings, not developmental screening stages or Tanner stages.
MAHLER	**How does psychological separateness develop within relationship?** Distinguish separation, "I am not you," from individuation, "I am me." Object constancy is the affective capacity to retain a whole loved person across absence and frustration; it is not Piagetian object permanence.
KOHLBERG	**How is a moral judgement justified?** Preconventional reasoning moves from punishment to exchange; conventional reasoning from approval to social order; postconventional reasoning evaluates law through rights and principles. Score the reason, not the verdict. Kaplan and Sadock gives only descriptive bands: before adolescence, school-aged children, some young adolescents, during adolescence, later in adolescence, and late adolescence or early adulthood. There are no sourced numeric ages.

DEVELOPMENTAL PSYCHIATRY: THEORIES, MILESTONES AND THE DEVIATION CALL	
VYGOTSKY	**What becomes possible through social mediation?** The zone of proximal development lies between independent and assisted performance; scaffolding is contingent support that is faded; social speech becomes private and inner speech. Vygotsky proposed **no stages**, so he belongs beside an age axis as a cross-cutting mechanism.
LANGUAGE ACQUISITION	**Skinner**: operant contingencies shape verbal behaviour. **Chomsky**: innate grammatical preparedness supports generative language. **Vygotsky**: shared speech is socially mediated and internalised. Consequence, grammar and mediation answer different parts of the same problem.
ATTACHMENT	**Bowlby** asks how proximity to a familiar caregiver provides safe haven and secure base; internal working models carry expectations of self, others and help. In **Ainsworth's Strange Situation**, reunion distinguishes secure use of comfort, avoidant minimisation, ambivalent or resistant approach with resistance, and disorganised absence of a coherent strategy. These are relationship patterns, not diagnoses.
TEMPERAMENT AND PARENTING	**Thomas and Chess** ask how activity, rhythmicity, approach or withdrawal, adaptability, threshold, intensity, mood, distractibility, and attention span or persistence fit the environment. Easy, difficult and slow-to-warm-up are constellations; outcome depends on goodness of fit. **Baumrind** maps responsiveness and demandingness: authoritative is high-high, authoritarian low-high, permissive high-low, and uninvolved low-low.
ADOLESCENCE AND ADVERSITY	Adolescence is asynchronous change in body, reward, control, identity and relationships. Dual-systems and maturational-imbalance models explain context-sensitive risk, not global irrationality. Marcia separates exploration from commitment. Deprivation removes expected input; threat adds danger. Resilience is better-than-expected adaptation produced by dynamic child-context processes, especially stable responsive care, not an invulnerable trait.
SOURCED MILESTONE ANCHORS	
WHO GROSS MOTOR WINDOWS	The WHO 1st-to-99th-centile windows are: sitting without support **3.8 to 9.2 months**; standing with assistance **4.8 to 11.4 months**; hands-and-knees crawling **5.2 to 13.5 months**; walking with assistance **5.9 to 13.7 months**; standing alone **6.9 to 16.9 months**; walking alone **8.2 to 17.6 months**. Beyond an upper boundary signals the need for appropriate screening. It is not a diagnosis or an independently sourced referral threshold.

DEVELOPMENTAL PSYCHIATRY: THEORIES, MILESTONES AND THE DEVIATION CALL	
FINE MOTOR	Berk expects a well-coordinated pincer grasp **by the end of the first year**, vigorous scribbling between **10 and 21 months**, and a tower of two cubes between **10 and 19 months**. These are expected attainments or ranges, not referral thresholds. Observe vision, posture, symmetry, tone, comprehension and opportunity.
LANGUAGE AND SPEECH	Kaplan and Sadock expects cooing at about **3 to 4 months**, meaningful words at about **12 months**, and word combinations at **18 months**. Speech is expected to be about **25 percent** intelligible to strangers at **18 months**, **50 percent** at **24 months**, **75 percent** at **36 months**, and nearly **100 percent** by **4 years**. These are expected values, not referral cuts.
SOCIAL AND COGNITIVE	Berk gives the social-smile window as **6 to 10 weeks**. Joint attention and pointing are expected around **12 months** in the New Oxford Textbook of Psychiatry; Dulcan expects symbolic play at **18 months**; explicit false-belief performance is expected at **4 or 5 years** in the cited account. None is an automatic referral threshold.
PUBERTY AND TANNER	Tanner stage is morphological: record breast or genital development and pubic hair separately, never infer stage from age or psychological maturity. Berk's expected ranges include breast budding at **8 to 13 years**, testicular enlargement at **9 to 13.5 years**, menarche at **10.5 to 14 years**, and spermarche at **12 to 16 years**. These are expected ranges, not clinical cut-offs.
SCREENING SIGNALS, RED FLAGS AND REFLEXES	
WHO SCREENING SIGNAL	The gross-motor windows describe variation and signal screening when a child appears late. About **4.3 percent** of children in the WHO study never exhibited hands-and-knees crawling, so absence of crawling alone is not a red flag. Judge progression, transitions, symmetry, tone and movement quality.
COMMUNICATION RED FLAGS	Arrange prompt developmental evaluation for no babbling or gesturing at **12 months**, no single words at **16 months**, no spontaneous two-word phrases at **24 months**, or loss of language or social skills at **any age**. These Developmental Psychopathology thresholds are referral signals, not diagnoses.
EXPECTED REFLEX DISAPPEARANCE	Keep the source attached: rooting at **3 weeks** in Berk; sucking after **4 months** in Berk; palmar grasp at **3 to 4 months** in Berk; stepping at **2 months** in Hutchison's Clinical Methods; asymmetric tonic neck reflex at **4 months** in Berk; Moro at **12 weeks** in Tasman but **6 months** in Berk and Hutchison. Do not average disagreement.

DEVELOPMENTAL PSYCHIATRY: THEORIES, MILESTONES AND THE DEVIATION CALL	
BABINSKI AND REFLEX RED FLAGS	Berk gives Babinski disappearance at **8 to 12 months**; Hutchison gives the extensor plantar response an upper limit of **18 months** and calls persistence beyond **2 years** a red flag. Hutchison also flags absence of sucking beyond the **36th week of gestation** and gives persistence of primitive reflexes beyond the **fourth month of life** as a general warning. Reflex-specific expectations, symmetry, tone and the neurological examination still govern interpretation.
THE DEVIATION CALL	
NAME THE TRAJECTORY	**Delay** is slow acquisition with broadly preserved sequence; **dissociation** is uneven development between domains; **deviance** is an unusual sequence or quality; **plateau** is failure to acquire new skills; **regression** is loss of a convincingly acquired skill. Also act on marked asymmetry, abnormal tone or movement, sensory concern, neurological findings and convergent multi-domain difficulty.
SURVEILLANCE TO ASSESSMENT	**Surveillance** repeatedly integrates concerns, history, observation, examination and trajectory. **Screening** applies a standardised risk filter and does not diagnose. **Assessment** characterises strengths and impairments across domains and investigates cause. A negative screen never overrules regression, a sourced red flag, abnormal examination or persistent concern.
INDIAN PATHWAY	The Trivandrum Development Screening Chart covers birth to **6 years**; **one item delay** is the positive screen termed TDSC delay. DASII yields Motor DQ and Mental DQ; Indian follow-up practice uses **DQ below 85** as a delay marker. A positive screen or quotient is not a diagnosis.
FINAL ACTION	Use **trajectory, pattern, construct, action**. Continue surveillance for a coherent progressing course within an expected window; screen when a WHO upper boundary is crossed; arrange comprehensive evaluation for regression, an explicit red flag, marked asymmetry, abnormal quality, neurological or sensory findings, multi-domain delay, or persistent clinical concern.

References

Normal development is a chapter where the sources disagree with each other more than they admit, and the reference list is built to show that rather than hide it. Every age, stage boundary, reflex age and instrument property in these notes was taken from a named source and checked against it; where two standard texts give different bands for the same stage, both are reported and neither is presented as the answer. The depth bar for the theories is Berk's *Development Through the Lifespan*, which is the source that aligns Freud, Erikson and Piaget on shared boundaries and therefore the source the alignment plate follows. Tasman and Kaplan and Sadock carry the

psychiatric framing, Lewis and Cicchetti's *Developmental Psychopathology* the child-psychiatry depth and the language red flags, Wolberg the Mahler subphases, Hutchison's *Clinical Methods* the primitive reflexes and their persistence, Schunk's *Learning Theories* the Vygotskian material, and Kaufman's *Clinical Neurology for Psychiatrists* the early-handedness sign. The Indian frame comes from the Indian Psychiatric Society child and adolescent guideline and from the primary validation literature for the Indian instruments.

Two sources carry more weight than the rest and deserve naming for what they are. The WHO Motor Development Study is the only source in this chapter that states the normative role of its own numbers: its windows are bounded by the 1st and 99th centiles, it followed children in Ghana, India, Norway, Oman and the USA, and it says in its own words that the windows exist to signal the need for screening rather than to diagnose. Every gross-motor boundary taught here comes from it, and comes labelled as what it is. The Trivandrum validation is the only Indian screening instrument in this chapter with published psychometrics, and its sensitivity, specificity and predictive values are reported from the primary paper rather than from a secondary summary.

Three absences are load-bearing and are stated rather than papered over. Nelson's *Textbook of Pediatrics*, the source a paediatric milestone chapter would normally lean on, was not available; the milestone ages here come from the developmental psychology and psychiatry texts instead. No Indian Academy of Pediatrics milestone chart was available, so no IAP milestone age is stated anywhere in this chapter. The DASII manual was not available, so its administration range, item structure and norming sample are not stated; only its two developmental quotients and the delay marker used in Indian follow-up practice are given, from the applied literature. Where a value could not be sourced, it was left out.

PAPER III

Intellectual disability & autism spectrum disorder

Six bands . one complete notes document

Intellectual disability: the concept and its measurement

1 · The neurodevelopmental frame

Begin with the person, not the label. Intellectual disability and autism spectrum disorder are developmental presentations that demand careful formulation rather than rapid categorisation. The marks lie in showing that one can move from a concern raised by a family or school to a coherent account of abilities, everyday functioning, communication, behaviour, context and need. A diagnosis may organise that account, but it does not replace it.

This chapter is best read as a clinical sequence. It first establishes the language and measurement needed to describe intellectual disability, then considers causes, associated psychiatric and practical concerns, and care across settings. It then develops autism spectrum disorder from its diagnostic framework through recognition, assessment, intervention and outcome. The final task is discrimination: deciding which explanation best fits the observed developmental pattern and what the distinction changes for the person and family.

ID	ASD	PERSON
CONCEPT AND MEASUREMENT	RECOGNITION AND FORMULATION	FUNCTION BEFORE LABEL

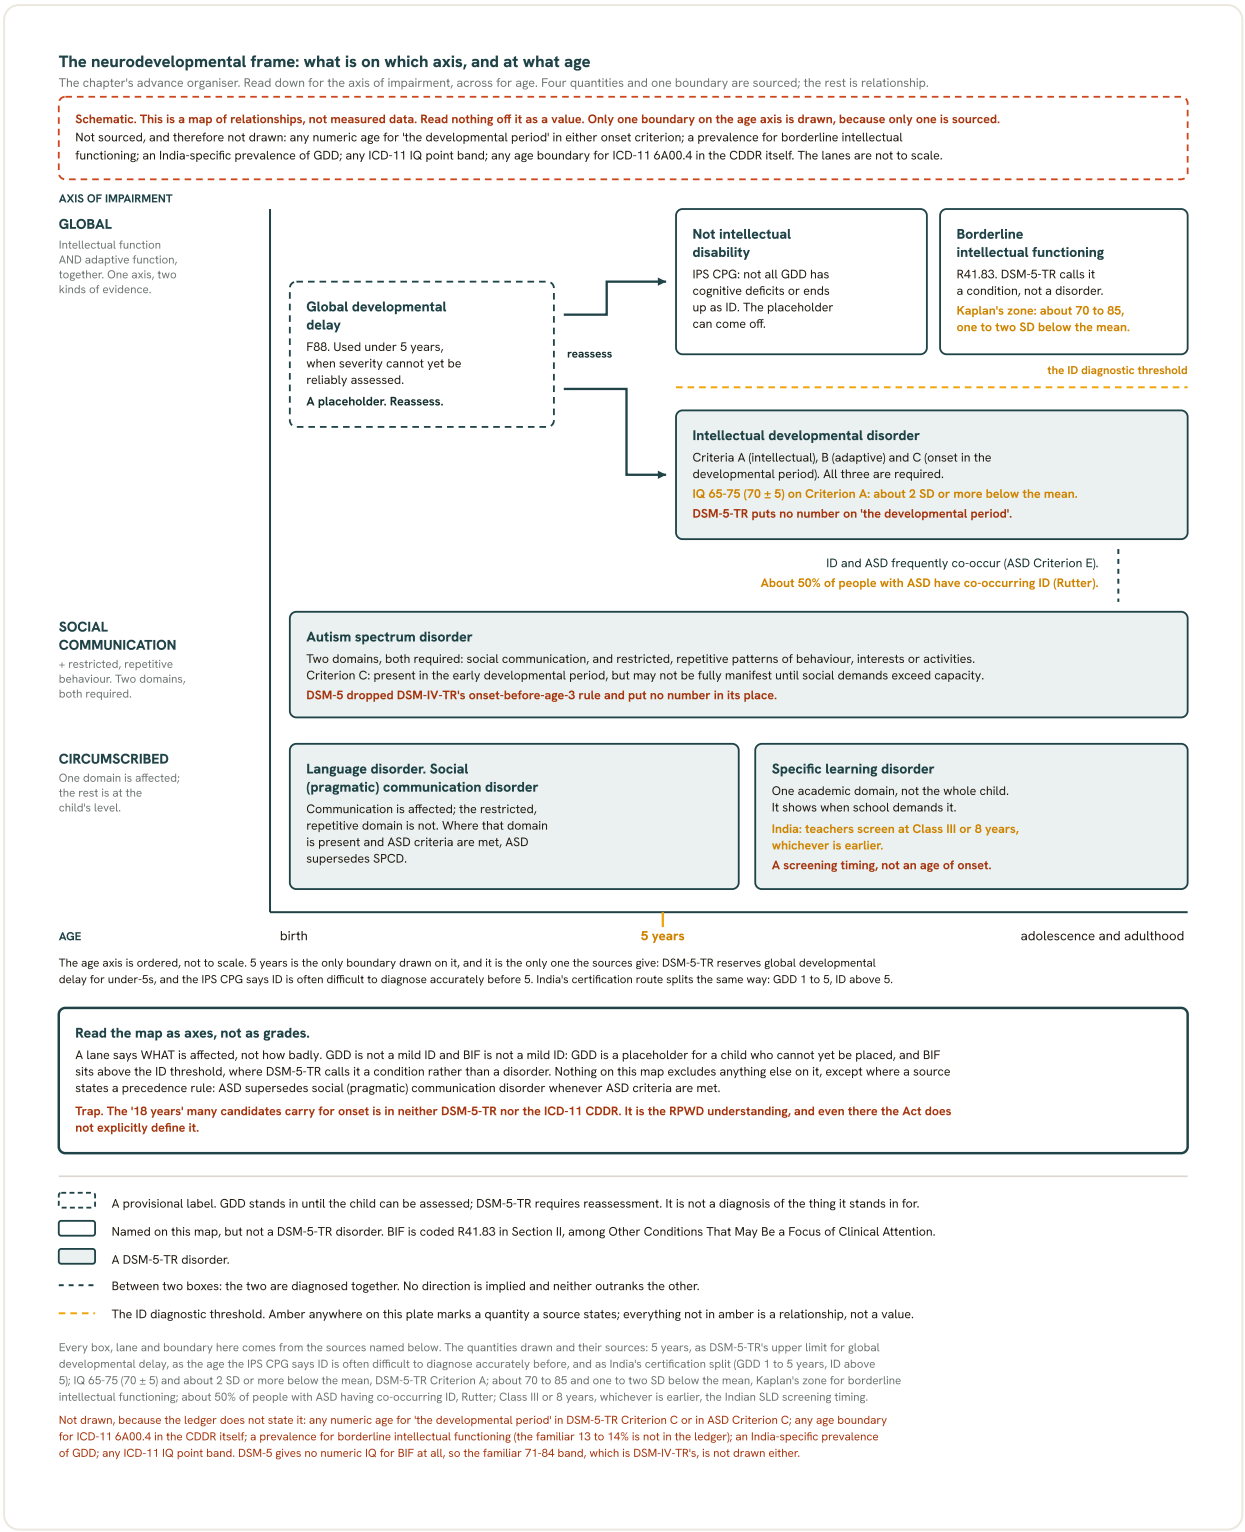

Fig 21.1 **The neurodevelopmental frame.** The chapter's advance organiser: age runs across, the axis of impairment runs down, and every entity the chapter teaches has a place on both. Global developmental delay is drawn with a dashed border because it is a placeholder, not a diagnosis, and it forks on reassessment; intellectual developmental disorder and autism spectrum disorder sit in different lanes and are joined by a dashed rule because they are diagnosed together rather than ranked; borderline intellectual functioning sits on the same global axis as ID but above the diagnostic threshold, where DSM-5-TR calls it a condition and not a disorder. The age axis is ordered rather than scaled, and carries the single boundary the sources give.

1.1 The organising clinical question

A **developmental formulation** is a working explanation of how a person has developed, what they can do in ordinary settings, what creates difficulty, and what may help. It is deliberately

broader than a diagnostic label. It prevents a clinician from mistaking a test result, a conspicuous behaviour, or a single historical detail for the whole clinical picture.

RULE **Formulate functioning in context before using a diagnostic label to organise the next step.** A label becomes clinically useful only when it clarifies the pattern of difficulty, the questions still to be answered, and the support that may be needed.

At the outset, hold several strands together:

- the **presenting concern** in the words of the person, family, school or referrer;
- a **longitudinal history** that asks how the current pattern emerged and changed;
- the person's **functional profile** across their actual environments; and
- the **contextual formulation** of relationships, opportunity, stress, culture and available support.

Developmental expectations belong in *the Normal child development and milestones notes*. A full child psychiatric assessment, service response and safeguarding approach belong in *the Child psychiatry: assessment, treatment, services and protection notes*. Those cross-references matter because a developmental formulation is only as good as the history and context on which it rests.

1.2 A map of the chapter

The chapter separates related questions so that each can be answered precisely. The following map is a reading aid, not a diagnostic algorithm.

CLINICAL QUESTION	CHAPTER FOCUS	WHY THE DISTINCTION MATTERS
How should intellectual ability and everyday functioning be described?	Concept, criteria, assessment and adaptive behaviour	Description needs interpretation in the person's life context.
What may account for the developmental presentation?	Causes and syndrome-specific discussions	Explanation can alter investigation, anticipatory care and counselling.
Is autism spectrum disorder the best account of the observed developmental pattern?	Diagnostic framework, clinical picture and assessment	Recognition requires a pattern-based judgement rather than an isolated feature.
What should change in the person's everyday life?	Interventions, health review, family support and prognosis	A **support plan** translates formulation into feasible action.

The questions interact, but they should not be collapsed. A person may need more than one explanatory frame, and the clinician must decide what each frame adds. Assessment methods, severity language, aetiological work-up and intervention are therefore developed in their own sections rather than treated as interchangeable.

TRAP **Examination trap:** do not let an early label replace description of the observed problem. Establish the pattern first, then use the relevant framework to explain it.

1.3 Reading findings without reductionism

GOOD TO REMEMBER

Interpret clinical information together: history may reveal a developmental trajectory; direct observation may show communication and response to change; assessment may characterise ability or practical skill; and collateral may reveal demands invisible in the consulting room. Check **ecological validity**: the account should fit the person's life outside the clinic as well as the clinician's impression inside it.

Use the chapter to ask progressively sharper questions: What is the pattern of strength, difficulty and participation? What information would materially change the formulation? Which co-occurring concerns require active recognition rather than attribution to the developmental diagnosis? What support is needed now, and what should be reviewed as circumstances change?

This approach resists **diagnostic reductionism**: the error of allowing one diagnosis to explain every difficulty, behaviour or need. It also makes room for the person's preferences and the family's realities. Good developmental psychiatry is exact about constructs while remaining practical about lives.

1.4 Master mnemonic: MAP

A compact way to retain the chapter. Use **MAP** as a sequencing aid when approaching a developmental presentation. It is not a substitute for assessment; it is a safeguard against beginning in the wrong place.

MNEMONIC

MAP

Map the developmental and functional story.
Ask which framework best explains the pattern.
Plan support around the person, family and participation.

The first step keeps the account anchored in lived function. The second directs the clinician to the chapter's conceptual and diagnostic material without forcing a premature conclusion. The final step prevents assessment from becoming an endpoint: the relevant outcome is a more useful, humane and workable response.

The durable answer in developmental psychiatry is a formulation that explains function, recognises pattern and directs support.

2 · Global developmental delay concept

Global developmental delay is a clinical description for an early developmental presentation, not a shortcut to a settled prognosis. It is used when a child has not acquired expected developmental abilities across several areas, but the clinician cannot yet make a reliable statement about the severity of intellectual impairment. The label is valuable precisely because it

preserves that uncertainty. It allows the record to acknowledge a real developmental concern, organise the next clinical steps, and communicate need without pretending that a premature measurement has answered the longer-term question.

The topic is frequently examined because it tests clinical reasoning at the boundary between observation and diagnosis. Candidates must distinguish a broad developmental delay from a definitive intellectual-developmental diagnosis, explain why early assessment can be limited, and avoid converting a description of current functioning into a prediction about lifelong ability. In DSM-5-TR, global developmental delay is recorded with the code **F88**. The code should serve the formulation, not replace it.

F88	below 5 years	between 3 months and 5 years	at least 2 domains
DSM-5-TR GDD CODE	DSM-5-TR AGE USE	INDIAN GUIDELINE WINDOW	OPERATIONAL THRESHOLD

2.1 What the label is for

Global developmental delay is reserved in DSM-5-TR for a child **below 5 years** when the clinical severity of intellectual impairment cannot yet be assessed reliably. This is not merely a matter of a child being young. The label is appropriate when the child has failed to achieve expected milestones in several areas of intellectual functioning and cannot undergo a systematic assessment that would permit a dependable severity judgement. Developmental variation, limited cooperation, sensory or physical difficulties, and the practical limits of formal assessment can all make an apparently precise conclusion unsound.

The key idea is **assessability**. A clinician may have persuasive evidence that development is not proceeding as expected while lacking a valid way to quantify the enduring intellectual and adaptive picture. The correct response is neither to deny the concern nor to force a severity label. Global developmental delay creates an honest interim formulation: there is a clinically meaningful developmental problem, its pattern must be described, and the formulation must remain open to revision.

RULE **Defining principle.** Use global developmental delay when delay is evident but a reliable developmental severity judgement cannot yet be made; make reassessment part of the diagnosis from the outset.

GOOD TO REMEMBER

Families often arrive seeking a definitive answer after a milestone concern, a referral from an educational setting, or an earlier clinical opinion. The psychiatrist must hold uncertainty without sounding evasive. Explain what has been observed, what remains difficult to judge, and what information will make the formulation more robust. A diagnostic label should reduce confusion, not offer a false certainty that later requires withdrawal.

Developmental expectations and their usual sequence belong in *the Normal child development and milestones notes*. The full approach to history-taking, examination, assessment planning, services and protection belongs in *the Child psychiatry: assessment, treatment, services and protection notes*. This section focuses on the conceptual work: when to use the label, what it means, and what it does not mean.

2.2 Why early developmental uncertainty is clinically real

Early childhood is a period of rapid acquisition, uneven performance and changing demands. A child may demonstrate an ability in a setting but not another, or show an emerging skill that cannot yet be relied upon in everyday life. Conversely, a striking delay may be clear before the clinician can determine whether it reflects a broad and persistent intellectual-developmental difficulty, a transient lag, a limitation of the available assessment, or a combination of these. The purpose of global developmental delay is to represent this clinical state accurately.

IN INDIA

The Indian guideline makes the same practical point: although intellectual disability may be recognisable early in development, it is often difficult to diagnose it accurately before 5 years of age. This is why the guideline uses global developmental delay as a **surrogate marker between 3 months and 5 years**. "Surrogate" should be read carefully. It means the term can organise recognition and follow-up during a period when the final intellectual-developmental formulation is not yet reliable. It does not mean that the two labels are interchangeable.

Diagnostic uncertainty is not diagnostic inaction. A useful **developmental formulation** states the abilities that are emerging, the activities that remain difficult, the contexts in which difficulty is most evident, and the collateral information needed to clarify the pattern. It also records uncertainty explicitly. This protects against a common clinical drift in which a provisional descriptive term is treated as though it had already settled questions about intellectual ability, adaptive functioning, cause or prognosis.

A child who cannot complete a systematic assessment should not be described as "untestable" and then left outside a formulation. The more accurate question is what has prevented a valid assessment on this occasion and how the clinician can obtain a better account of function over time. That may involve observation in familiar settings, informed collateral accounts, repeated contact, and attention to communication, motor, sensory and behavioural barriers. The methods and interpretation of intelligence testing are dealt with in the chapter's assessment material; the present point is that a score is not required before a developmental concern can be named responsibly.

TRAP **Examination trap:** do not write that global developmental delay is simply "intellectual disability in a young child". It is the appropriate label when the developmental concern is clear but the enduring degree of intellectual impairment cannot yet be judged reliably.

2.3 Operationalising a broad developmental delay

The Indian guideline cites **Shevell et al. (2008)** for an operational definition. In that approach, significant delay must be present in **at least 2** developmental domains. This is an operational framework for describing global delay, not a substitute for the diagnostic rationale about why a reliable severity assessment cannot yet be made. In an answer, it is good practice to name the framework being used rather than silently combining criteria from different systems.

The listed areas form a **developmental profile**, not a checklist to be ticked without context. A delay in a domain may affect performance in another. For example, limited motor opportunity can alter what is observed in self-care, and reduced communication can obscure social participation. The clinician's job is to decide whether the observed pattern reflects broad developmental delay rather than merely adding isolated concerns together.

DEVELOPMENTAL AREA	QUESTION FOR THE CLINICAL FORMULATION	COMMON REASONING ERROR TO AVOID
Gross and fine motor	What movement and hand-use abilities are established in ordinary routines?	Assuming that limited opportunity and intrinsic delay are automatically the same.
Speech and language	How does the child understand, express and use communication in context?	Equating a language difficulty with global delay without reviewing the broader profile.
Social and personal functioning	How does the child participate with familiar people and manage age-expected interactions?	Explaining every social difficulty through a single diagnostic label.
Cognition	How does the child learn, solve everyday problems and generalise an acquired ability?	Treating an isolated observed success or failure as the whole cognitive account.
Activities of daily living	What can the child do in dressing, feeding, routines and other everyday tasks?	Ignoring environmental support or opportunity when judging independence.

The table is deliberately descriptive. It does not convert the domains into a severity scale, an intelligence test, or a statutory disability assessment. Those are different constructs and are treated elsewhere in the chapter. For this topic, the useful result is a coherent account of which developmental abilities have not emerged as expected, which strengths are already present, and why the available evidence supports a broad developmental concern.

- Describe abilities in the child's actual routines rather than using only a global label.
- Identify whether delays are spread across the developmental profile or confined to a more limited concern.
- Record factors that may make observed performance underestimate the child's capacity on that occasion.
- State what should be reviewed when more reliable developmental information becomes available.

2.4 A provisional formulation, not a forecast

Global developmental delay is often clinically adjacent to intellectual developmental disorder, but adjacency is not identity. DSM-5-TR notes that some children younger than 5 years whose later presentation meets criteria for intellectual developmental disorder first meet criteria for global developmental delay. This is an account of a possible developmental pathway, not a rule that every child with global delay will later receive that diagnosis.

The Indian guideline is explicit about **prognostic non-equivalence**: global developmental delay is not an inevitable precursor to intellectual disability. Some children described as having global delay will not have cognitive deficits that persist as intellectual disability. This caution is more than a prognostic nicety. If the early label is treated as a permanent verdict, the family may be given an unnecessarily narrowed view of the child's possibilities, while the clinician may stop looking for change, emerging skills or a more differentiated explanation.

Equally, the opposite error is harmful. Because some developmental delays may change over time, clinicians should not minimise a broad delay in the hope that it will resolve without review. A longitudinal formulation balances both risks: it recognises current impairment and need, avoids premature permanence, and specifies the questions that subsequent assessment must answer. It is a way of being precise about the present without claiming ownership of the future.

MNEMONIC

PAUSE when the early developmental picture feels uncertain

Profile the child's functioning in ordinary settings.
Ask whether current assessment is genuinely valid.
Use uncertainty honestly rather than forcing a severity label.
See whether delay extends across developmental areas.
Evaluate again as the profile becomes clearer.

This is not a substitute for assessment. It is a guard against the familiar tendency to make the label carry more certainty than the evidence can support. The careful clinician does not wait passively for certainty; the clinician makes the uncertainty visible, develops a plan to reduce it, and documents the child's current needs in the meantime.

2.5 Reassessment is part of the diagnosis

The DSM-5-TR conditions of use for global developmental delay include **reassessment** after time has passed. That is not an administrative afterthought. The diagnosis has been chosen partly because present methods cannot support a reliable severity judgement; repeating the same unsupported conclusion at later contacts defeats its purpose. Reassessment asks whether the developmental trajectory has clarified, whether systematic assessment has become feasible, and whether the child's everyday functioning now supports a more definite formulation.

Good documentation makes this possible. It separates what was directly observed from what was reported, identifies the developmental areas of concern, records strengths and contextual supports, and states why the assessment could not yet be definitive. It also avoids language that

freezes a child into an early label. “Current presentation is consistent with global developmental delay; reassessment is planned as developmental information becomes more reliable” is clinically more useful than either an unsupported categorical diagnosis or a vague note that offers no plan.

The review is not solely a search for a new diagnostic name. It should ask whether the formulation has become more specific, whether the child’s functional needs have changed, and whether the initial pattern needs to be reconsidered. A broad developmental concern can coexist with communication, motor, sensory, medical or contextual contributors that alter what is seen. The fuller developmental and psychiatric assessment belongs in *the Child psychiatry: assessment, treatment, services and protection notes*; this label should prompt that work rather than close it down.

TRAP **Examination trap:** “provisional” does not mean “wait and see without a plan”. It means document the current developmental concern, address present need, and arrange the reassessment that the provisional formulation requires.

2.6 Coding boundaries and classification caution

Classification systems do not always provide a direct vocabulary correspondence for the same clinical presentation. DSM-5-TR supplies global developmental delay as F88 for the early-childhood situation described above. By contrast, the **ICD-11 CDDR** contains no category named global developmental delay. The safe clinical conclusion is not to invent a correspondence. Describe the child’s developmental presentation clearly, use the classification framework required in the setting, and record why diagnostic certainty is limited.

A related DSM-5-TR category is **Unspecified Intellectual Developmental Disorder**, coded **F79**. It is reserved for exceptional circumstances in an individual above 5 years when locally available procedures cannot establish the degree of intellectual developmental disorder because associated impairments or severe problem behaviours make this difficult or impossible. It also requires reassessment. This is a different problem from the expected early-childhood uncertainty represented by global developmental delay, and the age boundary should not be reversed in an examination answer.

CLINICAL SITUATION	LABELING LOGIC	ESSENTIAL CAUTION
Early childhood with broad developmental concerns and unreliable severity assessment	DSM-5-TR global developmental delay, F88, for a child below 5 years.	It is a provisional developmental formulation that needs review.
Later assessment made impracticable by associated impairments or severe problem behaviours	DSM-5-TR unspecified intellectual developmental disorder, F79, in exceptional circumstances above 5 years.	Do not use it as a routine substitute for a proper assessment.
ICD-11 terminology	The CDDR has no category named global developmental delay.	Do not assert an unverified direct counterpart.

Kaplan and Sadock's summary describes an ICD-11 provisional disorder-of-intellectual-development category for a child below 4 years when there is evidence of disorder but it is difficult to know whether observed impairments may be transient. This is a useful reminder of the underlying clinical problem, but it does not resolve the naming discrepancy in ICD-11. The relevant **provisional category** reflects uncertainty about whether early impairment will persist, rather than a licence to treat every early delay as a definite disorder of intellectual development.

2.7 Clinical communication and the referral-to-support link

The value of recognition is practical. Identifying global developmental delay gives the clinician a shared language for referral, follow-up and communication with caregivers. It tells other professionals that developmental concerns extend beyond an isolated complaint and that the child needs an organised account of function. It also preserves the imperative to review the formulation as the child becomes more assessable. That combination of recognition and openness is the clinical strength of the term.

Conversations with families should be clear about what is known and what is not. Avoid implying that a descriptive early label proves a fixed lifelong outcome. Avoid the opposite reassurance that a broad delay needs no active response because the future is uncertain. Explain that the current pattern warrants attention, that abilities and needs should be described in everyday terms, and that later reassessment can refine the understanding. The family's observations of what the child can do, what needs assistance, and which settings make participation harder are central clinical data, not decorative collateral.

Why identifying global developmental delay matters for referral and **early intervention** is developed in the management section of this chapter. The present diagnostic task is more limited: make the developmental concern visible early enough that appropriate support is not postponed while diagnostic certainty is still evolving. The service model, its evidence and its Indian delivery context belong to that owner section and should not be inferred from the label alone.

- Communicate the present developmental profile in plain, functional language.
- State clearly that global developmental delay is an interim formulation rather than a prediction of a fixed outcome.
- Document the reason a definitive severity judgement is not yet reliable.
- Build reassessment into the plan and record what information should clarify the next formulation.

> Global developmental delay names a genuine broad developmental concern while protecting the child from a severity judgement that the available evidence cannot yet support.

3 · Definition and diagnostic criteria of intellectual disability (DSM-5 and ICD-11)

The diagnostic task is to establish a developmental disorder of functioning, not to attach a label to a low test score. Intellectual disability is diagnosed when limitations in intellectual

functioning, adaptive functioning, and developmental onset form the same clinical picture. The criteria are deliberately conjunctive: each protects against a different error. Intellectual testing without functional assessment can medicalise a score; functional difficulty without developmental onset may represent an acquired disorder; and a developmental history without evidence of current limitation does not itself establish the diagnosis.

For examination answers and clinical records, the useful sequence is therefore simple: establish the nature of the intellectual limitation, establish its consequences for everyday independence and social responsibility in the person's sociocultural setting, and establish that the pattern began in development. The DSM formulation calls the condition **intellectual developmental disorder**, with intellectual disability retained in parentheses; the ICD formulation uses the equivalent term disorders of intellectual development. The difference in wording should not obscure their shared clinical core.

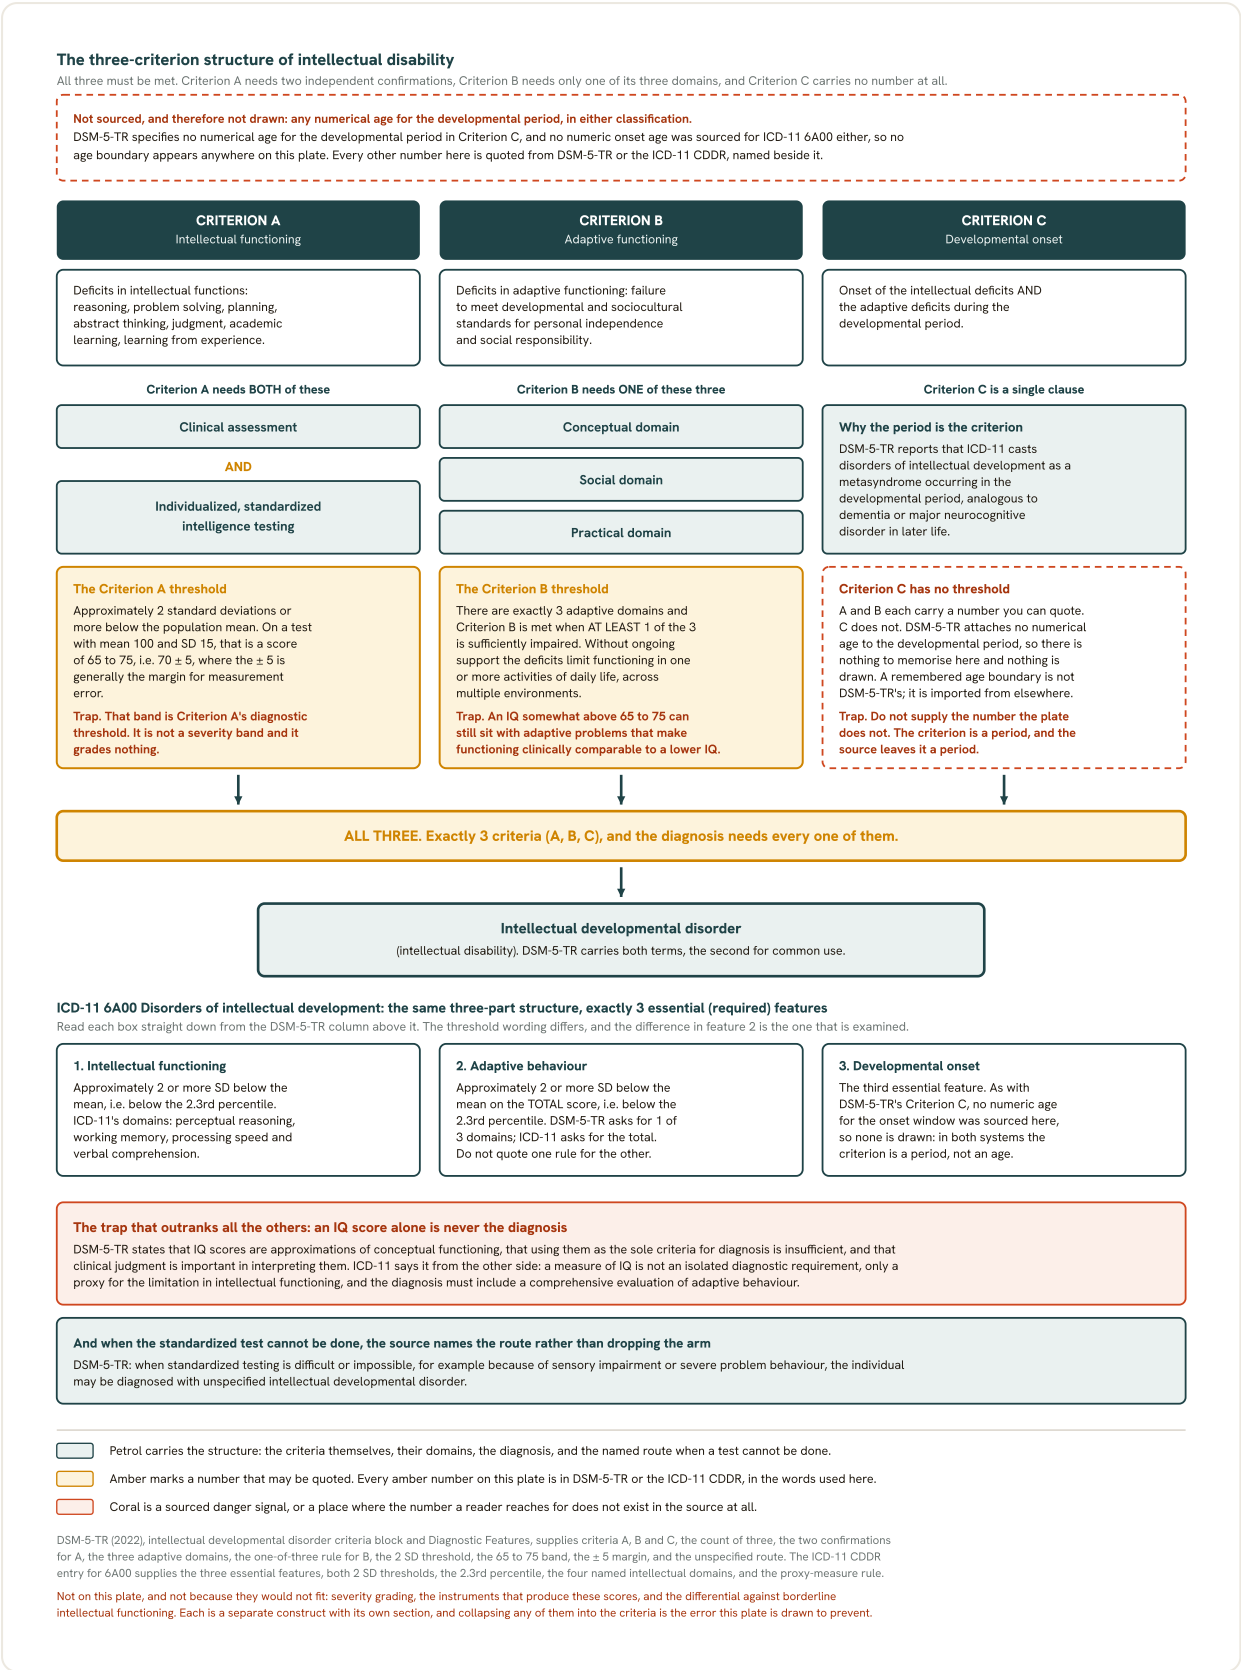

Fig 21.2 **The three-criterion structure of intellectual disability.** Criteria A, B and C are joined by a conjunction, not a menu: DSM-5-TR requires all three, and the two internal rules that decide A and B are examined more often than the criteria themselves. The ICD-11 6A00 strip reads straight down from each DSM column so the one real divergence stands out.

3.1 What the diagnosis is designed to capture

The diagnosis is about a persistent limitation in the person's capacity to understand, learn, reason and manage the ordinary demands of life, where that limitation has developmental origins. It is

neither a synonym for educational underachievement nor a shorthand for disadvantage, illness, sensory disability, behavioural disturbance, or inadequate opportunity. Each of these may complicate assessment, and some may impair performance in a testing situation, but none can substitute for the full diagnostic formulation.

DSM expresses this through **three** criteria that must all be met. Their structure is clinically elegant. The intellectual criterion asks whether the relevant cognitive functions are impaired. The adaptive criterion asks whether that impairment matters in real life. The onset criterion prevents an acquired cognitive disorder from being placed in a developmental category. The diagnosis consequently rests on convergent evidence, not on one encounter or one instrument.

RULE **Diagnostic principle:** diagnose intellectual disability only when intellectual limitation, adaptive limitation and developmental onset are demonstrated together.

This formulation is especially important where a family requests a certificate, school accommodation, or diagnostic clarification after a long period of difficulty. The clinician should keep the diagnostic question separate from the administrative question of whether services are known to the family or available locally. Service contact may reveal need, but it does not create the disorder. Conversely, absence of prior contact does not negate a developmental disability.

3.2 DSM diagnostic criteria: the diagnostic formulation

Criterion A concerns deficits in intellectual functions. In practice, the clinician looks for difficulty in reasoning, problem solving, planning, abstract thinking, judgment, academic learning, or learning from experience, and confirms the finding through both clinical assessment and individually administered standardised intelligence testing. The word “both” matters. A formal result gives disciplined comparison with an appropriate normative group, whereas the clinical assessment asks whether the result is coherent with the history, observed performance, language, education, sensory status and opportunities to learn.

Criterion B concerns **adaptive functioning**. The relevant question is whether deficits lead to failure to meet developmental and sociocultural expectations for personal independence and social responsibility. Without continuing support, the deficits must limit activity in everyday life across multiple settings. This moves assessment from an abstract estimate of ability to the person’s actual functioning at home, in education or work, and in the community. The criterion can be met where there is sufficient impairment in at least one adaptive domain; the domains are conceptual, social and practical.

Criterion C requires onset of both intellectual and adaptive deficits during the **developmental period**. This is a historical criterion, so it requires collateral. Developmental records, school reports, informant accounts and prior assessments may be more informative than a patient’s retrospective account alone. The question is not whether the person was ever labelled, but whether the characteristic pattern was present in development.

- Ask whether the cognitive difficulty is broad enough to affect reasoning and learning rather than reflecting a circumscribed academic problem.

- Ask what the person can do independently, what they can do only with prompting, and what remains unsafe or unachievable despite ordinary opportunities.
- Seek a developmental history from someone who knows the person's earlier functioning, while recognising that documentation may be incomplete.

The criteria are not a checklist to complete mechanically. A person may perform poorly because of an acute mental state, language mismatch, sensory limitation, poor engagement or an unsuitable test. Equally, a person may show apparently acceptable performance in a familiar, highly supported routine while being unable to generalise skills or assume responsibility in less structured settings. Clinical synthesis is what decides whether the three criteria describe one developmental condition.

3.3 Interpreting the intellectual-functioning criterion

Criterion A is met when intellectual functioning falls **two or more standard deviations below the population mean**. That is a diagnostic threshold, not a severity grade, and it must not be turned into one: this chapter grades severity by adaptive functioning, and the reasons are set out above. What an IQ score actually is, how far it can be trusted, and what makes an obtained score misleading are the business of the clinical-assessment section, which takes the normative distribution, the error margin around a score, the **Flynn effect**, practice effects and the instruments that cannot carry a diagnostic opinion in turn. Read it before you act on any number.

TRAP **Examination trap:** an IQ score is evidence for Criterion A, not a stand-alone diagnosis and not a substitute for adaptive assessment.

One consequence belongs here rather than there, because it is a statement about the criterion itself and not about the instrument. Discordance between intellectual testing and everyday performance deserves active thought rather than reflexive exclusion: DSM recognises that a person whose score lies somewhat above the conventional Criterion A band may nonetheless have adaptive problems so substantial that their actual functioning resembles that of people with lower scores. The response is not to lower a threshold by intuition. It is to review test validity, collateral information, the quality of adaptive evidence, and the developmental course before reaching a defensible formulation. The criterion is a floor for evidence, not a verdict delivered by a number.

3.4 Adaptive functioning and onset: turning scores into a diagnosis

Adaptive functioning is the bridge between ability and lived consequence. It asks whether the person can meet the expectations of independence and social responsibility that are reasonable for their developmental stage and sociocultural context. It is assessed through functioning, not inferred from social class, literacy, diagnosis already recorded in a file, or the wishes of a caregiver. The clinician should distinguish lack of opportunity from inability, and a task performed under extensive supervision from a task performed independently and reliably.

GOOD TO REMEMBER

Adaptive functioning asks what the person can do in everyday life across settings without ongoing support. Assess the quality and consistency of functioning, the scaffolding supplied by relatives or institutions, and what happens when that scaffolding is withdrawn. Measurement of adaptive behaviour belongs alongside, rather than in place of, this clinical enquiry. The framework specifies three domains: conceptual, social and practical.

Developmental onset has a second purpose beyond classification. It forces a chronological formulation. If the observed cognitive and functional decline is new, fluctuating, or clearly follows a later medical or psychiatric event, the clinician must consider an acquired cause rather than assume an intellectual developmental disorder. If early difficulties were present but were never assessed, the absence of a historic score should not itself defeat the diagnosis. What matters is whether reliable developmental evidence can establish the required pattern.

MNEMONIC

Think "mind, mastery, maturation"

Intellectual functions describe the mind; adaptive functioning demonstrates mastery of everyday demands; developmental onset establishes maturation as the time-course. The elements must point in the same direction.

In documentation, state the evidence for each criterion separately before writing the diagnosis. This prevents a report from using one broad phrase, such as "poor functioning," to conceal which element has actually been demonstrated. It also makes the reasoning reviewable when informants disagree, records are sparse, or testing conditions were imperfect.

3.5 ICD diagnostic framework

ICD-11 groups the condition under **6A00 Disorders of intellectual development**. It describes the construct as a **metasyndrome** occurring in the developmental period: a clinically useful reminder that the diagnosis identifies a pattern of developmental functional impairment, not a single aetiology. The aetiological formulation must therefore remain open and be pursued separately when indicated.

ICD specifies three essential features: significant limitation in intellectual functioning, significant limitation in adaptive behaviour, and onset during the developmental period. Its intellectual-functioning feature explicitly includes perceptual reasoning, working memory, processing speed and verbal comprehension. These named areas should not be substituted for the DSM Criterion A list, which is framed differently. The two systems overlap clinically but phrase their intellectual evidence in distinct ways.

DIAGNOSTIC QUESTION	DSM FORMULATION	ICD FORMULATION
Intellectual limitation	Deficits in intellectual functions, supported by clinical assessment and individual standardised testing.	Significant limitation in intellectual functioning, including the specified cognitive areas.
Functional consequence	Adaptive deficits that compromise expected independence and social responsibility.	Significant limitation in adaptive behaviour.
Time-course	Intellectual and adaptive deficits begin during development.	Both limitations have developmental onset.
Use of IQ	Interpret in clinical context; never use as the sole basis.	Treat as a proxy for intellectual limitation, alongside comprehensive adaptive evaluation.

ICD indicates significant limitation in intellectual functioning at approximately **two or more standard deviations below the mean, or below the 2.3rd percentile**. It uses the same statistical convention for a total adaptive-behaviour score. These thresholds describe the boundary with expected functioning; they do not remove the requirement for comprehensive clinical interpretation.

3.6 Assessment at the boundary: reliability, culture and unavailable tests

Both systems reject the seductive but unsafe idea that IQ alone separates disorder from normality. ICD states that IQ is a proxy measure rather than an isolated diagnostic requirement at this boundary, and diagnosis must include a comprehensive evaluation of adaptive behaviour. This protects against the false certainty produced when a numerical score is detached from language, culture, education, health, developmental opportunity and everyday functioning.

Scores may vary substantially across development. ICD consequently advises testing on repeated occasions across the developmental trajectory when a reliable estimate is required. A child can appear to meet diagnostic requirements at one assessment and not another; the clinician should interpret change before declaring either recovery or error. **Reassessment** is particularly valuable when the initial assessment was constrained by unfamiliarity, illness, poor engagement, communication difficulty, or an unstable environment.

Where appropriately normed standardised tests are unavailable, ICD places greater weight on **clinical judgement**, including behavioural indicators supplied in its diagnostic guidance. This is highly relevant to heterogeneous linguistic and educational contexts. Clinical judgement here means explicit, accountable reasoning from history, observation and functional evidence. It does not mean replacing assessment with a casual impression, assuming disability from poverty, or assigning a label merely because a formal test cannot be obtained.

- Record why a particular test result is credible, limited, or unavailable.
- State whose account supports developmental onset and what setting each adaptive observation represents.

- Describe the language and sociocultural context relevant to interpretation, rather than treating them as background decoration.

When standardised testing is difficult or impossible, such as in the presence of sensory impairment or severe problem behaviour, DSM permits the diagnosis of **unspecified intellectual developmental disorder**. This is a category for genuine diagnostic limitation, not a shortcut around careful clinical work. The report should make clear what cannot currently be established, what evidence is present, and what reassessment could clarify.

3.7 Terminology, prevalence and the distinction from service counts

Terminology has changed because diagnostic language affects how people are understood in families, services and law. DSM uses intellectual developmental disorder to align with ICD-11, while retaining intellectual disability because it remains widely used by professionals, advocacy groups and the public. In a clinical record, use respectful current terminology and describe the person's functioning and support context rather than allowing a historical label to stand in for a formulation.

Prevalence needs a denominator before it can be interpreted. DSM estimates overall general-population prevalence at approximately **10 per 1,000**, but figures derived from registers, schools or service rosters answer a different question from population studies. The concept of **administrative prevalence** concerns the people for whom a community would need services, and in practice often those whose needs are known to providers. It is useful for planning, but it should not be presented as an intrinsic biological rate.

10 per 1,000	16 per 1,000	9 per 1,000
DSM OVERALL ESTIMATE	DSM MIDDLE-INCOME ESTIMATE	DSM HIGH-INCOME ESTIMATE

IN INDIA

Reported Indian point prevalence lies between 1/1,000 and 32/1,000. A cited meta-analytic estimate is 10.37 per 1,000. In high-income settings, reported figures are 9.2 per 1,000 across all ages, 18.3 per 1,000 in child and young-person populations, and 4.9 per 1,000 in adult-only populations. The breadth of such estimates, including the reported Indian range, should make the reader ask how cases were defined, what population was sampled, and whether ascertainment relied on services, schools or household assessment. This is not pedantry. A prevalence figure used without its case definition and denominator can distort planning, obscure unmet need, or create a misleading comparison between settings.

Must remember: a low IQ score can support the diagnosis, but intellectual disability requires a developmental history and demonstrable adaptive limitation as well.

3.8 A defensible diagnostic conclusion

A high-quality conclusion names the diagnostic framework used, then shows how the evidence meets each required element. It identifies the source and limitations of intellectual assessment, gives a function-based account of adaptive impairment in relevant settings, and states the

developmental evidence. It should also acknowledge uncertainty when the evidence is incomplete. This is more clinically useful than a conclusion that merely reproduces a test result.

Do not use the diagnostic threshold to assign a severity category. The grading of intellectual disability is based on adaptive functioning and is addressed in the severity classification section. Do not confuse the diagnosis with borderline intellectual functioning, which is considered in the differentiation section. If the broader assessment has not yet been completed, say what is provisional and what collateral, functional assessment or repeat testing is still needed. The full assessment framework is covered in the Child psychiatry: assessment, treatment, services and protection notes.

4 · Severity classification (mild, moderate, severe, profound) by IQ and adaptive functioning

Severity is a description of lived support need. In intellectual disability, a severity label should help the clinician communicate what is difficult in everyday life, anticipate the breadth of assistance required, and organise a realistic plan with the person and family. It is not a shorthand for worth, potential, behaviour, or prognosis. The same label can conceal very different strengths, vulnerabilities, opportunities and barriers if it is treated as an identity rather than a clinical formulation.

Fig 21.3 Contemporary severity grading in intellectual disability is based on adaptive functioning across conceptual, social and practical domains. IQ contributes evidence but does not by itself determine the level of support a person needs.

The familiar grades run across **four** levels: mild, moderate, severe and profound. Their enduring examination relevance is that older systems linked them closely to IQ bands, whereas contemporary diagnostic practice grades severity through functioning in ordinary settings. Candidates need to be able to state both schemes, distinguish their purposes, and explain why the second is clinically more useful.

4	Adaptive	IQ	Supports
RECOGNISED SEVERITY GRADES	BASIS FOR CONTEMPORARY GRADING	SUPPORTING CLINICAL EVIDENCE	PRACTICAL CONSEQUENCE OF THE GRADE

4.1 What a severity classification is for

A **severity classification** is a communication tool, not a substitute for assessment. It gives a shared language for describing the extent of impairment, but the clinical account must still say what the person can do independently, what they can do with prompting or teaching, and where

risk or dependence becomes important. A label that is not linked to concrete functional information has little value to the family, school, employer or care team.

Severity must therefore be used at the level of the individual. It should be informed by functioning across conceptual, social and practical domains. Conceptual functioning includes the use of knowledge in everyday demands. Social functioning concerns interpersonal judgement, communication in relationships and the ability to understand social situations. Practical functioning concerns self-care, routine, safety, work-related tasks and participation in community life. These domains may be uneven. A person may show a relative strength in one setting and substantial dependence in another, particularly when a familiar and supportive environment masks difficulty that becomes apparent with changing demands.

The clinician's task is to translate this profile into a defensible grade without reducing the profile to the grade. Good documentation makes clear which examples support the judgement: what was directly observed, what reliable informants describe, and what the person manages when environmental scaffolding is withdrawn or new demands arise. It also separates lack of opportunity, sensory or motor limitations, language mismatch, physical illness and psychiatric symptoms from limitations attributable to intellectual disability. Otherwise severity can be overstated by deprivation or understated by unusually protective care.

RULE **Grade severity by the person's adaptive functioning, then use the IQ result as supporting clinical evidence.**

GOOD TO REMEMBER

This rule protects against a common distortion. A psychometric result can be highly informative, but it does not by itself show how the person manages money, relationships, self-care, safety, travel, routine, communication or unexpected change. Conversely, an apparently competent routine may depend on extensive family organisation and may not generalise beyond a familiar context. Severity is therefore a clinical judgement grounded in the person's actual life, not merely an arithmetic location on a test distribution.

4.2 The contemporary adaptive-functioning approach

Adaptive functioning is the organising principle of contemporary severity grading. The DSM-5-TR severity table describes each grade through conceptual, social and practical functioning rather than through an IQ column. This makes the table clinically legible: severity is not simply a description of test performance but a description of the gap between the person's abilities and the demands of their usual environment.

The reason for this shift is pragmatic as well as conceptual. Support needs are determined by what the person can and cannot accomplish safely and consistently in daily life. An IQ score contributes evidence about intellectual functioning, but it does not directly specify supervision, teaching, environmental adaptation, decision support or the degree to which another person must take responsibility for safety. In this approach, the grade predicts the nature of help that has to be planned, not a fixed ceiling on learning.

Adaptive information should be interpreted in context. The same skill may be performed independently in a familiar home and not be available in a more demanding environment. Families may compensate so effectively that important dependence is missed, while social exclusion or inadequate education may produce apparent deficits that are not a stable reflection of underlying capacity. The assessor should therefore ask about performance across settings, response to ordinary change, consistency over time and the amount of cueing, monitoring or physical assistance required. This is why collateral history is central rather than decorative.

The grading rule also prevents false precision. Two people with similar test results may differ materially in social judgement, practical safety, communication, co-occurring illness, sensory impairment, motor disability or access to support. Conversely, a person whose score is difficult to interpret because of language, behaviour or physical limitations may still have a clear adaptive profile. The clinical formulation should acknowledge uncertainty where it exists, rather than force a spurious numerical conclusion.

TRAP **Examination trap:** do not write that a contemporary severity grade is "based on IQ." State that severity is based on adaptive functioning, while IQ informs the wider assessment.

For DSM severity terminology, the crucial distinction is that the grade is decided from adaptive deficits. This is a useful sentence to carry into a long answer because it explains why the classification has clinical purpose. It also guards against a mechanical answer in which a candidate recites IQ ranges without demonstrating that they understand the modern framework.

4.3 DSM severity labels and coding language

The diagnostic labels are familiar, but they should be treated as severity specifiers attached to an individualised functional account. The codes below are useful for records and examinations. They do not replace a narrative description of the person's functioning, current supports, vulnerabilities or strengths.

The linked coding language is F70 for mild, F71 for moderate, F72 for severe, and F73 for profound. Pair the code and label with the adaptive profile and the help required in real settings. The code identifies a category; the formulation tells another clinician how to care for the person.

In clinical writing, the label should lead to action. A bare diagnosis may be sufficient for a register, but it is insufficient for care planning. The formulation should say which tasks need teaching, which require environmental adaptation, which need supervision, and which are currently managed with assistance. It should also identify how communication, choice and autonomy will be protected. Severity is most useful when it improves coordination between psychiatry, family, education, rehabilitation and community services.

Do not infer a person's adaptive profile from the label alone. Higher-grade disability can coexist with preferences, learning and meaningful participation, and lower-grade disability can be accompanied by marked risks in social judgement, exploitation or practical safety. The label alerts the team to likely breadth of need; the assessment tells the team what that need actually is.

4.4 IQ-based severity bands: their place and their limits

IQ-based severity bands belong to the older classification logic and remain examinable because they appear in legacy records, teaching material and administrative language. They are best presented as a historical mapping, then immediately qualified: a score range is not a contemporary severity judgement. The IQ construct, its interpretation and the choice of intelligence testing are addressed in the clinical assessment section; here the concern is only the mapping of an IQ result to a grade.

LEGACY GRADE	IQ BAND IN ONE REPORTED ICD-10 SCHEME	CLINICAL READING
Mild	**50-69**	Use as a historical IQ band, not as the sole current severity determinant.
Moderate	**35-49**	Interpret alongside the person's actual adaptive functioning.
Severe	**20-34**	Do not assume practical abilities from the band alone.
Profound	**below 20**	Functional observation remains indispensable, especially when testing has limits.

The legacy statement that the IQ cut-off is 70 is often quoted alongside the claim that ICD-10 categorised the grades by IQ. That statement accurately captures the older scheme, but should not be carried forward uncritically into contemporary diagnostic phrasing. The meaningful clinical question is not only where a score lies, but whether the individual can meet culture-appropriate everyday demands without assistance.

A source discrepancy deserves explicit caution. Another textbook presentation places the upper end of the mild band at 50-70, rather than at the upper boundary shown in the preceding table. This is not a reason to blend the two into an invented compromise. In an answer, name the classification framework being used, give its band accurately, and then state that contemporary severity is determined from adaptive functioning. That is safer than presenting a disputed edge value as universal fact.

The deeper lesson is that score bands create an appearance of sharp boundaries where clinical reality is continuous and context-dependent. Borderline intellectual functioning is a separate boundary concept and should not be folded casually into intellectual disability; its definition belongs in the differential-diagnosis discussion. Likewise, a test result affected by language, behaviour, fatigue, sensory limitations or unfamiliarity with the testing context should prompt careful interpretation, not an automatic severity label.

4.5 ICD-11: severity across ability and adaptive behaviour

The **ICD-11 approach** assigns severity according to the level in which the majority of the person's intellectual ability and adaptive-behaviour skills fall across conceptual, social and practical domains. This is an important refinement of single-score thinking. It accepts that a

profile can be uneven, yet asks the clinician to identify the level that best represents the predominant pattern rather than choosing the most impaired isolated skill or the most successful isolated activity.

The numerical bands in ICD-11 are expressed as distance from the mean and corresponding percentile information. They should be read as psychometric context, not as a replacement for the adaptive judgement. The accompanying table is deliberately dense because the codes and bands are examination material; in practice, the functional formulation remains the more clinically useful document.

ICD-11 GRADE	PSYCHOMETRIC BAND	CODE	KEY IMPLICATION
Mild	2-3 SD below the mean; approximately 0.1-2.3 percentile	6A00.0	Assign the grade with the adaptive profile in view.
Moderate	3-4 SD below the mean; approximately 0.003-0.1 percentile	6A00.1	Do not let the numerical band eclipse functional variation.
Severe	4 or more SD below the mean; less than approximately the 0.003rd percentile	6A00.2	Distinguish this grade through adaptive behaviour.
Profound	4 or more SD below the mean; approximately less than the 0.003rd percentile	6A00.3	Distinguish this grade through adaptive behaviour.

The apparent overlap between the highest-grade psychometric bands is deliberate and clinically instructive. Severe and profound are separated exclusively by adaptive-behaviour differences, because available standardised intelligence tests cannot reliably and validly distinguish people at the extreme lower end of intellectual functioning. This is not a defect to be repaired by making the score seem more exact. It is a recognition that the most meaningful discrimination at this level concerns what the person is able to do and the support required for comfort, safety, communication and participation.

ICD-11 also provides 6A00.4 for a provisional grade and 6A00.Z for an unspecified grade. These should be used thoughtfully when a definitive grade cannot yet be assigned, rather than guessing from incomplete information. A provisional label preserves diagnostic honesty while assessment continues. An unspecified label should prompt the clinician to record what information is missing and what will be needed to clarify the person's profile.

For longitudinal records that need a crosswalk to legacy coding, the mappings are 6A00.0 to F70, 6A00.1 to F71, 6A00.2 to F72, 6A00.3 to F73, 6A00.4 to F78, and 6A00.Z to F79. A crosswalk translates administrative language; it does not change the adaptive-functioning basis on which the current clinical grade is reached.

4.6 Reconciling discordant evidence in Indian practice

Apparent disagreement between intellectual testing and social-maturity findings is not unusual. It should not be treated as a nuisance to be averaged away. First check whether either result is invalid or unrepresentative because of communication barriers, behaviour, physical limitations, fatigue, unfamiliarity or an unsuitable testing context. Then return to the central clinical question: how does the person meet everyday demands in their own cultural and environmental setting?

IN INDIA

Where IQ and social-maturity results indicate different grades, the Indian guideline directs the clinician to decide in favour of the **social-maturity result**. The rationale is clinically coherent: social maturity reflects the degree to which the person meets culture-appropriate demands of daily life and generally better represents severity in ordinary circumstances. This is not an invitation to dismiss intellectual assessment. It is a reminder that the outcome of classification should describe functioning, not reward a deceptively precise test number.

The assessment method, the score it yields and its limitations belong in the adaptive-behaviour assessment section. Statutory disability quantification is a separate legal process and must not be confused with clinical severity or with adaptive functioning. In a clinical report, make the distinction explicit: describe the diagnostic severity formulation, describe the evidence used to reach it, and deal with certification through the relevant disability-certification pathway.

- Check that the intellectual and functional information reflects the person's usual, not merely best or worst, performance.
- Explain discordance rather than concealing it behind a single label.
- Prefer the evidence that best captures everyday functioning when a severity judgement is required.
- Record strengths, communication preferences and environmental supports alongside limitations.

4.7 From severity label to support profile

A grade becomes clinically useful only when it changes the plan. It should lead the team to ask what support is needed to enable learning, choice, health care, family participation, education, work, relationships and safety. The answer should be revisited as circumstances change. Severity is relatively stable as a description of pervasive need, but support can be improved through accessible communication, structured teaching, environmental adaptation and respect for the person's established competencies.

The **AAIDD** classification links the grades to a **profile of supports** instead, and is multidimensional rather than categorical. Its four intensities of support, in ascending order, are **intermittent, limited, extensive and pervasive**. Two qualifications keep that list honest. It belongs to the ninth edition of the AAIDD system and was not carried into the later editions, which found it lacked the standardised data to support graded intensities, so it is a historical

scheme that remains examinable rather than a current classification. And it is a description of what a person needs, not a fifth way of grading them: the four intensities are often lined up against mild, moderate, severe and profound, but the mapping is a convenience and the whole point of a supports model is that two people at the same severity grade may need very different support. Reproduce the four-word list as written: one widely used textbook prints extreme supports at the severe tier, but the term in general use, and the one an examiner expects, is extensive. These words should not be used as a rigid prescription for any one person. They are a reminder to specify intensity, consistency and context of help rather than to leave the plan at the level of a diagnostic adjective.

A support profile is also more humane than deterministic language. It turns the clinical focus from what the person lacks to the conditions under which the person can participate. It permits planning around autonomy as well as risk: who should provide information in an accessible form, how decisions can be supported, what routines promote competence, what supervision is proportionate, and how family burden can be recognised without erasing the person's voice.

MNEMONIC

GRADE

Ground the decision in daily functioning; Reconcile discrepant evidence; Avoid IQ-only classification; Describe supports; Explain the functional basis in the record.

The defensible severity statement is the one that explains the person's adaptive functioning and consequent support needs, not merely the one that reports an IQ range.

4.8 A disciplined answer and documentation approach

For a short-answer question, begin with the names of the grades, state the modern principle that adaptive functioning determines severity, and then contrast this with the legacy IQ-linked scheme. If asked for a classification table, present the requested framework cleanly. If the question is clinical, move beyond the table: identify the adaptive domains affected, state the basis for the grade, and outline the supports that follow. This sequence shows the examiner that the candidate understands both taxonomy and clinical reasoning.

For a case record, avoid language that makes the severity label sound final in isolation. State the diagnosis, the current grade, the evidence from functioning, the degree and type of assistance required, relevant contextual modifiers, and the plan to address identified needs. Be cautious when information comes only from one informant or one setting. A carefully qualified assessment is stronger than a confident but unsupported label.

The same discipline protects against two opposite errors. One is overmedicalisation, in which a score becomes the whole person. The other is under-recognition, in which a person's dependence is minimised because they have learned familiar routines or because relatives quietly perform the demanding parts of daily life. Both errors lead to mismatched care. Severity classification is

valuable precisely because, done well, it keeps clinical language anchored to the reality of support.

5 · Clinical assessment and IQ testing in ID

Assessment is a clinical act, not a score-collecting exercise. In suspected intellectual disability, the psychiatrist has to decide whether an observed difficulty represents a broad limitation in intellectual functioning, a barrier to showing ability in the assessment setting, a circumscribed learning problem, or a mixture of these. The task is therefore to obtain a valid account of how the person reasons and learns, and then to set that account beside history, observation, collateral information and adaptive-behaviour assessment. The numerical result matters, but it is never self-interpreting.

The marks in this area are usually won by showing disciplined interpretation. A candidate should be able to explain what an IQ score represents, why it is reported as an interval rather than treated as an infallible point, how a poor-quality administration can mislead, and why a patterned profile may be more clinically useful than an overall score. The assessment must also stay within its proper boundary: severity grading and the formal measurement of adaptive behaviour are separate tasks, addressed elsewhere in this chapter.

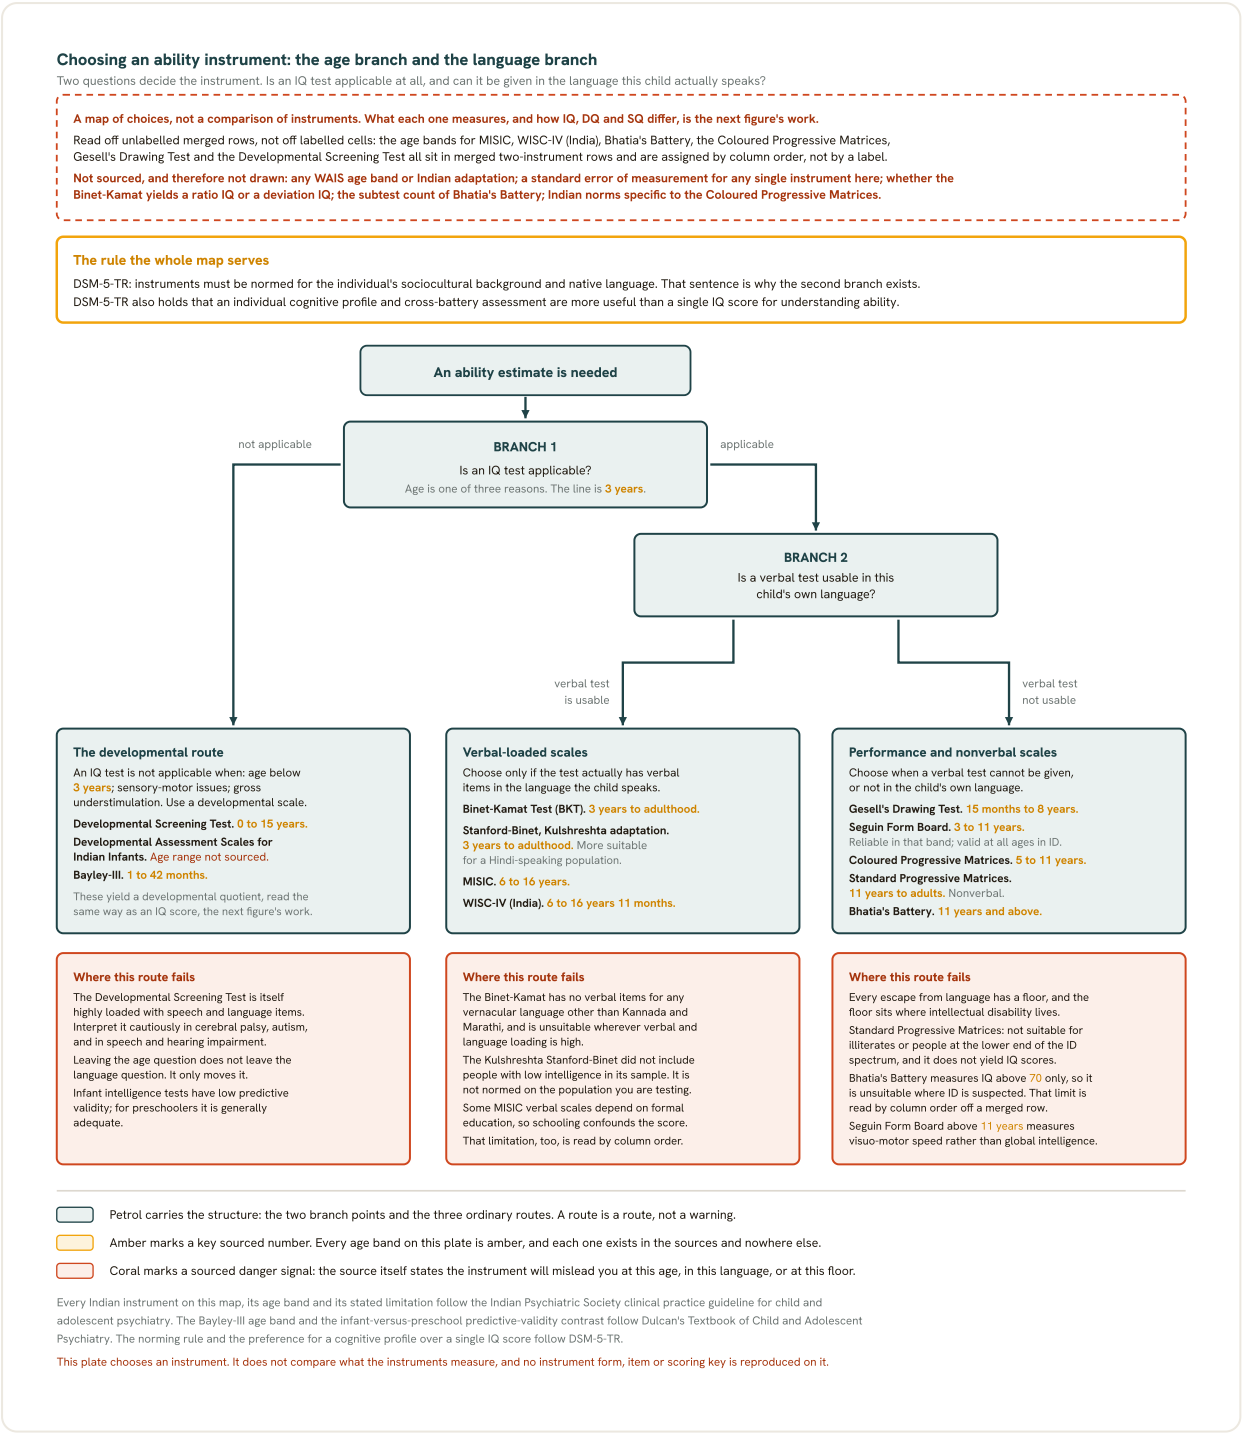

Fig 21.4 Choosing an ability instrument by age and by language. Two branch points, not a catalogue: whether an IQ test applies at all, and whether a verbal test can be given in the language the child actually speaks. Each of the three routes is named with its instruments and their sourced age bands, and each is drawn with the limit its own source states, because every escape from the language problem has a floor and the floor sits where intellectual disability lives.

5.1 The clinical question before testing

Begin with the referral question. “What is the IQ?” is usually an impoverished question. The useful question is: what decision will a careful estimate of intellectual functioning help the team make? The answer may concern the nature of a broad learning difficulty, the credibility of an apparent decline, the meaning of an uneven school record, the person’s capacity to engage with an explanation, or the supports that should be considered. Stating the question first protects the assessment from becoming an administrative ritual.

Intelligence can be understood clinically as a broad capacity to act with purpose, reason coherently and deal effectively with the environment. An intelligence test samples that capacity under defined conditions; it does not sample every ability a person possesses, every opportunity they have had, or every demand made by ordinary life. The psychiatrist should therefore ask what the test performance means in this person's lived context rather than asking the score to speak beyond its remit.

The first interview establishes whether testing is likely to answer the question. Clarify the presenting concern in the informant's own language, the course of learning and functioning, the educational and occupational setting, sensory or motor barriers, communication style, behaviour during unfamiliar tasks, and the person's current mental and physical state. Review available records for consistency rather than assuming that a label in a previous document is a conclusion. A recent deterioration in performance, acute distress, reduced alertness or inability to engage may change the meaning of a low obtained score. The full developmental history and child psychiatric assessment framework belong in the *Child psychiatry: assessment, treatment, services and protection notes*; here, their relevance is that they determine whether a test session is interpretable.

RULE **Use psychometry to refine clinical judgment, not to replace it.** A score becomes useful only when the referral question, the testing conditions and the person's real-world functioning have been considered together.

- Formulate the decision that testing is meant to inform before selecting the assessment.
- Establish whether communication, sensory, motor, emotional or situational factors could distort performance.
- Obtain collateral evidence sufficient to judge whether the test result fits the longitudinal clinical picture.
- Keep the estimation of intellectual functioning distinct from adaptive-behaviour measurement and from severity grading.

5.2 What an IQ score is, and what it is not

An IQ is a standardised comparison of an individual's performance with that of the reference group used by the test. Its clinical value lies in making the comparison explicit and reproducible. It is not a direct measure of worth, potential, character, family effort or entitlement to care. Nor does an overall score reveal the route by which a person reached it. People with a similar overall result may have quite different cognitive strengths, educational experiences, communication demands and support needs.

Older teaching may describe **ratio IQ** using the expression IQ = (mental age / chronological age) x 100. This formulation is historically useful because it explains the term "IQ", but it should not be casually substituted for the standard-score framework used in contemporary interpretation. A clinician should state which metric the report provides rather than sliding between different meanings of the same abbreviation.

For the test metric assumed when deriving the diagnostic convention, the mean is 100 and the standard deviation is 15. The phrase “standard deviation” expresses the spread of scores around the mean in the reference population. It allows a clinician to describe the distance of a result from the population average without converting that distance into a moral or deterministic statement about the person.

100	15	≥2 SD below population mean	65-75
ASSUMED TEST MEAN	ASSUMED STANDARD DEVIATION	CLINICAL CONVENTION	SCORE INTERVAL REQUIRING INTERPRETATION

The intellectual-functioning convention lies **approximately 2 standard deviations or more below the population mean**. This is a convention for interpreting a result in relation to a population distribution, not permission to diagnose from arithmetic alone. The clinician still asks whether the obtained result is valid, whether the reference group is appropriate, and whether the person’s presentation is consistent with the assessment as a whole.

A report should name the metric before interpreting it. This is especially important because a composite score and a subtest score are not interchangeable. The overall number is a summary; it should not erase clinically meaningful variation within the assessment. Equally, a striking isolated weakness is not automatically evidence of a broad intellectual impairment. Interpretation requires pattern recognition, corroboration and restraint.

5.3 Measurement error and the discipline of reporting a range

An obtained score is an estimate. Every psychometric result contains uncertainty arising from the instrument, the testing occasion and the person’s performance on that occasion. The relevant question is therefore not “what is the person’s true IQ?” but “what range of intellectual performance is reasonably supported by this assessment, given its quality and context?” This language is more accurate and prevents a falsely precise clinical conclusion.

The generally applicable margin around an obtained full-scale score is **plus or minus 5 IQ points**. Thus, once measurement error is considered, the score interval associated with the intellectual-functioning criterion is **65-75**. The range must be read as an interval requiring clinical interpretation, not as a new single cut-off and not as a device for negotiating a preferred label.

GOOD TO REMEMBER

A result near the relevant convention calls for particularly careful attention to the quality of administration, the person’s engagement, collateral evidence and adaptive-behaviour assessment. An isolated point score does not settle a complex clinical question: explain how the assessment was conducted and what may have affected it.

TRAP **Examination trap:** treating an IQ result as exact. A technically sound answer states the obtained score, acknowledges measurement error, interprets the interval, and then integrates the wider assessment.

INTERPRETIVE QUESTION	WHAT THE ASSESSMENT CAN CONTRIBUTE	WHAT STILL REQUIRES CLINICAL JUDGMENT
Is the score low?	It locates performance relative to relevant norms.	Whether the administration and norms make that comparison valid.
Is the result stable enough to use?	It provides an estimate with a stated margin of uncertainty.	Whether state factors or testing conditions make the estimate misleading.
Is there a broad difficulty?	It summarises performance across sampled tasks.	Whether the pattern fits history and everyday functioning.
Does a single total tell the whole story?	It offers a convenient summary score.	Whether uneven abilities make the profile more informative than the summary.
What support is needed?	It may identify cognitive demands likely to be difficult.	Adaptive-behaviour assessment and the real-world support context.

5.4 Selecting and conducting a valid assessment

Choice of assessment follows the person, not the convenience of the clinic. Select an individually administered, appropriately standardised measure that can address the referral question and can be administered meaningfully to the person in front of you. Language, communication access, sensory and motor capacity, familiarity with formal testing, educational opportunity and current state all affect the evidentiary weight that can be placed on an obtained result.

Norming for sociocultural background and native language is a requirement, not a courtesy. A score derived from unsuitable norms risks measuring distance from the test's expected experience rather than the intellectual ability the clinician intends to estimate. This is particularly important when the assessment language is not the person's strongest language or when the testing situation makes culturally specific knowledge carry disproportionate weight. The report should make any limitation transparent rather than concealing it behind a number.

Standardisation means that the conditions of administration, scoring and comparison are controlled as far as possible. In clinical practice, that does not mean rigidly ignoring a person's needs. It means recording adaptations, interruptions and barriers, then judging whether they preserve or weaken the interpretability of the score. Rapport, a quiet setting, comprehensible instructions and adequate opportunity to respond are not cosmetic features. They are part of the validity of the encounter.

Observe the process as carefully as the final result. Does the person understand the task? Do they persist, become overwhelmed, guess rapidly, seek repeated reassurance, lose the instruction, or show a discrepancy between verbal explanation and non-verbal problem solving? Such

observations can clarify a profile, expose a threat to validity or indicate the need to defer a conclusion. They should be documented in clinically intelligible language, not reduced to a vague statement that the person was “cooperative”.

Assessment should be paced to protect effort without coaching the answer. The examiner may clarify the task only within standardised rules, attend to physical comfort, and recognise when fatigue or distress has made further performance unrepresentative. If a session is not interpretable, the responsible clinical conclusion may be that the assessment has not answered the question yet. A forced total score is not more scientific than an honest limitation.

- Explain the purpose of the assessment in language the person and family can understand.
- Record the assessment language, relevant accommodations and any barriers to participation.
- Describe behavioural observations that bear on validity, rather than using generic reassurance.
- State clearly when a result should be treated as provisional or when re-assessment is needed.

5.5 Composite scores, subtests and cognitive profiles

Do not confuse the ruler with its markings. A composite or index score uses a different metric from an individual subtest scaled score. **Wechsler composite and index scores: mean 100, SD 15**; **Wechsler subtest scaled scores: mean 10, SD 3**. Mixing these metrics is a basic interpretive error: a subtest value should not be read as though it were an IQ, and a composite should not be treated as though it describes a single task.

A **cognitive profile** is the pattern of relative strengths and weaknesses across the assessment, interpreted cautiously in context. It directs attention to how the person approaches demands rather than merely where the overall score falls. Profiles are most useful when they explain an observed clinical discrepancy, guide further assessment or suggest a practical way to communicate and support learning. They are least useful when they are turned into speculative labels unsupported by history or observation.

The preference for individual cognitive profiles over a single IQ is reflected in **cross-battery intellectual assessment**, which is more useful for understanding intellectual abilities than a single overall score alone. This does not mean that every patient needs an elaborate battery. It means that the breadth of assessment should match the clinical ambiguity. Where the total score and the observed person tell the same coherent story, a focused assessment may suffice. Where they diverge, the divergence is data, not an inconvenience to be averaged away.

Large differences across tasks require interpretation before the full-scale result is treated as a stable global estimate. Highly discrepant individual subtest scores may make an overall IQ score invalid. The key word is “may”: discrepancy prompts clinical scrutiny rather than an automatic rejection of the entire assessment. Consider whether the pattern is understandable from language demands, attention, motivation, sensory or motor factors, emotional state, educational experience or a specific cognitive weakness. The conclusion should describe what is known and what remains uncertain.

This distinction prevents a common diagnostic shortcut. Specific learning disorder may show a verbal-performance discrepancy, usually with performance IQ higher, and an ACID pattern of relative weakness in Arithmetic, Coding, Information and Digit-span. It may also show weaknesses in verbal comprehension, working memory and processing speed. These findings concern an uneven learning profile; they must not be converted mechanically into a severity statement about intellectual disability. The broader formulation belongs with the educational and communication assessment described in the *ADHD and specific learning/communication disorders notes*.

5.6 Threats to validity and misleadingly high or low results

Flynn effect refers to the risk of spuriously high IQ scores when test norms are out of date. It is a norms problem, not a personal change in ability. **Practice effects** are different: repeated testing can yield spuriously high scores because the person has learned from prior exposure. The distinction matters because the remedy is different. In one situation the concern is the currency of the reference norms; in the other it is the interpretive impact of repeated familiarity with the material.

Before accepting an unexpectedly high or low score, ask whether the test was suitable and whether the score was generated in a valid way. A brief intelligence screening test or group test may produce an invalid IQ score. Such tools can be useful for triage or as one source of information, but they do not automatically carry the evidentiary weight of a comprehensive individual assessment. The report should identify the method used and resist upgrading a screen into a definitive estimate simply because it has yielded a number.

Other validity threats are often visible in the room. A person who cannot hear or understand the instruction, whose motor difficulty prevents the intended response, or whose distress and fatigue collapse effort may obtain a result that reflects the barrier more than the target ability. The same caution applies when language mismatch or unfamiliarity with the testing format changes what is being sampled. The clinical response is not to “correct” the score by intuition. It is to document the limitation, seek appropriate assessment conditions and integrate other evidence.

Validity is not an all-or-none property. Some results provide useful minimum estimates, some are broadly representative but qualified, and some should not be interpreted as an IQ estimate at all. This graded approach is more honest than either rejecting every imperfect assessment or accepting every printed total. It also makes the report usable to colleagues: they need to know how much confidence to place in the result and why.

> An IQ score is clinically meaningful only when the test, norms, administration and interpretation are all appropriate for the individual.

5.7 Integrating and communicating the result

The final account should read like a clinical formulation, not a laboratory slip. Start with the reason for referral and identify the assessment method and conditions. State the obtained result as an estimate, include its uncertainty where relevant, describe important profile findings, and

explain the factors that strengthen or limit confidence. Then integrate this with the history, observation, collateral information and adaptive-behaviour assessment. This sequence allows another clinician to see how the conclusion was reached and where its boundaries lie.

Families commonly hear an IQ result as a verdict. The psychiatrist's language can either amplify that harm or restore accuracy. Explain that the assessment describes performance on a defined set of tasks compared with relevant norms. Discuss strengths as well as difficulties, avoid presenting a score as a ceiling on development, and translate findings into practical implications. Do not use technical uncertainty as evasiveness: it can be explained plainly as the ordinary fact that a single testing occasion estimates rather than perfectly captures ability.

When a low score appears inconsistent with everyday functioning, do not decide in advance which source is wrong. Re-examine the referral question, test validity, language and norming, profile variability, collateral quality and the possibility that a different condition is influencing performance. When everyday difficulties seem greater than the score would predict, the same discipline applies. Intelligence testing and adaptive-behaviour assessment answer related but non-identical questions; neither should be used as a shortcut for the other.

Finally, communicate the scope of the opinion. A psychometric assessment may inform diagnosis and care planning, but it does not replace medical evaluation, aetiological work-up or adaptive-behaviour measurement. The laboratory investigation of possible causes is addressed in the etiological work-up section of this chapter, and formal adaptive-behaviour instruments are addressed in the adaptive behaviour assessment section. Keeping these strands separate while integrating their conclusions is the hallmark of a defensible intellectual-disability assessment.

5.8 Choosing intelligence instruments in Indian practice

IN INDIA

Selection is a clinical discrimination: fit the instrument to age, language and schooling, not departmental familiarity. A verbal age scale may be technically well administered yet answer the wrong question when the child is being tested outside the language of its norms. Conversely, a performance measure is not a lesser substitute for a "real" intelligence test when language is the obstacle: it samples ability through a different route. Before choosing a battery, decide whether the task requires a broad verbal and performance profile, a brief performance estimate, or a nonverbal reasoning measure, and be explicit about what the chosen instrument actually reports.

RULE **Choose the instrument by construct, age and language before choosing it by familiarity.** The score is interpretable only when the test's norms and task demands fit the child in front of you.

INSTRUMENT	AGE BAND AND FORM	WHAT IT YIELDS	WHEN IT IS THE BETTER FIT - AND ITS LIMIT
Binet-Kamat Test of Intelligence	**3 years to adulthood**; a **predominantly verbal age scale**.	**Age-scale estimate**, not a language-free performance measure.	Use only when the verbal demands and language are appropriate. Its verbal items are unavailable in vernacular languages other than **Kannada and Marathi**.
Stanford-Binet, Kulshreshta Indian adaptation	**3 years to adulthood**; **predominantly verbal age scale**.	**Age-scale assessment**.	It is more suitable for a **Hindi-speaking population**; its norms did not include people with low intelligence.
Malin's Intelligence Scale for Indian Children	**6-16 years**; **Indian adaptation of the original Wechsler child scale**.	**Performance IQ, Verbal IQ and Full-scale IQ**.	Useful when a Wechsler-style profile is needed, but some verbal scales depend on **formal education**.
Bhatia's Battery of Intelligence	**standardised on Indian boys aged 11 to 16**, though the Indian guideline prints the range as 11 years and above; **indigenous performance battery**.	**Performance-based intelligence assessment**.	Choose it when verbal load is the principal barrier. It measures IQ only **above 70**, so it is unsuitable for establishing lower-range intellectual functioning.
Seguin Form Board	Reliable at **3-11 years**; valid across age groups of people with ID.	**Performance test and quick measure of general intelligence**.	A valuable low-verbal-demand option. Above **11 years**, it increasingly reflects visuo-motor speed rather than global intelligence.
Raven's Standard Progressive Matrices	**11 years to adulthood**; **nonverbal matrices**.	**Does not yield an IQ score**.	Assesses general ability through form comparison and analytical reasoning. It is not suitable for **illiterates or people at the lower end of the ID spectrum**.
Raven's Coloured Progressive Matrices	**5-11 years**.	**Percentile ranks**, not an IQ.	Use when a developmentally younger child needs a matrix task, while reporting the actual metric rather than relabelling it as IQ.

INSTRUMENT	AGE BAND AND FORM	WHAT IT YIELDS	WHEN IT IS THE BETTER FIT - AND ITS LIMIT
WISC-IV India	**6 years to 16 years 11 months**; a full child battery.	A full-scale score with an index profile, reported in this edition as **verbal comprehension, working memory and processing speed** alongside perceptual reasoning.	Use where age and language permit a full child battery. Do not describe this edition's output as a verbal/performance split: that is the older Wechsler structure, and some Indian teaching sources still print it. Do not wrongly transfer Bhatia's stated **above-70 floor** to WISC-IV India.

The **Binet-Kamat** and the **Kulshreshta Stanford-Binet adaptation** are the classic age-scale choices, but both are predominantly verbal. That is their clinical cost. If the child cannot comprehend the assessment language with the same ease as the norm group, a low result may partly index linguistic distance, schooling or test familiarity rather than the intended construct. Binet-Kamat's language restriction makes this concern concrete. The Hindi orientation of the Kulshreshta adaptation is similarly a selection rule, not a minor reporting footnote. Neither should be used merely because it is available in the department.

MISIC is often the most useful familiar-scale option for a school-age child because it derives from the Wechsler child scale and separates performance, verbal and full-scale results. The separation matters clinically: an uneven verbal-performance pattern can signal that the overall total conceals how the child is managing the tasks. It does not remove the education dependence of some verbal scales. A child with limited formal schooling should not be made to look globally less able because a verbally loaded test has been treated as culture-free.

The performance instruments address this problem directly. **Bhatia's Battery** includes many indigenous subscales and is the performance route for an older child, within its norms. Two limits govern its use and both are examinable. Its stated floor prevents it from being the decisive measure when lower-range intellectual functioning is suspected. And although the Indian guideline prints its range as 11 years and above, the battery was standardised on Indian boys aged 11 to 16 in the 1950s, so reading an adult against it applies sixteen-year-old norms to a grown patient. That is an extrapolation beyond the instrument, not normative adult use, and the open-ended phrasing of the guideline is exactly what invites it. The **Seguin Form Board** is a quick performance measure, useful where verbal demands obstruct assessment, but its changing emphasis after the relevant age means that fast visuo-motor work must not be misread as a global estimate of intelligence.

TRAP **"Raven's gives an IQ" is wrong. Standard Progressive Matrices does not output an IQ**. Do not convert a percentile or a matrix result into an IQ merely because the test is familiar.

Raven's Standard Progressive Matrices has Indian norms and is culture-fair to a large extent, but that does not make it universally suitable or make it an intelligence quotient. It evaluates form comparison and analytical reasoning, and its limits in illiteracy and more severe intellectual impairment are clinically important. **Coloured Progressive Matrices** supplies percentile ranks for younger children. State the result in the metric provided. Finally, **WISC-IV India** offers a full child battery across its specified age range, reporting a full-scale score with an index profile rather than the verbal/performance split of the older Wechsler editions. It may be the appropriate comprehensive choice only after language, schooling and tolerance of formal testing have been considered. Selection is a defensible match between construct and patient.

6 · Adaptive behaviour assessment (Vineland, DST, VSMS, Gesell)

The question is not merely what the person can do in a testing room. Adaptive-behaviour assessment asks how a person manages the ordinary demands of life in the setting in which they live. It therefore supplies information that a performance score cannot supply: whether an observed difficulty is translated into dependence in self-care, communication, social participation, safety, or practical daily routines. For intellectual disability, this is clinically decisive because support planning must follow real-world functioning, not the elegance of a single test result.

The instruments often grouped together in examination answers do not measure one thing. A developmental screen estimates developmental progress; a social-maturity scale yields a social quotient; an adaptive-behaviour scale documents functioning through an informant; and a drawing screen provides only a screening impression. The candidate who first identifies the construct, the respondent, and the output is much less likely to call a developmental quotient an IQ score or to use a social-maturity result as though it were a statutory disability percentage.

0-15	0-15	0-90
DST AGE SPAN, YEARS	VSMS AGE SPAN, YEARS	VINELAND-3 AGE SPAN, YEARS

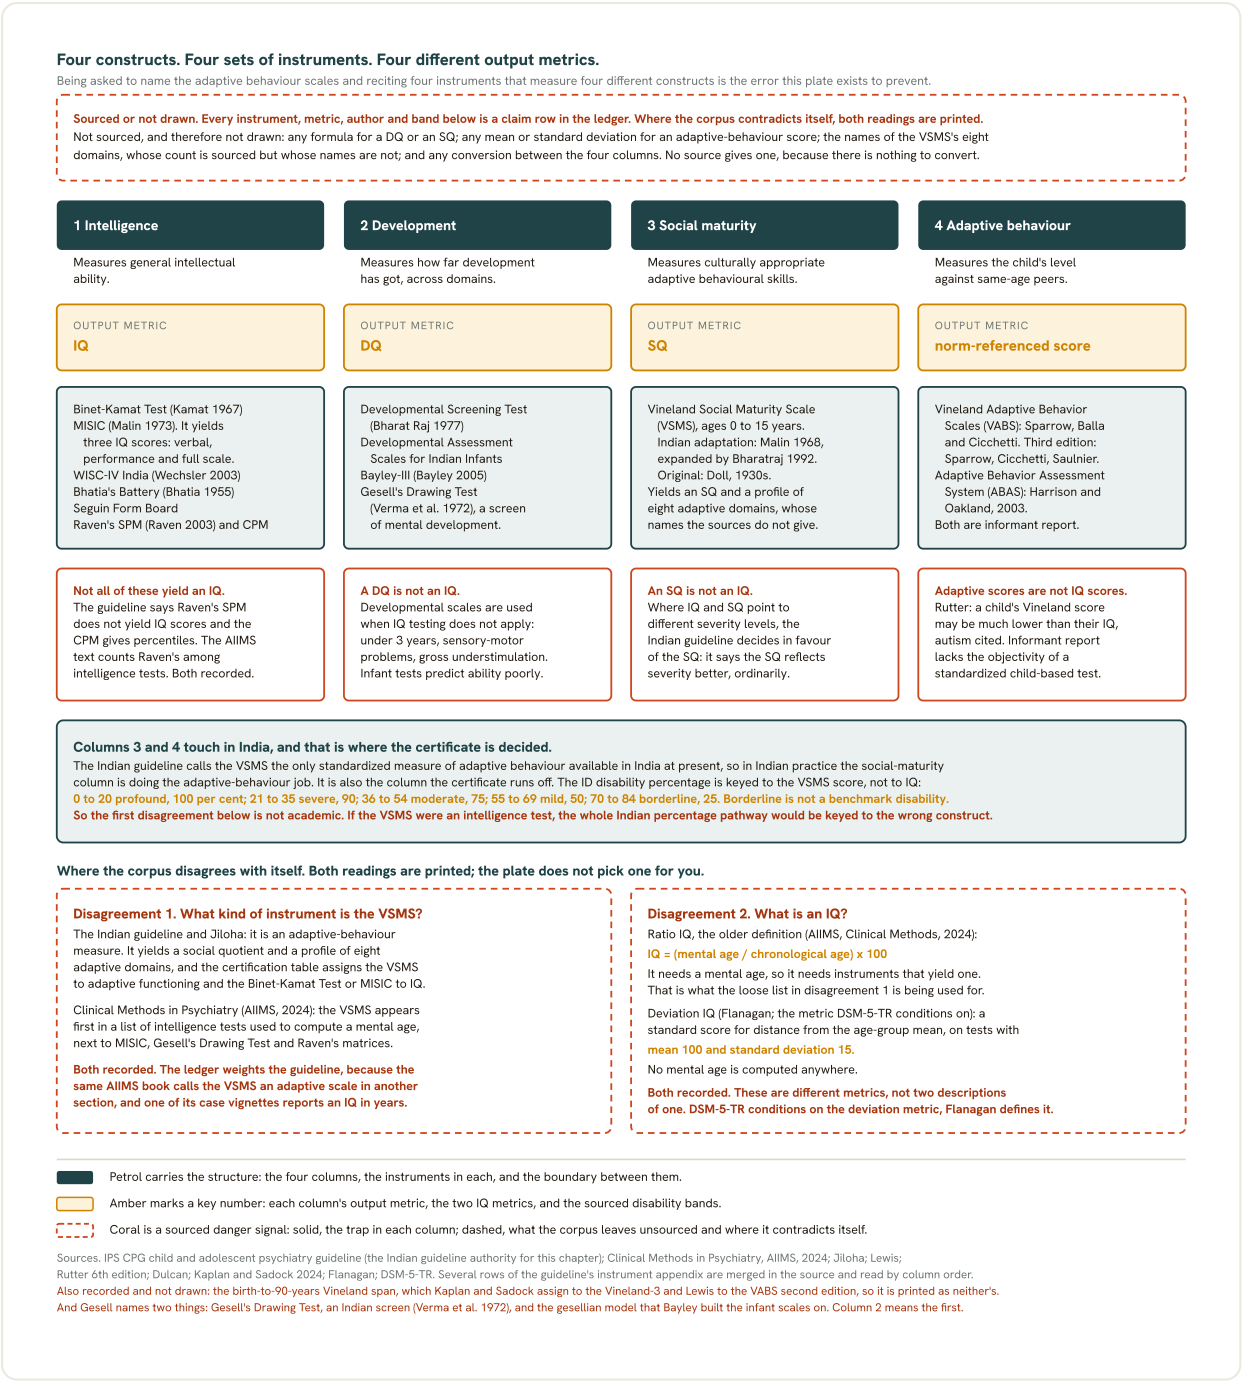

Fig 21.5 **Four constructs, four instruments.** Intelligence, development, social maturity and adaptive behaviour are four separate constructs with four separate instrument sets and four different output metrics, and no score in one column converts into a score in another. The plate also prints the two places the corpus contradicts itself, rather than resolving them: whether the VSMS is an intelligence test or the adaptive-behaviour instrument, and whether an IQ is a ratio of mental to chronological age or a deviation score with a mean of 100 and a standard deviation of 15. Choosing an ability instrument by age and language is the previous plate's job; this one is only about what each column measures and what it reports.

6.1 Begin with the construct, not the familiar name

Adaptive-behaviour measurement is a structured account of habitual functioning. It is not an abbreviated intelligence test. The best information comes from a respondent who has seen the person across ordinary situations and can distinguish what is done independently, what is done with prompting, and what is not yet part of the person's routine. The assessor then integrates this account with direct observation, history, opportunities for learning, physical or sensory

limitations, and the quality of the informant's knowledge. A score may be useful, but the clinical formulation is stronger when it retains the profile behind the score.

This distinction matters especially when opportunity and capacity have been confused. A person may fail to perform a task because it has never been taught, because the setting does not permit it, because the task is inaccessible, or because of a primary developmental limitation. Conversely, an apparently competent answer from a family member may describe what the family does for the person rather than what the person can actually do. Adaptive assessment should therefore examine typical performance, not an idealised report and not a one-off best performance in clinic.

RULE **Rule:** treat an adaptive score as an organised summary of everyday functioning, then return to the underlying profile whenever the score and the clinical picture do not fit.

The terminology itself provides a useful safeguard. **Developmental quotient** is the output of developmental testing and is interpreted in the same metric logic as an IQ score, but it describes developmental assessment rather than a conventional intelligence battery. **Social quotient** is the output of the Indian social-maturity scale. Neither label should be casually substituted for the other. A developmental result, a social-maturity result, and a formal ability result answer overlapping but non-identical clinical questions.

CLINICAL QUESTION	APPROPRIATE CONSTRUCT	ILLUSTRATIVE OUTPUT	WHAT IT MUST NOT BE CALLED
Has the child's overall development progressed as expected?	**Developmental screening**	DQ	An IQ result
How does the person manage socially and practically in their milieu?	Social maturity and adaptive profile	SQ with domain profile	A developmental quotient
What is the person's functioning across adaptive domains by informant report?	Adaptive behaviour	Adaptive profile	A direct performance battery
Is a rapid developmental screen needed before fuller assessment?	Performance screening	Screening impression	A definitive diagnostic quotient

6.2 The Indian social-maturity scale in practice

The **Vineland Social Maturity Scale**, in its Indian adaptation, is the central practical instrument for this purpose. The adaptation is attributed to Malin and was later expanded by Bharatraj. It assesses culturally appropriate adaptive behavioural skills across **eight** important domains and yields an SQ. The domain profile is often more clinically useful than a compressed global statement because it shows where the person is independent, where cueing is enough, and where sustained assistance is needed.

IN INDIA

In the cited guideline, the VSMS has a unique place among standardised adaptive-behaviour measures in India. This gives it an established role in Indian assessment, without implying that every clinical population, language group, or contemporary setting is equally represented. Document the sociocultural context of responses: functioning is enacted in a household, school, neighbourhood, and set of expectations.

GOOD TO REMEMBER

Administration is not a mechanical interview. Identify who knows the person's usual functioning best, and ask for concrete examples. Caregiver disagreement may reveal different opportunities, supervision, or settings, or an informant who has not observed the task. Test implausibly high or low responses with observation and collateral information rather than forcing premature consensus.

- Ask what the person does on an ordinary occasion, not what they have done once under exceptional help.
- Clarify whether initiation, sequencing, supervision, and completion are independent.
- Separate lack of opportunity from inability, while recording both as clinically relevant.
- Interpret a scattered profile as a starting point for formulation and support planning, not as a nuisance to be averaged away.

The VSMS is an adaptive-behaviour instrument: it yields a social quotient plus a profile of 8 domains of adaptive behaviour, never an IQ. Naming it, the DST or Gesell among intelligence tests is the single commonest error in this topic, and where a social quotient and an IQ disagree the severity decision is made on adaptive grounds, as the severity discussion sets out.

This is a measurement rule, not a licence to ignore contradictory evidence. Discordance should prompt a review of language demands, test engagement, motor or sensory barriers, educational opportunity, and the reliability of the informant account. It should also prompt a return to the person's actual support needs. Grading intellectual disability is dealt with separately; the point here is narrower but essential: everyday adaptation has priority when the two numerical summaries pull in different directions.

If the scale cannot be administered, the recommended fallback is to ask socioculturally relevant questions and use DSM-5 severity specifiers as an interim clinical reference, pending ICD-11 guidance. This fallback must be documented as a clinical assessment rather than presented as a scored scale. It is particularly important to make explicit who supplied the history, which settings were represented, and which ordinary activities could not be meaningfully assessed.

6.3 Vineland scales: distinguish the scale family from the Indian VSMS

The **Vineland Adaptive Behavior Scales** are distinct from the Indian VSMS despite their similar names. The scale family is associated with Sparrow, Balla and Cicchetti; later editions are separately attributed in the source. The earlier social-maturity tradition is associated with Edgar Doll. In a viva, naming "Vineland" without specifying which instrument invites avoidable ambiguity about the form, the respondent, the norms, and the result being discussed.

The Vineland scales assess adaptive capacities for self-sufficiency across domains that include **communication, daily living skills, socialization, and motor skills**. They can be administered as a survey interview, expanded interview, informant-administered rating form, or teacher rating form. This range is clinically useful because the person's everyday capacities are often expressed differently at home and in an educational setting. It also creates an interpretive obligation: a discrepancy between parent and teacher reports should be explored as a context effect, not dismissed as an error.

Vineland-3 provides an age-normed framework for adaptive functioning and has self-report, parent-report, and teacher-rated youth forms. Its reported age span runs from **birth to age 90**. The strikingly broad span is a reminder that adaptive behaviour is not a childhood-only construct. Nevertheless, a score gains meaning only when the clinician considers the person's communication style, culture, opportunities, environmental supports, and the informant's frame of comparison.

Informant scales can compare a child with peers of the same age, but their parent-report basis lacks the objectivity of standardised child-based assessment. This is not a reason to discard informant data. It is a reason to use it intelligently. Direct testing samples what the person can show under examination conditions; an informant scale samples what is habitually enacted across time. These evidence streams should be reconciled, not forced into a false competition.

TRAP **Examination trap:** do not use VSMS and VABS as interchangeable labels. They are distinct instruments with different stated adaptations, formats, and assessment frameworks.

6.4 Developmental assessment: where the DST and DQ belong

The **Developmental Screening Test** was developed by Bharat Raj. It uses developmental tasks to assess global development across the stated childhood age range. The result is developmental screening, not an IQ test. This distinction is not semantic fussiness. A developmental screen is appropriate when the clinical question is whether development is globally delayed and whether fuller assessment is needed; it should not be made to carry a conclusion that its construct does not support.

Developmental scales are used when formal IQ tests are inapplicable, including very young age, sensory-motor issues, and gross understimulation. The Indian instruments named for this role are the Developmental Screening Test and the Developmental Assessment Scales for Indian Infants. Such selection is clinical reasoning, not a lesser substitute for formal testing. If a child cannot access the demands of an ability test, the clinician should choose a measure that captures the available developmental evidence and record why the conventional approach was not suitable.

The DST is highly loaded with speech and language items. It therefore requires cautious interpretation in cerebral palsy, autism, speech impairment, and hearing impairment. A low score in these circumstances may reflect the route through which the test asks for competence rather than the global developmental capacity one is trying to understand. The report should make the limitation visible and integrate nonverbal observation, history, and relevant specialist assessment. It should not quietly convert a language-loaded result into a global intellectual conclusion.

SITUATION	ASSESSMENT IMPLICATION	CLINICAL SAFEGUARD
Very young child, sensory-motor difficulty, or gross understimulation	Developmental scales can replace inaccessible IQ testing.	State why a conventional ability test could not answer the question.
Marked speech or language limitation	DST results need guarded interpretation.	Do not equate verbal loading with global developmental capacity.
Need for an adaptive account in an Indian setting	VSMS supplies the adaptive component.	Keep its SQ and profile separate from an IQ result.
Motor deficit affects an ability-test performance	Binet-Kamat profile analysis can separate a motor contribution.	Refer detailed IQ-instrument selection to the clinical assessment and IQ testing discussion.

6.5 Gesell: developmental model, drawing screen, and infancy

The **Gesellian model** starts with the newborn and tracks normal developmental trends across distinct but interrelated domains, rather than reducing infancy to a single factor of intellectual ability. This is a conceptual advance worth retaining in practice. Infancy is a period in which posture, movement, communication, social engagement, regulation, and emerging problem solving may develop unevenly. A developmental account should preserve that pattern rather than overstate the precision of an infant intelligence label.

The older infant-IQ model did not successfully extend conventional IQ assessment into infancy and has largely fallen out of use. The practical lesson is modest: report developmental findings with appropriate caution about what they predict, and explain the functional significance of the observed pattern. Prediction from infant intelligence testing is limited, whereas preschool testing is generally more informative. This is why longitudinal clinical review and repeated observation often matter more than attaching undue certainty to an early numerical label.

The **Gesell's Drawing Test** is an Indian screening instrument adapted by Verma and colleagues and later revalidated by Venkatesan. It is a performance screen for mental development in the stated age span. It obtains a rough estimate of intelligence from the child's ability to draw age-expected shapes. That word "rough" is the safeguard: the task can orient an assessment, but it cannot carry the authority of a comprehensive diagnostic conclusion.

Drawing performance is inseparable from opportunity and motor access. The test is not valid for children with no school attendance, no experience with a pencil, or specific finger-dexterity problems. A poor drawing response in such circumstances should be treated as a limitation of the

method, not as evidence of global inability. The same discipline applies to all brief screens: a screen should direct the next clinical question, never close it.

In the broader infant-assessment lineage, Nancy Bayley drew heavily on Gesell's developmental tasks and techniques. The Bayley-III assesses **five** domains: cognitive, language, motor, adaptive behaviour, and social-emotional functioning. It is reported for children from **1 to 42 months**. This breadth explains why infant assessment cannot be compressed into the question, "What is the IQ?" The clinician must communicate which developmental dimensions were sampled and which require follow-up.

6.6 Selecting and reporting measures when access is uneven

Test choice should begin with access to the task. Vision, hearing, motor control, expressive language, familiarity with materials, schooling, and cooperation can all change what a score represents. For screening in intellectual disability alone or with visual impairment, the stated pairing is DST with VSMS. With hearing impairment, the guideline pairs Gesell's Drawing Test and Seguin Form Board with VSMS; with cerebral palsy or locomotor difficulty, it pairs DST and Gesell's Drawing Test with VSMS. These are selection aids, not substitutes for clinical judgement about whether the child could genuinely engage with each task.

The Binet-Kamat Test may be unsuitable where its verbal and language demands dominate the child's route to a response. Detailed selection among IQ instruments belongs with formal clinical and IQ assessment; the important point here is to resist an instrument's familiar name when its route of administration is mismatched to the child. A defensible report says what was selected, why it was selected, what barriers remained, and how the barriers temper the conclusion.

A good report makes uncertainty useful. State the construct assessed, the source of information, the settings represented, any access barriers, and the practical implications of the profile. Avoid converting a screening estimate into a diagnostic certainty, an informant account into an objective observation, or an adaptive score into a legal percentage. The final formulation should identify present abilities, difficulties, supports, and the next assessment step. It should also state which conclusions are well supported, which remain provisional, and what observation or collateral history would reduce the uncertainty. That is more clinically valuable than a crowded list of scales.

TRAP **Examination trap:** DST, VSMS, and Gesell's Drawing Test are not interchangeable IQ tests. They respectively address developmental screening, social maturity and adaptive profile, and developmental screening.

The causes of intellectual disability

7 · Etiology of intellectual disability (genetic, prenatal, perinatal, postnatal)

Aetiology is clinical work, not a label-collecting exercise. Intellectual disability (ID) is the final common developmental outcome of heterogeneous influences on the developing brain. The

useful question is not merely “what diagnosis does this person have?”, but whether the history, examination and targeted investigations can identify a cause that changes care, anticipatory guidance, recurrence discussion, or surveillance. A causal formulation should preserve timing, mechanism and certainty. It should also distinguish a demonstrated cause from an associated finding and from an unexplained presentation.

For the examination candidate, a timing-based account gives a dependable spine: prenatal influences, events around birth, and postnatal acquired influences. This is not a claim that every presentation fits a clean compartment. Developmental vulnerability may begin before birth and become clinically apparent later; genetic susceptibility and environmental exposure can coexist. The classification is useful because it structures the history, directs investigation, and keeps preventable acquired causes visible without reducing a complex developmental history to a single event.

50-70% ESTIMATED PRENATAL CONTRIBUTION	**10-20%** ESTIMATED PERINATAL CONTRIBUTION	**5-10%** ESTIMATED POSTNATAL CONTRIBUTION	**25-50%** GENETIC CAUSES OVERALL

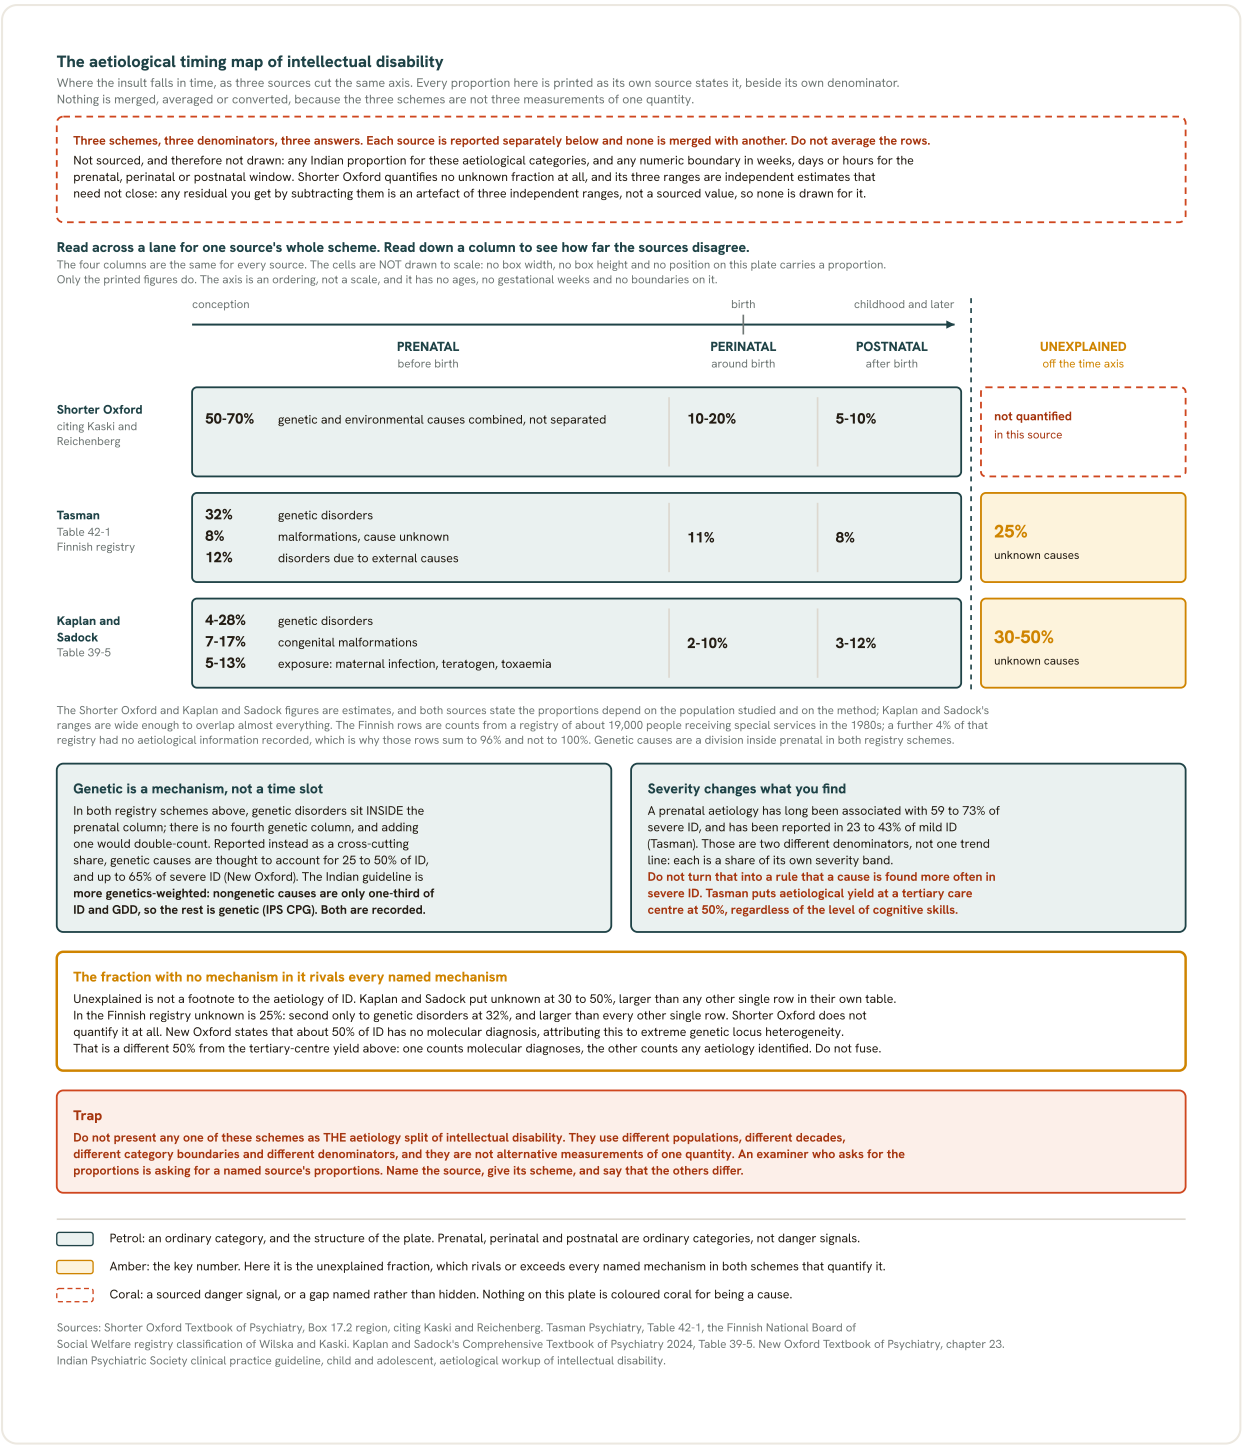

Fig 21.6 **The aetiological timing map of intellectual disability.** The causes of ID sorted by when the insult falls, and the reason a single answer does not exist: three sources cut the same axis with different category boundaries, different populations and different denominators, so their proportions are reported lane by lane and never merged. The plate teaches three things at once. Genetic is a mechanism that sits inside the prenatal column, not a fourth time slot. Severity shifts the prenatal and genetic share upward without licensing the conclusion that a cause is found more often. And the fraction with no mechanism in it rivals or exceeds every named mechanism in both schemes that quantify it. Shorter Oxford quantifies no unknown fraction, and none is inferred for it here.

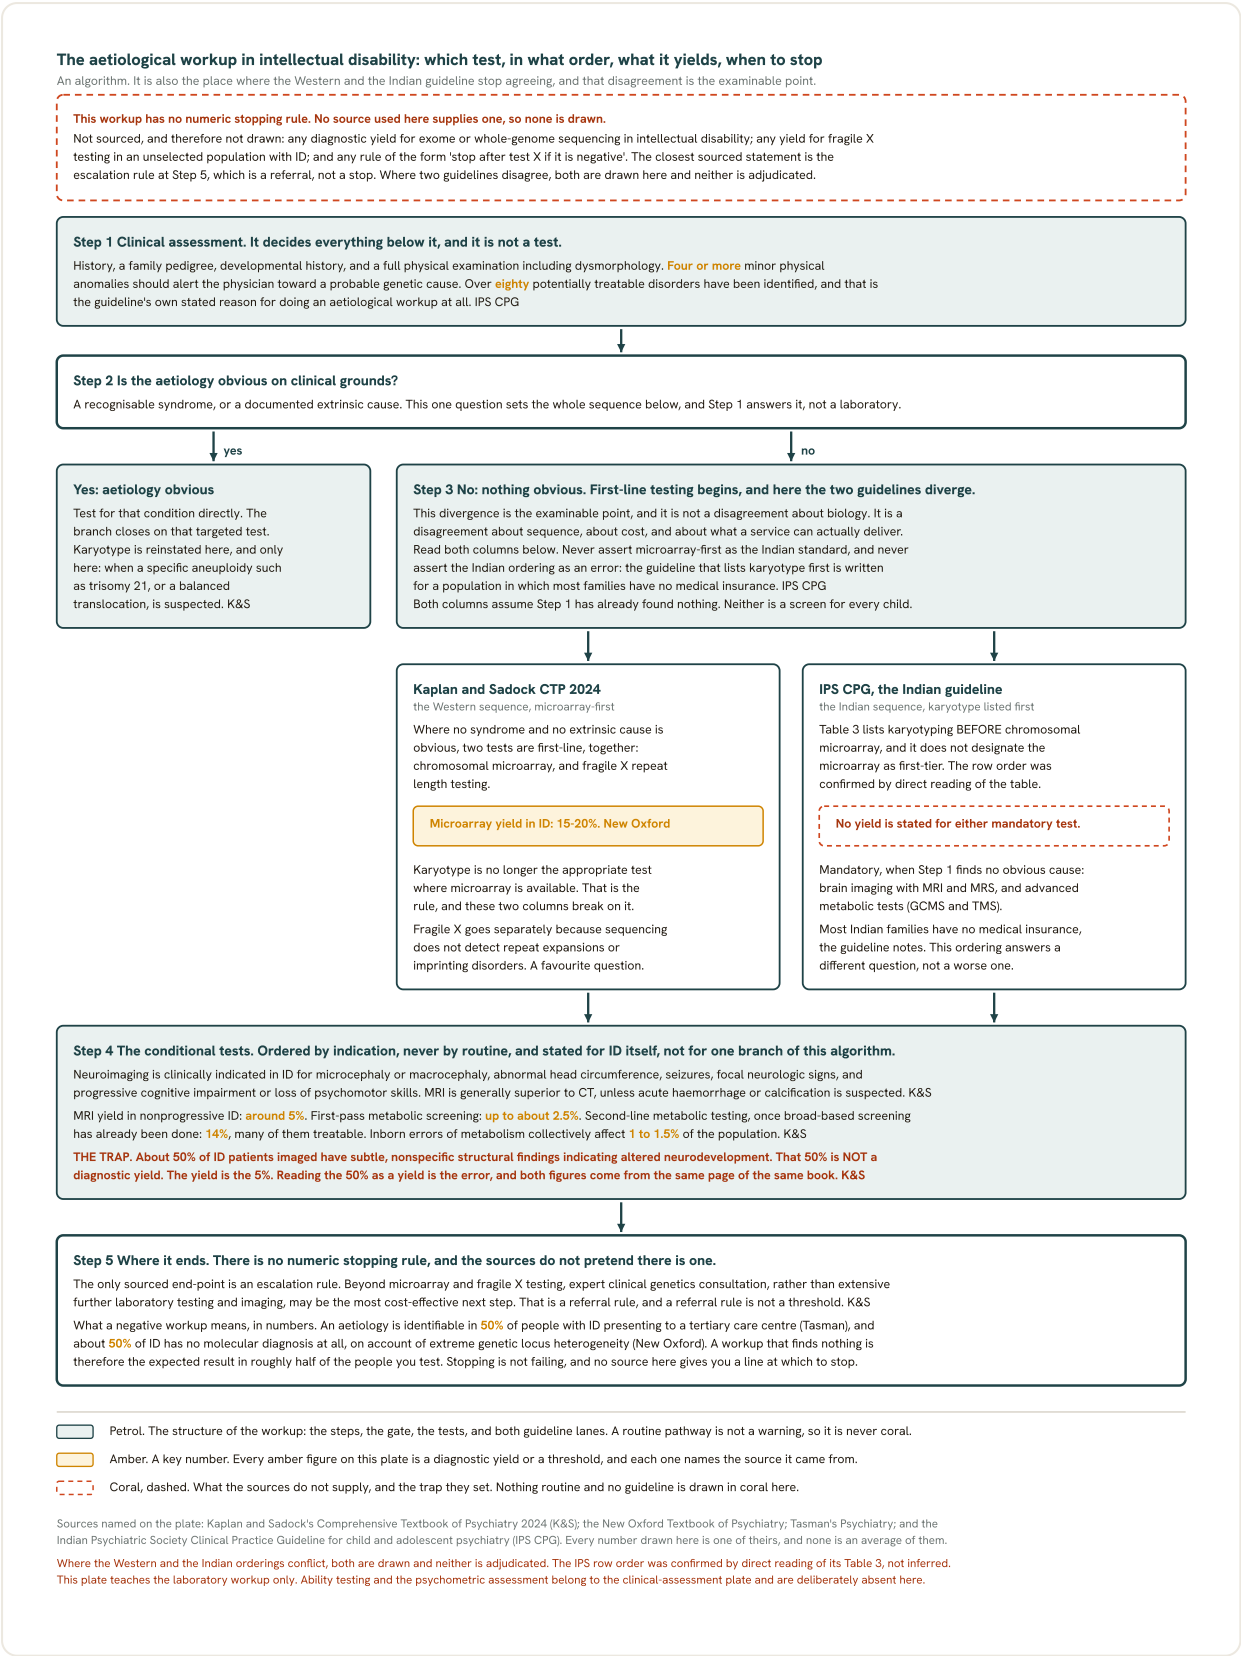

Fig 21.7 The aetiological workup in intellectual disability. The sequence a clinician actually runs: clinical assessment first, then a single gate that asks whether the aetiology is already obvious, then first-line testing, where the Western and the Indian guideline diverge and both orderings are drawn without either being called correct. Each test carries its own sourced diagnostic yield, and the yields are deliberately shown to be small. The workup ends not at a threshold but at a referral, because no source used here supplies a numeric stopping rule, and because an aetiology is found in only about half of the people tested.

7.1 A timing-based causal framework

Prenatal aetiology includes genetic causes, congenital malformations and adverse intrauterine exposures. Across all severities, prenatal factors are estimated to account for 50-70% of cases. The figure is best read as an orientation, not as a prediction for an individual patient. It combines genetic and environmental pathways, and its apparent size will vary with ascertainment, availability of neonatal care, diagnostic methods and the population being studied.

Perinatal aetiology refers to influences operating around birth. It is estimated to contribute 10-20% of ID overall. The central clinical discipline is temporal: obtain the obstetric and neonatal narrative carefully, but do not convert a difficult delivery into a causal conclusion without corroborating developmental, neurological and investigation findings. A birth complication may be relevant, incidental, or one part of a broader developmental disorder.

Postnatal aetiology comprises acquired influences after birth that affect brain development. It is estimated to account for 5-10% of cases. In practice, the history asks whether there was a previously acquired skill that was lost, a period of severe illness or injury, or evidence that development changed trajectory. Such questions protect against prematurely calling a presentation genetic or unexplained.

Causal language should match the evidence. A documented exposure or event can be part of the history without being sufficient to explain the developmental phenotype. Concordance matters: the proposed timing, neurological findings, developmental course and investigation results should tell a coherent story. Where they do not, retain alternative explanations and revisit the formulation as new records or findings become available. This avoids both diagnostic anchoring and the equally unhelpful practice of listing every historical event as a cause.

RULE **Timing is a map for enquiry, not proof of causation.** The history proposes a mechanism; examination and appropriately chosen tests decide how securely it can be attributed.

The categories also overlap in a meaningful way. A congenital brain malformation is prenatal in origin even if recognised only after delivery. A genetic condition may make a child more vulnerable to an intercurrent insult. Conversely, an exposure can cause a developmental phenotype without yielding a pathognomonic laboratory result. Good formulation therefore states the strongest supported explanation and records residual uncertainty honestly.

7.2 Reading frequencies without misreading the patient

Published distributions are not interchangeable. In a broad classification, prenatal genetic disorders were estimated at **4-28%**, congenital malformations at 7-17%, and prenatal exposure at 5-13%. The wide ranges are themselves the lesson: aetiological proportions are shaped by what a service can recognise and whom it sees. The same classification estimated perinatal causes at 2-10%, postnatal causes at 3-12%, and unknown causes at 30-50%.

Severity also changes the diagnostic landscape. Prenatal aetiology has been reported in **59-73%** of severe ID and in 23-43% of mild ID. This does not make mild ID “non-biological”, nor does it authorise an assumption that a severe presentation must be genetic. It means the threshold for

pursuing a careful aetiological workup should remain high across presentations, while the pattern of findings and the probable yield may differ.

CLINICAL QUESTION	WHAT IT PROTECTS AGAINST	HOW TO USE THE ANSWER
When did concern first become apparent?	Assigning timing from a single memorable event	Place the concern beside pregnancy, birth and developmental history.
Was development static, delayed, or did skills diminish?	Missing an acquired or progressive process	Use the trajectory to decide how urgently neurological and metabolic causes need consideration.
Are there family, physical or neurological clues?	Calling a pattern idiopathic before examining it	Integrate inheritance, morphology and examination into the testing plan.
Is a cause demonstrated, probable, or still unknown?	Overstating causality to families	Document the degree of certainty and keep a route for review.

Unknown cause is not synonymous with inadequate care. It can reflect extreme genetic heterogeneity, limitations of the available test, incomplete historical information, or an interaction of influences that cannot be disentangled. In tertiary care, an aetiology is identifiable in 50% of people presenting with ID, yet about 50% of cases may lack a molecular diagnosis. These statements refer to different denominators and endpoints. One is a clinically identifiable cause; the other is a molecular answer. They should never be treated as competing estimates of the same thing.

7.3 Genetic architecture: why no single test tells the whole story

Genetic does not mean simple inheritance. Genetic causes are thought to account for **25-50%** of ID overall, and family and twin studies suggest heritability between 30-90%, depending on diagnostic category and study design. These broad estimates should not be turned into an individual recurrence estimate. They establish that inherited and newly occurring genomic changes deserve active consideration, particularly when the phenotype, family history or examination points in that direction.

Copy number variation refers to a deletion or duplication of genomic material. Cumulatively, CNVs are described as the commonest genetic abnormality class causing ID. Array-based CNV analysis identifies microdeletions or duplications in approximately **15-20%** of tested patients with ID. This is why a genomic test that can detect dosage imbalance belongs early in the assessment rather than being reserved only for those with striking dysmorphism.

Single-gene heterogeneity is equally important. Mutations in more than 700 genes are estimated to be capable of causing ID. In severe sporadic non-syndromic ID, trio-based exome sequencing has identified de novo heterozygous variants or small indels in 13-55%. The range should prevent opposite errors: neither assume that an apparently isolated case lacks a genetic explanation, nor promise that sequencing will always deliver a definitive answer.

X-linked intellectual disability provides a reason to elicit family history with attention to affected males and the maternal lineage. Mutations in known X-linked genes account for **10-12%** of males with ID, and yet no single one of those X-linked genes explains more than **0.1%** of intellectual disability. This is locus heterogeneity in practical form: a recognisable inheritance pattern does not identify the molecular diagnosis by itself. The syndrome-specific genetics and recurrence counselling belong with the relevant syndrome discussions, not with a generic workup.

Autosomal recessive intellectual disability deserves particular attention when the pedigree suggests shared ancestry or recurrence among siblings. In outbred populations it may account for 10-20% of ID; autosomal recessive disorders are reported to be up to threefold more frequent among inbred than non-inbred cases. The history must be asked respectfully and documented neutrally. Its purpose is to guide diagnosis and counselling, never to assign blame.

7.4 From phenotype to an ordered genetic evaluation

The diagnostic interview begins before the requisition form. Obtain a pregnancy and birth history, a developmental trajectory, a pedigree, previous records and the parents' account of strengths as well as difficulties. On examination, look for growth pattern, head size, minor anomalies, skin findings and focal neurological signs. The presence of at least four minor physical anomalies should alert the clinician to a probable genetic cause. The value of this threshold is not that it diagnoses a syndrome; it is that it changes the prior probability and supports a more deliberate genetic examination.

In a person without an obvious syndrome or clear extrinsic cause, **first-line genetic testing** comprises chromosomal microarray and fragile X repeat-length testing.

> **GOOD TO REMEMBER**
>
> These tests answer different questions and are complementary: microarray looks for chromosomal copy-number abnormalities, whereas a separate fragile X assay addresses a repeat-length abnormality. Do not assume that one result substitutes for the other merely because both are called genetic tests.

Karyotyping is no longer the appropriate routine test when chromosomal microarray is available. It remains indicated when a specific aneuploidy or a balanced translocation is suspected. This is a test-selection distinction, not a hierarchy of "old" and "new" medicine: the suspected abnormality determines which technique can answer the question.

TRAP **Examination trap:** a normal sequencing result does not exclude every genetic mechanism. Currently available sequencing tests do not detect **repeat expansions and imprinting disorders**.

After initial testing, a negative result should trigger re-phenotyping and **expert clinical genetics consultation**, rather than indiscriminate laboratory panels and imaging. A genetics assessment can refine the phenotype, determine whether a different genomic method is appropriate, revisit

the pedigree and frame the residual uncertainty for the family. This is also the right setting for generic counselling: explain what is known, what remains unresolved, and why recurrence discussion must be based on the established or suspected mechanism rather than on a generic population figure.

Test ordering should remain hypothesis-led. A phenotype can make a particular mechanism more plausible, but it should not be used as a gate that excludes broad genetic evaluation solely because dysmorphism is subtle or family history is unrevealing. Conversely, a long list of investigations is not a substitute for a better history and examination. Reassessment after each result is often more informative than simply adding tests: ask whether the new finding explains the developmental picture, whether it is concordant with the family history, and whether it creates an actionable surveillance or counselling question. This is how the workup stays both clinically rigorous and proportionate.

> A negative initial genetic screen ends neither the clinical search nor the duty to explain uncertainty clearly.

7.5 Metabolic and neuroimaging pathways

Inborn errors of metabolism are individually uncommon but collectively affect 1-1.5% of the general population. Their importance in ID is disproportionate to their frequency because some are potentially modifiable and because clinical clues may be subtle. First-pass metabolic screening accounts for up to approximately 2.5% of screened patients with ID. A low yield is not an argument for abandoning clinical reasoning; it is an argument against indiscriminate testing in the absence of a phenotype-driven question.

When broad screening has already been undertaken, second-line metabolic testing identified an IEM in **14%** of those tested, many of which were treatable. Progressive change, loss of psychomotor skills, episodic deterioration, unusual neurological features or a family pattern should therefore prompt reconsideration of metabolic disease. The detailed disorders and their treatment are addressed in the section on inborn errors of metabolism; here, the point is to keep an aetiology that may alter outcome within the diagnostic field of view.

Neuroimaging is clinically indicated with microcephaly or macrocephaly, abnormal head circumference, seizures, focal neurological signs, progressive cognitive impairment, or loss of psychomotor skills. MRI is generally superior to CT, except when acute haemorrhage or calcification is suspected. Imaging must answer a clinical question. Subtle nonspecific findings may support altered neurodevelopment without establishing a diagnosis, whereas a structural abnormality may reorganise the entire workup.

Guidelines can differ by setting and resource pathway. The candidate should state the local recommendation accurately while retaining the principle that testing is most useful when integrated with phenotype and clinical trajectory.

IN INDIA

Where obvious clinical aetiologies are not found, the Indian Psychiatric Society guideline designates **brain MRI with MRS and advanced metabolic tests using GCMS and TMS** as mandatory investigations.

7.6 Prenatal, perinatal and acquired causes in the clinical narrative

After the genetic and structural possibilities have been considered, return to the developmental history and ask what may have acted before birth, around birth or after birth. Prenatal exposure categories include maternal infection, teratogen exposure and toxaemia. The purpose of asking is to establish timing and biological plausibility, not to retrospectively place moral responsibility on a mother or family. The same non-judgemental stance applies to histories of substance exposure, obstetric difficulty, neonatal illness and later acquired insults.

Perinatal history should be reconstructed from records wherever possible. The more remote the event and the less specific the account, the more cautious the attribution should be. The examiner's answer becomes stronger when it separates a reported event from evidence of its neurological consequence. Likewise, a postnatal history should seek changes in development, neurological symptoms and the sequence between illness and altered functioning. Aetiological formulation can then state whether the acquired explanation is established, plausible or insufficiently supported.

- Start with timing, then ask what mechanism could link the event to altered development.
- Seek corroboration from records, examination and the developmental trajectory before naming causation.
- Keep genetic and acquired explanations open together when the evidence supports neither as exclusive.

This approach matters especially when families arrive with a single explanatory story, such as a difficult delivery or a relative with developmental problems. Both may be important. Neither should stop the clinician from completing the rest of the formulation. The respectful task is to test the story, preserve what is supported, and correct what is overconfident without making the family feel dismissed.

7.7 Aetiological formulation and communication

A useful written formulation has a layered structure: developmental phenotype, best-supported timing category, demonstrated mechanism where available, associated comorbid findings, and a statement of certainty. It is better to write "ID with a probable prenatal genetic aetiology under evaluation" than to attach a speculative syndrome name. This language guides follow-up and is safer for families, schools and other clinicians who may read the record later.

Explain the purpose of testing before ordering it. Families should understand that testing may identify a diagnosis, clarify future health needs, inform recurrence discussion, or remain non-diagnostic. They should also be prepared for findings whose significance is uncertain. Counselling is a process of interpretation and decision support, not simply the handing over of a laboratory

report. When a family pattern is suspected, referral allows the family to discuss who else may benefit from assessment without converting a probability into a certainty.

The clinical payoff is precision with humility. Aetiology helps prevent a treatable contributor from being missed, prevents unnecessary investigations from accumulating, and makes recurrence counselling more honest. Yet the person's current needs do not wait for molecular closure. Diagnostic workup should proceed alongside support planning and management, with each service informed by the level of certainty rather than delayed by it.

8 · Down syndrome and other chromosomal causes

Why this cause deserves its own clinical frame. Down syndrome is the chromosomal condition most likely to turn a general discussion of intellectual disability into a real consultation: the clinician has to recognise a developmental profile, separate appearance from diagnosis, look for treatable contributors to disability or behavioural change, and explain why the cytogenetic result matters to a family. It is therefore not enough to say that the person has an extra chromosome. The mechanism determines the meaning of the result for relatives and future pregnancies.

For the psychiatry candidate, the useful mental model is a sequence: establish the syndrome and its chromosome mechanism; understand the pattern of associated health needs; then interpret new symptoms against the person's usual functioning. Intellectual disability is part of the presentation, but its definition, assessment and severity grading belong in their respective sections. Equally, a behavioural change should not be dismissed as an inevitable consequence of the syndrome. It may be the presentation of an associated medical disorder, sensory loss, or a co-occurring psychiatric condition.

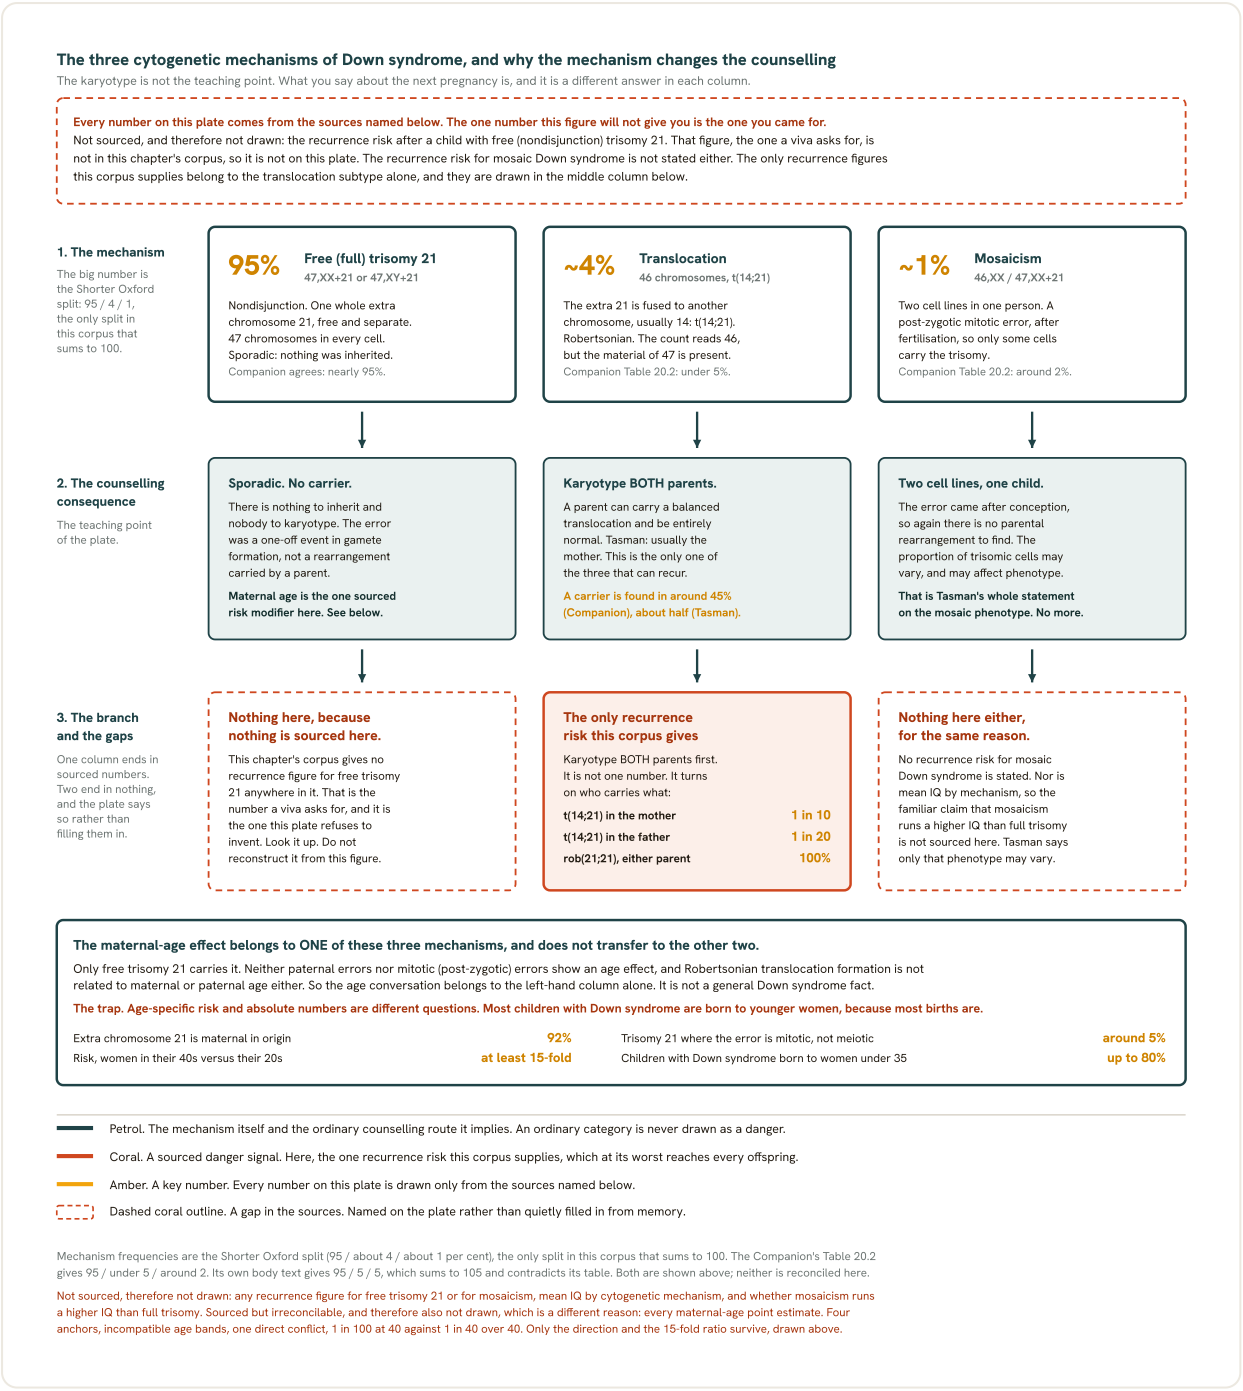

Fig 21.8 The three cytogenetic mechanisms of Down syndrome. Free trisomy, translocation and mosaicism read across from the karyotype to the only thing that changes management, which is what you tell the parents about the next pregnancy. The plate is built so the three columns diverge exactly where the counselling diverges: only the translocation column earns a parental karyotype, and only that column ends in recurrence figures the sources actually supply. The other two columns end in a named gap, because this chapter's corpus states no recurrence risk for free trisomy 21 and none for mosaicism, and the plate declines to supply from memory the figure a viva asks for. The maternal-age effect is shown last and bound to one mechanism only.

8.1 Epidemiological position and clinical significance

Down syndrome is a leading chromosomal cause of intellectual disability and is clinically important precisely because it is common enough to be encountered across child, adult and liaison settings. Textbook birth estimates differ: Shorter Oxford gives about **1 in 650** live births, whereas Tasman gives **1 in 800** live births. These are not competing bedside tests. They illustrate that a quoted frequency depends on the source population and the outcome counted. A figure

expressed per pregnancies must not be treated as interchangeable with a live-birth figure: a cited source estimates trisomy 21 at 1.5 in 1000 pregnancies.

Within the population of people with intellectual disability, Down syndrome accounts for between **6-8%**. That burden explains why psychiatrists need fluency in its medical context, not only recognition of its phenotype. The consultation often occurs at a transition point - concern about development, a new behavioural presentation, family anxiety about recurrence, or declining function in an adult - when an apparently familiar label can obscure the actual clinical question.

95%	about 4%	about 1%
FREE TRISOMY 21	TRANSLOCATION	MOSAICISM

8.2 Cytogenetic architecture: the mechanism is the counselling clue

RULE **State the chromosome mechanism before discussing recurrence: the phenotype may be similar, but the family implication is not.**

Down syndrome results when there is extra chromosome 21 material. In **full trisomy 21**, the additional chromosome is present as a separate chromosome. This is the usual arrangement and, in the source cited here, applies to nearly 95% of people with Down syndrome. The extra material arises through a chromosome-separation error, conventionally termed **nondisjunction**. The molecular event makes it essential to distinguish this arrangement from a structural rearrangement identified in a parent.

In **translocation Down syndrome**, the extra chromosome 21 material is attached to another chromosome, usually chromosome 14, designated t(14;21). The total count can still be 46 chromosomes, but chromosomal material from 47 is present. This is the exam discriminator: counting chromosomes alone does not tell the whole genetic story. The relevant question is whether the chromosome complement is balanced in a parent or unbalanced in the child. The answer changes the recurrence discussion and is why a cytogenetic report must be read rather than merely filed.

Mosaicism means that different cell lines are present. Its presence should prompt precision in description rather than casual prediction from appearance or a presumed developmental outcome. The safe clinical teaching point is not to manufacture a hierarchy of functioning from a mechanism alone. Mechanism informs counselling; it does not replace individual assessment of development, communication, adaptive functioning and health.

CHROMOSOME ARRANGEMENT	WHAT THE REPORT MEANS CLINICALLY	WHY PSYCHIATRY SHOULD CARE
Full trisomy	An extra chromosome 21 is present as a separate chromosome.	It frames the syndrome but does not predict an individual's support needs.
Unbalanced translocation	Extra chromosome material is attached to another chromosome.	Parental chromosome studies become central to the family discussion.
Mosaicism	Different cell lines are present.	Do not infer clinical ability from the label alone; assess the person.

The accompanying figure is useful as a memory aid because it puts these arrangements beside their counselling consequence. It should prevent a common error: treating every Down syndrome result as if it carried the same familial implication.

Read the report in a clinically disciplined way. **Cytogenetic interpretation** starts by identifying whether it describes a separate extra chromosome, attached extra material, or differing cell lines. Next ask whether the wording establishes a structural rearrangement that could also be present in a parent. Finally, distinguish what the report establishes from what still needs direct clinical assessment. A chromosome result explains the syndrome's mechanism; it does not by itself describe communication, capacity, family resources, psychiatric symptoms or the cause of a new behavioural change. This prevents genetic language from becoming a shortcut around formulation.

The same distinction helps when communicating with other clinicians. “Down syndrome confirmed” may be adequate as a diagnostic headline but is incomplete as a handover when the mechanism has not been stated. Record the arrangement in words, note whether parental studies are relevant, and separate known information from questions that remain open. This makes later counselling more coherent and stops a vague family-history statement from acquiring unwarranted certainty as it passes between services.

8.3 Origin of the extra material and maternal-age reasoning

Most molecularly studied trisomy 21 cases have an extra chromosome of maternal origin, reported as 92%. Maternal meiotic error is therefore the dominant framework, but a candidate should avoid turning that into an indiscriminate statement about every pathway. Around 75% of nondisjunction errors are reported at the first maternal meiotic division, although the cited source does not make the denominator sufficiently explicit to claim more than that. In contrast, 60% of paternal meiotic errors occur at the second meiotic division, and mitotic error is estimated in around 5% of trisomy 21 cases.

The maternal-age association belongs mainly to the maternal meiotic pathway. **Paternal and mitotic errors do not show an age effect, and Robertsonian formation is not related to parental age.** This distinction matters because a risk factor should be linked to the biological pathway it plausibly modifies, not applied as a universal explanation after the event.

Age-specific risk rises substantially. Shorter Oxford reports about 1 in 2000 live births among mothers aged 20-25, compared with 1 in 30 among those aged 45 years or over. Another table gives 1 in 2000 at maternal age 30 and 1 in 100 at age 40. The direction is the high-yield point, not the temptation to merge differing source anchors into a fabricated universal rate. Women in their forties have at least a 15-fold increase in risk compared with women in their twenties.

TRAP **Do not confuse high age-specific risk with where most affected children are born.**

Up to 80% of children with Down syndrome are born to mothers under 35. This is not a paradox. Population impact depends on both individual risk and the number of births in each age group. It is the cleanest way to explain why counselling cannot be reduced to stereotypes about maternal age.

8.4 Phenotype, development and associated health needs

The physical phenotype is a recognition aid, not a diagnostic algorithm. Individual signs vary, and no individual sign is universal. The most consistent physical feature, upslanting palpebral fissures, is still restricted to 80% of people with Down syndrome. A transverse palmar crease occurs in 53%, while a protruding tongue is present in fewer than 50%. The practical implication is simple: absence of a familiar sign should not overrule a chromosome result, and presence of an isolated sign should not be treated as proof of the syndrome.

Intellectual ability varies considerably. Tasman reports a mean IQ of approximately 50, but the number is not a prognostic verdict for an individual and must not be used to grade intellectual disability. The clinician should describe present skills, communication, daily functioning and the support environment. The sections on clinical assessment, IQ testing and adaptive behaviour explain how to do that without mistaking a test score for the person.

ASSOCIATED FINDING	REPORTED FREQUENCY	CLINICAL CONSEQUENCE IN A PSYCHIATRIC ASSESSMENT
Congenital heart disease	40-50%	Medical history and exertional symptoms shape both assessment and treatment planning.
Gastrointestinal atresias	12%	Past surgical and nutritional history can clarify the developmental context.
Hearing loss	75%	Often conductive and related to otitis media; it can mimic inattention, withdrawal or a language problem.
Ocular findings	approximately 50%	Visual difficulty may alter engagement, learning and apparent behaviour.
Gluten intolerance	4-20%	Gastrointestinal symptoms should not be reduced to a behavioural complaint.
Autoimmune thyroid dysfunction	up to 20%	In adolescents and adults, consider it when behaviour, mood or cognition changes.

GOOD TO REMEMBER

These are not decorative associations. Hearing and visual difficulty alter how a person is read in the clinic. Pain, discomfort or endocrine disturbance may appear as irritability, reduced participation, slowing, sleep change or loss of previously reliable skills. In particular, thyroid dysfunction is a crucial differential when behavioural disturbance, depression or an apparent dementia presentation emerges. Start with a change from baseline and ask what has changed in the body, the sensory environment and the person's routines before assigning a psychiatric explanation.

Some children with Down syndrome also meet criteria for autism spectrum disorder, estimated at approximately 7%. Autism should be assessed using its own diagnostic framework. The diagnostic criteria, clinical features and differential diagnosis of autism are dealt with in the autism sections of this chapter. Here the point is narrower: a known chromosomal diagnosis does not make an additional neurodevelopmental diagnosis impossible, nor does it make assessment dispensable.

8.5 A psychiatry assessment that does not miss the treatable problem

RULE **A new symptom is a clinical question, not an automatic feature of Down syndrome.**

Begin by identifying the change in observable terms: what is different from the person's own baseline, where it occurs, and what has altered in eating, sleep, activity, communication, comfort or social participation. A **baseline comparison** prevents the interview from confusing a lifelong trait with a fresh symptom. Establish the time course from people who know the person well, but

do not let collateral description substitute for direct engagement. A quieter person may be depressed, unwell, hearing less well, overwhelmed, or responding to a changed environment. These possibilities require clinical discrimination.

- Review hearing and vision when apparent inattention, language difficulty or withdrawal is new or worsening.
- Ask about physical discomfort and gastrointestinal symptoms when behaviour becomes irritable or avoidant.
- Consider thyroid dysfunction when there is behavioural disturbance, depressive symptomatology or cognitive decline.
- Keep autism assessment criterion-based rather than treating the chromosomal diagnosis as either proof or exclusion.

This approach guards against diagnostic overshadowing, discussed fully in the dual-diagnosis section. The syndrome-specific safeguard is especially important here because associated health conditions can change behaviour without announcing themselves in conventional psychiatric language. The clinical record should preserve the observed baseline, the reported change, the relevant physical and sensory questions, and the working explanation. Doing so makes it possible for the next clinician to see whether the proposed explanation accounted for the change or merely accompanied it.

MNEMONIC

CHROME

: **C**hromosome mechanism; **H**earing and vision; **R**eview change from baseline; **O**rgan-system contributors; **M**ood and mental-state assessment; **E**xplain the recurrence implication. Use it as an interview sequence, not as a substitute for examination.

When behaviour changes in Down syndrome, look for a change in health, sensory input or environment before attributing it to the syndrome.

8.6 Family implications of translocation Down syndrome

The family conversation becomes most specific when a translocation is identified. In about half of translocation Down syndrome cases, a parent has a balanced translocation; a related source estimates that around 45% of Robertsonian translocation Down syndrome cases are inherited from a balanced carrier parent. The practical message is not that every parent is a carrier, but that parental chromosome status is material to that particular family's recurrence discussion.

For a balanced **t(14;21) translocation**, the cited recurrence risk for a subsequent child with Down syndrome is **1 in 10** when the mother carries the translocation and **1 in 20** when the father carries it. These are mechanism-specific figures. They must not be offered as the risk after ordinary full trisomy, nor copied into a discussion before the parental studies have established the relevant arrangement.

A familial balanced **rob(21;21) fusion** has a qualitatively different implication: all offspring will have Down syndrome (100%). This is exactly why wording matters. “Down syndrome runs in the family” is too imprecise to guide care. The chromosome report, the parent who carries any balanced rearrangement, and the specific rearrangement together determine what can responsibly be said.

Refer families for genetic counselling and interpret recurrence as a syndrome-specific issue, not as a generic estimate. The general approach to aetiological investigation and counselling referral is covered in the etiology of intellectual disability section. The psychiatrist's contribution is to recognise when the mechanism makes that referral urgent, to communicate uncertainty honestly, and to ensure that distress does not prevent the family from receiving a clear explanation.

8.7 Examination synthesis: how to write the answer safely

A strong answer begins with Down syndrome as a chromosomal cause of intellectual disability, then moves from cytogenetics to clinical care. Describe full trisomy, translocation and mosaicism as different chromosome arrangements; explain that translocation has particular implications for parental studies and recurrence; then show why sensory, endocrine, gastrointestinal and cardiac associations matter to psychiatric formulation. Finish with the warning against diagnostic overshadowing. This structure demonstrates reasoning rather than reciting a facial-feature list.

TRAP **The classic examination mistake is to give a single recurrence figure for every form of Down syndrome.**

That answer is unsafe because it erases the distinction that the cytogenetic result is meant to reveal. A further mistake is to treat the physical phenotype as diagnostic while ignoring the associated health review. The better answer states that phenotype prompts recognition, cytogenetics establishes mechanism, and longitudinal assessment identifies the problem requiring action now.

Other chromosomal causes of intellectual disability need syndrome-specific evidence on their phenotype, mechanism and recurrence patterns. This fragment deliberately does not generalise Down syndrome data to them. Where a person has a chromosomal finding without the characteristic Down syndrome arrangement, the clinical task is to read the individual report and pursue the aetiological pathway rather than forcing it into a familiar template.

9 · Fragile X syndrome

Why this syndrome deserves a deliberate search. Fragile X syndrome is a recognisable cause of intellectual disability, but it cannot safely be reduced to a facial gestalt or a single childhood phenotype. It is the most common inherited cause of intellectual disability, while among all specific causes it is described as second to Down syndrome. Its importance extends beyond the proband: the same locus can produce a developmental disorder in one family member and late-life neurological or reproductive disorders in relatives who carry a premutation.

The useful clinical stance is therefore syndromic and family-based. Recognise the developmental and behavioural pattern, examine without over-relying on dysmorphology, confirm the molecular finding with an appropriate repeat-expansion assay, and explain that molecular category and parent of origin determine the implications. The accompanying figure can be used to hold the relationship between repeat expansion, gene silencing and the distinct premutation disorders in mind.

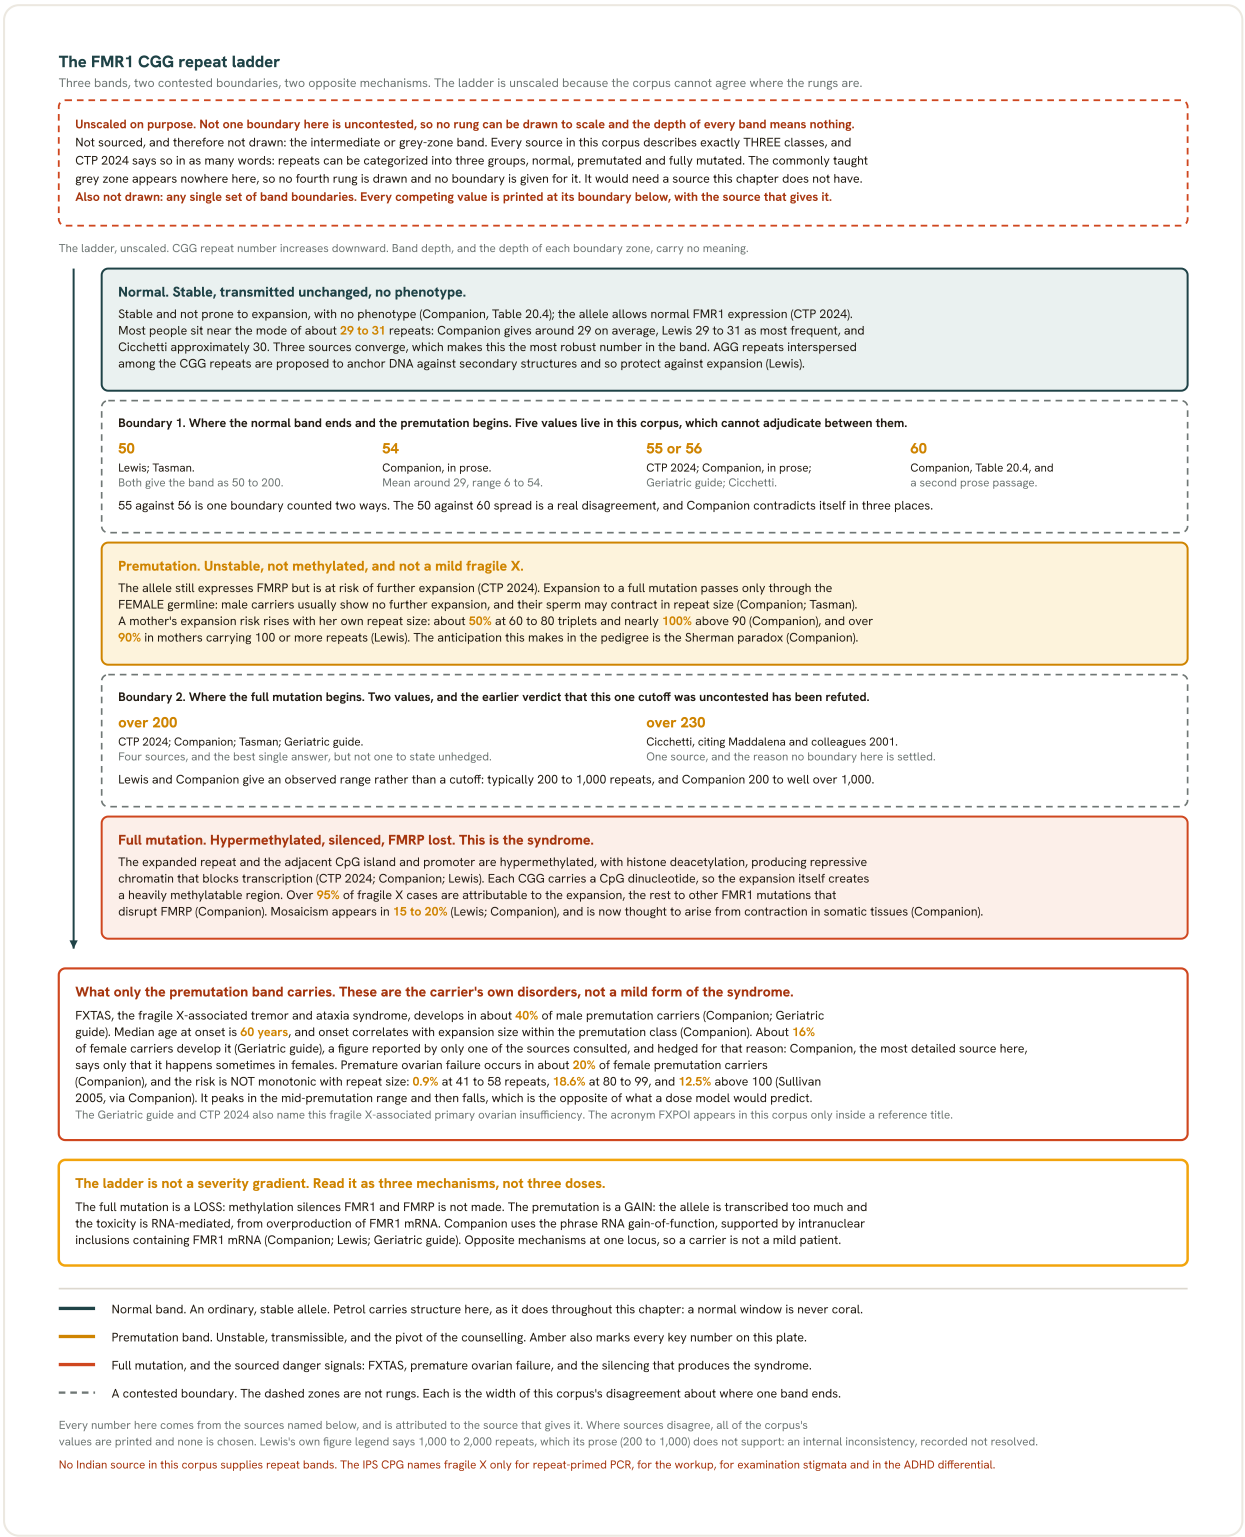

Fig 21.9 The FMR1 CGG repeat ladder. The three repeat classes this corpus supports, what each one carries, and the fact that neither boundary between them can be stated as a single number.

9.1 Molecular lesion and its consequences

Fragile X syndrome results from loss of function of **FMR1 (fragile X mental retardation gene 1)**, located at **Xq27.3**. The unstable sequence is a **CGG (cytosine-guanine-guanine)** repeat in the promoter-adjacent 5' untranslated region. It is worth retaining the anatomical wording rather than insisting on a single exon label, because the sources differ at that finer level while agreeing that the repeat is non-coding and close to the promoter.

Repeat expansion accounts for **more than 95%** of affected cases. In the full-mutation state, the expanded sequence and neighbouring regulatory region become hypermethylated; histone deacetylation and repressive chromatin then prevent transcription. Thus the mutation is not simply a long piece of DNA. It converts a transcriptionally active locus into one that is functionally silent. The extent of methylation is directly related to the loss of functional protein, which helps explain why repeat size alone is not a complete clinical predictor.

The protein product, **FMRP, an RNA-binding protein**, normally binds polyribosomes in dendrites and synaptic spines and largely restrains local translation of synaptic proteins. Loss of that restraint provides a coherent bridge from molecular change to altered synaptic maturation, learning, attention and behaviour. It also prevents a simplistic conclusion that every clinical feature is fixed at birth: the disorder concerns regulation of developing neural systems and its expression changes with development.

RULE **Full mutation means loss of FMRP through epigenetic silencing; premutation disorders arise through excess FMR1 messenger RNA, not a mild form of the same process.**

This distinction is the organising principle of the chapter. In a premutation, the locus is not silenced in the same way. Instead, **RNA-mediated toxicity from overproduction of FMR1 mRNA** is implicated. Calling a premutation carrier “mildly affected with fragile X syndrome” is therefore biologically misleading and clinically unhelpful. One state is principally a protein-loss developmental disorder; the other is an RNA gain-of-function state with its own age-related and reproductive associations.

9.2 Repeat categories, instability and anticipation

Repeat-length bands are useful in laboratory interpretation, but their lower boundaries vary modestly across reference texts. A normal stable allele is reported in ranges such as 5-55 CGG repeats, while a commonly used premutation band is **55-200 repeats**. The clinically robust distinction is that a full mutation is generally defined as more than 200 repeats, although a cited source uses a higher threshold. A report must be interpreted using the laboratory’s stated classification rather than by treating a disputed boundary as a universal biological cliff.

Normal alleles tend to be stable. **AGG interruptions** interspersed within the repeat are proposed to stabilise the sequence by reducing secondary structures during replication. Long uninterrupted stretches are more prone to expansion. This is why molecular counselling cannot be reduced to a family member’s label alone: the repeat architecture and its transmission context matter.

The inheritance is **X-linked**, but it does not behave like a simple static X-linked mutation. Expansion from a premutation to a full mutation occurs through the female germline; male carriers usually transmit without further expansion and may show contraction in sperm. This parent-of-origin effect explains the apparently paradoxical pedigree in which an unaffected transmitting man has daughters who are carriers, yet the more severely affected descendants emerge through subsequent maternal transmission.

TRAP **Do not infer full-mutation risk from "X-linked" alone.** The relevant question is whether the premutation is being transmitted through a woman, because that is the route in which expansion to a full mutation occurs.

The historical pattern of worsening expression in successive generations is called the **Sherman paradox**. It was an observation before it had a molecular explanation. The repeat-expansion mechanism now turns that observation into a counselling problem: a pedigree should be drawn across generations, noting cognitive and developmental histories as well as tremor, ataxia and early ovarian failure in relatives. Recurrence counselling should be syndrome-specific and undertaken with clinical genetics support; the generic framework belongs in the etiological assessment discussion.

- Ask which side of the family carries the molecular result and whether transmission has been maternal or paternal.
- Obtain an extended pedigree history rather than stopping at developmental delay in the child.
- Explain that a premutation and a full mutation have different clinical implications.
- Offer cascade evaluation to relatives through an appropriately supported genetics service.

9.3 Population burden and the diagnostic place of fragile X

Published prevalence estimates differ because ascertainment and molecular methods have changed. A sensible examination answer is to state the estimate with its denominator: fragile X syndrome occurs in about 1 in 4,000 males and around 1 in 8,000 to 1 in 9,000 women. Female prevalence is described as approximately one-half of the male rate. These figures refer to the syndrome, not to premutation carriage, which is much more frequent and has a different sex distribution.

1 in 4,000	1 in 8,000-9,000	~40%	~20%
MALES WITH SYNDROME	WOMEN WITH SYNDROME	MALE PREMUTATION CARRIERS WITH FXTAS	FEMALE PREMUTATION CARRIERS WITH POF

The distinction between affected syndrome and carrier state changes the conversation with families. Premutation carriage is reported at 1 in 150-200 females and 1 in 400-450 males in the general population. It should not be quoted as the prevalence of fragile X syndrome, nor should syndrome prevalence be used to dismiss the relevance of a premutation in an extended family.

Fragile X is also clinically relevant in autism assessment. It is described as the most commonly known single genetic cause of autism spectrum disorder. The direction of the statistic is the trap:

the proportion of people with fragile X who meet autism criteria is not the same as the proportion of autism attributable to fragile X. Reported rates of autism-spectrum diagnosis within fragile X vary substantially with the diagnostic construct and method, so they should be read as evidence of overlap rather than as a single invariant percentage. The medical and genetic workup of autism is addressed in the autism workup section.

9.4 Recognising the phenotype without overcalling it

The physical phenotype is developmental and variable. In adults, the familiar pattern includes an elongated face, prominent or cupped ears, a high arched palate and connective-tissue features. **Large anteverted ears, smooth velvet-like skin, hyperextensible finger joints, flat feet and mitral valve prolapse** are the useful connective-tissue cluster. Macro-orchidism becomes relevant after pubertal development and should be asked about and examined for sensitively, with appropriate consent and privacy.

ADULT PHYSICAL FEATURE	APPROXIMATE FREQUENCY AMONG ADULT CASES	CLINICAL USE
Macro-orchidism	~90%	Most evident after puberty
Elongated face	~80%	Supports, but never establishes, suspicion
Prominent or cupped ears	~65%	Look for it in the broader phenotype
High arched palate	~60%	Examine as part of a general dysmorphology review
Flat feet	~60%	Connective-tissue clue rather than a diagnostic sign

GOOD TO REMEMBER

These are group frequencies, not a checklist diagnosis. Up to 20% of affected children may have no obvious physical features, while individual facial or connective-tissue traits occur in many people without the syndrome. Developmental history, family history and a coherent behavioural phenotype raise suspicion; molecular testing establishes the diagnosis.

Associated physical morbidity deserves ordinary clinical attention. Seizure disorder occurs in 20% of individuals with fragile X syndrome. Visual and hearing assessment, cardiac review when indicated, and review of neurological symptoms should be integrated into care rather than deferred because the presenting concern is developmental. The specific diagnostic approach to epilepsy in autism belongs to the autism medical-workup section, but a seizure history in fragile X is directly relevant to this syndrome review.

9.5 Cognitive, language and behavioural profile

In males with a full mutation, intellectual disability is often moderate, with an average IQ of **about 40**; individual functioning is nevertheless broad and must not be assumed from a molecular result. In females with a full mutation, random X inactivation offers partial protection,

and cognitive impact is correspondingly variable. The assessment of IQ, adaptive behaviour and intellectual-disability severity is covered elsewhere in this chapter; here, the key point is that the fragile X profile is uneven, not merely globally delayed.

Short-term memory, visuomotor coordination, arithmetic and sequential processing are relative weaknesses, while simultaneous processing and long-term storage or retrieval may be relative strengths. This matters clinically. A child may do better when information is presented as a whole visual structure than when it is delivered as a long serial verbal sequence. It also matters in the consultation: apparently inconsistent performance can be a profile effect rather than evidence of poor effort or oppositionality.

The behavioural phenotype has a distinctive social-anxious quality. **Gaze aversion or reduced eye contact, shyness and social anxiety, hand-flapping and repetitive mannerisms, hyperactivity with short attention span, and poor peer relations** can co-occur. These features invite diagnostic shadowing in both directions: gaze avoidance and repetitive behaviour can be assumed to establish autism, while an established genetic diagnosis can lead the clinician to overlook a co-occurring autism-spectrum condition. Evaluate the person's actual social communication, restricted behaviour and functional needs rather than using the syndrome label as a shortcut.

Disruptive behaviour is reported to peak in preschool years and to decline progressively with age, although attentional difficulties may remain. This course is useful when setting family expectations: a difficult early behavioural phase does not predict a static trajectory. ADHD itself and its formal assessment are dealt with in the ADHD and specific learning/communication disorders notes. In fragile X, practical supports should take account of attention, anxiety, sensory responses, communication and the relative cognitive profile rather than treating "behaviour" as a single symptom.

MNEMONIC

FRAME the consultation

Family transmission, **R**epeat category, **A**ppearance across development, **M**ind and behavioural profile, **E**xtended-family premutation effects. This is a clinical sequence, not a diagnostic score.

9.6 Females, mosaicism and the premutation family phenotype

Female presentation requires particular care because it is often quieter and more variable. **Random X inactivation (lyonization)** protects many full-mutation females from full clinical expression. About half of females with the full mutation show cognitive deficits. A clinician should therefore neither assume that all female relatives are unaffected nor equate absence of intellectual disability with absence of a meaningful molecular result.

Mosaicism is described in 15-20% of individuals with FMR1 mutations. Different cell lines can carry different molecular profiles, which is one reason phenotype, repeat length and methylation pattern may not align in a simple linear fashion. The clinical response to an apparently

discordant result is not to reject it, but to interpret it with the reporting laboratory and genetics team in the context of the person's functioning and family history.

Premutation-associated disorders are not peripheral footnotes. **FXTAS (fragile X-associated tremor/ataxia syndrome)** is a late-onset neurodegenerative syndrome in premutation carriers, characterised by intention tremor and cerebellar ataxia, with later neuropathy, autonomic symptoms and cognitive or behavioural change in some individuals. Its median onset is 60 years. When an adult relative of a child with fragile X reports these symptoms, the family history has become a neurological referral issue, not merely background information.

Female premutation carriers may also develop premature ovarian failure, also termed fragile X-associated primary ovarian insufficiency. Around **20%** are reported to develop premature ovarian failure. The risk does not rise in a simple straight line with repeat size, so counselling should avoid a crude "more repeats always means more ovarian risk" message. Reproductive, neurological and developmental implications should be held together in family counselling while respecting the different needs of each relative.

9.7 Confirmation, interpretation and management

Confirmation is molecular, not morphological. The diagnostic method of choice is **DNA-based fragile X repeat-length testing, using PCR and/or Southern blot methods including repeat-primed PCR**. Cytogenetic fragile-site methods are historical: culturing lymphocytes without sufficient folic acid made an apparent X-chromosome breakpoint visible, but that laboratory phenomenon is not a treatment rationale. In particular, folic acid should not be prescribed as therapy for the primary disorder on the basis of the old cytogenetic technique.

Testing is especially appropriate when intellectual disability is unexplained, when the developmental and behavioural pattern is suggestive, or when the pedigree contains compatible developmental, neurological or reproductive histories. The broader etiological workup for intellectual disability is covered in the causes-and-workup discussion; this section's responsibility is to ensure that the fragile X assay is a dedicated repeat-expansion test. Routine sequencing alone may not detect repeat expansions, so the test request must match the suspected mechanism.

The written report should be read as a molecular category, not merely as a positive or negative result. A full mutation directs attention to the developmental phenotype and its supports; a premutation redirects the family conversation toward transmission, reproductive implications and later neurological symptoms. Mosaic findings require correlation rather than dismissal. This interpretive step protects against two opposite errors: making the molecular result the whole explanation for a person's needs, or treating a clinically relevant finding as incidental because the current phenotype is subtle.

TRAP **A normal-looking child does not exclude fragile X, and a standard sequencing result is not automatically a fragile X test.** Suspect from the phenotype and pedigree; confirm with the repeat-expansion assay.

There is no established treatment for the primary disorder; management is of associated conditions. This is not therapeutic nihilism. It means that care is organised around developmental assessment, communication support, educational adaptation, treatment of target symptoms and associated medical conditions, and genetic counselling for the family. Developmental interventions and educational planning belong to the management section of this chapter. A syndrome diagnosis should improve the precision of that plan, not replace person-centred assessment.

Must remember: Fragile X is an X-linked repeat-expansion disorder in which maternal transmission can convert a premutation into a full mutation; full mutation silences FMR1 and reduces FMRP, whereas premutation disorders are mediated by toxic excess messenger RNA.

10 · Inborn errors of metabolism causing ID (PKU and others)

Why this group earns disproportionate attention. Inborn errors of metabolism are individually uncommon causes of intellectual disability, but they matter because a metabolic diagnosis may change the trajectory of a child and the advice offered to the family. The useful clinical question is not whether every person with developmental difficulty has a metabolic disorder. It is whether the pattern contains enough biological coherence to make a potentially modifiable cause worth pursuing. For the psychiatrist, these disorders are also a reminder that intellectual disability can be the long-term expression of a disturbance in a biochemical pathway rather than a fixed label detached from mechanism.

Inborn errors of metabolism are best approached as disorders in which a missing or ineffective metabolic step has consequences for the developing brain and, often, for other organs. Their psychiatric relevance lies in the combination of developmental phenotype, neurological signs, behaviour, systemic clues and the possibility of pathway-directed treatment. A good answer therefore does more than list syndromes: it links substrate, enzyme, clinical pattern and the therapeutic implication.

1 in 10,000 to 1 in 20,000	first 3 months	below 20%
PKU BIRTH INCIDENCE	LATEST WINDOW TO BEGIN PKU DIETARY RESTRICTION	ADULTS WITH PKU PERHAPS MAINTAINING DIETARY CONTROL

10.1 Clinical frame: think pathway, phenotype and treatability

Metabolic disorders should not be reduced to an examination catalogue. They are a way of thinking about causation. A child may have global developmental difficulty or established intellectual disability as one part of a wider disorder, while another person may present later to psychiatry because attentional, behavioural or affective symptoms have become more conspicuous than the developmental history. The history and examination should therefore remain alert to discordance: a developmental presentation that sits alongside altered growth, pigment, eyes, skeleton, movement, episodic illness or a distinctive form of self-injury deserves a broader explanatory frame.

The pattern matters more than any isolated sign. A physical clue is not merely a dysmorphology spotter's flourish; it can identify the organ system in which the metabolic disturbance is declaring itself. Similarly, an apparently psychiatric symptom may be a direct consequence of altered neurochemistry, a response to neurological disability, or both. This is why a formulation should preserve the medical diagnosis, the developmental phenotype and the current mental-state problem as separate but connected layers.

RULE **Define the problem by the disrupted pathway, then ask what can still be modified.** The same developmental endpoint can arise from very different biochemical mechanisms, and treatment must follow the mechanism rather than the behavioural surface.

There is an important boundary here. The detailed sequence of aetiological tests and the general genetic-counselling process belong to the wider intellectual-disability assessment. This section instead explains the recognised metabolic conditions and the clinical reasoning that makes their recognition consequential. When a metabolic disorder is known or suspected, psychiatric care works alongside paediatrics and metabolic medicine, rather than attempting to translate a complex behavioural presentation into a purely psychiatric diagnosis.

10.2 Phenylketonuria: the prototype of preventable metabolic neurodevelopmental injury

Phenylketonuria (PKU) is an autosomal recessive disorder and remains the classic example of a biochemical defect in which early recognition changes neurodevelopmental outcome. It is described as the commonest inborn error of metabolism. Textbook estimates give an incidence between **1 in 10,000 and 1 in 20,000 births**; a further estimate is 1 in 10,000 live births. These figures are useful as scale, but the clinical lesson is larger: rarity at the level of an individual clinic does not make a reversible diagnosis unimportant.

The primary defect is deficiency of **phenylalanine hydroxylase**, a hepatic enzyme. In ordinary biochemical terms, this enzyme mediates conversion of phenylalanine to tyrosine. The relevant gene is the PAH gene, located on chromosome 12, with a reported locus at 12q22-24.1. This is not genetic detail for its own sake. It explains why the disorder is familial in pattern and why a diagnosis has implications beyond the presenting child.

When this metabolic conversion fails, the brain is affected through more than one route. Low tyrosine contributes to depletion of central monoamines, including dopamine and serotonin. Reduced availability of large neutral amino acids also compromises synaptogenesis and myelination. That dual mechanism makes sense of a phenotype that crosses developmental cognition, attention, executive control and behaviour. It also prevents a simplistic conclusion that a child who survives the early developmental period without profound disability has necessarily escaped neurocognitive consequences.

MNEMONIC

PKU clinical spine: pathway, prevention, persistence

Start with the failed phenylalanine-to-tyrosine step; connect it to early dietary treatment; then remember that later executive, attentional and affective symptoms still deserve active review.

10.3 PKU phenotype: untreated disease and the treated survivor are different clinical questions

Untreated PKU is associated with intellectual disability and developmental delay. The recognisable untreated phenotype may include reduced pigment with fair or blond hair and blue eyes, microcephaly, eczema, epilepsy, growth retardation and hyperactivity. These features should be understood as clinical clues within a syndrome, not as a diagnostic shortcut. No one sign establishes the diagnosis, and a psychiatric assessment should not turn a physical sign into a substitute for biochemical confirmation.

The name itself reflects the secondary pathway. **Phenylketones**, produced through phenylpyruvic acid in the secondary pathway, are excreted in urine. This is a compact but useful examination link between the disease name and its biochemistry. It also illustrates a broader metabolic principle: once the usual route is blocked, diversion products can become clinically informative.

The early-treated adult or adolescent requires a different formulation from the untreated child described in older accounts. Even with early treatment, there can be subtle reductions in IQ with executive and attentional impairment. The psychiatrist should therefore ask concrete functional questions about planning, sustained attention, error monitoring, academic or occupational organisation, adherence to a demanding diet and the emotional burden of living with a lifelong disorder. This avoids two equal errors: attributing every difficulty to PKU, or dismissing cognitive and emotional concerns because gross intellectual disability has been prevented.

TRAP **Examination trap:** do not present early-treated PKU as synonymous with absence of neuropsychiatric morbidity. Early treatment changes the expected phenotype; it does not make follow-up unnecessary.

There is evidence of elevated depression, anxiety disorders, particularly agoraphobia, and attention-deficit disorder in early-treated adolescents with PKU compared with matched healthy individuals. In practice, this means that a symptom review needs ordinary psychiatric discipline. Establish the symptom's time course and impairment, consider medical and psychosocial contributors, and do not write off distress as an inevitable accompaniment of a metabolic label.

10.4 PKU screening and treatment: timing is part of the treatment

PKU illustrates why a metabolic diagnosis must be made early enough for the intervention to matter. Neonatal screening uses blood or urine. For prevention of severe, irreversible cognitive deficit, dietary phenylalanine restriction must begin within the **first 3 months of life**. The phrasing is deliberately temporal: a correct diet begun too late cannot be assumed to restore an already altered developmental pathway.

A low-phenylalanine diet maintained for at least the **first decade of life** is associated with an essentially normal cognitive outcome. The diet is not a casual instruction to avoid a food group. It is a sustained medical treatment whose implementation, monitoring and acceptability need specialist support.

IN INDIA

In the Indian Psychiatric Society clinical practice guidance, tetrahydrobiopterin with a low-phenylalanine diet is listed as a small-molecule intervention for PKU.

Longitudinal care needs to acknowledge that adherence can become difficult when parents no longer organise every meal and social life broadens. Perhaps **below 20%** of adults with PKU maintain dietary control throughout adulthood. This is not a reason to moralise about non-adherence. It is a reason to explore practical constraints, autonomy, cognition, family support, mood and the person's own understanding of risk. The psychiatrist's role includes making these barriers discussable while ensuring that metabolic management remains with the specialist team.

The broader lesson is that screening, diagnosis and treatment cannot be separated into unrelated facts. In PKU, the specimen identifies the condition, the biochemical pathway explains the diet, and the time window explains why developmental prevention is possible. That integrated chain is what candidates should reproduce rather than a bare list of enzyme and symptoms.

10.5 Homocystinuria: systemic clues should change the psychiatric formulation

Homocystinuria is an important contrast to PKU because the developmental presentation sits alongside striking extra-central-nervous-system findings. These include ocular lens dislocation, pectus excavatum, and a tall, thin, long-limbed Marfan-like stature. It is also associated with strokes in young and middle-aged adults.

GOOD TO REMEMBER

In a psychiatric setting, this combination should prevent diagnostic compartmentalisation: intellectual disability, compulsive symptoms or altered personality should not obscure systemic vascular and physical risk.

Intellectual disability occurs in almost all cases, and the behavioural phenotype can include obsessive-compulsive symptoms and personality disorders. These associations do not permit a psychiatrist to infer homocystinuria from an obsessive-compulsive presentation. They do, however, show why apparently ordinary phenomenology becomes diagnostically different when it appears with developmental and somatic clues.

Treatment may include pyridoxine, or vitamin B6, which increases homocysteine metabolism and reduces methionine and homocysteine. The Indian guidance also lists pyridoxine with vitamin B12 and folate among small-molecule approaches. Pyridoxine reduces these biochemical levels in approximately **50%** of patients. This is a treatment-response fact, not a licence for a psychiatrist to manage metabolic therapy independently.

A particularly useful negative finding is that folate plus vitamin B6 does not reduce stroke risk in adults with elevated homocysteine. The distinction matters because biochemical improvement and clinical vascular protection cannot simply be treated as interchangeable outcomes. It is the kind of nuance that strengthens an answer and, more importantly, prevents overconfident counselling.

10.6 Other named metabolic disorders: recognise the syndromic pattern

DISORDER	METABOLIC BASIS	CLUES THAT SHOULD REDIRECT THE FORMULATION	SPECIFIC THERAPEUTIC IMPLICATION
Galactosaemia	Autosomal recessive deficiency of one of three enzymes in galactose metabolism, including GALT	After milk introduction: failure to thrive, hepatosplenomegaly and cataracts	Galactose-free diet; if treated, intellectual disability is usually mild.
Lesch-Nyhan syndrome	X-linked mutation of the HGPRT gene causing a purine-metabolism defect with excessive uric acid production and excretion	Severe self-injurious behaviour with compulsive biting of fingers and lips, with spastic cerebral palsy and choreoathetoid movements	Behavioural risk management must be integrated with neurological and metabolic care.
Hurler syndrome (MPS I)	Autosomal recessive alpha-L-iduronidase deficiency	Storage disorder phenotype requires a multisystem formulation rather than an ID-only label.	Enzyme replacement for MPS and bone marrow transplantation for MPS I are listed interventions.

Galactosaemia teaches the importance of a feeding-linked systemic presentation. The triad of failure to thrive, hepatosplenomegaly and cataracts after milk introduction should redirect attention from an isolated developmental formulation toward galactose metabolism. The therapeutic link is equally direct: removing galactose is an intervention aimed at the pathway, not merely at a developmental consequence.

Lesch-Nyhan syndrome is especially memorable because the self-injury is severe and compulsive, rather than a generic behaviour problem. The child may be normal at birth before developing low-to-mild intellectual disability. The associated movement disorder and self-biting should prompt a syndrome-level formulation. In the consultation room, the practical priority is safety without losing explanatory precision: pain, communication difficulty, environmental response and the underlying neurobiological disorder can all shape the observed behaviour.

For the mucopolysaccharidoses, **Hunter syndrome (MPS II)** and Sanfilippo syndrome (MPS III) are both described as milder than Hurler syndrome (MPS I). The examination value is to recognise that MPS is a family of disorders rather than an eponym to be memorised in isolation. The clinical value is to retain the possibility that a developmental and behavioural presentation belongs to a multisystem storage disorder.

10.7 Treatability across metabolic disorders: use a mechanism-led therapeutic map

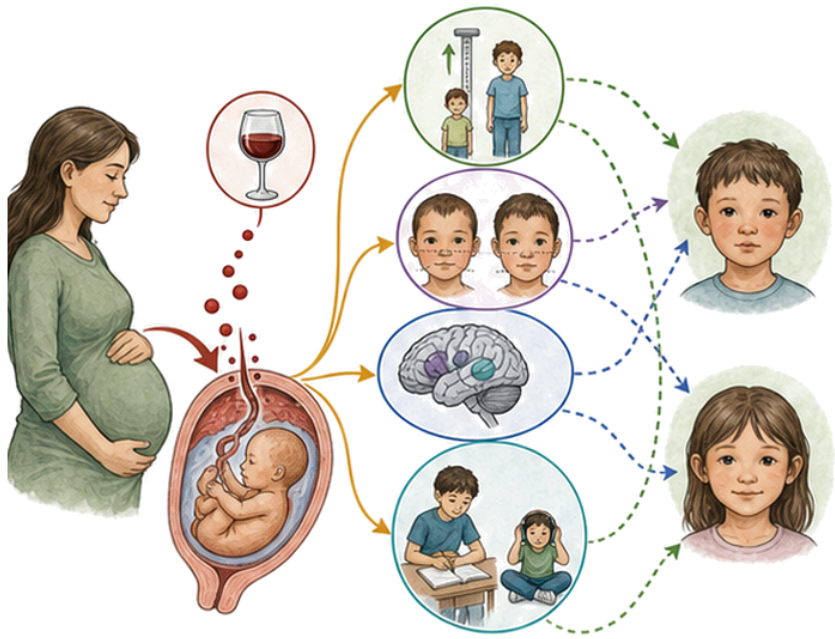
The key contrast across these conditions is not simply treated versus untreated. It is the kind of intervention that fits the disrupted biology. The Indian Psychiatric Society guidance identifies special or modified diets for many organic acidurias and aminoacidopathies, including PKU, glutaric aciduria type 1 and maple syrup urine disease. This should be read as an illustrative list, not as a claim that every metabolic disorder responds to dietary restriction.

- Replacement of deficient molecules includes thyroxine for hypothyroidism, enzyme replacement for mucopolysaccharidoses and copper histidine for Menkes disease.
- Small-molecule therapy includes creatine monohydrate for cerebral creatine deficiency syndromes and pyridoxine, vitamin B12 and folate for homocystinuria.
- Bone marrow transplantation is listed for alpha-mannosidosis and MPS I.
- Pharmacotherapy with vigabatrin and chelation of excess metals for Wilson disease and manganese transporter deficiency are further listed approaches.

These modalities are conceptually useful because they prevent therapeutic nihilism while also preventing indiscriminate treatment. A diet is appropriate when the disease mechanism supports dietary modification; replacement is appropriate when a missing molecule can be supplied; chelation addresses a harmful excess. The psychiatrist needs this map to understand why treatment is being offered and to recognise how psychiatric symptoms, adherence and family burden may affect it. Selecting the regimen, monitoring response and managing disease-specific risk remain specialist tasks.

> When intellectual disability is linked to a metabolic pathway, the decisive question is whether recognition permits pathway-directed treatment before or alongside irreversible developmental consequences.

10.8 Psychiatric practice: formulate, do not overshadow



Metabolic diagnosis should sharpen psychiatric assessment, not end it. A person may require assessment for depression, anxiety, attentional difficulty, obsessive-compulsive symptoms, personality change, severe self-injury or behavioural distress. The diagnosis helps the clinician ask better questions about timing, cognitive baseline, neurological change, diet, treatment burden and family interpretation. It must not become a blanket explanation that erases a treatable psychiatric syndrome or a preventable safeguarding problem.

Conversely, a familiar psychiatric label should not absorb clues that point beyond psychiatry. In PKU, executive and attentional impairment can coexist with mood and anxiety disorders. In homocystinuria, a psychiatric presentation sits beside ocular, skeletal and vascular clues. In Lesch-Nyhan syndrome, self-injury needs immediate compassionate management, yet its form and accompanying neurological signs carry diagnostic information. The senior clinical move is to hold both truths at once: symptoms deserve direct care, and their biological context may alter risk, referral and prognosis.

For examination writing, organise the answer around the prototype, then demonstrate range. Begin with PKU - inheritance, enzyme, biochemical block, phenotype, newborn screening and dietary treatment. Use homocystinuria to show why systemic findings and psychiatric symptoms must be integrated. Add galactosaemia, Lesch-Nyhan syndrome and mucopolysaccharidoses as concise pattern-recognition examples, and finish with the principle of mechanism-matched intervention. That organisation conveys clinical understanding rather than memorised accumulation.

11 · Fetal alcohol spectrum disorder

Why this diagnosis earns its place in an intellectual-disability chapter. Fetal alcohol spectrum disorder (FASD) is the clinical umbrella for developmental consequences attributed to prenatal alcohol exposure. It matters because the developmental phenotype is often broader than the visible phenotype: a child may have substantial difficulty with learning, regulation and everyday functioning without displaying the full facial pattern of fetal alcohol syndrome (FAS). Conversely, the recognisable physical pattern should prompt a careful account of neurodevelopment, rather than being treated as a diagnosis made from appearance alone. FAS is **probably the most common nongenetic cause of intellectual disability**, but FASD must not be reduced to intellectual disability alone.

- Prenatal alcohol exposure
- Growth
- Facial pattern
- Brain development
- Function may be impaired without facial signs

Fig 21.10 Fetal alcohol spectrum disorder is an umbrella for developmental consequences associated with prenatal alcohol exposure. Neurodevelopmental impairment may occur without the complete growth and facial pattern of fetal alcohol syndrome.

The useful clinical stance is therefore developmental and longitudinal. Ask whether prenatal exposure is documented, look deliberately for the phenotype, establish whether growth or brain-development indicators are present, and describe the functional profile in its own right. The label should bring order to a scattered presentation; it should not become a shortcut that explains every behaviour, nor should an absent facial phenotype be used to dismiss a credible exposure-related neurodevelopmental disorder.

11.1 Scope, language and diagnostic lineage

FASD is an umbrella, not a synonym for FAS. Its subdiagnoses include FAS, partial FAS (PFAS), alcohol-related neurodevelopmental disorder (ARND), alcohol-related birth defects (ARBD), and neurobehavioural disorder associated with prenatal alcohol exposure (ND-PAE). This terminology is clinically useful because it separates a full syndromic presentation from partial physical phenotypes and from neurodevelopmental presentations in which physical signs are not

demonstrable. ARBD is primarily a physical diagnosis and is not the focus of this neurodevelopmental discussion.

The original FAS criteria were set out by **Jones and Smith in 1973**. Contemporary clinical criteria are commonly described as the **Hoyme criteria**, updated from earlier Institute of Medicine criteria. For examination answers, the important point is not to recite a lineage of labels. It is to show that FASD diagnosis is organised around a coherent set of diagnostic domains: prenatal alcohol exposure, facial anomalies, growth deficiency, deficient brain growth or abnormal morphogenesis, and neurobehavioural impairment. These domains provide the framework for deciding which diagnosis best fits the available evidence.

RULE **Diagnostic principle.** In FASD, exposure history, physical findings and neurodevelopmental findings are interpreted together; none should be allowed to stand in for the others.

This framework also explains an apparently counterintuitive feature of the full syndrome. A diagnosis of **FAS** rests on the characteristic physical and neurobehavioural domain combination, so documentation of confirmed prenatal alcohol exposure is not required for that diagnosis. That is not permission to treat exposure history as unimportant. It reflects the specificity attributed to the combination when it is present, while recognising that reliable retrospective histories can be unavailable.

MNEMONIC

Use the spine, not a checklist blur

Think *exposure, face, growth, brain, behaviour*. It keeps the assessment ordered and makes it less likely that a clinician will mistake a single facial observation or a behavioural complaint for the whole diagnosis.

11.2 Biology and the syndromic phenotype

Alcohol is a developmental teratogen, so the clinical phenotype should be understood as the outcome of disruption during development rather than as a static cosmetic syndrome. A proposed mechanism is inhibition of **NMDA receptors** that mediate postsynaptic excitatory effects of glutamate, with effects on cell proliferation. This provides a biologically intelligible bridge between structural findings and later developmental difficulties. It does not, however, permit one to infer a particular cognitive profile from mechanism alone. Developmental outcomes are heterogeneous, and clinical formulation remains more informative than mechanistic shorthand.

Recognising the face requires discipline. The classic sentinel pattern is a **triad of short palpebral fissures, a smooth philtrum and a thin upper lip**. These are midfacial findings, not a general impression that a child "looks dysmorphic". The examiner should observe and document each component carefully, because casual facial judgement is vulnerable to expectation, ancestry-related variation and poor-quality photographs. In the facial-anomaly domain, **at least two** characteristic features are required. A palpebral fissure length at or below the **10th centile**

qualifies as a facial feature; a thin vermilion border or smooth philtrum is assessed on a racially normed lip-philtrum guide at **rank 4 or 5**.

TRAP **Examination trap.** Do not diagnose FASD from a nonspecific statement such as "typical facies". State the individual facial findings, then relate them to the wider diagnostic domains.

Growth and brain-development indicators add clinical weight when present. Growth deficiency is represented by height or weight at or below the 10th centile. Deficient brain growth or abnormal morphogenesis may be reflected by head circumference at or below the 10th centile, structural brain abnormalities, or recurrent nonfebrile seizures. These are diagnostic indicators, not interchangeable measures of the same process. A growth measurement answers a different question from head growth, and neither replaces a careful account of neurobehavioural functioning.

DIAGNOSTIC DOMAIN	WHAT THE CLINICIAN ESTABLISHES	WHY IT CHANGES REASONING
Prenatal alcohol exposure	A reliable history when it is available.	It is essential for some FASD diagnoses and strengthens causal attribution.
Facial anomalies	The sentinel midfacial pattern, measured rather than guessed.	It distinguishes a recognisable physical phenotype from a purely behavioural presentation.
Growth deficiency	Appropriate anthropometric evidence.	It contributes a separate developmental domain.
Brain growth or morphogenesis	Head-growth, structural or seizure indicators.	It links the physical assessment to neurodevelopmental risk.
Neurobehavioural impairment	Impairment on a global estimate or a relevant neurobehavioural or behavioural domain.	It prevents the diagnosis becoming a morphology exercise.

The threshold for neurobehavioural impairment in this clinical framework is performance at least 1.5 SD below the mean on a global cognitive estimate or on a single relevant neurobehavioural or behavioural domain. The key clinical inference is modest but important: a child can require a detailed functional evaluation even when the physical findings are incomplete. The physical phenotype and the developmental phenotype overlap, but they are not identical.

11.3 Distinguishing FAS, partial FAS and ARND

The diagnostic categories are best used as descriptions of the configuration before you, not as a hierarchy of "real" and "less real" disorders. FAS is the full syndromic pattern described above. PFAS retains facial anomalies and neurobehavioural impairment in the presence of confirmed exposure. When exposure is not confirmed, PFAS requires those findings together with impairment in either growth or brain growth. This additional requirement is logically necessary: without a documented exposure history, the clinician needs a more specific configuration before making an exposure-attributed diagnosis.

Alcohol-related neurodevelopmental disorder is made in the absence of the physical indicators of face and growth, but requires confirmed prenatal alcohol exposure and neurobehavioural impairment. This category is especially important because it captures children whose most disabling difficulties are cognitive, behavioural and functional rather than dysmorphic. Its existence protects against a common diagnostic error: assuming that the absence of the FAS face excludes alcohol-related neurodevelopmental harm.

- For FAS, look for the characteristic syndromic combination and do not make documented exposure a false prerequisite.
- For PFAS, decide first whether prenatal exposure is confirmed, because that changes the required domain configuration.
- For ARND, do not demand facial or growth indicators when a documented exposure history and neurobehavioural impairment are present.

These distinctions should improve the quality of documentation. Record what was observed, what was measured, which part of the exposure history is corroborated and which diagnostic domain is not established. That language is more clinically defensible than forcing a label from an incomplete record. It also keeps diagnostic uncertainty visible, which is preferable to either overcalling a syndrome or making a false reassurance from an absent physical feature.

11.4 ND-PAE: the proposed neurodevelopmental diagnosis

Neurobehavioural disorder associated with prenatal alcohol exposure is placed in the DSM appendix under Conditions for Further Study, with proposed rather than full diagnostic criteria. This status matters in a written answer: ND-PAE is a structured clinical construct, but it is not a full DSM diagnosis. It should therefore be described accurately rather than presented as though it had identical nosological standing to every routine DSM diagnosis.

Its exposure criterion specifies more-than-minimal gestational exposure as more than 13 drinks per month during pregnancy, or more than 2 drinks on any one occasion. This threshold is a criterion for the proposed diagnosis, not a declaration that exposure below it is safe. There is **no established safe threshold** or safe period of gestational alcohol exposure. The effects of exposure remain difficult to reduce to a single number because developmental stage and maternal and fetal factors modify risk.

The ND-PAE structure makes the clinical interview more precise. It requires impairment in at least one neurocognitive domain, at least one self-regulation domain, and at least two adaptive-functioning domains, one being communication or social communication and interaction. The neurocognitive domains include global intellectual performance, executive functioning, learning, memory and visual-spatial reasoning. The self-regulation domains include mood or behavioural regulation, attention and impulse control. Adaptive difficulties can involve communication, social communication and interaction, daily living skills or motor skills.

Global intellectual performance may be demonstrated by an IQ or comprehensive developmental standard score at or below 70. That is one route within the neurocognitive criterion, not the

definition of the whole condition. A sound assessment asks which abilities fail in ordinary demands and whether the pattern coheres with the exposure history. Neurocognitive deficits, regulation problems and adaptive limitations are clinically separable, though they often compound one another in a child's life.

Diagnosis should be deferred at or below 3 years, because reliable neurocognitive assessment is limited at that stage. Deferral is not abandonment. It means recording exposure and developmental concerns, following the child's profile over time, and avoiding a prematurely fixed label. ND-PAE can be diagnosed in alcohol-exposed children with or without FAS, including those without facial dysmorphology. That independence is precisely why the clinician must inspect the neurodevelopmental phenotype rather than use the face as a gatekeeper.

11.5 Cognitive and behavioural clinical correlation

FASD creates a frequent conceptual trap in intellectual-disability teaching. The presence of FASD does not mean that every affected child has intellectual disability, and a normal-looking child should not be assumed to have intact higher functions. The majority of children with FASD do not have IQ below 70; observed ability spans from severe intellectual impairment to average performance. In children with FAS, the average full-scale IQ is around 72, compared with around 80 in children with heavy prenatal alcohol exposure without FAS. Intellectual disability in FAS is usually mild to moderate, though it may be severe.

Interpretation of intelligence testing itself belongs in the intellectual-disability assessment material.

GOOD TO REMEMBER

Do not let a single global score decide whether FASD is clinically important. A child with broadly higher measured ability may still struggle with executive demands, new learning, memory, visual-spatial reasoning, attention, impulse control or social communication. Translate these findings into difficulties at school, with home routines and in judgement; do not misread them as wilful noncompliance.

Psychiatric comorbidity adds a second layer of complexity. **Attention-deficit/hyperactivity disorder** is the most common co-occurring psychiatric diagnosis, with reported prevalence among children with FASD between 44% and 96%. Mental health problems have been identified in more than 90% of people with histories of significant prenatal alcohol exposure. These figures should not invite indiscriminate diagnostic labelling. They should prompt the clinician to ask whether attention, impulsivity and emotional dysregulation are being described carefully, rather than folded uncritically into a single explanatory story.

The absence of the classic face does not exclude an alcohol-related neurodevelopmental disorder; assess exposure history and functional phenotype together.

11.6 Differential diagnosis and disciplined attribution

Attribution is a clinical conclusion, not a moral judgement. Prenatal alcohol exposure may be difficult to establish and the behavioural presentation is not pathognomonic. The diagnostic task is therefore one of pattern recognition followed by active exclusion of alternatives. A credible history is valuable, but history alone cannot establish that every developmental difficulty is caused by alcohol. Equally, uncertainty in history should not lead to a careless assumption that a distinctive physical and neurobehavioural pattern is irrelevant.

The named differential includes genetic conditions such as Williams syndrome, Down syndrome and Cornelia de Lange syndrome, and other teratogenic conditions such as fetal hydantoin syndrome and maternal phenylketonuria. These conditions can share physical and behavioural characteristics with ND-PAE. The practical lesson is to seek positive evidence for the proposed diagnosis and contradictory evidence for alternatives. “Alcohol exposure reported” is not a substitute for a differential diagnosis; “facial features absent” is not a substitute for one either.

TRAP **Examination trap.** A documented exposure history does not remove the need for differential diagnosis, and an undocumented history does not automatically rule out FAS when the required syndromic configuration is present.

- Separate observations from inferences: document anthropometry, facial examination, neurodevelopmental findings and exposure evidence distinctly.
- Ask whether each finding belongs to the FASD configuration or whether it suggests an alternative developmental or teratogenic condition.
- State the limits of the available evidence rather than converting an uncertain history into false certainty.

For a broader developmental formulation, use the relevant sections of the *Child psychiatry: assessment, treatment, services and protection notes*. Assessment of adaptive behaviour, intellectual testing and the multidisciplinary management of intellectual disability are deliberately treated elsewhere in these notes. Here, the point is narrower: recognise when alcohol-related developmental injury is a plausible organising diagnosis and describe why.

11.7 Epidemiology, prevention boundary and clinical significance

Reported prevalence varies greatly with population, case definition and completeness of assessment, so a single headline figure can mislead. The mean global general-population prevalence of FASD reported for 2012 was 7.7 per 1,000. The corresponding mean for the Americas was 8.8 per 1,000. In the United States, FASD has been estimated at between 1.1% and 5.0%, whereas the reported estimate for FAS itself is between 2 and 7 per 1,000 children. These are not competing answers. They measure differently framed populations and, crucially, the spectrum is wider than the full syndrome.

7.7 per 1,000	8.8 per 1,000	1.1% to 5.0%	251.5 per 1,000
FASD: GLOBAL MEAN	FASD: AMERICAS MEAN	FASD: UNITED STATES ESTIMATE	ND-PAE: CHILDREN IN CARE SETTINGS

Ascertainment is not a technical footnote. ND-PAE estimates in fully evaluated children have ranged between 31.1 and 98.5 per 1,000, and a meta-analytic estimate among children in care settings was 251.5 per 1,000. The latter should never be generalised to all children. It does, however, underline why a high-risk care context should lower the threshold for a thoughtful developmental history and a careful search for unmet needs.

The clinical preventive message is uncomplicated: there is no established safe threshold or safe period for alcohol exposure in pregnancy. The public-health framework for prevention is addressed in the *Prevention of intellectual disability* material. In this section, the practical diagnostic corollary is that clinicians should discuss exposure without blame. Shame drives concealment, while accurate histories and respectful care improve recognition of children who need a fuller developmental evaluation.

12 · Tuberous sclerosis, neurofibromatosis and neurocutaneous syndromes in ID

Why these disorders matter in intellectual disability. Neurocutaneous syndromes make the aetiological assessment of intellectual disability clinically visible. The examination of skin, eyes and nervous system can connect a developmental presentation to a multisystem disorder, while the psychiatric formulation must remain alert to seizures, cognitive change, behaviour, family burden and the practical implications of a long-term condition. They reward disciplined observation: a lesion on the skin is not a diagnosis by itself, but it may be the clue that makes the whole developmental history intelligible.

These syndromes are especially useful for teaching this approach. **Tuberous sclerosis complex** brings developmental, epileptic and systemic manifestations into a formulation. **Neurofibromatosis type 1** likewise has cutaneous signs that may point to neurodevelopmental and neurological needs. The task for the psychiatrist is neither to reduce the patient to a syndrome nor to overlook the syndrome while treating only behaviour.

1 in 7000	**about 70%**	**above 90%**	**50%**
TSC POPULATION PREVALENCE	TSC DE NOVO MUTATIONS	TSC SEIZURES AT PRESENTATION	NF1 NEW CASES IN UNAFFECTED FAMILIES

12.1 Neurocutaneous syndromes as a clinical frame

A neurocutaneous syndrome should be approached as a pattern across organ systems rather than as a dermatological label. In a person with intellectual disability, the clinician asks whether physical stigmata, epilepsy, cognition and change in functioning can be explained by a shared condition. This is useful because the consequences of an established syndrome are not merely diagnostic. It changes the threshold for collateral history, medical liaison and surveillance for new symptoms.

For tuberous sclerosis, older texts may use **epiloia** or tuberose sclerosis. The classical teaching spine comprises **three** linked manifestations: epilepsy, intellectual disability and facial angiofibromas on the malar surface. It remains a memorable clinical entry point, but it is not a substitute for examining the person or for recognising that features evolve across development.

In particular, facial angiofibromas may first become apparent in adolescence; their absence earlier in life should not falsely reassure the clinician.

MNEMONIC

E-I-F for the classical TSC spine

epilepsy, intellectual disability and facial angiofibromas. Use it to prompt a whole-person review, not as a rule-out checklist.

RULE **When intellectual disability coexists with characteristic skin or neurological signs, formulate the syndrome as a multisystem condition and reassess for changing neurological function.**

Physical signs are most useful when they sharpen the examination rather than when they create diagnostic tunnel vision. In tuberous sclerosis, look deliberately for facial angiofibromas, hypomelanotic macules including ash-leaf spots, shagreen patches over the lower trunk or buttocks, ungual fibromas and retinal phakoma. These findings support a coherent clinical hypothesis, yet the psychiatrist should also document what they mean functionally: distress about appearance, stigma, pain, caregiving burden and barriers to education or work can all influence the presenting complaint.

12.2 Tuberous sclerosis complex: genetics and mechanism

Tuberous sclerosis is inherited in an **autosomal dominant** pattern, although many presentations are sporadic. What varies between affected people, and even within one family, is the **expressivity** of the disorder rather than its penetrance: current genetic sources put penetrance at essentially complete, so a relative who carries the pathogenic variant is affected, but the severity and organ pattern of that involvement differ widely. Older texts, including some in common examination use, describe this as variable penetrance. Say expressivity, and know why the distinction matters: it means a mildly affected parent is affected, not a non-penetrant carrier, and their apparently trivial skin sign is a reason to examine them properly. This matters when taking a family history: the history may be apparently negative without making a genetic disorder implausible. In conventional testing, an alteration in TSC1 or TSC2 is identified in 80% to 90% of people with the condition. The choice and sequence of tests belong to the ID aetiological work-up; the syndrome-specific result is interpreted alongside phenotype and family context rather than in isolation.

TSC1, located at 9q34, encodes hamartin. **TSC2**, located at 16p13, encodes tuberin. Their products act as tumour suppressors that restrain Rheb-mediated mTOR kinase activity. This molecular account is clinically valuable because it explains why mTOR-directed treatment has a rational place in selected manifestations; it does not imply that every cognitive or behavioural difficulty is directly reversible by treating a lesion.

The broad developmental lesson is that a molecular diagnosis describes risk and mechanism, not destiny. Cognitive ability in tuberous sclerosis has been reported as bimodally distributed, with a

group having normal IQ and another in the profoundly affected range. Such heterogeneity makes an individual developmental and adaptive assessment indispensable. It also prevents the opposite errors of assuming that every person with the syndrome has intellectual disability, or overlooking substantial support needs in someone whose physical signs dominate the consultation.

GENETIC OR BIOLOGICAL LEVEL	CLINICAL MEANING	PSYCHIATRIC IMPLICATION
TSC1 and TSC2 encode hamartin and tuberin	The disorder has a defined tumour-suppressor pathway	Family history and physical findings should be integrated with the syndrome phenotype
The complex restrains mTOR activity	Selected structural manifestations have a pathway-based treatment rationale	Do not equate lesion-directed treatment with a complete explanation or cure for developmental needs
Variable penetrance and sporadic presentation	A negative family history does not settle the question	Give counselling within the wider genetic-work-up framework and avoid premature certainty

12.3 TSC phenotype: seeing the syndrome without missing the person

The skin examination is often the most accessible part of recognition. **Facial angiofibromas** are classically malar, while hypomelanotic macules, shagreen patches and ungual fibromas provide other cutaneous clues. Describe what is actually seen rather than using a label as shorthand. A careful record helps later clinicians distinguish longstanding stigmata from new change and allows the family to understand why a psychiatric consultation involves a full physical review.

Central nervous system lesions account for much of the developmental and neurological burden. Subependymal tubers may line the ventricles. Their reported size is **1 to 3 cm**, but the clinical question is not their size alone: one must ask whether a growing lesion could be producing seizures, headache, altered alertness, loss of skills or progressive cognitive impairment. **Subependymal giant cell astrocytomas** may compress and irritate adjacent cortex, and obstruction at the foramen of Monro can cause obstructive hydrocephalus. New deterioration should therefore trigger medical rather than purely behavioural attribution.

TRAP **Do not call a new behavioural change "part of the intellectual disability" before considering seizure activity, lesion-related change or hydrocephalus in a person with TSC.**

Systemic review is equally important. Tuberous sclerosis can involve renal cysts and angiomyolipomas, and cardiac rhabdomyomas that may cause dysrhythmias. These are not incidental facts for the psychiatrist. Pain, sleep disruption, repeated admissions, frightening cardiac symptoms and treatment demands can present indirectly as irritability, avoidance, low mood or family conflict. A liaison formulation distinguishes a psychiatric syndrome from a psychological response to a medical burden, while allowing both to be present.

Liaison also requires intellectual humility. Each specialty may see a valid but partial account of the person: the lesion, the seizure, the renal issue, the visible skin finding, the behaviour, or the

family's exhaustion. The psychiatric assessment can integrate these accounts around daily functioning and distress. It should make uncertainty explicit, identify the next clinically answerable question and avoid implying that a behavioural description can settle a neurological concern.

For candidates, the practical inference is simple: findings in brain, skin, heart, eye and kidney make the syndrome multisystem. The specialist medical team directs organ surveillance. Psychiatry contributes longitudinal developmental description, a baseline of behaviour and cognition, assessment of emotional symptoms at the person's communication level, and support for carers faced with uncertainty.

12.4 Epilepsy, intellectual disability and behaviour in TSC

Epilepsy is central to the neuropsychiatric phenotype of tuberous sclerosis. Partial motor and complex partial seizures are particularly characteristic. Other seizure forms may occur, with classic absence seizures a probable exception; severe presentations may begin with infantile spasms. This seizure history should be taken with attention to onset, semiology, treatment response, injuries, sleep, postictal behaviour and apparent developmental plateau or loss. A family's account of "spells" may be much more informative than a single label in an old record.

Vigabatrin is particularly effective for infantile spasms in tuberous sclerosis. A randomised, single-masked trial in young children found the subgroup with TSC-related spasms particularly responsive. This is a responsiveness observation, not a licence to treat without specialist epilepsy oversight.

IN INDIA

The Indian psychiatric guideline also lists tuberous sclerosis among its relevant uses.

The limitation is clinically serious. Vigabatrin can cause progressive, permanent bilateral vision loss, including concentric visual field constriction. It has also been associated with behavioural disturbance or ADHD symptoms, depression and psychosis, with no beneficial psychotropic effect reported.

GOOD TO REMEMBER

When behaviour worsens after an antiseizure treatment change, the formulation must consider medication effect as well as seizure control, environment and the person's baseline vulnerabilities.

- Obtain a careful seizure and medication chronology before attributing agitation or decline to a primary psychiatric disorder.
- Ask carers for concrete examples of change in sleep, attention, mood, behaviour and daily functioning.
- Escalate new focal neurological symptoms or progressive cognitive change to the relevant medical team.

There are useful risk associations, but they must not become deterministic predictions. TSC2 mutations are associated with more severe epilepsy and cognitive impairment; moderate to severe intellectual disability is more common in people with infantile spasms. These associations support vigilance and early support planning; they do not replace an assessment of the individual's communication, strengths, behaviour or family resources.

TSC also has a limited reverse relationship with autism at population level: **less than 4%** of all autism is attributable to TSC. The point is diagnostic humility. TSC may be relevant to autism in an individual with the syndrome, but it does not explain autism generally, and autism assessment should still be conducted on its own clinical evidence.

12.5 TSC management: targeted treatment and longitudinal formulation

The psychiatric role in a multisystem syndrome is coordinative and longitudinal. First, identify the current problem in concrete terms: seizure-related risk, a change in cognition, behavioural disturbance, emotional symptoms, school or vocational difficulty, caregiver strain, or difficulty navigating multiple specialties. Next, establish the baseline against which change can be judged. Finally, communicate concerns in a form useful to neurology, paediatrics, dermatology, ophthalmology, cardiology and renal services as appropriate.

For subependymal giant cell astrocytomas, the mTOR inhibitors everolimus and sirolimus can shrink the lesion. Topically applied mTOR inhibitors can reduce facial angiofibromas. These examples clarify an important distinction: a medicine can be directed at a structural or skin manifestation, while the psychiatrist still addresses developmental support, distress, adherence, family understanding and the lived effects of a chronic disorder.

In TSC, a change in behaviour or cognition is a clinical event to explain, not a baseline feature to dismiss.

Generic genetic counselling principles and the sequence of laboratory investigation are addressed in the ID aetiological work-up. In this syndrome-specific setting, the clinician should explain that inheritance may be variable and that sporadic presentation is common, then ensure that the family receives appropriately coordinated counselling. Avoid giving a falsely precise recurrence discussion from a psychiatric interview alone, especially when the molecular result and the family phenotype have not yet been clarified.

12.6 Neurofibromatosis type 1: recognition and diagnostic reasoning

NF1 is associated with the tumour-suppressor gene product **neurofibromin**, at 17q11.2. Neurofibromin is involved in regulation of cell division and tumour suppression. As in TSC, the psychiatric significance lies in recognising a medical context for developmental and behavioural needs while retaining ordinary clinical discipline: a person can have NF1 and an independent mood, anxiety, psychotic or behavioural disorder.

Diagnosis usually requires **at least two** diagnostic features from the established list. The recognised features span skin lesions, peripheral tumours, regional freckling, ocular findings, optic-nerve involvement, bony lesions and an affected first-degree relative. The list is best used as

a structured prompt for referral and documentation, not as an invitation for the psychiatrist to make a final diagnosis without appropriate examination.

NF1 FINDING DOMAIN	FEATURES TO LOOK FOR OR ELICIT	WHY IT MATTERS IN AN ID ASSESSMENT
Skin	**Café-au-lait macules**, axillary or inguinal freckling	May supply the first clue to a syndromic formulation
Peripheral tumours	Neurofibromas, including **plexiform neurofibroma**	Symptoms and visible difference may affect distress, self-image and help-seeking
Eye, bone and family history	Lisch nodules, optic nerve glioma, bony lesions, affected first-degree relative	Signals the need for appropriately coordinated specialist assessment

The café-au-lait threshold is a common recall point but should be applied with precision. The cited criterion specifies **six or more** lesions, larger than 5 mm before puberty or 15 mm after puberty. An alternative source frames the sign as more than six lesions, each larger than 5 mm in children and 1.5 cm in adults, and notes that individual café-au-lait spots occur in normal individuals. Therefore, a single lesion should not be over-interpreted; the pattern, associated signs and clinical context matter.

TRAP **Do not diagnose NF1 from an isolated café-au-lait spot, and do not mistake a referral criterion for a psychiatric explanation.**

12.7 A psychiatrist's practical synthesis

When a neurocutaneous syndrome is known or suspected in a person with intellectual disability, begin by separating the immediate clinical question from the aetiological label. Is the consultation about new seizures, progressive cognitive difficulty, aggression, emotional distress, medication adverse effects, family conflict or a support failure? That distinction prevents a syndrome name from becoming a catch-all explanation and makes the response clinically useful.

A good formulation has parallel layers. The biological layer records the established or suspected syndrome, current neurological concerns and treatment exposure. The developmental layer records the person's baseline abilities, communication and pattern of support. The psychological layer asks how the person understands symptoms, procedures, visible differences and restrictions. The social layer identifies who observes change, who carries care and what makes access to coordinated treatment difficult. Writing these layers separately helps the team avoid both diagnostic overshadowing and fragmented, organ-by-organ care.

Communication with families deserves the same precision as communication with specialists. Explain why a new symptom is being taken seriously, what the immediate safety concern is, and which clinician will address it. Invite carers to retain their observations rather than dismissing them as vague. In people with limited spoken language, an account of altered routine, sleep, facial expression, mobility, appetite, engagement or self-care may be the earliest available evidence of a

medical or emotional change. The psychiatrist's value is often to translate this observation into an actionable question for the wider team.

- Examine and document relevant skin signs, while asking what they mean to the patient and family.
- Seek a longitudinal account of development, seizures, cognition, behaviour and treatment exposure.
- Compare the present state with the person's own baseline rather than with an abstract stereotype of the syndrome.

These disorders are a reminder that psychiatry in intellectual disability is whole-person medicine. The syndrome gives a framework for anticipation; it does not erase the individual's personality, preferences, communication style, social context or capacity for psychological distress. The best answer in the examination, and the best practice in the clinic, links a recognisable phenotype to a thoughtful developmental and psychiatric formulation without claiming more certainty than the evidence supports.

13 · Behavioural phenotypes of genetic syndromes

The useful question is not "what behaviour does this syndrome cause?" A behavioural phenotype is a clinically recognisable pattern that can sharpen observation, guide anticipatory enquiry and prevent diagnostic overshadowing. It is not a substitute for seeing the person in front of us. In intellectual disability, knowing the aetiology may provide **clues to psychiatric comorbidity**, because some syndromes are repeatedly associated with particular behavioural patterns. The practical gain is disciplined curiosity: ask about the pattern that is plausible, then establish whether it is actually present, distressing and functionally important.

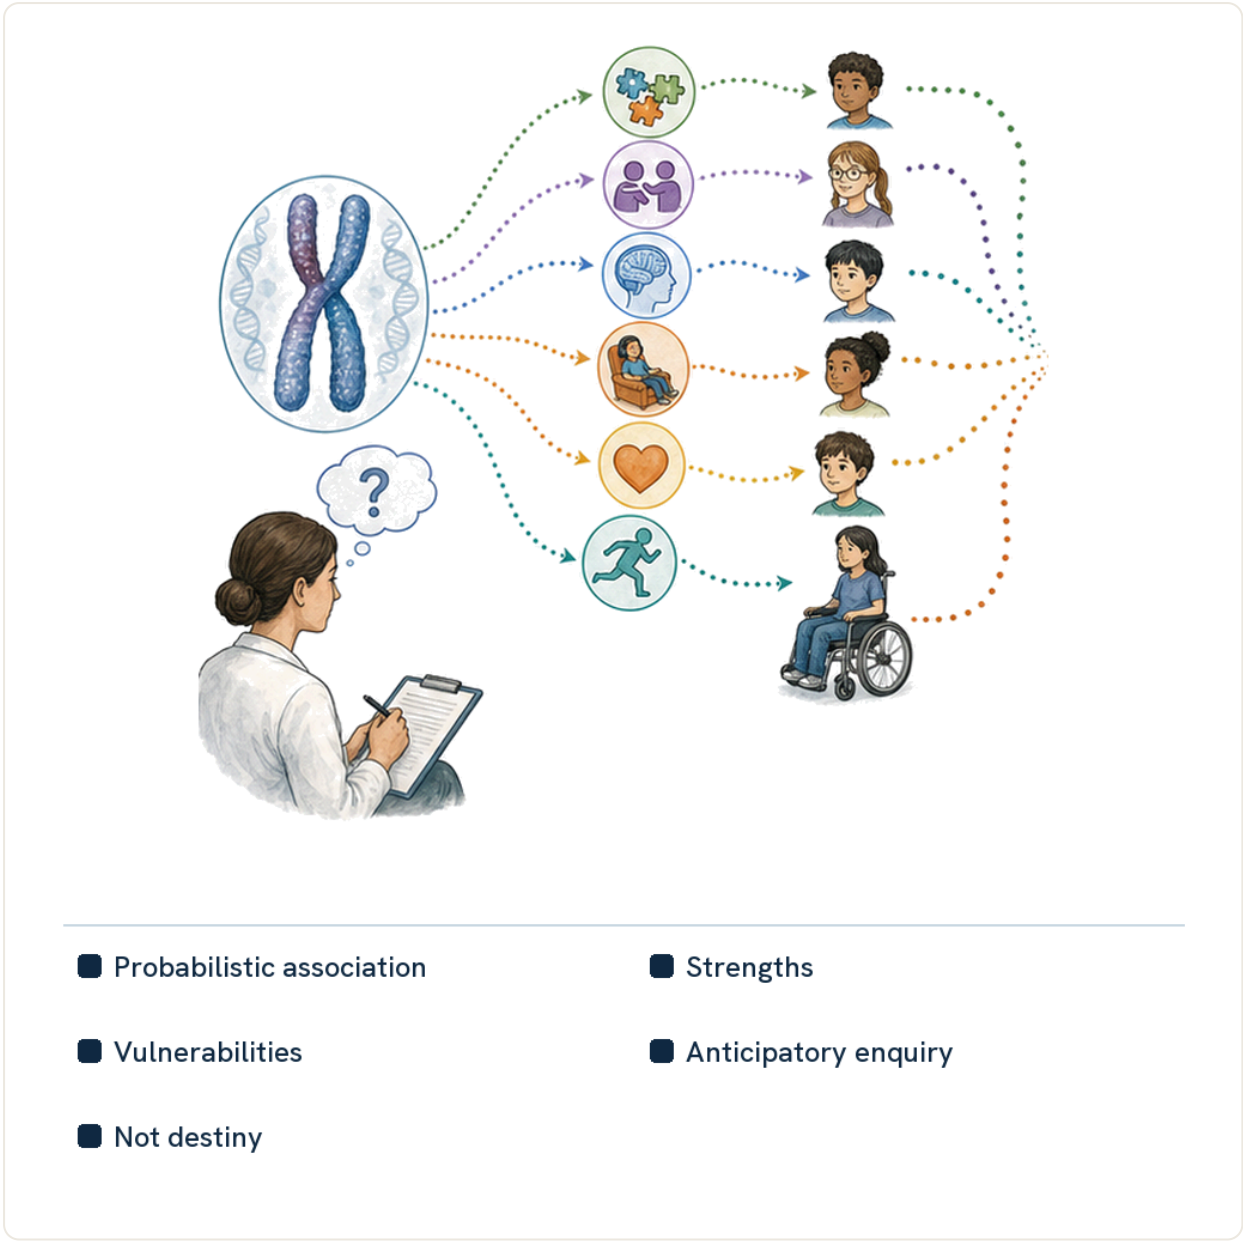


Fig 21.11 A behavioural phenotype is a raised probability of a pattern, not a behaviour caused in every person by a syndrome. It guides anticipatory enquiry while preserving individual strengths, context and diagnostic assessment.

The term **behavioural phenotype** was introduced by Nyhan. Earlier clinical observers such as Penrose had noted a distinctive social presentation in Down syndrome, but the modern concept is broader and more cautious. Its working definition is associated with Dykens: a syndrome is associated with a raised likelihood of a behavioural or developmental outcome when compared with people without that syndrome. That is a **probabilistic association**, not a diagnostic label attached to every individual.

13.1 What the concept does - and does not - mean

A behavioural phenotype is best understood as a pattern of vulnerabilities, strengths and recurrent clinical problems that occurs more often in a defined condition than outside it. This distinguishes a useful phenotype from an attractive anecdote. The clinician is looking for the **combination of features and its association with a condition**, rather than claiming that an isolated common symptom identifies a syndrome. Attentional difficulty, social anxiety, sleep

disruption, stereotypy and self-injury all occur across diagnostic groups. Their meaning comes from their form, timing, associated features and clinical setting.

RULE **A behavioural phenotype changes prior probability; it does not determine the individual's behaviour.**

The concept explicitly rejects genetic determinism. Behavioural expression is shaped by developmental level, communication, physical illness, sensory experience, family responses, opportunity and the person's own temperament. A syndrome may create a particular vulnerability while the environment influences how often it is triggered, how it is understood and how much disability follows. This is why a behavioural phenotype should lead to more careful assessment, not to premature explanation.

Equally, no behavioural phenotype is invariant. The absence of a familiar feature should not be used to dismiss a molecular or clinical diagnosis; its presence should not be used to make one. This is especially important in adults, in people with co-occurring sensory or neurological problems, and where developmental history is incomplete. The phenotype is a clinical map, not a gatekeeping criterion.

Specificity lies on a spectrum. A broad feature may be shared across several syndromes, whereas a particular form of that behaviour may be unusually informative. For example, a particular form of stereotyped hand wringing is almost invariably seen in Rett syndrome, even though hand stereotypies occur in many clinical contexts. The distinction protects against the common error of treating the category "stereotypy" as though it carried the specificity of its most characteristic form.

TRAP **Do not turn a phenotype into a personality stereotype.** A recurring association may help formulate a question, but it never excuses failure to assess pain, communication, mood, safeguarding, environmental demands or co-occurring psychiatric illness.

13.2 How to use a phenotype in assessment

Use the syndrome to improve the interview, not to abbreviate it. Start with a baseline account of communication, adaptive functioning and the person's usual temperament. Then ask about the behaviours linked to the syndrome in a neutral, concrete way: their form, onset, antecedents, consequences and effect on family life, education, work and health. A behavioural signature has most value when it prompts a question that might otherwise not have been asked.

When a behaviour is established, the next task is formulation. Food-seeking, self-injury, withdrawal, agitation or sleep disruption can be part of a phenotype, but can also signal an untreated medical problem, a mismatch between demands and ability, a communication failure or a psychiatric disorder. The syndrome changes the differential weighting; it does not make competing explanations disappear. The assessment of psychiatric comorbidity in intellectual disability is addressed in the chapter's discussion of dual diagnosis, and the general assessment framework belongs in the Child psychiatry: assessment, treatment, services and protection notes.

- Describe the behaviour precisely before naming it as syndrome-related.
- Establish what has changed from the person's own baseline and what has changed around them.
- Look for the linked behavioural cluster, not an isolated headline symptom.
- Use the formulation to anticipate risk and support needs without attributing blame.

This approach matters to families. A **strong behavioural phenotype** describes a vulnerability that may be evident even in a supportive environment. In such situations, parents and teachers who have worked hard should not be invited to conclude that the behaviour proves a failure of care. The right message is more exact: environment still matters greatly for safety, distress and functioning, but it may not fully remove a syndrome-linked vulnerability.

The historical literature illustrates why this caution is necessary. Reviews in the 1970s discussed only **five** chromosomal syndromes in this context. The concept has since become clinically richer, but a larger catalogue does not make its inferences categorical. The contemporary task is to be specific enough to notice a pattern and humble enough not to overread it.

13.3 Cross-syndrome signatures: a working comparison

The table is a pattern-recognition aid, not a diagnostic algorithm. It deliberately pairs the most discriminating feature with the clinical caution that prevents overclaiming. Several entries contain symptoms that are common in many people with intellectual disability; their value comes from the surrounding phenotype.

SYNDROME	USEFUL BEHAVIOURAL OR COGNITIVE SIGNATURE	CLINICAL READING
Down syndrome	Relative strength in social communication, with a wide variety of behaviour.	Do not replace assessment with the old "very sociable" personality stereotype.
Fragile X syndrome	Gaze aversion, shyness, social and performance anxiety, social withdrawal and hyperarousal, often with attention and activity difficulties.	Social avoidance can coexist with interest in others and must not be equated automatically with autism.
Prader-Willi syndrome	Hyperphagia with food seeking, foraging or hoarding, and lifelong food preoccupation.	Food access and supervision are central environmental issues, while the wider formulation must also consider distress and routine.
Angelman syndrome	Episodic paroxysmal or inappropriate laughter with absence of speech.	The apparently happy expression should not conceal major communication needs.
Williams syndrome	High, sometimes indiscriminate sociability with reduced social flexibility.	Warm approach behaviour can coexist with poor peer relationships, anxiety and vulnerability in unfamiliar social settings.

SYNDROME	USEFUL BEHAVIOURAL OR COGNITIVE SIGNATURE	CLINICAL READING
Smith-Magenis syndrome	Severe self-injury, disruptive or aggressive outbursts, tantrums and hyperactivity.	Ask specifically about sleep, because disturbed sleep can amplify daytime behavioural difficulty.
Cri-du-chat syndrome	High-pitched cat-like cry in infancy.	This is an early developmental clue; later assessment should address language, attention and activity rather than treating the cry as a complete phenotype.
Lesch-Nyhan syndrome	Severe self-injury, typically compulsive biting of fingers and lips.	Its form and apparent compulsion make this a high-priority safety phenotype.
22q deletion syndrome	Childhood ADHD, autistic features and mood swings, with an important later psychosis vulnerability.	Developmental and psychiatric surveillance must extend across developmental transitions.
Rett syndrome	Loss of purposeful hand skills, replaced by stereotyped hand wringing and clapping.	The course and the exact hand phenomenology matter more than the label “stereotypy”.
Cornelia de Lange syndrome	Self-injury, autistic features and pleasurable responses to vestibular stimulation.	Communication may be disproportionately impaired relative to adaptive function, which should shape the formulation.

Attentional problems demonstrate the point about shared symptoms: they are frequent in fragile X, Williams and cri-du-chat syndromes. They are therefore clinically important but not syndrome-specific. By contrast, relatively characteristic forms include the unusual hand behaviour in Rett syndrome and extreme hyperphagia in Prader-Willi syndrome. An examination answer is stronger when it says whether a feature is shared, relatively specific or simply one component of a wider pattern.

13.4 The phenotype is often richer than its headline feature

The classic “Down personality” stereotype is difficult to verify. A safer clinical account is that Down syndrome has a relative social-communication strength and a broad behavioural range. It is also associated with less frequent and less severe psychopathology than in other groups with intellectual disability, while still requiring ordinary clinical vigilance. In later life, the phenotype includes high rates of dementia or Alzheimer disease in middle-aged to late adulthood. The teaching point is not that people with Down syndrome are protected from psychiatric problems; it is that group-level tendencies should never flatten individual presentation.

Fragile X syndrome is often recognised through its anxious, avoidant social style. In full-mutation males, the tabled phenotype also includes anxiety, perseverative language, an ADHD-like presentation, aggression, stereotypies and ASD-like behaviours. Yet men with fragile X syndrome are usually affectionate and lack the aloof quality typical of autism, despite social impairment.

This is a useful discriminator, not a rule that excludes autism. It directs the clinician to observe the quality of social engagement rather than inferring it from gaze aversion alone.

The food phenotype of Prader-Willi syndrome extends beyond hunger. Skin-picking, hoarding, concerns with symmetry, exactness, ordering, cleanliness and sameness, tantrums, aggression, stubbornness, underactivity and emotional lability may form part of the behavioural picture. Sleep also deserves active enquiry: excessive daytime sleepiness with sleep-architecture abnormalities can contribute to apparent inattention, irritability or reduced participation. The assessment should separate an environmental response to restricted food access from a mood, anxiety or behavioural disorder, while recognising that these may coexist.

In Angelman syndrome, laughter is only the opening clue. Other observed features include overactivity with short attention span, enjoyment of social and physical contact, mouthing objects and fascination with water. The older label “happy puppet” arose from a particular combination of nonverbal presentation, ataxia, frequent laughter and flexed arms. It may help recall the history, but it is not respectful shorthand for the person’s needs. The clinically relevant point is severe to profound intellectual disability with absence of speech, requiring an active search for nonverbal communication and distress signals.

Williams syndrome is another corrective to superficial impressions. It may show loquaciousness with “cocktail party manners” and a relative strength in language, auditory processing and music alongside poor visuospatial performance. However, friendliness may coexist with anxiety, including specific phobia and generalized anxiety. Treating verbal fluency as evidence of social comprehension is the trap. The person may initiate readily yet struggle with reciprocal flexibility, boundaries or sustained friendships.

13.5 Self-injury, stereotypy and sleep: read the mechanism before the behaviour

Self-injury is a description, not an explanation. Its diagnostic and safety significance depends on form, function and context. Lesch-Nyhan syndrome illustrates a highly characteristic pattern: stereotypic dystonic movements and self-mutilation of fingers, lip biting and other self-injury occur unless the individual is restrained. This is not interchangeable with all self-injury in neurodevelopmental conditions. It should prompt urgent attention to tissue protection, pain, oral injury, family burden and specialist coordination.

In Rett and Cornelia de Lange syndromes, self-injury may arise secondarily from hand-to-mouth stereotypies. The mechanism matters because it changes the clinical questions: is the injury a direct repetitive motor act, a response to distress, a communication of pain, or an outcome of a hand-to-mouth movement? The same visible lesion may therefore require very different prevention plans.

Contrasting source lists make a useful methodological warning. The DSM-5-TR names Lesch-Nyhan, Rett, fragile X, Cornelia de Lange and Smith-Magenis syndromes as examples of neurogenetic disorders with stereotypies. Another source instead names Cornelia de Lange, fragile X, Smith-Magenis, cri-du-chat and Rett syndromes in relation to stereotypic movements and self-injurious behaviour. Neither list should be treated as an exclusion list. They illustrate

overlapping clinical territory, while the detailed phenotype supplies the discriminating information.

Smith-Magenis syndrome is especially instructive because its phenotype links daytime behaviour and sleep. Alongside self-injury and outbursts, a **self-hug** can be a useful signature gesture, and the sleep problem may include absence of REM sleep. The reported disruption of melatonergic control of the sleep cycle provides a plausible bridge between sleep management and behavioural or cognitive functioning. This is not an invitation to prescribe from a syndrome name; it is a reminder that sleep assessment may be central rather than incidental.

MNEMONIC

PATTERN before label

Precise form, **A**ntecedents, **T**rajectory, **T**riggering pain or sleep problem, **E**ffect on function, **R**elated syndrome features, **N**eeds and safety.

13.6 Developmental trajectories and later psychiatric risk

Some phenotypes are defined as much by change over time as by a single behaviour. In Rett syndrome, loss of hand skills occurs with language regression, communication deficits, social withdrawal, hyperventilation or breath-holding, bruxism, sleep irregularities and some autistic symptoms. The early withdrawal should not be read as a fixed autism phenotype: socialization may later improve, with intense eye gaze in many patients. Rett syndrome itself is considered in the regression discussion elsewhere in this chapter; here, its course demonstrates why a behavioural phenotype must be longitudinal.

For 22q deletion syndrome, the crucial temporal pattern is a childhood developmental and behavioural presentation followed by risk of psychosis in adolescence or adulthood. About **25%** develop schizophreniform psychosis. At the same time, no other single risk factor is so strongly associated with psychosis. These findings belong together: striking association does not imply universal penetrance.

nearly 100%	~25%	up to 30%
OBESITY RISK IN PRADER-WILLI SYNDROME WITHOUT AGGRESSIVE DIETARY INTERVENTION	SCHIZOPHRENIFORM PSYCHOSIS IN 22Q DELETION SYNDROME	MAJOR PSYCHIATRIC ILLNESS IN VELOCARDIOFACIAL SYNDROME

The final statistic measures a broader outcome. In velocardiofacial syndrome, up to **30%** develop major psychiatric illness, a category that includes schizophrenia and bipolar disorder. It must not be substituted for the figure for schizophreniform psychosis. This is a classic exam error: the number may be familiar, yet the construct and denominator are wrong. Anticipatory follow-up should therefore ask about emerging psychotic and affective symptoms without assuming that developmental or autistic features are their explanation.

13.7 Communicating the formulation without blame or fatalism

A syndromic formulation can be relieving when it gives a family language for a pattern that had previously been interpreted as wilfulness, poor parenting or inevitable deterioration. It should be

communicated as a vulnerability profile: “this condition makes this cluster more likely; we will look carefully at it and address what is modifiable.” That preserves realism and agency. It also makes room for strengths, relationships and the person’s own preferences, which a list of syndrome behaviours can easily erase.

GOOD TO REMEMBER

Use the phenotype to organise monitoring, environmental support and safety planning. For a food-related phenotype, explore access, supervision and conflict around food. For self-injury, define the topography, injuries, pain and immediate safeguarding needs. For a sleep-related phenotype, obtain a sleep history before interpreting daytime behaviour as purely psychiatric. For social disinhibition or withdrawal, assess vulnerability, consent, peer context and anxiety. These are clinical applications of the phenotype, not a generic management programme.

Be precise when discussing uncertainty. “Characteristic” does not mean inevitable; “shared” does not mean trivial; and “not specific” does not mean unimportant. The most defensible clinical note describes observed behaviour, names the syndrome-linked hypothesis, records alternative explanations and states what will be monitored. This reasoning protects the person from diagnostic overshadowing as well as from ignoring a syndrome-specific safety signal.

Must remember: A behavioural phenotype is a raised probability of a characteristic developmental or behavioural pattern, not genetic predestination. Read the whole cluster, its course and its context - then use it to anticipate needs without stereotyping the individual.

Living with intellectual disability

14 · Comorbid psychiatric disorders in ID (dual diagnosis)

Dual diagnosis is ordinary psychiatry, adapted rather than abandoned. In intellectual disability (ID), a psychiatric disorder may coexist with the developmental condition and must be sought as an additional clinical problem. In this setting, **dual diagnosis** means the coexistence of ID with an identifiable mental illness or personality disorder. The phrase originated in learning-disability psychiatry, although it has subsequently acquired a different substance-use meaning; state the context whenever using it.

The examination task is not to label every difficult behaviour as illness, nor to excuse illness as inevitable in ID. It is to establish whether there has been a meaningful change from the person's usual functioning, determine the function and context of that change, exclude physical and environmental explanations, and then decide whether a psychiatric syndrome is present. This is clinically consequential because communication differences can alter both the account available to the clinician and the outward form of distress.

3-5-fold	40%	9-18%
RELATIVE RISK OF ANY PSYCHIATRIC DISORDER	AROUND CUMULATIVE PREVALENCE	ESTIMATED ADHD IN ID

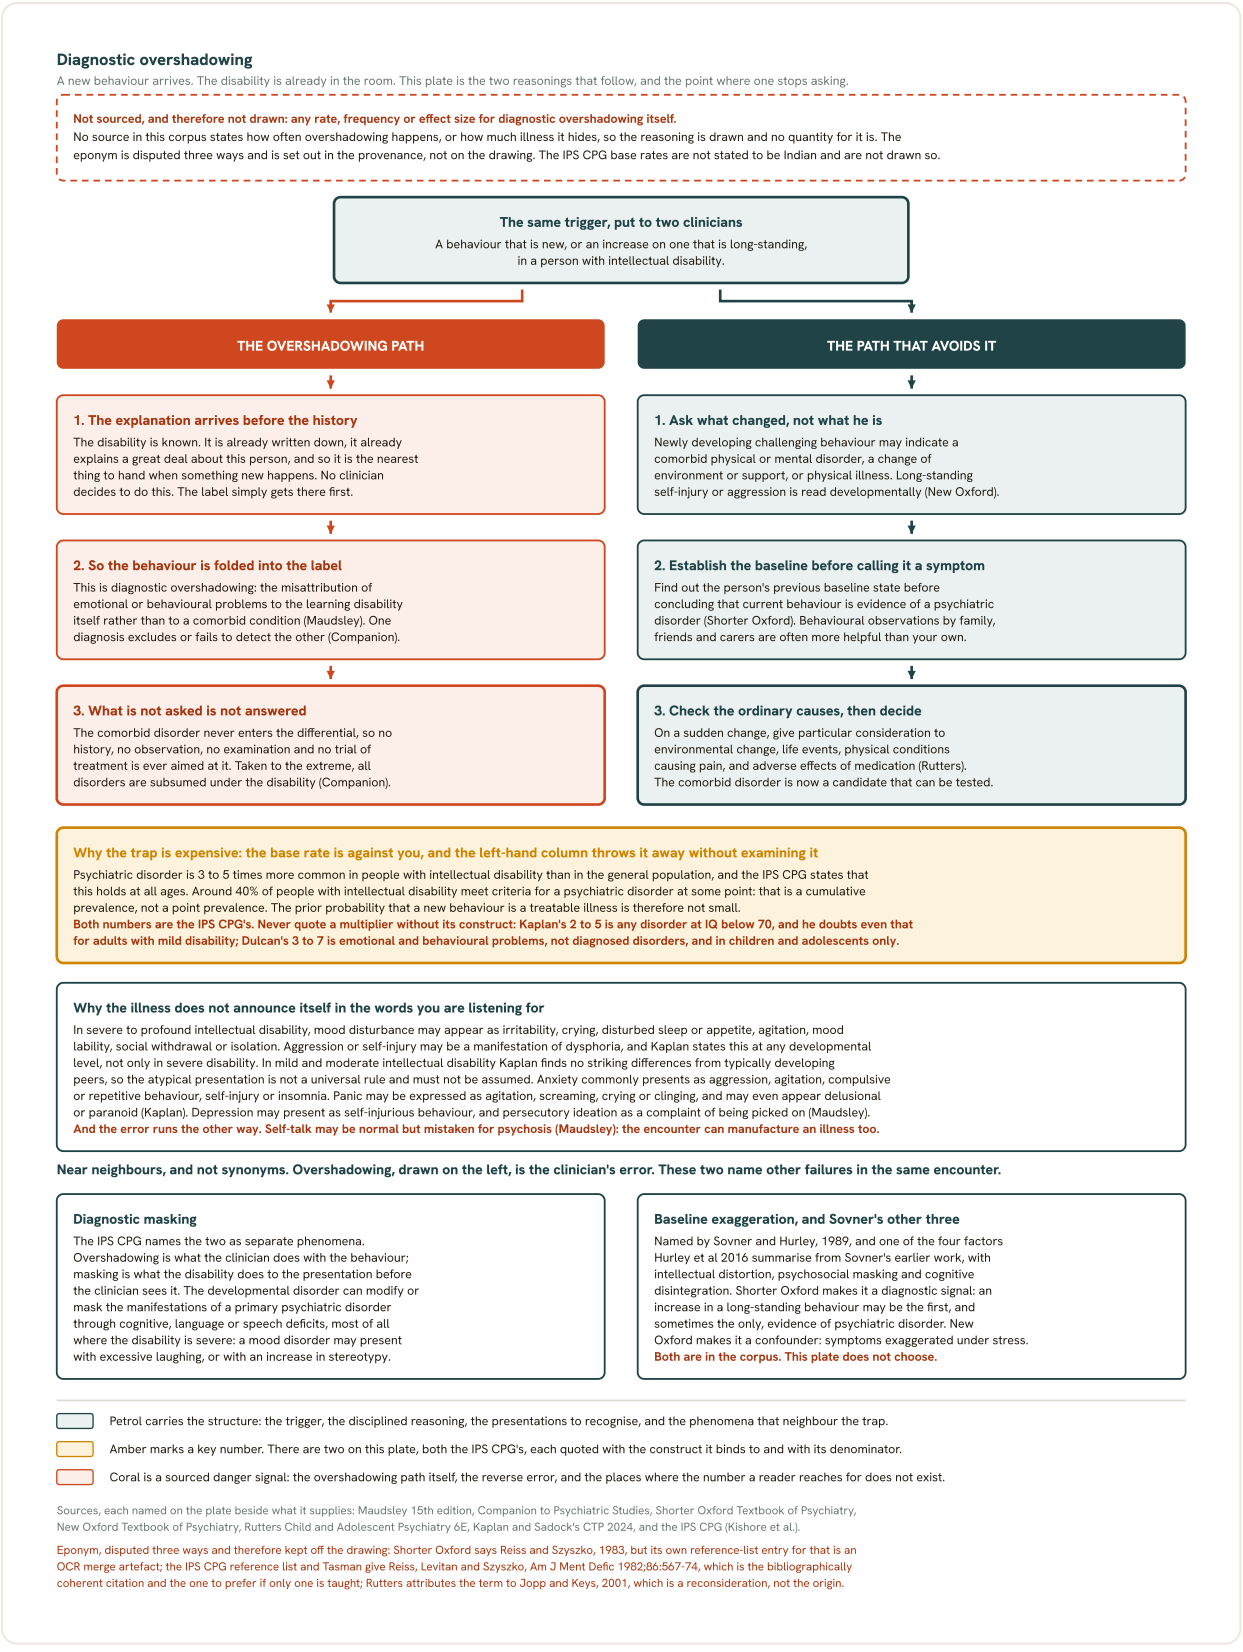

Fig 21.12 Diagnostic overshadowing, drawn as the reasoning it actually is. One trigger, a behaviour that is new or an increase on a long-standing one in a person with intellectual disability, is put to two clinicians, and the plate follows each of them through three steps to a different place. The amber strip is why the error is expensive: on the IPS CPG's figures psychiatric disorder is 3 to 5 times more common in intellectual disability and around 40% meet criteria at some point, a prior probability the left column discards. No rate for overshadowing itself is drawn, because no source in this corpus gives one.

14.1 Burden and the meaning of excess risk

Psychiatric comorbidity is not an occasional complication of ID. Across the lifespan, the relative risk of any psychiatric disorder is **3-5**-fold that in the general population. In children and adolescents, studies similarly report a 3-5-fold excess compared with typically developing peers. These figures should change the clinician's threshold for asking an additional psychiatric question, but not the threshold for making a diagnosis without evidence.

Prevalence estimates differ substantially between studies, with reported values ranging from **10-39%**. The variation is informative: samples differ in age, severity of disability, setting, informants, case definitions, and whether the measure captures a current disorder, symptoms, or cumulative morbidity. A rate is therefore a prompt to assess, not a shortcut to diagnosis. Historical comparisons also remind us that ascertainment matters. In an Isle of Wight comparison, psychiatric disorder was identified in **50%** of children with intellectual disability and in 7% of children with normal IQ.

Risk is unevenly distributed. The severity gradient reported across epidemiological studies means that psychiatric disorder is more often identified with greater intellectual impairment. By contrast, the evidence is less clear for excess prevalence in adults with mild ID. Child and family risk markers include more substantial intellectual impairment, adaptive-behaviour and language difficulties, poor socialisation, and adverse family social circumstances. These are not diagnostic criteria and not explanations that make a person's symptoms less worthy of assessment. A co-occurring autistic spectrum disorder is itself an important risk context for anxiety and depression, bipolar-spectrum presentations, severe obsessional behaviour, anger disorders, and psychosis-like episodes that do not meet schizophrenia criteria.

RULE **Rule:** treat a changed mental state or behaviour in ID as a clinical question with several possible answers, not as proof of either psychiatric illness or developmental disability.

14.2 Diagnostic overshadowing, masking and the baseline

The central diagnostic hazard is **diagnostic overshadowing**: emotional or behavioural problems are attributed to ID itself instead of being considered as a coexisting disorder. At its extreme, the developmental diagnosis becomes so dominant that a second condition is never detected. Overshadowing is a clinician error of attribution. It can lead to a missed depressive episode, psychosis, anxiety disorder, delirium, pain state, or an environmental crisis because the referral is prematurely translated into “part of the disability”.

Diagnostic masking is different. Here, a developmental disorder modifies or obscures the manifestations of a primary psychiatric illness through cognitive, language, or speech limitations, particularly when disability is more severe. The illness has not been dismissed as ID; rather, it is harder to recognise because its usual verbal and phenomenological markers are inaccessible or altered. A mood disturbance, for example, may appear as excessive laughter or an increase in stereotyped behaviours rather than as a verbally reported low mood.

A third concept is **baseline exaggeration**. An increase in a long-standing behaviour may be the first, and occasionally the only, evidence of psychiatric disorder. Thus an established repetitive

act, irritability, aggression, or self-injury should not be dismissed merely because it is familiar. The question is whether its frequency, intensity, setting, consequences, or controllability has changed. The baseline is not background detail. It is the reference point that converts a behaviour into a possible symptom.

TRAP **Examination trap:** "Self-injury in a person with ID" is a presenting problem, not a diagnosis. Do not infer a psychiatric syndrome from the behaviour alone, and do not use the developmental diagnosis to end the enquiry.

PROBLEM IN REASONING	WHAT GOES WRONG	CORRECTIVE CLINICAL MOVE
Diagnostic overshadowing	A new psychiatric or physical problem is assigned to ID.	Ask what is new, then actively consider coexisting illness.
Diagnostic masking	The primary disorder has an altered, less verbal presentation.	Use behaviour, chronology, and informants alongside the interview.
Baseline exaggeration	A familiar behaviour is treated as clinically meaningless.	Compare current frequency, intensity, context, and impact with baseline.
Intellectual distortion	Answers to mental-state questions are overinterpreted.	Adjust language and seek corroboration rather than forcing adult phenomenology.
Psychosocial masking	Developmental symptom expression is mistaken for mental illness.	Interpret the observation in developmental context before diagnosing.
Cognitive disintegration	Acute disorganisation is equated immediately with chronic psychosis.	Assess for an evolving illness, stressor, physical cause, and change in supports.

14.3 Why the mental-state examination needs translation

Increasing severity of ID and associated communication impairment make diagnosis more complex. This does not imply that psychiatric diagnosis is impossible. It means that the clinician must translate the clinical question from a reliance on subjective report to a synthesis of observable behaviour, longitudinal change, collateral history, environmental context, and the person's own communication at their best level.

One useful framework describes **four** sources of diagnostic uncertainty: baseline exaggeration, **intellectual distortion**, **psychosocial masking**, and **cognitive disintegration**. Intellectual distortion concerns how the person understands a question about mental state and whether its implication can be appreciated. Psychosocial masking, in this formulation, describes developmental symptomatology that is misconstrued as mental illness. Cognitive disintegration describes disproportionate disorganisation during an emerging mental illness when cognitive reserve is limited, which can make the person look apparently psychotic. These are prompts for better assessment, not alternative diagnoses.

Behavioural equivalents are particularly important when verbal description is limited. In severe to profound ID, mood disturbance may be signalled by irritability, crying, dysregulation of sleep or appetite, agitation, mood lability, withdrawal, or isolation. Aggression or self-injury may express dysphoria at any developmental level, but neither is specific to mood disorder. Anxiety may present with aggression, agitation, compulsive or repetitive behaviour, self-injury, or insomnia. Panic may appear as agitation, screaming, crying, or clinging and may even look paranoid or delusional to an unwary observer.

Conversely, unfamiliar does not mean pathological. Self-talk can be a normal behaviour that is mistaken for psychosis. A complaint of being picked on may be the accessible form of persecutory ideation, but it also needs ordinary contextual testing. The task is phenomenology by approximation: ascertain what the person experiences where possible, establish what others observe, and decide whether the whole pattern forms a syndrome over time. In mild to moderate ID, mood disorders do not show striking differences in expression from those of typically developing peers; do not exoticise a presentation simply because ID is present.

14.4 A disciplined assessment sequence

Begin with change, not with labels. Assessment begins with the individual's baseline and interprets change with collateral information, behavioural observation, and context.

> **GOOD TO REMEMBER**
>
> Before treating current behaviour as psychiatric evidence, establish the person's previous baseline state. Family, friends, and carers often provide observations more useful than the brief assessment encounter. Use the interview alongside a period of behavioural observation. From first contact, consider approach, activity level, attachment to the informant, response to transitions, spontaneous communication, affective range, and reaction to demands against that baseline.

Build the history around the following dimensions rather than around a checklist of adult symptoms:

- onset and chronological evolution of the change;
- intensity and frequency of the behaviour or symptom;
- the context in which it appears and what follows it;
- precipitating factors, including changes in relationships, routine, supports, or expectations;
- relieving factors and the response to ordinary environmental adjustment.

This sequence gives the history a causal structure. Newly developing challenging behaviour can indicate a comorbid physical or mental disorder, an environmental or support change, or physical illness. Long-standing self-injury or aggression is more often understood developmentally or behaviourally. When change is sudden, give particular consideration to environmental changes, life events, painful physical conditions, and medication adverse effects. In the most disabled person with sensory deficits, exclude physical illness and stressful events before considering whether communicative frustration and understimulation are contributing.

Antecedent-Behavior-Consequences analysis is a functional method for clarifying what precedes a behaviour, what the behaviour achieves, and what consequences may maintain it. It is not a substitute for diagnosis. It prevents a false dichotomy: a psychiatric disorder can coexist with behavioural reinforcement, and a behaviour with an understandable function can still be an expression of distress. Prospective simple ABC or sleep charts are particularly useful when the care environment produces discrepant staff reports, since variation may reflect differing tolerance thresholds or attributions.

> The most reliable discriminator is a documented departure from the individual's own baseline, interpreted with collateral observation and context.

14.5 Disorder patterns: recognise without overcalling

Detection of psychiatric syndromes in ID is shaped by communication, developmental level, and context. Schizophrenia should be diagnosed from a coherent longitudinal syndrome rather than from odd behaviour, self-talk, or a single report of suspiciousness. In a community sample of people with learning disability, point prevalence of schizophrenia was **over 4%**. Among people with learning disability and schizophrenia, auditory hallucinations are reported in around 90%; this is helpful when a reliable account can be obtained, but its absence or inaccessibility cannot settle the diagnosis.

Attention-deficit/hyperactivity disorder is also relevant: estimated prevalence among people with ID is 9-18%. The core diagnostic safeguard is developmental proportionality. Symptoms must be excessive for the person's mental age, and the threshold should be higher in severe to profound ID. Inattention, overactivity, impulsivity, poor frustration tolerance, and a chaotic environment can mimic each other. The clinician should seek a pervasive pattern rather than equating high activity in one setting with ADHD.

Anxiety estimates vary widely, from 1-25%, in part because diagnosis is difficult. This is a reminder to search for anxiety when distress is expressed behaviourally, not a basis for diagnosing it indiscriminately. Mood symptoms require the same restraint. Appetite and sleep change, social withdrawal, loss of usual enjoyment, tearfulness, agitation, or altered stereotyped behaviour gain significance when they are new, clustered, sustained, and not better explained by pain, medication, or altered circumstances.

TRAP **Examination trap:** do not diagnose psychosis from self-talk, depression from self-injury, or ADHD from activity level without establishing change, phenomenology, developmental proportionality, and context.

14.6 Instruments and adapted diagnostic systems

Questionnaires and structured interviews designed for children of average ability have a serious norming limitation in ID: almost none are normed for ID populations, and their scores or cut-offs may therefore be invalid. They may inflate symptoms or underestimate them depending on the setting. Use them as aids to gathering information, never as a rule-in or rule-out mechanism. This caution does not mean that all measures are unsuitable. The **Developmental Behavior**

Checklist is comprehensive and provides norms and subscales for the ID population, making it particularly useful where general-population measures fit poorly.

The clinical interview, observations, informant account, and functional data must retain primacy. ID-specific instruments may identify general psychopathology, yet studies do not show clear agreement between such instruments in detecting specific psychiatric disorders. A positive screen should trigger a more focused assessment; a negative screen should not override a persuasive longitudinal history. This is why an apparent numerical score is less important than the quality of the behavioural description from which it arose.

Modified diagnostic systems can support clinical reasoning where conventional criteria rely heavily on subjective experience or developmentally inappropriate thresholds. **DC-LD** was developed to address diagnostic issues in moderate to severe learning disability. **DM-ID** is another adapted diagnostic resource. Such systems do not create a separate psychiatry for ID; they make explicit the adaptations required to apply psychiatric nosology fairly. For eating disorders whose criteria depend substantially on subjective experience, conventional diagnoses such as anorexia nervosa and bulimia are effectively precluded in severe or profound ID. Pica is perhaps the most common eating disorder in this population.

14.7 Formulation and diagnostic accountability

A defensible formulation has parallel tracks. One track describes the person's developmental profile and baseline repertoire. A second describes the current change in behaviour, affect, cognition, biological rhythm, and functioning. A third examines physical illness, pain, sensory impairment, epilepsy, medication effects, interpersonal stress, care environment, and reinforcement contingencies. A fourth asks whether the data support a psychiatric syndrome, and if so what evidence distinguishes it from the alternatives. Writing these tracks separately prevents the developmental diagnosis from swallowing the entire formulation.

Behaviour that challenges has person-specific associations, including male sex, lower adaptive functioning, poorer communication, autism, and painful physical conditions. Unlike oppositional defiant or conduct disorder, it is not associated with family adversity. This distinction guards against importing a formulation from typically developing populations without testing whether it fits. Similarly, a psychiatric presentation may coexist with environmental contingencies; neither cancels the other.

Carefully document the source of every observation, the degree of confidence in the person's self-report, baseline evidence, collateral agreement or disagreement, and the physical and environmental exclusions considered. This makes diagnostic reasoning reviewable and protects against therapeutic drift toward medication for an unclearly defined target. Management of ID itself, including multidisciplinary support and educational planning, is addressed in the management section of this chapter. The full child psychiatric assessment battery, services and protection are covered in the Child psychiatry: assessment, treatment, services and protection notes.

Formulation should also preserve the person's perspective. A carer's account may be essential, but it should not replace direct engagement with the person. Adapt the pace, language, and mode of communication; allow time for response; and test important inferences gently rather than relying on a single answer. The purpose is not to force adult verbal psychopathology into a developmentally mismatched interview. It is to make the available evidence as fair, transparent, and clinically useful as possible. Where uncertainty remains, state it explicitly, define what further observation would discriminate between competing explanations, and avoid converting uncertainty into a confident label.

The practical standard is neither diagnostic minimalism nor diagnostic enthusiasm. It is intellectual humility with enough structure to notice a second disorder. When the pattern, chronology, collateral history, and context converge, people with ID deserve the same diagnostic seriousness afforded to anyone else.

15 · Management of ID (multidisciplinary, early intervention, special education)

Management is the organisation of opportunity. Intellectual disability is not managed by a single clinic, a prescription, or a school placement in isolation. The clinical task is to turn an assessment of abilities, barriers, health and family circumstances into a coherent plan that improves participation and preserves dignity. This makes management a longitudinal exercise: the clinician must help the person acquire useful skills, reduce avoidable barriers, respond to mental or physical illness when present, and keep the family able to continue caring.

Marks are usually earned by showing this architecture rather than by naming a succession of therapies. A good answer begins with coordinated goals, places early intervention and education within the person's everyday settings, explains how behaviour is understood before it is treated, and recognises that medical treatment has a limited, target-led role. Severity should be named only as a descriptor of support need; its classification belongs with the assessment and severity sections of this chapter.

15.1 The multidisciplinary plan

Multidisciplinary care is the appropriate treatment model because intellectual disability has biological, psychological, social and developmental consequences at the same time. It is therefore multimodal: psychoeducation, psychological work and medication, where indicated, are coordinated rather than offered as competing alternatives. The plan also has to restore wellbeing within the family system. In practice, the psychiatrist's distinctive contribution is diagnostic clarification, assessment of mental and physical contributors to change, risk formulation, judicious prescribing, and helping the team keep a shared hierarchy of goals.

The team should not be imagined as a referral list. Its work is to translate a common formulation into actions that can actually happen at home, in education, and in the community. For optimal management, coordination includes at least six disciplines, including psychiatry, psychology, occupational therapy, speech and language therapy, genetic counselling and nursing. This is not an exhaustive job description. It illustrates why a locally available team should be assembled around the person's needs rather than around an idealised service chart.

RULE **Rule:** Start with shared functional goals, then assign one accountable person for coordination; referrals without a joint plan merely move fragmentation from one service to another.

SERVICE FUNCTION	CLINICAL PURPOSE	WHAT COORDINATION PREVENTS
Prevention and prompt recognition	Identify needs before they become fixed barriers to development or participation.	Late referral after family strain or school failure has already escalated.
Strengthening family capacity	Make everyday care, communication and goal-setting possible.	Advice that is technically sound but impossible to sustain.
Learning and productive roles	Build participation and future roles around meaningful skills.	Care that remains custodial when the person can learn more.
Health and mental-health care	Address health needs and emotional or behavioural presentations without diagnostic overshadowing.	Attributing a new problem automatically to the disability.
Living support and self-care	Match support to real-world functioning and safety.	Discharge plans that fail because ordinary living demands were ignored.

The level of specialist involvement should follow complexity. Mainstream mental-health services may prescribe for mild or borderline intellectual impairment, while assessment and treatment of behavioural or emotional disorders in more marked or atypical cognitive impairment should be undertaken with specialist clinical input. This is a service-triage principle, not a claim that a mainstream clinician should work alone when communication barriers or atypical presentation make assessment uncertain.

Family work is clinical work. Families need an explanation that can be revisited, not a single overwhelming disclosure. Parents may require repeated discussion before the implications can be absorbed; the clinician should return to prognosis, available help and the family's active role as understanding changes. Family support must be individualised to the caregiving burden and its meaning for that particular household. Parents and primary caregivers should also be routinely screened for stress-related disorders. This is not a courtesy add-on: depleted carers have less capacity to implement a plan, and their distress deserves treatment in its own right.

15.2 Early intervention as a developmental service

Early intervention begins before a child has entered an educational system. The Indian guideline permits a starting point from the prenatal period, with recognition of high-risk pregnancies, appropriate health care and attention to psychosocial adversity. After birth, the plan is not simply stimulation exercises. It begins with accurate identification of developmental and associated needs, then creates opportunities for sensory-motor, communication and socioemotional development in the child's ordinary relationships and routines.

The central relational mechanism is healthy bonding and attachment between the child and mother. The practical implication is important: early stimulation can also be delivered by any

stable caregiver. Programmes should stabilise current developmental achievements while opening the next achievable task. Play-based work and culturally rooted early-child-care practices are often more usable than imported materials; when materials are inaccessible or culturally mismatched, parents can become overwhelmed and the programme loses its place in daily life.

Evidence supports a measured, not triumphalist, account. **Family-centred intervention** can be effective, but uncertainty remains about the active components and how help is best delivered. This is why the clinician should set observable functional goals and revise them with the family, rather than promise a uniform developmental result. One intensive compensatory-education experience illustrates both the possibility and the limits of inference: teaching began at 3 months; at a later preschool assessment the intervention group had a mean advantage of 27 IQ points over controls. The finding does not prove a durable individual IQ gain, and its design limitations matter. Its defensible teaching point is that sustained, skilled effort with socially disadvantaged families can make a meaningful difference.

3 years	3-6	6-18
INITIAL LEARNING PHASE	SCHOOL-READINESS PHASE	CONSOLIDATION PHASE

A life-span skill plan has three **developmental stages**. In the initial years, work addresses sensory-motor ability, socio-communication, basic self-help and concepts. The subsequent school-readiness period emphasises readiness skills and culturally appropriate adaptive behaviour. Later childhood and adolescence consolidate academic and independent personal skills in preparation for vocational training, employment and adult living. These are organising priorities, not rigid age-based ceilings. The immediate task is always to find the skill that will increase autonomy in the child's own context.

IN INDIA

For formal early intervention in India, referral can be made to the District Early Intervention Centers of the Rashtriya Bal Swasthya Karyakram and the Anganwadi Centers of the Integrated Child Development Services. The referral should carry a concise developmental formulation and the family's priorities, so that the service encounter becomes part of a continuing plan rather than a one-time certification exercise.

The clinical details of normal milestones and attachment are covered in the Normal child development and milestones notes.

15.3 Education, participation and placement

Normalization is the guiding principle of arranging a pattern of life as close to ordinary life as possible, supported by specialist help that allows the person to reach potential. It directs attention away from segregation as a default and toward family life, community participation, education, work and self-advocacy. It does not mean pretending that support needs do not exist. Normalisation becomes clinically useful only when the necessary teaching, communication support, supervision and environmental adjustments are actually provided.

Placement is a clinical and ethical judgement. Ordinary-school education may offer more normal social surroundings, social integration, expectation of progress and learning for peers that participation is ordinary. It may also lack the teaching skills, equipment and methods required by some learners, particularly where specific language and communication teaching is needed. The evidence cited here does not settle which children benefit from ordinary schooling. Therefore, do not turn inclusion into a slogan or special education into a failure. Consider the child's learning needs, social experience, available supports and family preference, then review the placement when the fit changes.

TRAP **Exam trap:** "Mainstream" and "beneficial" are not synonyms. Educational inclusion without the support needed to learn or remain safe is not meaningful participation.

The ethical tension is real. In secondary schools, children with special needs were reported to be bullied **three times more often** than other children. This should prompt active safeguarding and a discussion of the individual child's present interests, not a simplistic conclusion that community education is always unsafe. At a service level, a systematic review found better outcomes with community-based services than with institutional care. The practical inference is to design community support well, monitor the child's experience, and address exclusion rather than treating it as inevitable.

Education should be functional. Literacy, numeracy, communication, self-care and social learning have value insofar as they enlarge the person's choices in daily life. At the end of school, reassessment and vocational guidance are necessary before a young person is expected to make an adult transition. Opportunities should be ambitious but realistic, and should not be narrowed merely because others hold limited expectations. The fuller approach to disability certification, benefits and statutory entitlements belongs in the disability certification and benefits section of this chapter.

15.4 Behavioural formulation before behavioural control

Behaviour that challenges is a question, not a diagnosis. Its onset or worsening should lead first to a search for communication difficulty, environmental demand, reinforcement, health problems and mental disorder. A **comprehensive personalised functional assessment** considers behaviour in its setting and improves the chance of a plan that can be managed psychologically and environmentally. It can consequently reduce, and sometimes remove, the need for psychotropic medication.

Functional behaviour analysis asks what consequence may be maintaining the behaviour. Challenging behaviour may serve three functional classes: obtaining a social positive reinforcer such as attention, escaping a demand through social negative reinforcement, or obtaining sensory reinforcement. These possibilities are hypotheses to test against observation, not labels to attach from a brief history. Parents, teachers and other caregivers are indispensable informants because they see the antecedents and consequences that a clinic visit cannot reproduce.

The behavioural plan should be least intrusive and culturally appropriate. The Indian guideline describes **three** linked levels: restructure the environment to alter antecedents, reinforce adaptive behaviour differentially, and prevent inappropriate reinforcement of problematic behaviour. Its basic premise is functional substitution. If a problematic behaviour communicates a need, the plan must create and reinforce a socially acceptable behaviour that serves the same function. Suppression alone leaves the original need unanswered and is likely to fail once the therapist has left.

- Define a small number of observable target behaviours in the settings where they occur, and prioritise those causing exclusion, stigma or interference with learning.
- Record antecedents, behaviour and consequences with carers, then decide which maintaining contingencies are plausible.
- Teach and reinforce an adaptive alternative that achieves the relevant function more safely.
- Change environmental triggers and caregiver responses together, then review whether the person's participation has improved.

Positive behavioural support is a useful framework because it combines reinforcement with changes to triggers, minimal use of aversive strategies and planned reactive responses such as distraction. Its components should not be applied as a menu of techniques. Selection follows the formulation. Techniques using negative reinforcement should not be used. A discipline-heavy behaviour programme is best developed and implemented by a behavioural psychologist or board-certified behavioral analyst, although psychosocial interventions delivered by non-specialist carers can produce better outcomes than no treatment or treatment as usual. In settings with few specialists, this supports task-sharing with supervision and training, not abandonment of formulation.

15.5 Medication stewardship and specialist liaison

GOOD TO REMEMBER

Medication treats a defined target symptom, coexisting mental disorder or physical contributor; it does not replace a formulation of behaviour. **Psychological intervention**, including functional behavioural analysis, should be considered first-line when no identifiable mental illness with clear treatment implications is present, except in the most serious or intractable behavioural disturbance. The same discipline applies when diagnostic information is inadequate: try psychosocial intervention before converting uncertainty into a prescription.

Antipsychotics remain the most widely prescribed psychotropic class in intellectual disability, yet their current positioning is as a later option for older children or adults when intensive behavioural intervention or other medication options have failed. This apparent contradiction is a warning about service reality, not a reason to disregard behavioural care. A functional formulation may reveal a modifiable trigger that makes medication unnecessary, whereas a clear psychiatric syndrome or severe risk may require simultaneous medical treatment and behavioural support.

When a dopamine antagonist is considered for behaviour that challenges, the NICE guideline NG11 identifies **three** alternative qualifying circumstances: psychological or other intervention alone has not changed the behaviour within an agreed time, treatment of a coexisting mental or physical problem has not reduced it, or risk is very severe. These are alternatives, not a checklist in which every condition must be met. Once medication is begun, prescribe the lowest possible dose and reassess whether continuation remains justified after target symptoms improve, when there is non-response, or when adverse effects affect functioning or quality of life.

> The management sequence is: clarify function and illness, strengthen environmental and behavioural supports, prescribe only for a defined target, and keep asking whether the drug is still needed.

Deprescribing needs the same care as initiation. The NICE guideline NG54 suggests slow withdrawal of antipsychotics for people without psychotic symptoms. This does not mean that withdrawal is consequence-free: discontinuation studies commonly, though not invariably, show re-emergence of problem behaviours. The appropriate response is preparation, monitoring of the original target behaviour, and readiness to revise environmental support, rather than assuming either that every drug must continue or that every drug can be stopped without difficulty. The UK STOMP programme promotes antipsychotic deprescribing but also shows a crucial pitfall: an antipsychotic may be replaced by another psychotropic rather than reducing overall medication burden.

Drug choice for a diagnosed condition may in general resemble practice in the wider population, but good prescribing practice is to start at lower doses and increase more slowly. This distinction resolves an apparent contradiction between using standard treatments and being more cautious in a person who may have communication barriers, neurological vulnerability or difficulty reporting adverse effects. A review should document the target symptom, benefit, adverse effects, family observation and whether non-drug supports remain active. Annual health checks are generally recommended for people with intellectual disability; they are health surveillance, not a substitute for medication review whenever treatment changes.

15.6 Continuity into adult life

Management succeeds when it survives transitions. A community-care model is judged less by its label than by the detail of planning and the commitment with which it is carried out. Planning needs both an understanding of the local population and an individual account of what this person can do, wants to do, and needs help to do. A named coordinator can prevent families from receiving inconsistent advice across health, education, social and voluntary-sector services.

Families often need additional help at puberty and school leaving; moving from child to adult services can be especially stressful. These periods should trigger anticipatory planning rather than a crisis referral. Reassessment and vocational guidance before school leaving protect against the common drift from education into inactivity. For school leavers with mild intellectual disability, vocational planning may lead to ordinary or sheltered work; adults with severe

disability are more likely to need the support of a day centre. The point is not to predict a person's future from a label, but to plan enough support for a real adult role.

Referral and linkage in India should map the person's needs to education and vocational routes, rehabilitation centres, national institutes and local nongovernment agencies. Whenever possible, link the family to agencies in their locality so that rehabilitation costs and travel do not quietly defeat the plan. The clinician should retain a longitudinal role: explain the plan repeatedly, detect emerging health or psychiatric problems, coordinate with the relevant team, and protect the person's right to participate in family and community life.

16 · Prevention of intellectual disability

Prevention is a life-course clinical task. Prevention of intellectual disability is not a promise that every case can be avoided. It is the organised reduction of preventable risk before conception, during pregnancy and birth, through the newborn period, and after disability is recognised. The examination value of the topic lies in distinguishing prevention of a condition from prevention of avoidable functional disadvantage once a person already has intellectual disability. A good answer therefore shows a framework, gives a few high-yield examples at the correct level, and retains ethical humility.

The field uses several overlapping taxonomies. The most useful approach in an intellectual-disability answer is to state the purpose of the intervention rather than force every programme into a label. Public health measures reduce exposure to risk; screening creates an opportunity for timely action; and habilitative care limits the secondary disabilities that arise when a person's needs are neglected. These are connected steps in one pathway, not competing lists.

16.1 What prevention means in intellectual disability

The conventional framework has **three** categories. **Primary prevention** acts before a disorder develops, so its clinical purpose is to reduce new cases. For intellectual disability, this means combining medical care with public-health, educational and social measures before an avoidable insult has produced disability. The point is causal timing: an intervention is primary when it removes or reduces the exposure before the outcome arises.

Secondary prevention aims to reduce the burden of established disease in the general terminology, but the intellectual-disability application is more clinically practical: recognise a condition that can lead to disability as early as possible and treat it before disability follows. This makes screening meaningful only when a result can lead to confirmation, treatment, counselling or follow-up. A test with no route to action may collect information, but it does not by itself achieve prevention.

Tertiary prevention concerns disability associated with an existing illness. In intellectual disability it is best understood as **habilitation**: helping the person attain the best attainable functioning despite the disability. This includes biomedical and sociocultural work, but it is not a synonym for cure. The target is participation, competence and protection from avoidable loss of function.

RULE **Rule:** Classify a preventive intervention by its intended point of action: before disability arises, while a remediable pathway is still open, or after disability is present to prevent additional functional loss.

PREVENTIVE LEVEL	CLINICAL QUESTION	INTELLECTUAL-DISABILITY APPLICATION	COMMON ERROR
Primary prevention	Can the causal exposure or pathway be avoided?	Genetic counselling, population health, safer pregnancy, nutrition, immunisation and prevention of toxic or traumatic injury.	Calling every antenatal test prevention without asking what action follows, or filing genetic counselling under care that comes after a diagnosis.
Secondary prevention	Can a disorder that may cause disability be found and treated early?	Early recognition and treatment of metabolic conditions or congenital hypothyroidism.	Equating screening with treatment.
Tertiary prevention	How can further functional disadvantage be reduced after disability is present?	Habilitation, education, family support and treatment of comorbid conditions.	Presenting support as an afterthought rather than prevention of secondary disability.

The alternative language of universal, selective and indicated prevention is also useful in public health. Universal work reaches whole populations, selective work addresses groups with increased risk, and indicated work is directed at people with individual evidence of heightened risk. Do not casually equate every use of indicated across classifications. The later Institute of Medicine model, published in 1994, uses indicated intervention for people with early or prodromal symptoms, whereas the earlier approach used it for asymptomatic people identified as higher risk. The boundary between selective and indicated work can be clinically blurred; the safer answer is to state the target population and the reason for intervention.

TRAP **Exam trap:** Primary, secondary and tertiary prevention are not interchangeable labels for antenatal, postnatal and rehabilitation services. Timing matters, but the decisive issue is what the intervention is meant to prevent.

16.2 Primary prevention before and during pregnancy

Primary prevention begins before pregnancy is recognised. Good preconception and antenatal care allows the clinician to identify modifiable risks, improve maternal health and support informed reproductive decisions without converting counselling into coercion. The Indian guideline specifically identifies malnutrition, diabetes, teratogenic drugs and substance use as maternal factors that may be treatable or preventable in subsequent pregnancies. A prior child with intellectual disability should prompt a respectful etiological review and a plan for the next pregnancy, not an assumption of parental fault. That review is where **genetic counselling** belongs, and it belongs here rather than later: the standard account of primary prevention opens with genetic counselling and continues with education of pregnant women about behaviours that may put the fetus at risk, early detection of fetal abnormalities during pregnancy, and good

obstetric and perinatal care. Counselling a couple before a further conception acts on the next pregnancy, so it removes the exposure before the outcome arises, which is the test this section has just set. Reading it as an after-the-fact service, because the conversation happens after a diagnosis in an older child, is the classic misplacement, and naming the primary preventive measures is a canonical examination question whose first answer is this one.

Risk reduction works through ordinary care. Primary measures include prevention of lead poisoning, avoidance of substance exposure during pregnancy, prevention of teenage pregnancy, improved neonatal care and injury prevention such as infant car seats. Prenatal vitamin supplementation is included because it prevents neural tube defects. The phrasing matters: prenatal supplementation should not be inflated into a guarantee against all developmental disorders. Likewise, childhood lead exposure is a risk factor for low IQ and intellectual disability, which supports environmental prevention without claiming that every exposed child will develop disability.

Maternal infections are another preventable pathway. Toxoplasmosis, cytomegalovirus, rubella and herpes are recognised maternal infections associated with infant morbidities that include intellectual disability. Rubella immunisation is therefore an important prevention measure. Prenatal care may begin before conception, including rubella immunisation for women without immunity. Prevention of rhesus sensitisation uses **anti-D antibody**. These examples should be used to show an integrated maternal-health strategy, not as a memorised infection list detached from antenatal care.

Alcohol deserves direct enquiry in all settings where it is accessible. In such societies, alcohol is the leading toxin cause of intellectual disability. Fetal alcohol syndrome has an incidence of **0.5-3 per 1000 births** and may account for as much as 3 percent of all intellectual disability. These are different denominators, and they must not be swapped. Apparent rates also depend on diagnostic practice: use of both physical signs and a history of heavy prenatal alcohol exposure produces lower rates than use of exposure history alone, with underdiagnosis and overdiagnosis possible at the two extremes.

Nutritional prevention has its own logic. Iodine deficiency is described as the most common preventable cause of learning disability worldwide. Where endemic iodine deficiency threatens pregnancy, periconceptional injection of **iodized oil** has attenuated endemic cretinism and subsequent intellectual disability in at-risk populations. A pharmacology source also states that daily maternal iodine intake of **150-200 microgram** can prevent endemic goitre and cretinism due to iodine deficiency, with iodised edible salt as the preferred delivery method. This is a prevention claim, not an invitation to prescribe an unsupervised supplement outside local obstetric and public-health practice.

one-third	over eighty	over 50
ID/GDD CASES WITH NONGENETIC CAUSES	POTENTIALLY TREATABLE DISORDERS IDENTIFIED	CONDITIONS DETECTED BY CONTEMPORARY NEWBORN SCREENING

The limits are as important as the opportunities. Nongenetic factors account for approximately one-third of ID/GDD cases, so environmental prevention is necessary but cannot remove all intellectual disability. At the same time, advances in therapeutics have identified over eighty potentially treatable disorders. This justifies careful diagnosis and prompt action without selling prevention as total control. Prevention priorities differ by setting: maternal and perinatal health are central public-health opportunities in low- and middle-income countries, while reduction of genetic causes of severe intellectual disability remains important in high-income countries. It is unlikely, however, that prevention can substantially alter the incidence of mild intellectual disability.

16.3 Antenatal screening, diagnosis and ethical care

Non-invasive prenatal screening is based on cell-free fetal DNA in maternal plasma. Its value is risk estimation and selection for counselling or diagnostic evaluation, not a diagnosis by itself. First-trimester screening combines an ultrasound marker with maternal blood testing. An ultrasound assessment for major malformations is often performed at approximately 20 weeks of gestation. These routes should be explained as complementary rather than as competing tests.

CLINICAL ROUTE	WHAT IT CAN CONTRIBUTE	TEACHING POINT
First-trimester screening	Risk assessment through ultrasound and maternal blood analytes.	A positive screen requires counselling and a diagnostic pathway.
Mid-trimester AFP testing	Screening for neural tube defects in the specified screening context.	An analyte result is not a diagnosis and is not specific to one disorder.
Amniocentesis	Diagnosis of chromosomal and metabolic disorders.	Use the test for the question it can answer.
Chorionic villus sampling	Chromosomal and molecular genetic studies.	Do not transfer amniocentesis metabolic role to CVS.

In one psychiatric-text account, amniocentesis or chorionic villus sampling is recommended for all women aged **35 years or more**. Another account frames amniocentesis as an indication-based decision for pregnancies with relevant prior or familial history, or a clinically significant current risk. The defensible clinical response is to know that recommendations are guideline- and context-dependent, establish the indication, explain benefits and limitations, and refer for current specialist obstetric or genetics advice rather than use a textbook threshold as a stand-alone rule.

Screening needs careful language. Maternal serum alpha-fetoprotein is a marker with more than one possible clinical explanation; it is not a disease label. For in-utero diagnosis of Down syndrome, the source describes a blood-based route, ultrasound assessment and invasive testing. These options differ in what they establish and what follow-up they entail. Carrier screening should be offered to all persons in high-risk populations, but named examples should follow locally relevant, verified services rather than stereotype or assumption.

Prenatal diagnosis followed by elective termination raises a boundary that clinicians should not obscure. It is a matter of deeply personal values because termination prevents childbirth rather than treating or preventing the disorder in the fetus. The psychiatrist's role is to support informed, non-directive decision-making, recognise family distress, avoid coercive framing, and ensure that a decision is not driven by misinformation about disability or by a lack of support for families who continue a pregnancy. The syndrome-specific genetics and recurrence discussion belongs with the relevant aetiology sections of this chapter.

16.4 Newborn screening and time-sensitive treatment

Newborn screening refers to tests undertaken within the first hours or days of life when early action can prevent severe health problems. Contemporary systems detect over 50 different conditions. A blood spot collected by heel stick is the established specimen method in the settings described in the source.

> **GOOD TO REMEMBER**
>
> An abnormal screen is a signal for confirmation, not a diagnosis or a moral judgement about the family. Communicate promptly and compassionately, then ensure confirmatory testing, treatment and longitudinal follow-up.

Congenital hypothyroidism illustrates the time-sensitive logic. With newborn screening, levothyroxine may be initiated by **4-6 weeks of life**. Screening of neonates is described as the best preventive strategy for cretinism. This should not be reduced to a prescription detail: early identification links a population programme to a child developmental outcome. The quoted treatment timing is not the time at which the blood sample must be collected.

The overall verdict on newborn metabolic screening is appropriately strong but bounded: it has been extremely successful in reducing the incidence and severity of some intellectual-disability syndromes. The qualifier some is crucial. A screening programme may also generate false-positive results, which can produce acute parental distress and unnecessary follow-up unless communication is prompt and compassionate.

Phenylketonuria is a classic screenable metabolic disorder, but its genetic mechanism and diet belong in the inborn errors of metabolism section. Here, the prevention lesson is narrower: early diagnosis and treatment of PKU, other metabolic conditions and congenital hypothyroidism are examples of secondary prevention because they intervene before disability develops.

16.5 Preventing secondary disability after diagnosis

Once intellectual disability is present, the preventable outcome is often loss of function rather than intellectual disability itself. Tertiary prevention therefore uses early support, education, family support and timely attention to mental or physical conditions that suppress functioning. This is habilitation in action. It safeguards developmental opportunity and reduces the additional disability created by untreated epilepsy, pain, sensory difficulty, psychiatric illness, behaviour problems, exclusion or caregiver exhaustion.

Do not wait for a crisis to begin support. Early intervention may start in the prenatal period by identifying high-risk pregnancies, arranging appropriate health care and addressing psychosocial adversities.

IN INDIA

For formal early intervention, the guideline names the District Early Intervention Centres of the Rashtriya Bal Swasthya Karyakram and the Anganwadi Centres of the Integrated Child Development Services. The preventive point is timely connection before a modifiable disadvantage becomes entrenched.

The service model, developmental methods and general evidence for early intervention are covered in the management section of this chapter.

Comorbidity management is central, not peripheral. Epilepsy affects 15-30 percent of persons with intellectual disability. Problematic behaviours may occur in 20-80 percent of the ID population. These figures do not authorise diagnostic overshadowing. A new behavioural change may be communication of pain, distress, environmental difficulty or mental illness. Prevention in tertiary care means looking actively for such contributors and treating them before they further reduce learning, relationships or family capacity. The psychiatric-comorbidity assessment itself is addressed in the dual-diagnosis section of this chapter.

Families may need genetic counselling alongside causal investigation and reproductive planning. It should be offered without blame and without making a risk discussion substitute for the family's own values or choices. The generic genetic-counselling process and diagnostic work-up are developed in the aetiology section.

16.6 Public-health priorities and realistic expectations

Prevention is most effective when it reaches the conditions in which children develop. ID risk factors are considerably increased in low-income countries, contributing to their increased rate of intellectual disability. This is why a prevention answer should move beyond rare disorders and include maternal health, nutrition, safety, infection control, toxic exposure and access to perinatal and neonatal care. It is also why prevention must be paired with equity: a family cannot implement advice that depends on services, food security or safe housing it cannot access.

Evidence supports interventions at more than one level. Programmes aimed at psychosocial stimulation were more effective than nutritional supplementation for improving both cognition and behaviour in growth-retarded children in the cited comparison. This does not diminish nutrition. It teaches that development depends on both biological provision and responsive social experience, and that a single nutrient-focused programme may not repair the effects of deprivation. Similarly, prevention programmes should be evaluated for whether they can be delivered consistently and whether they improve real developmental participation.

A comprehensive service begins with prevention and early detection and then connects families to the educational, health, social and practical supports that sustain participation. Prevention is therefore the first element of a continuum of care, not a separate campaign that ends after a

screening test. Appropriate referrals should follow the person across early, educational and adult life. The statutory eligibility and benefits themselves are dealt with in the disability certification and benefits section of this chapter.

MNEMONIC

PREVENT

Prepare before conception; **R**educe maternal, toxic and nutritional risks; **E**valuate antenatal and newborn screens; **V**erify a positive result; **E**ngage family support; **N**otice comorbidity; **T**arget function through habilitation.

The mature answer is neither fatalistic nor triumphalist. It recognises preventable pathways, acts early when an actionable condition is found, and continues to prevent additional disability through support and treatment. It also respects the person with intellectual disability as more than the outcome of a risk factor. Prevention should enlarge future choice, not become a language for blaming parents, narrowing reproductive autonomy or measuring a life only by what might have been avoided.

- Ask which preventable exposure or remediable condition is relevant at the present point in the person's life course.
- Make sure a positive screen has a confirmation, treatment and follow-up pathway.
- After diagnosis, look for treatable illness and avoidable barriers to participation rather than assuming that decline is inevitable.

For intellectual disability, prevention is a continuum: reduce avoidable risks before disability arises, detect and treat remediable conditions early, and use habilitation to prevent avoidable loss of function after diagnosis.

17 · Disability certification and benefits for intellectual disability in India (IDEAS, National Trust Act)

Certification is a clinical document with legal consequences. For a person with intellectual disability, it can convert an assessment into access to education, work, social protection and supported decision-making. The psychiatrist's task is therefore not merely to write a diagnosis. It is to distinguish clinical formulation from statutory quantification, obtain defensible evidence of functioning, explain what the certificate does and does not establish, and help the family navigate a system that can otherwise feel opaque.

The contemporary legal frame is the **Rights of Persons with Disabilities Act, 2016**, notified on **28 December 2016**. It replaced the **Persons with Disabilities (Equal Opportunities, Protection of Rights and Full Participation) Act, 1995**. Intellectual disability is a specified disability under this framework, alongside other conditions relevant to psychiatric practice. This section concerns the certification route for intellectual disability, its practical consequences, the limited role of IDEAS, and the National Trust framework for adulthood and guardianship.

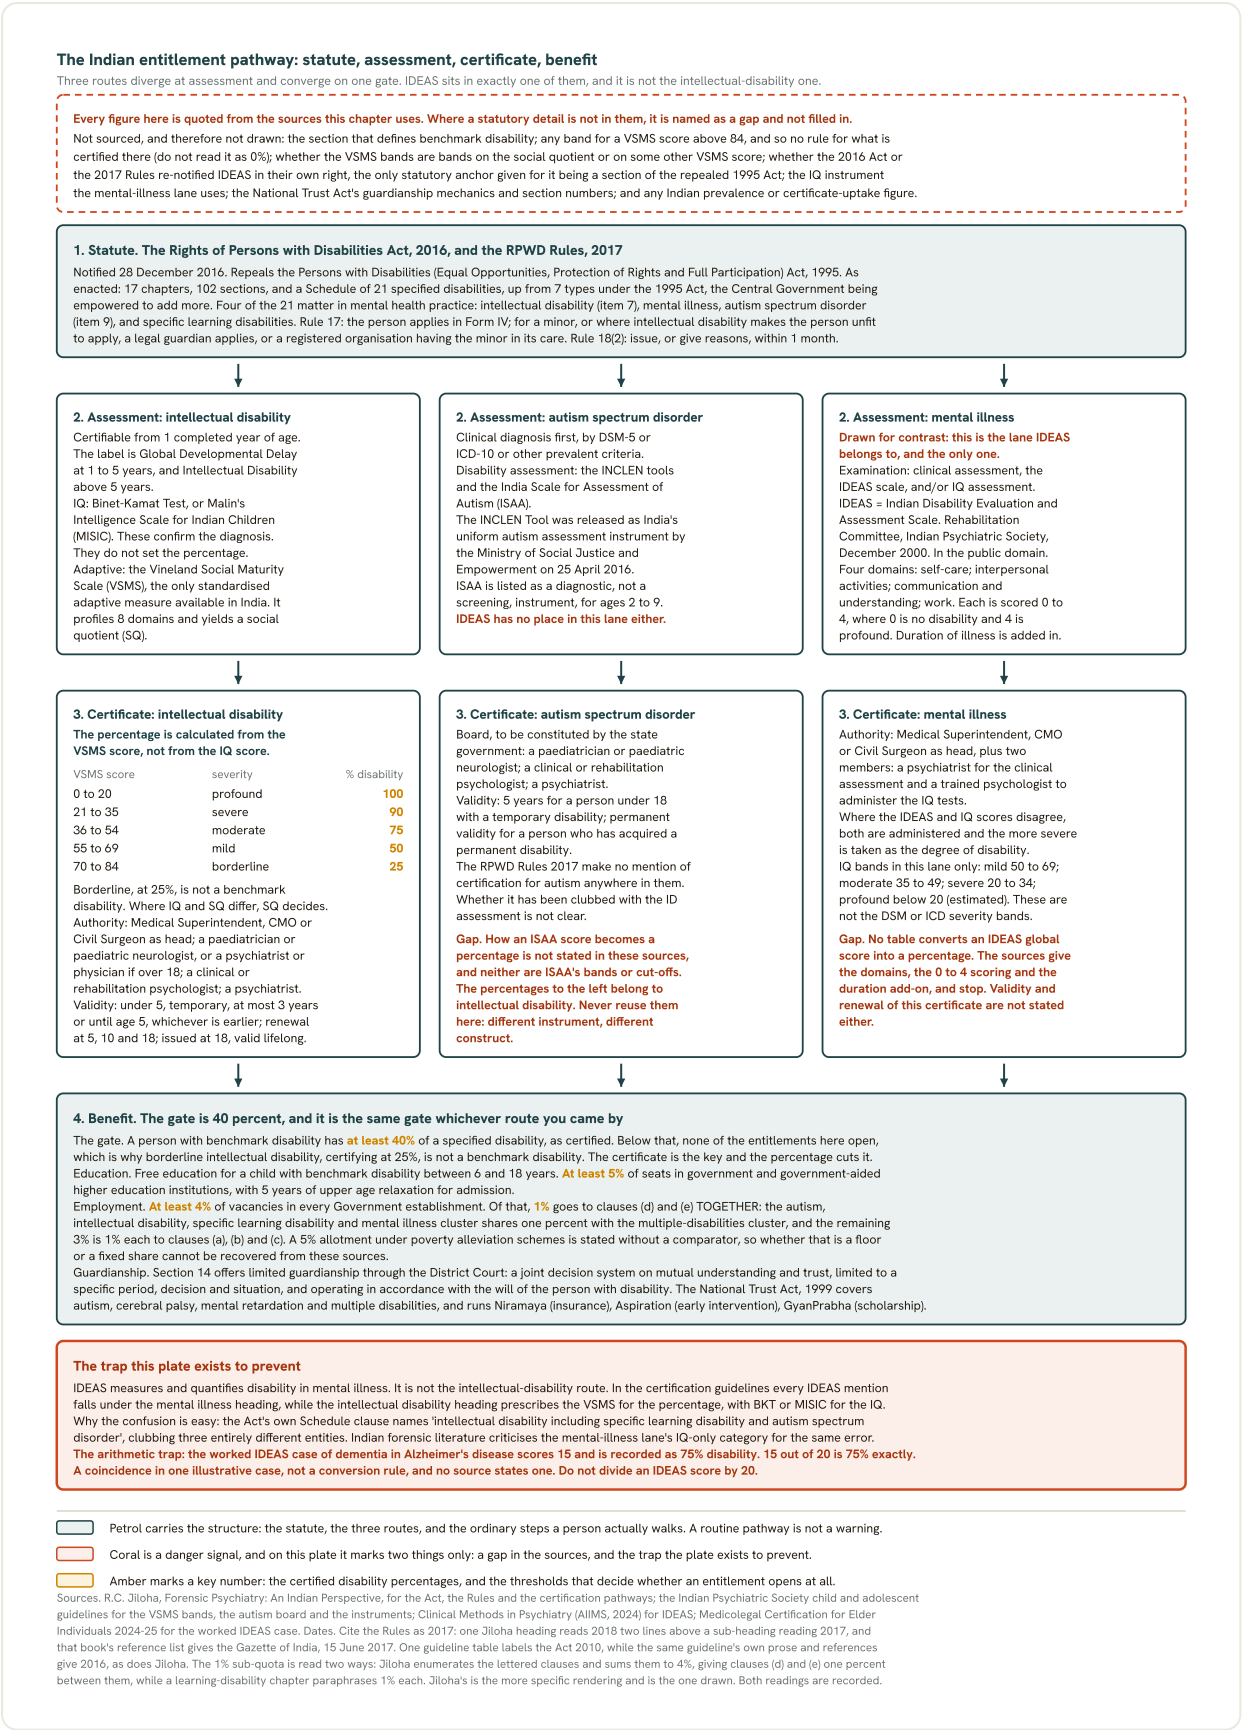

Fig 21.13 The Indian entitlement pathway: statute, assessment, certificate, benefit. One statute, three routes that diverge only at assessment, and one gate at 40 percent that all three converge on. The distinction the chapter turns on: IDEAS is the mental-illness disability instrument, not the intellectual-disability route, whose certified percentage comes from the VSMS score.

17.1 The legal frame: from diagnosis to enforceable participation

The Act is not a diagnostic manual. Its purpose is to translate disability into rights, duties and institutional remedies. It has 17 chapters and 102 sections; its Schedule names 21 specified disabilities, compared with 7 disability types in the earlier law. Within the Schedule, intellectual disability appears at serial 7 and autism spectrum disorder at serial 9. The nomenclature matters: the Act replaces **"mental retardation" with "intellectual disability"**. In clinical records and communication, use the current term consistently.

The statutory definition recognises limitation in intellectual functioning together with adaptive behaviour in everyday social and practical skills. That overlap with clinical assessment is important, but the questions asked are different. A clinical assessment asks what the person can do, what has changed, which supports work and whether there are treatable coexisting problems. A certificate establishes disability in the form required for rights and entitlements. It should never flatten the person into a percentage or be allowed to substitute for an individualised care plan.

RULE **Clinical severity and certified disability are related, but they are not interchangeable labels.** Clinical formulation guides care; statutory quantification establishes eligibility under a legal scheme.

For intellectual disability, the statutory schedule describes significant limitation in intellectual functioning together with limitation in adaptive behaviour. It does not legislate an IQ number, and a candidate should resist the temptation to supply one: the percentage on the certificate is derived from adaptive functioning, not from the IQ score. This is an easily missed distinction. A numerical cognitive test can corroborate intellectual impairment, but it does not itself produce the statutory percentage. Candidates who equate the two have confused an assessment construct with a legal outcome, and quoting a legal IQ cut-off that the statute never states is the sharpest form of that error.

- Use the diagnosis to organise clinical understanding and intervention.
- Use the certificate to document statutory disability and enable access to rights.
- Explain to caregivers that the certificate records function for a stated purpose, not the person's potential or worth.

17.2 The intellectual-disability certification assessment

Start with the correct question. The assessment must establish intellectual disability and then quantify disability in the prescribed manner. Careful administration and a credible developmental history are especially important; a rushed score, divorced from the person's actual opportunities and supports, is a poor foundation for a legal document.

IN INDIA

The Indian guideline identifies the VSMS as the currently available standardised adaptive-behaviour measure. The prescribed adaptive-functioning instrument is the **Vineland Social Maturity Scale (VSMS)**; it yields a **social quotient (SQ)** and an adaptive profile. Intellectual functioning is assessed using the **Binet-Kamat Test** or **Malin's Intelligence Scale for Indian Children**.

Cognitive testing in this pathway provides diagnostic confirmation, not percentage derivation. Where IQ and SQ suggest different grades, the SQ should guide the decision, because social maturity more closely reflects the ability to meet culture-appropriate demands of daily life.

GOOD TO REMEMBER

An implausible or discordant result should prompt review of the history, test conditions, language, sensory or motor barriers, educational opportunity, behaviour during testing and the informant's understanding of the items.

A statutory assessment should be clinically thorough even when its output is concise. Establish the developmental course and current adaptive abilities from an informant who knows the person across settings. Consider whether communication difficulty, behavioural disturbance, sensory impairment, physical illness or an untreated psychiatric disorder has distorted apparent function. Record observed abilities as well as deficits. The certificate process should protect against both overestimation, which deprives a person of support, and underestimation, which may unnecessarily restrict autonomy.

TRAP **Do not use an IQ score to calculate the intellectual-disability percentage.** In this certification pathway, the percentage follows the VSMS-based adaptive-functioning assessment; IQ testing confirms the intellectual impairment.

The categories below are statutory bands, not a substitute for the clinical severity discussion elsewhere in this chapter. They answer the specific legal question of what disability percentage is certified. The row should be read as a mapping: identify the applicable VSMS band, then document the corresponding percentage without improvising a conversion.

CERTIFICATION CATEGORY	VSMS SCORE BAND	CERTIFIED DISABILITY	PRACTICAL INTERPRETATION
Profound	0-20	100%	Highest statutory disability band
Severe	21-35	90%	Benchmark-disability threshold is met
Moderate	36-54	75%	Benchmark-disability threshold is met
Mild	55-69	50%	Benchmark-disability threshold is met
Borderline disability	70-84	25%	Does not meet benchmark-disability status

The borderline-disability row is clinically useful because it makes the eligibility boundary explicit. It is not a reason to dismiss need. A person may still need educational, vocational, family or mental-health support even when the statutory benchmark threshold is not met. Conversely, a benchmark certificate creates a legal entitlement pathway but does not tell the clinician which supports will be effective. Keep these two conversations separate and honest.

17.3 Application, medical authority and validity

The route should be explained before the family is sent from counter to counter. An application for a disability certificate is made in **Form IV**. When a person with intellectual disability cannot apply, a legal guardian may apply; an organisation registered under the Act may also apply where it has a minor in its care. This provision is practical rather than merely administrative: it avoids making access to certification contingent on an ability that is itself affected by the disability.

The medical authority is headed by the Medical Superintendent, Chief Medical Officer, Civil Surgeon or an equivalent state-notified authority. Its clinical membership includes a paediatrician or paediatric neurologist where available, with age-appropriate alternatives specified for adults, a clinical or rehabilitation psychologist, and a psychiatrist. The psychiatrist's contribution is more than signing a completed form. It includes diagnostic coherence, review of developmental and behavioural information, recognition of coexisting psychiatric illness, communication with the family and protection of the person's dignity during examination.

Certification can be issued after at least **1 completed year of age**. The label is age-sensitive: the guidance uses Global Developmental Delay from ages 1 to 5 years and Intellectual Disability after age 5 years. This distinction avoids premature certainty while preserving access to assessment and support. Do not delay a needed certificate simply because the child's development is still being clarified; use the appropriate certification label and plan review.

WHEN THE CERTIFICATE IS ISSUED	VALIDITY APPROACH	CLINICAL IMPLICATION
Before age 5 years	Temporary; it ends at the earlier of age 5 or 3 years.	Plan reassessment rather than treating the early certificate as final.
Between ages 5 and 17 years	Review is scheduled at ages 5, 10 and 18 years.	Make renewal part of transition planning, not a crisis near a deadline.
At age 18 years	Lifelong validity	Use the adult review to address future support and decision-making.

The medical authority must issue the certificate or communicate the reason for rejection within at most **1 month from receipt of the application**. In practice, clinicians can reduce avoidable delay by ensuring that reports identify the tool used, the functional basis of the percentage, the diagnosis appropriate to age and any need for follow-up. Keep a copy of the assessment record: it is clinically useful at renewal and can clarify an apparent discrepancy without making the family repeat an entire evaluation.

17.4 Benchmark disability and the rights that certification can activate

A **person with benchmark disability** has certified disability of at least **40%**. This is an eligibility threshold, not a clinical threshold. It determines access to several statutory provisions, whereas care should respond to need at every level of disability. Explain this plainly. Families often hear "eligible" as "severely disabled" or "ineligible" as "no help is possible"; both inferences are wrong.

40%	5%	4%	1%
BENCHMARK THRESHOLD	HIGHER-EDUCATION SEATS	GOVERNMENT VACANCIES	SHARED JOB-RESERVATION CLUSTER

A child with benchmark disability has a right to free education between 6 and 18 years. Government and government-aided higher-education institutions reserve at least 5% of seats for persons with benchmark disabilities, with an upper-age relaxation of 5 years for admission. In every Government establishment, at least 4% of vacancies are reserved. These provisions should not be presented as a promise of a particular educational placement or job. The clinician should document function accurately and direct the family toward the relevant institutional process rather than make an outcome guarantee.

The employment reservation has a subtle but examinable structure. Autism, intellectual disability, specific learning disability and mental illness form one listed cluster. That cluster does not receive a separate one-percent allocation by itself: it shares exactly 1% of vacancies with the multiple-disabilities cluster. This clarification prevents the common answer that incorrectly assigns the whole sub-quota to intellectual disability or to the listed cluster alone.

- Discuss educational entitlement early enough for the family to use it meaningfully.

- Frame reservation as an access mechanism, alongside realistic skill-building and accommodation.
- Check the current administrative pathway locally before advising on an application or placement.

17.5 IDEAS: important scale, wrong shortcut for ID certification

The acronym is a frequent source of error. **IDEAS** means Indian Disability Evaluation and Assessment Scale. It was developed by the Rehabilitation Committee of the Indian Psychiatric Society in December 2000. IDEAS is designed for disability due to mental disorders and is recommended for disability associated with mental illness. It is publicly available and remains important for psychiatric disability work.

IDEAS rates four functional domains: self-care, interpersonal activities, communication and understanding, and work. Each domain is scored from 0 to 4, from no disability to profound disability, and duration of illness is incorporated into the global score. These features explain why IDEAS may look superficially attractive in an adult with longstanding functional impairment. They do not make it the intellectual-disability certification instrument.

TRAP **IDEAS must not be substituted for the ID certification route.** Its place is the mental-illness pathway, whereas intellectual-disability certification follows its own prescribed assessment route.

This distinction is more than a technicality. Intellectual disability is a neurodevelopmental condition, and its certification requires an account of adaptive functioning. IDEAS includes illness duration, which answers a different question. Importing it into an ID certificate can create a legally vulnerable assessment and obscure the actual statutory basis of the percentage. Where intellectual disability and mental illness coexist, formulate and treat both conditions, but do not let the presence of psychiatric symptoms alter the prescribed ID percentage route.

17.6 Supported decision-making and the National Trust framework

Certification often brings families to the question they had postponed: who will help the person make decisions in adult life? Begin with the person's own preferences, abilities and participation. The **limited guardianship** model under the Act is offered by the District Court. It is a joint decision-making arrangement based on mutual understanding and trust, confined to a specified period and decision or situation, and intended to operate according to the person's will. This is conceptually different from taking over a person's life because support is convenient for others.

Clinicians should avoid treating guardianship as an automatic consequence of diagnosis or a certificate. Assess the decision at hand, the person's capacity to participate with support, the risks of coercion and the least restrictive way to enable a meaningful choice. Documentation should describe function and support needs rather than make sweeping declarations of incapacity. This approach also keeps the consultation aligned with rights, not merely family anxiety.

The **National Trust for the Welfare of Persons with Autism, Cerebral Palsy, Mental Retardation and Multiple Disabilities Act, 1999** covers four conditions: autism, cerebral

palsy, mental retardation and multiple disabilities. It creates a national body intended to support independent, community-close living and meaningful participation, rather than segregation or passive care. With an adult who has intellectual disability, the clinician must provide information about guardianship and National Trust provisions.

MNEMONIC

SUPPORT before substitution

Start with the person's wishes, identify the decision and the support required, protect against undue influence, and use the least restrictive lawful arrangement.

- Raise future decision-making before an emergency forces the issue.
- Include the adult with intellectual disability in the discussion in a communication-accessible manner.
- Separate financial or property concerns from a global assumption that the person cannot decide anything.

17.7 Documentation, advocacy and protection from procedural harm

Good certification is disciplined advocacy. The final document should make its reasoning auditable: diagnostic conclusion, adaptive assessment, IQ assessment where used, the statutory basis of the percentage, validity and the need for review. Avoid pejorative wording, casual estimates and unexplained contradictions between narrative and score. Discuss the result with the person and family in plain language. A certificate can open doors, but careless language can also follow a person into school, employment and adult services.

Rights under the Act have enforcement mechanisms. A first contravention of the Act or its rules attracts a **fine which may extend to Rs 10,000**, and a subsequent contravention a **fine of not less than Rs 50,000 and up to Rs 5 lakh**. Neither tier carries imprisonment, and the first-tier figure is a ceiling rather than a flat penalty. Fraudulently availing a benefit meant for persons with benchmark disabilities is a separate and graver offence, punishable with imprisonment which may extend to 2 years, or fine which may extend to Rs 1 lakh, or both. A separate group of offences of atrocities carries imprisonment of not less than 6 months and up to 5 years, and with fine, and their elements are examinable precisely because dropping them broadens the offence. Insult or intimidation qualifies when it is intentional, done with intent to humiliate, and in a place within public view. The sexual-exploitation limb requires the offender to be in a position to dominate the will of a woman or child with disability and to use that position to exploit her. The section runs to several further limbs, each with its own elements, and they are worth reading in the Act itself rather than in summary: a paraphrase that drops an element is precisely how these offences get overstated. Special Courts are designated in each district to handle violations.

The psychiatrist is not expected to become the family's lawyer. The clinical role is to recognise when rights may be at stake, document the relevant functional facts clearly, avoid false reassurance and direct the family toward appropriate legal or administrative assistance. For

broader assessment, service planning and protection issues, consult the Child psychiatry: assessment, treatment, services and protection notes. The practical aim is simple: certification should increase access, participation and safety without becoming a mechanism for unnecessary exclusion.

Must remember: In intellectual-disability certification, diagnose clinically, confirm intellectual functioning with the Binet-Kamat Test or Malin's Intelligence Scale for Indian Children, and calculate the statutory percentage from VSMS-based adaptive functioning - not from IDEAS, and not from the IQ score, which does not enter the percentage at all.

Autism: concept, causes and criteria

18 · Historical evolution (Kanner, Asperger, DSM-IV subtypes to spectrum)

Why this history matters. Autism did not move from obscurity to its current spectrum formulation simply by acquiring a new name. Each classificatory change reflected a different answer to a clinical question: is the presentation a distinct childhood syndrome, a developmental disorder with several recognisable patterns, or a dimensional condition whose boundaries cannot be reliably divided into neat subtypes? For the clinician, this history explains why older notes use unfamiliar terms, why families may still identify with a former label, and why current assessment must not be constrained by obsolete diagnostic partitions.

The examinable spine is therefore not a recital of dates. It is the movement from carefully described clinical prototypes, through a broad pervasive-developmental-disorder framework, to a single spectrum diagnosis. That movement also records an important correction in psychiatric thinking: explanatory models have to be accountable to observation and evidence, particularly when they risk locating blame in parents.

1943	11	1944	2013
FIRST PAPER	CHILDREN DESCRIBED	PARALLEL ACCOUNT	SPECTRUM SHIFT

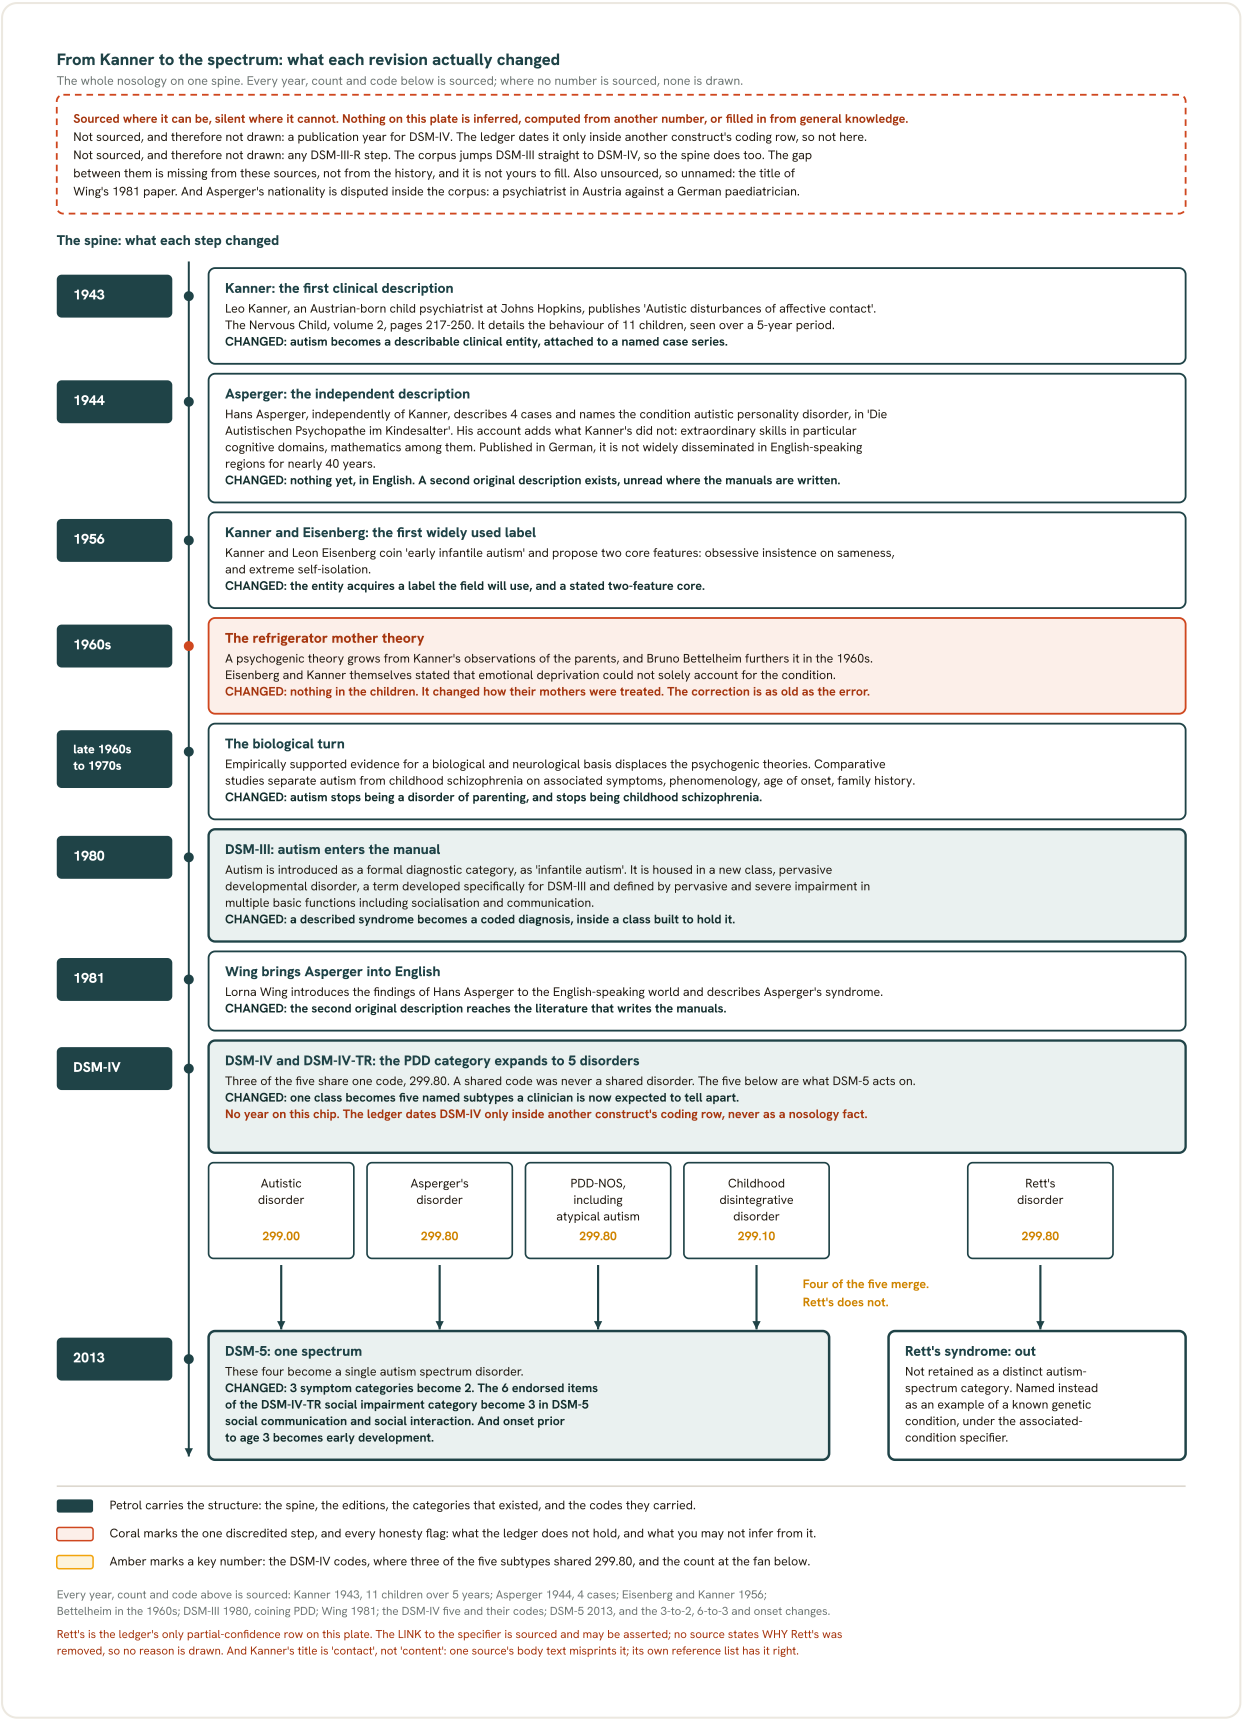

Fig 21.14 From Kanner to the spectrum: the nosological timeline and what each revision changed. The fan at the foot answers the examined question: four of the five DSM-IV subtypes merged into autism spectrum disorder and Rett's did not, surviving instead as an example of a known genetic condition under the associated-condition specifier. No year is drawn for DSM-IV and no DSM-III-R step is shown, because the sources cited hold neither.

18.1 From descriptive observation to a clinical syndrome

The starting point is the clinical description associated with **Leo Kanner, an Austrian-born child psychiatrist working at Johns Hopkins University**. He is credited with the first clinical portrayal of autism in the scientific literature. The importance of that contribution lies in the act of delineation: a set of children who might otherwise have been subsumed under broad and unhelpful psychiatric categories were described as sharing a distinctive developmental pattern. Good historical reading is not hero worship. It is an appreciation that a diagnostic entity begins when clinicians can show, with enough precision, what belongs together and what does not.

The paper, ***Autistic disturbances of affective contact***, concerned a series of **11 children** accrued over 5 years. It appeared in *The Nervous Child*, volume 2, pages 217-250. The title itself is instructive. Its language belongs to its period, but it directs attention to a disturbance in the child's way of relating rather than merely to disruptive conduct or low measured ability. That emphasis helped establish autism as a problem of developmental organisation and social relatedness, rather than a label for any child who was withdrawn, unusual, or difficult to manage.

A later follow-up is a useful corrective to retrospective romanticising of early accounts. Kanner's 1971 follow-up traced 9 of the original 11 children into adulthood; only two were eventually employed, and they remained single and lived with their parents. These observations should not be converted into a modern prognostic rule. They arose from a small historical cohort and a very different service context. Their value is conceptual: a diagnostic history should remain connected to the life course, participation, support, and family circumstances of the people being described.

RULE **Read the early descriptions as clinical prototypes, not as a checklist that limits whom autism can include.** A prototype establishes a recognisable pattern; later classification must test whether its boundaries remain valid in wider clinical populations.

18.2 Asperger's parallel account and its later influence

Independently of Kanner's work, **Hans Asperger** published an account based on **4 cases**. In his 1944 paper, *Die "Autistischen Psychopathen" im Kindesalter*, he used the term “autistic personality disorder”. The parallel descriptions matter because they prevent an overly simple origin story. Autism was not manufactured by a later committee out of a single author's observations. Different clinicians, working separately, identified related developmental phenomena, while giving different weight to their most striking features.

The feature that especially distinguished that account was attention to **extraordinary skills in particular cognitive domains**. This is often simplified into a stereotype of universal talent, which is clinically unhelpful. The historical point is narrower: ability can be strikingly uneven, and the presence of a particular strength does not erase social-developmental difficulty or establish a separate disease entity. Conversely, the absence of a striking skill never argues against autism. A mature formulation should describe the person's actual profile rather than infer ability from a historical label.

The work was published in German and was not widely disseminated in English-speaking settings until nearly 40 years later. **Lorna Wing**, in 1981, introduced these findings to the

English-language literature and described Asperger's syndrome. This delay helps explain why the label became prominent after many clinicians had already learned the original account of autism. It also explains why the label acquired cultural and personal significance for some patients and families. Respecting that significance does not require preserving a classification that later evidence found difficult to delimit consistently.

- Historical labels may illuminate how a person and family first understood a developmental profile.
- They should not be treated as a shortcut to current assessment or assumptions about cognition, language, education, or independence.
- When reviewing an old record, translate the label into a current description of developmental history, functioning, and support needs.

18.3 Early labels, aetiological error, and scientific correction

An influential early label emerged when **Kanner and Leon Eisenberg, in 1956, used "early infantile autism" and emphasised obsessive insistence on sameness and extreme self-isolation**. The label concentrated attention on early developmental presentation and on behavioural patterns that clinicians continue to recognise. Yet it also shows why diagnostic terminology should not be mistaken for a complete explanation. A name can draw attention to a pattern while still carrying assumptions about timing, causation, or typical presentation that later evidence will revise.

One of the most damaging examples was the **"refrigerator mother" theory, furthered in the 1960s by Bruno Bettelheim**. It interpreted autism through a psychogenic account of parenting and emotional deprivation. Its clinical legacy is not merely historical embarrassment. It can lead to guilt, adversarial relationships with caregivers, and neglect of the child's developmental and practical needs. The lesson for a psychiatrist is to separate careful inquiry about family relationships, which remains clinically relevant for every child, from unsupported causal attribution. Families require collaborative assessment, not retrospective blame.

Empirical work displaced this theory by providing **evidence for biological and neurological foundations, while comparative studies distinguished autism from childhood schizophrenia through associated symptoms, phenomenology, age of onset, and family history**. This was a methodological advance as much as an aetiological one. It required investigators to compare syndromes rather than rely on surface impressions, and to ask whether apparently similar social withdrawal had the same developmental meaning. The distinction remains clinically valuable: resemblance in a single symptom is not enough to establish diagnostic equivalence.

TRAP **Examination trap:** do not present the refrigerator-mother account as an historical "cause" that later became less important. It was a discredited psychogenic theory, not a competing aetiology to be balanced against contemporary evidence.

For present practice, history supports a disciplined stance. A developmental diagnosis does not make family context irrelevant, nor does it justify reducing the child to biology. It means that causal claims should match evidence, while formulation still attends to caregiver stress, communication, schooling, access to services, stigma, and the child's strengths. The causes of autism and the clinical features used for diagnosis are addressed elsewhere in this chapter; history here teaches why those domains must not be confused.

18.4 DSM-III and the pervasive developmental disorder framework

Autism entered a formal diagnostic manual in **1980**, when DSM-III used the label “infantile autism”. Formal recognition mattered because it placed the presentation within a reproducible diagnostic framework rather than leaving it dependent on individual clinical tradition. It also created the possibility that criteria could be studied, criticised, revised, and compared across settings.

The broader home created for it was **pervasive developmental disorder (PDD)**, a term developed specifically for DSM-III. It denoted pervasive and severe impairment across basic functions, including socialisation and communication. The word “pervasive” captured an attempt to distinguish a broad developmental organisation from an isolated symptom. Its limitation became clearer over time: a useful umbrella can inadvertently suggest that the conditions beneath it are naturally separate, even when the boundaries between them prove unstable.

The PDD framework nevertheless performed an important transitional task. It organised clinical observation around developmental patterns and made room for presentations that did not resemble a narrow prototype. It also created a common language for research and services. Candidates should understand this as a stage in nosology, not as a rival to the current diagnosis. The historical PDD term is still encountered in case records, educational reports, and older research, so it must be recognised and translated rather than dismissed as meaningless.

There is a broader lesson in this transitional category. Classification is most useful when it makes a clinician ask better questions, not when it supplies a prematurely final answer. The PDD framework encouraged clinicians to look across domains of development, but its named divisions could tempt them to treat a label as a complete account of the person. The later spectrum formulation retained the need for careful description while moving the centre of gravity from deciding which box fits best to explaining the individual's pattern. That is a more demanding task: it requires longitudinal history, direct observation, collateral information, and attention to functioning in ordinary settings.

> The key historical transition is from separately named pervasive developmental disorders to one autism spectrum diagnosis: the clinical task moved from choosing a former subtype to applying a common framework precisely.

18.5 DSM-IV: expansion into named subtypes

The DSM-IV and DSM-IV-TR PDD category contained exactly 5 disorders: autistic disorder, Asperger's syndrome, Rett's syndrome, childhood disintegrative disorder, and PDD-NOS. This

scheme is worth knowing because it shaped generations of clinical records and examination questions. It was also an attempt to represent heterogeneity, especially differences in developmental course and the degree to which an individual resembled the original prototypes. The weakness was not that heterogeneity was unreal; it was that named categories did not reliably carve that heterogeneity at its natural joints.

DSM-IV / DSM-IV-TR SUBTYPE	DIAGNOSTIC CODE
Autistic disorder	299.00
Asperger's disorder	299.80
PDD-NOS, including atypical autism	299.80
Rett's disorder	299.80
Childhood disintegrative disorder	299.10

Do not let the table mislead you into seeing the former codes as a clinical hierarchy. Codes record a classification decision; they do not tell you how a person communicates, what repetitive patterns are present, how development unfolded, or which supports are needed. The full diagnostic criteria, severity framework, and specifiers of current ASD are addressed elsewhere in this chapter. Here, the important point is that a subtype name in an older file is historical data to be interpreted, not a final formulation.

- Do not infer that former subtypes represented neatly separated biological entities.
- Do not convert a former subtype automatically into a contemporary severity statement.
- Do preserve the original developmental account, because it may contain useful information that a code alone cannot carry.

18.6 DSM-5: from subtype boundaries to a spectrum

The decisive revision came with **DSM-5 in 2013. Autistic disorder, childhood disintegrative disorder, Asperger's syndrome, and PDD-NOS were reconceptualised as a single autism spectrum disorder**. This was not a claim that all autistic people are alike. It was a claim that the prior labels did not consistently identify separate disorders, whereas variation could be described more meaningfully within a shared diagnostic framework.

The change also altered the architecture of symptoms: the 3 DSM-IV-TR symptom categories became 2 DSM-5 categories, and the item architecture beneath them was rebuilt. DSM-IV-TR required a total of 6 or more items across its 3 categories, with at least 2 drawn from the social-interaction category, which itself listed 4; DSM-5 carries 3 items in the single social-communication and social-interaction category. The threshold rule is worth reading twice, because it is widely misquoted as though the six were six social items: the six was the total across all three categories, and the social category alone never contained six. These are historical contrasts, not a substitute for learning current criteria. The critical conceptual shift was to bring social communication and social interaction together, while retaining restricted and repetitive

patterns as the other major domain. The diagnostic-criteria discussion should be used for the present rule set; history explains why it was reorganised.

The onset wording changed as well. DSM-IV-TR required onset before age 3, whereas DSM-5 specifies early development. This prevents an arbitrary historical cut-off from overriding a careful developmental history. It does not mean that onset history has become unimportant. Rather, the clinician has to establish whether the overall developmental pattern is compatible with ASD and whether later recognition reflects changing social demands, masking, missing early history, or another explanation.

RULE **Spectrum does not mean vague.** It replaces unstable subtype labels with a common diagnostic framework while requiring a more precise individual description of developmental history and current functioning.

18.7 Rett syndrome, coding legacies, and reading old records safely

The spectrum consolidation had an explicit exception. **Rett syndrome was not retained as a distinct autism-spectrum category; it is cited under the associated-condition specifier as an example of a known genetic condition.** This is a useful guard against a common historical error: assuming that every condition previously housed within PDD was simply renamed ASD. The detailed clinical account of Rett syndrome and childhood disintegrative disorder belongs with their dedicated discussion; the classification point here is that historical placement and present diagnostic status are not the same thing.

The manual pairs that reclassification with a differential instruction, set out where each of those syndromes is discussed in full. The classification principle is what belongs here, and it generalises: a symptom that appears during a particular phase of another condition must not be treated as sufficient evidence for a lifelong co-occurring diagnosis. Diagnostic overlap calls for full criteria, developmental context, and longitudinal reasoning.

Older ICD-10 documentation may use the following labels. The list is useful for record translation, but it must not be read as a DSM-IV row-by-row conversion.

ICD-10 CODE	LABEL PRINTED IN THE HISTORICAL PDD LISTING
F84.0	childhood autism
F84.1	atypical autism
F84.2	Rett's syndrome
F84.3	childhood disintegrative disorder
F84.4	overactive disorder associated with mental retardation and stereotyped movements
F84.5	Asperger syndrome
F84.8	other pervasive developmental disorders
F84.9	pervasive developmental disorders, unspecified

For the ICD-11 ASD stem, the back-mapping permits F84.0 childhood autism, F84.1 atypical autism, or F84.5 Asperger syndrome; use F84.1 when onset before age 3 is unclear, and use F84.5 regardless of onset when there is no general impairment in intellectual functioning or functional language. This is a coding bridge, not a licence to reintroduce obsolete diagnostic distinctions into the clinical formulation.

Finally, modern ASD encompasses historical terms that will appear in legacy material:

- early infantile autism, childhood autism, and Kanner's autism
- high-functioning autism, atypical autism, and PDD-NOS
- childhood disintegrative disorder and Asperger's disorder

GOOD TO REMEMBER

When encountering a historical label, first establish which classification system was used, then recover the descriptive evidence behind it, and finally apply the current framework without erasing the person's history. Taxonomy should improve clinical understanding, not replace it.

19 · Diagnostic criteria of ASD (DSM-5 dyad, ICD-11)

The diagnostic task is to recognise a pattern, not to count isolated oddities. Autism spectrum disorder is formulated from a persistent developmental pattern that is organised around **two** core domains. The value of the formal criteria is that they force the clinician to establish both the social-communication disturbance and the restricted or repetitive pattern, then to ask whether the pattern began developmentally and matters in the person's present life. This protects against diagnosing autism from one striking mannerism, a narrow interest, or social discomfort alone.

The criteria are best understood as a clinical argument. Symptoms must be described in their developmental context, linked to real-world functioning, and weighed against the person's general developmental level. The classification language is concise; the clinical work is not. A good answer therefore states the diagnostic structure first and then explains why each element is necessary. This section addresses the criteria in DSM-5-TR and ICD-11, before showing how their different formats lead to the same disciplined diagnostic reasoning.

2	3	at least 2	6A02
DSM CORE DOMAINS	CRITERION A ELEMENTS REQUIRED	CRITERION B ELEMENTS REQUIRED	ICD-11 PARENT STEM

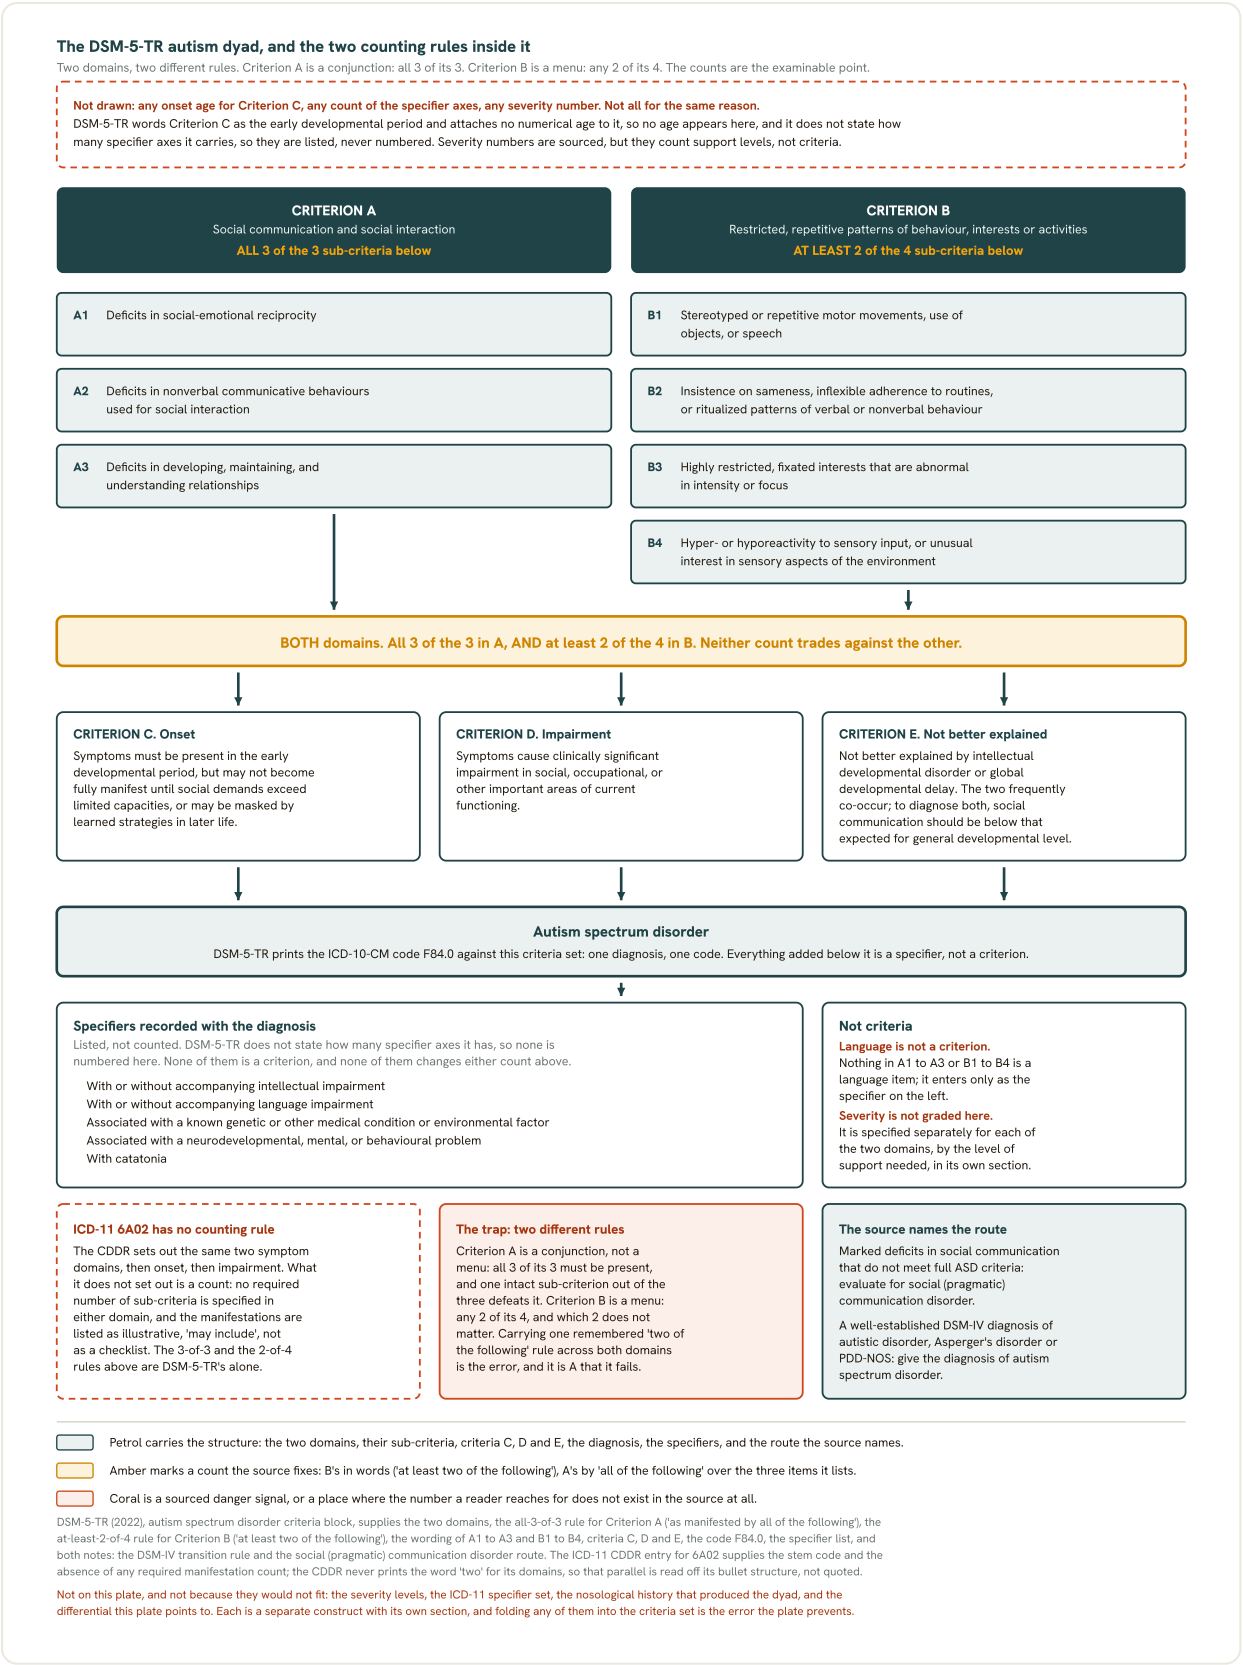

Fig 21.15 The DSM-5-TR autism dyad, and the two counting rules inside it. Two symptom domains, two different rules. Criterion A needs all 3 of its 3 sub-criteria, so one intact sub-criterion defeats it; Criterion B needs any 2 of its 4, and which 2 does not matter. Criteria C, D and E add onset, impairment and the not-better-explained rule against intellectual developmental disorder. Specifiers hang off the diagnosis, not the counts, where language and severity sit, outside the criteria set. ICD-11 6A02 has the same two domains and no counting rule, so these counts are DSM-5-TR's alone. No onset age is drawn: DSM-5-TR attaches none to the early developmental period, and the specifier axes are listed, never numbered, because it does not state how many there are.

19.1 The diagnostic architecture: a dyad with developmental and functional anchors

The DSM-5-TR dyad has one domain concerning social communication and social interaction, and another concerning restricted, repetitive patterns of behaviour, interests, or activities. The dyad is not merely a shorter checklist. It requires the examiner to decide whether social difficulty is part of a broader reciprocal-interaction disturbance and whether the behavioural pattern has the characteristic quality of repetition, inflexibility, restriction, or unusual sensory engagement.

A useful way to read the criteria is vertically as well as horizontally. Vertically, the clinician first establishes the core phenotype, then asks about developmental onset, present impairment, and competing explanations. Horizontally, each core domain must be examined across ordinary contexts rather than inferred from a single consultation. A person may use rehearsed social behaviours in a structured setting and still have difficulty when reciprocity, flexibility, or contextual understanding are demanded. Conversely, a single unusual habit without the wider pattern does not establish the diagnosis.

This structure also explains why a symptom inventory is insufficient. Checklists are useful prompts for enquiry, but their items are not interchangeable. An affirmative response about a repetitive act does not repair missing evidence from the social domain, and a history of social discomfort does not establish the repetitive domain. The clinician must decide whether each observation belongs to the required construct, whether it is persistent, and whether the observations form one developmental syndrome. That is the safeguard against both overinclusive diagnosis and the dismissal of a coherent but subtle presentation.

RULE **Diagnostic rule:** establish the complete pattern across both core domains before using onset, impairment, and exclusion criteria to confirm that it is autism spectrum disorder.

The printed DSM diagnosis carries the code F84.0. In an examination answer, however, the code is less important than showing the logic of the dyad. The examiner should be able to see that the candidate understands why a social-communication presentation without the required restricted or repetitive pattern is not simply labelled autism by default.

19.2 Criterion A: social communication and social interaction

Criterion A concerns deficits that are persistent and span the social-communication field. DSM-5-TR requires **all three** listed components. This matters because conversational difficulty, poor eye contact, or social isolation in isolation can arise for many reasons. The criterion asks for a coherent disturbance in reciprocity, in the use of nonverbal communication for social purposes, and in relationships.

- **Deficits in social-emotional reciprocity** concern the give-and-take of social exchange. The clinical question is whether the person can initiate, respond to, and sustain a reciprocal interaction in a manner appropriate to the context.
- **Deficits in nonverbal communicative behaviours used for social interaction** concern how nonverbal signals are used to regulate and share interaction, rather than a superficial judgement about one gesture or one gaze behaviour.

- **Deficits in developing, maintaining, and understanding relationships** require attention to the person's grasp of social expectations, adjustment of behaviour to context, and capacity to participate in relationships.

The phrase “social communication” should not be reduced to spoken language. A fluent speaker can have marked difficulty with reciprocity, social interpretation, or relationships, while a person with limited speech may show a clear wish to engage and share. The diagnostic question is how social communication functions between people. **Language impairment is not itself a core DSM-5-TR criterion**; its specifier framework is addressed in the severity-level and specifier discussion in this chapter. Detailed language phenomenology belongs with the clinical features of ASD.

Clinical interpretation. Criterion A is often easiest to misread when an observer relies on a socially compelling moment during an interview. The purpose is not to decide whether a person can make contact at all; it is to understand the consistency, flexibility, reciprocity, and context-sensitivity of social communication over development. A single competent performance, particularly in a familiar or highly structured interaction, is not by itself a substitute for that broader account.

For the same reason, Criterion A should not be phrased as a personality judgement. Reserve descriptive language for observable interaction and its functional meaning. Ask how the person shares attention, responds when another person changes the topic, reads the interpersonal situation, and adapts communication to the relationship. Such questions convert a loose impression of being “socially awkward” into evidence that can be placed, or not placed, within the criterion. They also make it easier to explain the reasoning to the person and family without reducing the assessment to a label.

19.3 Criterion B: restricted and repetitive patterns

Criterion B captures a style of behaviour and interest that is repetitive, circumscribed, inflexible, or unusually related to sensory experience. DSM-5-TR requires **at least two** of the listed manifestations. The threshold deliberately prevents a single preference, hobby, or repetitive action from carrying the diagnosis. What counts is the pattern's persistence, context, intensity, and relationship to the rest of the clinical picture.

The manifestations include stereotyped or repetitive motor movements, use of objects, or speech. The point is not simply that behaviour is repeated. Repetition must be interpreted as part of the characteristic pattern, rather than as an isolated self-soothing act, play preference, or response to a transient stressor.

A further manifestation is insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behaviour. Here, the clinical task is to ask what happens when an expected sequence changes. The diagnostic relevance lies in the rigidity and the way the need for predictability shapes functioning, not in whether a household happens to have routines.

The domain also includes highly restricted, fixated interests that are abnormal in intensity or focus. A strong interest should be evaluated for its quality and consequences, not judged by whether its topic seems unusual to the clinician. An ordinary subject can become diagnostically relevant when engagement is unusually narrow or dominant; an unusual subject can be entirely non-pathological when it is flexible and proportionate.

Finally, DSM-5-TR includes **hyper- or hyporeactivity to sensory input, or unusual interest in sensory aspects of the environment**. This places sensory experience within the restricted and repetitive domain. It does not mean that sensory sensitivity alone is diagnostic. Its value is greatest when it helps explain a broader pattern of behaviour, distress, avoidance, fascination, or difficulty adapting to ordinary environments.

MNEMONIC

Memory spine: A is all, B is a selected set

Establish every social-communication element in A, then establish the required threshold within B. Use this as a recall aid only after understanding what the observations mean clinically.

TRAP **Examination trap:** do not diagnose ASD from social-communication deficits alone. The restricted and repetitive domain is required, and it must be demonstrated rather than assumed.

19.4 Criteria C to E: timing, impact, and developmental explanation

The core phenotype is necessary but not sufficient. Criterion C requires that symptoms are present in the **early developmental period**. Recognition may occur much later because demands become more complex or because a person has learned strategies that conceal difficulty. The criterion is therefore about developmental presence, not the age at which a family, school, or clinician first names the concern. A late recognition narrative should prompt careful developmental reconstruction, not an automatic rejection of ASD.

Criterion D requires **clinically significant impairment** in social, occupational, or other important areas of current functioning. Impairment is the bridge from descriptive traits to a disorder. It should be considered in the person's actual environment, including the effort needed to maintain functioning and the consequences when familiar supports are absent. The clinician should avoid both extremes: treating every difference as disorder, or dismissing substantial hidden burden because outward performance appears adequate.

Criterion E says that the presentation must not be better explained by intellectual developmental disorder or global developmental delay. It also permits co-occurring diagnoses when **social communication is below that expected for general developmental level**. This is a comparative judgement, not a shortcut based on an intelligence score. The issue is whether the social-communication profile is disproportionately affected relative to the person's overall developmental functioning. Intellectual disability and its assessment are covered in the relevant sections of this chapter.

- **Timing:** establish a developmental history that can account for the current pattern, including why it became visible when it did.
- **Impact:** describe what the pattern changes in daily participation, relationships, education, work, or other important roles.
- **Explanation:** decide whether the social-communication disturbance exceeds what would be expected from the person's general developmental level.

The transition note is clinically important: an individual with a well-established DSM-IV diagnosis of autistic disorder, Asperger's disorder, or PDD-NOS should receive the diagnosis of autism spectrum disorder. This is a diagnostic transition rule, not an invitation to recreate older subgroup boundaries in current formulation. For a person with marked social-communication deficits who does not meet the full ASD criteria, the DSM directs that they should be evaluated for social (pragmatic) communication disorder. The full differential is considered elsewhere in this chapter.

19.5 ICD-11: essential features and a clinically judged threshold

ICD-11 places ASD under the parent stem 6A02. Its essential features have two required symptom domains, structurally paralleling the DSM dyad. The practical message is the same: social-communication disturbance and restricted or repetitive patterns are both indispensable to the syndrome.

The important structural contrast is that ICD-11 does not set a numerical sub-criterion threshold within either domain. Instead, manifestations are illustrative rather than a required count. This calls for disciplined clinical judgement, not diagnostic laxity. The clinician must still establish that the required domains are convincingly represented and persistent. A list of examples is not a licence to infer a domain from a vague or isolated concern.

When working from ICD-11, document the evidence that makes each domain essential rather than simply reproducing several examples. This keeps the record auditable: another clinician should be able to see why the pattern was judged to meet the domain, how it has persisted developmentally, and how it affects functioning. The same discipline is useful when DSM criteria are used. Counting is a decision aid, not a replacement for a coherent account of the person's development and current life.

The ICD onset requirement is that onset occurs during the developmental period, usually becoming apparent early, although characteristic symptoms may become fully manifest only when social demands exceed the person's capacities. Its functional requirement is significant impairment in important areas of functioning; diagnosis remains appropriate when adequate functioning is achieved only through exceptional effort. This wording is especially useful for presentations in which compensation can obscure the burden of the condition.

ICD-11 also notes that a true regression pattern may typically begin between **1 to 2 years of age**, while loss of previously acquired skills is rarely observed above **3 years of age**. This is a narrow

classification observation, not a substitute for the clinical assessment of regression or its differential diagnosis.

19.6 DSM-5-TR and ICD-11: compare the logic, not merely the wording

DIAGNOSTIC AXIS	DSM-5-TR	ICD-11	CLINICAL CONSEQUENCE
Core structure	Two core domains	Two essential symptom domains	Both require a dyadic phenotype rather than a single-domain formulation.
Within-domain threshold	Every Criterion A component is required; Criterion B requires its stated minimum.	No required sub-criterion count is specified.	DSM is more operationally counted; ICD relies more explicitly on judgement about the essential pattern.
Developmental timing	Symptoms are present in the early developmental period.	Onset occurs during the developmental period.	Recognition can be delayed without converting a developmental condition into an adult-onset one.
Functional significance	Clinically significant current impairment is required.	Significant impairment remains relevant despite exceptional compensatory effort.	Assess current consequences and effort, not symptoms in abstraction.

The classifications should therefore not be treated as rival definitions. They are two formats for the same central clinical problem: determining whether a developmental social-communication pattern is accompanied by the required restricted or repetitive pattern and causes meaningful difficulty. DSM makes the internal threshold more visible. ICD makes the need for judgement in a variable phenotype more visible. In either system, the best formulation is evidence-based, developmental, and functionally anchored.

19.7 A disciplined way to write and defend the diagnosis

GOOD TO REMEMBER

In practice, begin by naming evidence under each core domain. Then state the developmental course, the present functional impact, and the developmental comparison required when intellectual disability or global developmental delay is relevant. This sequencing prevents the common error of beginning with a favourite label and searching selectively for confirming behaviours.

A concise formulation can therefore be written as a chain of reasoning: the person has evidence for the social-communication domain; evidence for the restricted or repetitive domain; a developmental history compatible with the condition; current functional consequences; and no more complete developmental explanation for the social-communication profile. If any link is weak, the right response is to clarify that link rather than to stretch another criterion. This

approach is especially valuable when the presentation is compensated, when history is incomplete, or when more than one developmental difficulty is present.

Do not turn the criteria into a proxy severity scale. Severity levels and accompanying intellectual or language impairment are specifiers, not replacements for the core diagnostic argument. Likewise, screening and diagnostic instruments may organise information, but they do not remove the need to establish the criteria. Their selection and use are addressed in the assessment section of this chapter.

> ASD requires the dyad, developmental presence, clinically meaningful impact, and a developmental explanation that does not account for the social-communication profile more fully.

The final formulation should make its reasoning transparent. It should show why the observed pattern belongs together, why it is developmental, why it matters now, and why the chosen diagnosis is more accurate than a partial description. That is the difference between reproducing a checklist and using a diagnostic classification responsibly.

20 · Epidemiology and changing prevalence of ASD

Epidemiology is more than a prevalence figure. In autism spectrum disorder, the number reported by a survey depends on whom it reaches, how cases are found, which diagnostic concept is used, and whether a record, a service register, or direct assessment establishes the diagnosis. The examination task is therefore not to recite one figure as though it were universal. It is to state the population and method to which a figure applies, distinguish occurrence from detection, and explain why apparently conflicting estimates may all be credible within their own settings.

Autism is diagnosed across the life course, but ascertainment is shaped by developmental surveillance, referral pathways, educational provision, clinical expertise, and families' ability to reach assessment. These influences make epidemiology clinically relevant. They determine which children come to attention, which adults remain unidentified, and how a service should interpret a rising caseload. Prevalence describes the burden recorded in a defined population; it should not casually be converted into a claim about causation or a proof that the underlying incidence has changed.

20.1 Reading an ASD prevalence estimate

Prevalence is the proportion of a defined population meeting a case definition at a stated time or over a stated period. For ASD, it is an output of both the condition in the population and the process used to recognise it. A direct, structured assessment can identify people who have never entered services, whereas an administrative dataset captures only those who have acquired a diagnostic label. Neither approach is automatically superior in every setting: each answers a somewhat different question.

A useful distinction is between a population survey, a clinical series, and a service count. A clinic denominator is strongly influenced by referral, affordability, and local diagnostic practice. A

school or disability register may be especially sensitive to eligibility rules. A population study can reduce some of these effects, but still depends on participation and on the screening and diagnostic pathway. Thus, when comparing papers, the candidate should ask: who was sampled, what constituted a case, and how was that case established?

Case definition is equally important. Research that asks whether a person meets a current diagnostic formulation is not directly equivalent to a historical study that used a narrower formulation. Nor is a parent-reported label equivalent to an assessment made after direct observation and developmental history. The point is not to rank methods in the abstract. It is to understand the direction in which each method may shape a result and to avoid comparing unlike estimates as though they measured precisely the same construct.

For clinical readers, this also explains why a service's experience can diverge from published population data. A tertiary service may receive people with complex presentations, delayed recognition, or accompanying needs that make referral more likely. A community survey may capture people whose needs have not brought them to a specialist. Both can be valuable sources of information, but neither should be used to invalidate the other without considering its sampling frame. Epidemiology becomes clinically useful when it trains that habit of interpretation.

RULE **Never quote an ASD frequency without naming its population, period, and ascertainment pathway.** The same label can yield different observed frequencies when the pathway into the numerator changes.

Ascertainment means the process by which potential cases are found and verified. It is not a minor methodological footnote. A wider net may identify people whose presentations were previously overlooked; an altered threshold may change who qualifies; and better access to assessment may turn an unmet need into a recorded diagnosis. These processes can change measured prevalence even when the underlying population risk has not changed.

- State whether the estimate is local, national, or multinational.
- Identify whether it is a survey estimate, a diagnosed-rate estimate, or a service-derived estimate.
- Describe a temporal increase as a change in **measured prevalence** unless the evidence separately establishes an increase in incidence.

20.2 Contemporary frequency: use the denominator carefully

Published figures support a broad conclusion: ASD is not rare in contemporary clinical and public-health practice. They do not support treating one jurisdiction's figure as the world's figure. The DSM-5-TR describes a reported frequency in the United States of **between 1% and 2%**. In the same source, the median global prevalence is **0.62%**, while prevalence across non-United States countries has approached 1%. These are estimates from differently assembled evidence, not interchangeable constants.

1-2%	0.62%	approaching 1%	3:1
UNITED STATES REPORTED FREQUENCY	MEDIAN GLOBAL PREVALENCE	NON-UNITED STATES REPORTS	WELL-ASCERTAINED EPIDEMIOLOGICAL SEX RATIO

The Kaplan & Sadock's Comprehensive Textbook of Psychiatry gives a current estimate of about 69 per 10,000, or about 1 in 145 children. Lewis's Child and Adolescent Psychiatry describes 6.6 per 1,000 as a reasonable overall estimate. The immediate lesson is not to calculate a false reconciliation between these reports. Rather, each estimate needs its source and denominator attached when it is quoted.

IN INDIA

An international or United States surveillance number may be useful as context, but it must not be relabelled as an Indian prevalence estimate. The Indian Psychiatric Society guideline cites a United States surveillance estimate of 1 in 68; its provenance must travel with the number. A responsible answer acknowledges the need for locally representative ascertainment rather than importing a denominator from another health and education system.

20.3 Sex and gender: distinguish epidemiology from diagnosis

Sex ratio is often quoted as a compact epidemiological fact, but it carries an important methodological warning. In well-ascertained epidemiological samples, the global male:female ratio is 3:1. That figure should not be conflated with the ratio among people who receive a diagnosis. The DSM-5-TR states that ASD is diagnosed between three and four times more often in males, while the ICD-11 Clinical Descriptions and Diagnostic Requirements describes males as diagnosed at a 4:1 male:female ratio.

The difference between a diagnostic ratio and an epidemiological ratio matters because diagnosis is a social and clinical event. Referral expectations, recognition of less stereotyped presentations, language and cognitive profile, and co-occurring difficulties can all shape who crosses the threshold into a dataset. Therefore, a male predominance in a clinical register must not be interpreted automatically as a direct measure of the sex distribution of autistic traits in the wider population.

Other textbook summaries similarly report a male excess, but their scope should be retained. Kaplan & Sadock's Comprehensive Textbook of Psychiatry reports on the order of three to five boys for every girl in clinical and epidemiological samples, and notes that the predominance is greater among those with higher cognitive ability. Lewis's Child and Adolescent Psychiatry reports that boys are affected between three and four times more often. These formulations should be presented as source-specific descriptions, not as permission to under-recognise ASD in girls or women.

TRAP **Examination trap:** a diagnosed male:female ratio is not automatically a population prevalence ratio. Name the numerator before interpreting the ratio.

20.4 Why recorded prevalence has risen

The historical contrast is striking, but the correct inference is nuanced. Early epidemiological studies described autism as roughly 1 per 2,000, whereas current estimates are much higher. This temporal pattern establishes that the recorded frequency has changed. It does not, by itself, identify why it changed. Trends are especially difficult to interpret when the diagnostic category, awareness, service incentives, and methods of finding cases evolve together.

REPORT	FIGURE AND INTENDED USE	INTERPRETIVE BOUNDARY
Early studies	Roughly 1 per 2,000	Historical baseline, not a current estimate.
Kaplan & Sadock	About 69 per 10,000, or about 1 in 145 children	Contemporary textbook estimate.
Lewis	6.6 per 1,000	Reasonable overall estimate in that text.
Indian Psychiatric Society guideline	1 in 500 historically, compared with 1 in 68	Both figures are historical comparison and United States surveillance context, not Indian population prevalence.

Secular increase refers to an apparent change across time. It may reflect a real change in occurrence, an altered measurement process, or both. Lewis interprets the **apparent rise** through evolving diagnostic concepts, broader recognition of the spectrum, and access to relevant services, rather than as proof that population occurrence has increased. This is a disciplined reading of time trends: the conclusion should remain proportionate to what the underlying studies can establish.

The evidence base has expanded substantially. Kaplan and Sadock refers to over 60 epidemiological studies. More studies improve the visibility of variation and methodological limitations; they do not erase those limitations. An increased research base should make the clinician more careful about denominators, not more casual about generalisation.

20.5 Mechanisms that inflate or alter measured frequency

Diagnostic broadening or change in diagnostic practice can alter measured frequency. When a category is conceptualised differently, people previously placed outside it, or given another developmental label, may now meet the contemporary definition. Awareness also matters: families, teachers, and clinicians who recognise a broader range of presentations are more likely to refer and document concerns. Service availability can have a similar effect, because visible assessment and educational support make diagnosis more feasible and more relevant to a family.

Diagnostic substitution is a related, but more specific, phenomenon. In the United States in particular, a single diagnostic label is commonly used to identify students for service eligibility. As awareness rose, schools and parents became more likely to use the autism label; estimates can consequently be inflated when service records, rather than direct assessment of children, establish caseness. This is not a claim that every increase is artificial, nor should this United States-specific mechanism be exported uncritically to all countries.

Kaplan and Sadock likewise regards **the measured rise** as partly shaped by evolving diagnosis, professional practice, educational policy, and public recognition; higher rates often occur where awareness and services are more available. It leaves the possibility of a true incidence increase unresolved. That restraint is the correct clinical posture. A service observing more diagnosed children may be seeing a mixture of changing need, changing recognition, and changing access.

MNEMONIC

FRAME the rising count

Find out how cases were found; **R**eview the diagnostic rule; **A**sk about awareness and access; **M**ap service and educational incentives; **E**xpress uncertainty about true incidence.

- Do not call a rise an epidemic merely because a surveillance figure rose.
- Do not dismiss all increase as artefact merely because ascertainment has improved.
- State which mechanisms are supported by the source and which remain unresolved.

20.6 Ethnoracial, social, and cultural interpretation

Within United States child data reported in the DSM-5-TR, prevalence is lower in African American children at 1.1% and Latinx children at 0.8% than in White children at 1.3%, even after socioeconomic resources are taken into account. This is an observed comparison in that source. It should not be rewritten as established proof that the difference is wholly caused by underdiagnosis or differential ascertainment. The same source says reported prevalence may be affected by misdiagnosis, delayed diagnosis, or underdiagnosis, which is a cautious possibility rather than a completed causal explanation.

Ascertainment bias is the distortion introduced when some people are more likely than others to be identified, referred, or recorded. It is a useful hypothesis when interpreting group differences, but it is not a substitute for evidence. A good answer separates the observed distribution from proposed explanations and avoids converting a plausible clinical concern into a settled epidemiological conclusion.

Social-class arguments require the same historical discipline. **Kanner's original observation** involved highly achieving, high-social-status parents, but Kaplan and Sadock regards the sample as likely biased by case ascertainment and notes that epidemiological studies have generally not found such an association. The lesson extends beyond ASD: impressions formed from a selective clinic population should never be mistaken for a population association.

20.7 Applying epidemiology in clinical and service work

What the clinician should do with a rate. Epidemiology should improve case-finding and service planning, not replace individual assessment. A family does not become more or less likely to need a careful developmental evaluation because the clinician has memorised a national estimate. Conversely, a service cannot plan workforce, assessment capacity, or educational liaison responsibly if it assumes that a historical clinic count captures all people who may need support.

GOOD TO REMEMBER

Treat an apparent rise in caseload as an audit question, not a reflex conclusion. Check referral, assessment pathways, education or disability processes, age groups, and the catchment population. This helps distinguish increased recognition from a changed denominator, so planning is based on demand visible to the service.

At the level of a research appraisal, ask whether the study has separated screening from confirmation and whether non-participants might differ from participants. Ask whether a diagnostic record had to pre-exist for inclusion, and whether the study would identify people with a subtle or previously unrecognised presentation. Such questions are transferable across settings. They also keep the clinician from treating an attractive headline figure as more precise than the study design permits.

When counselling families, use population data with humility. Explain that frequency figures vary across settings and methods, and that an epidemiological association cannot determine the cause of one person's ASD. Avoid implying blame from parental characteristics, social position, or the fact that a diagnosis became visible after a change in school or service access. The aetiology of ASD, including genetic and environmental architecture, belongs in the etiological discussion of this chapter; epidemiology here explains how cases are distributed and counted.

For a written answer, a compact but high-quality structure is: define prevalence and ascertainment; quote a source-qualified contemporary estimate; state the male predominance while distinguishing diagnosed from epidemiological ratios; then explain the rise through diagnostic concepts, awareness, practice, educational policy, and service access. End with the unresolved point: changing measured prevalence alone cannot settle whether underlying incidence has changed.

The rise in recorded ASD prevalence is real as a measurement trend; its causes are multiple, and it must not be equated automatically with a proven rise in true incidence.

20.8 High-yield synthesis

The epidemiology of ASD is best understood as a conversation between population occurrence and the systems that recognise it. Contemporary estimates demonstrate substantial need, while their variation demonstrates why source, denominator, geography, and ascertainment must be stated. Sex ratios have the same requirement: a well-ascertained epidemiological ratio and a diagnosed-rate ratio answer different questions. Historical increases should prompt examination of diagnostic change, awareness, education, services, and record-based case definition before claims are made about causation.

This approach protects against opposite errors. Minimisation assumes that ASD is uncommon because an older estimate was lower. Overstatement treats every rise in a recorded rate as proof of a new environmental cause. The clinician's role is to recognise the public-health burden, assess

the individual in front of them, and communicate uncertainty precisely. That combination is more useful than a detached list of figures and more defensible than a single dramatic number.

21 · Etiology of ASD (genetic, neurobiological, environmental)

Aetiology is plural, not a single cause. Autism spectrum disorder arises through developmental pathways in which inherited liability, rare genetic events, brain development and environmental exposures may intersect. The clinical task is therefore not to offer families a simplistic cause, but to explain that association is not destiny, that aetiological formulation can identify relevant medical conditions, and that a cause is not required before support can begin. The examination task is similar: distinguish evidence for familial aggregation from proof of an individual mechanism, and distinguish a risk factor from a cause.

The evidence is strongest for a substantial genetic contribution, but ASD is genetically heterogeneous. Its neurobiology is likewise a set of converging developmental observations rather than a diagnostic test. Environmental findings need particularly careful reading because many exposures are correlated with parental characteristics, obstetric events and ascertainment. A good answer therefore moves from genetic architecture to neurodevelopmental correlates, then appraises environmental association and vaccine misinformation without conflating any of these levels of explanation.

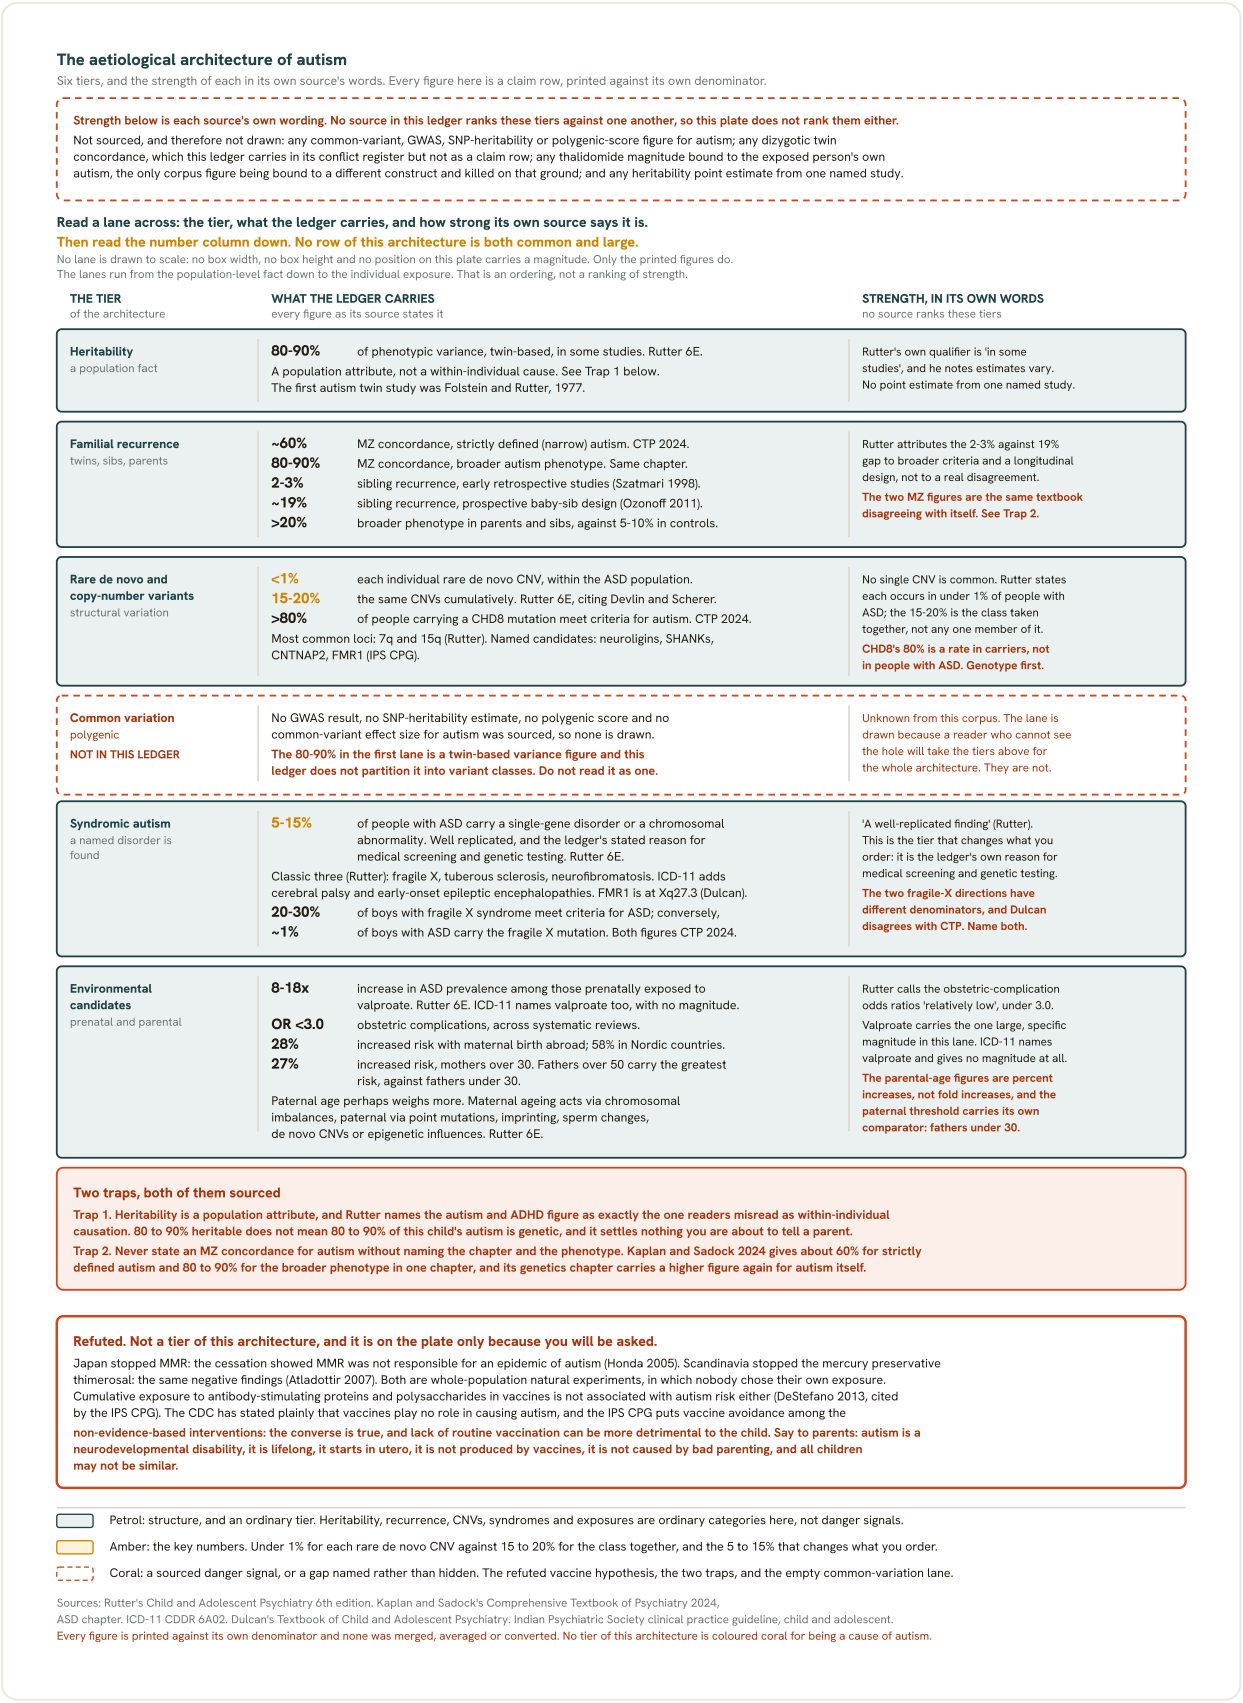

Fig 21.16 **The aetiological architecture of autism.** Six tiers, each printed with the strength its own source claims for it and against its own denominator. The plate teaches one shape: no row beneath twin-based heritability is both common and large, and the one row the ledger ties to a clinical action is syndromic autism. The common-variation lane is drawn empty because no such figure was sourced, and a hole in the map is not a hole in the world. The two traps and the refuted vaccine hypothesis are marked on the plate itself.

21.1 What an aetiological formulation means in ASD

Aetiological heterogeneity means that similar clinical phenotypes can arise through different causal routes. In practice, this prevents the error of treating all ASD as one disease with one lesion. Some presentations occur alongside a recognisable medical or genetic disorder; others reflect the combined effect of many inherited and developmental influences.

> **GOOD TO REMEMBER**
>
> Use the formulation to connect a person's developmental history, physical examination and family pattern to an appropriate medical work-up; choice of ASD genetic tests belongs to the ASD medical workup section.

RULE **Read causation at the right level:** a population estimate of genetic influence does not tell us what caused ASD in one child.

Heritability is a population statistic: it describes the share of variation in a population that is associated with genetic differences under the conditions studied. In some studies, twin-based estimates for autism lie **between 80-90** percent of phenotypic variance. This is compelling evidence that genetic factors matter, but it does not mean that this proportion of any individual's ASD was "caused by genes," nor does it make environmental influences irrelevant. Heritability can change when a population or its exposures change.

Historical twin work made the importance of genetic factors visible after **Folstein and Rutter, 1977**. Twin and family designs are complementary. Twin concordance asks whether co-twins share the phenotype; family studies ask whether traits cluster among relatives. Neither design, on its own, identifies a gene or predicts the outcome for an individual pregnancy. A careful answer also states whether it is discussing narrowly defined autism or the broader phenotype.

approximately 60%	80-90%	approximately 19%	5-15%
MZ CONCORDANCE: NARROWLY DEFINED AUTISM	MZ CONCORDANCE: BROADER AUTISM PHENOTYPE	PROSPECTIVELY FOLLOWED INFANT SIBLINGS	SINGLE-GENE DISORDER OR CHROMOSOMAL ABNORMALITY

21.2 Familial aggregation and the broader phenotype

For strictly defined autism, monozygotic twin concordance is approximately 60%. When the outcome includes the **broader autism phenotype**, concordance is between 80-90%. The broader phenotype refers to subthreshold autistic-like traits in relatives, not to an assertion that every relative has ASD. This contrast is clinically instructive: genetic liability may be expressed as traits rather than as the full diagnostic phenotype, and the phenotype being measured changes the estimate.

Older retrospective family studies reported sibling recurrence between 2-3%. In prospectively followed infant siblings, the estimate is approximately 19%. These figures should not be presented as a contradiction. The later design observes siblings from birth and works with broader contemporary diagnostic ascertainment; both features can increase detection. For

counselling, it is more honest to explain that familial recurrence is elevated and that an individual family needs a personalised assessment rather than a memorised population figure.

Subthreshold autistic-like traits occur in above 20% of parents and siblings of ASD probands, compared with between 5-10% in control families. Such aggregation supports a dimensional account of inherited liability. It must not be turned into blame: a parent's communication style, temperament or isolated trait is not evidence that parenting caused ASD.

TRAP **Examination trap:** do not quote the broader-phenotype twin figure as the concordance for narrowly defined autism, and do not use an early retrospective sibling estimate as though it came from a prospective infant-sibling design.

21.3 Genetic architecture: common liability, rare variants and syndromic ASD

Genetic architecture describes the kinds of genetic contribution found across a condition, rather than seeking one "autism gene." ASD includes polygenic liability, rare inherited or de novo variation, copy-number variation and recognised syndromic disorders. These categories can overlap in a person, and the presence of a genetic finding should be interpreted alongside the phenotype. A result may clarify associated medical surveillance and family discussion, but it does not reduce the child to a laboratory label.

ARCHITECTURE	WHAT IT CONVEYS CLINICALLY	IMPORTANT DISTINCTION
Familial liability	Traits and diagnoses may aggregate in relatives.	Aggregation is not a single-gene explanation.
Rare de novo copy-number variation	A rare genomic event may contribute substantially in an affected individual.	Each individual rare event is below 1% of the ASD population, yet such variants cumulatively account for between 15-20%.
Chromosomal abnormality	May place ASD in a broader medical and developmental formulation.	Reported abnormalities involve many loci; 7q and 15q are described as common sites.
Syndromic association	Prompts attention to syndrome-specific physical and neurological features.	Association does not imply that every person with ASD has a syndrome.

Recognisable syndromic associations include fragile X, tuberous sclerosis, and neurofibromatosis. ICD-11 additionally lists cerebral palsy and early-onset epileptic encephalopathies among medical disorders associated with ASD, alongside chromosomal abnormalities and neurocutaneous disorders. These are associations that enrich clinical assessment; syndrome-specific genetics, phenotype and recurrence belong to their respective disorder sections.

Copy-number variation refers to a genomic deletion or duplication. The useful clinical contrast is frequency against collective contribution: any one rare de novo CNV occurs in **below 1%** of the ASD population, but the group taken together may account for between 15-20%. This is why a negative search for one famous variant never excludes a genetic contribution, and why genetic architecture cannot be understood by memorising a short gene list.

- Candidate genes named in the Indian guideline include neuroligins, SHANKs, CNTNAP2 and FMR1.
- FMR1 is the fragile X gene, and it is the single commonest monogenic contributor a candidate is asked to name here; its locus, repeat mechanism and phenotype are taught with the syndrome itself.
- CHD8 mutations illustrate a genotype-first association: above 80% of carriers meet diagnostic criteria for autism spectrum conditions.

Direction of a proportion is a frequent exam trap. Between 20-30% of boys with fragile X syndrome meet criteria for ASD, whereas approximately 1% of boys with ASD carry the fragile X mutation. These are different denominators and neither can be inverted. This distinction is also why a syndrome association supports targeted clinical consideration, not indiscriminate causal certainty.

21.4 Neurobiological findings: correlates, pathways and limits

Neurobiology informs models; it does not diagnose ASD. Studies of neurotransmitters, brain growth, imaging and postmortem tissue have identified group-level differences. They are heterogeneous, often developmentally timed, and may be affected by sampling, clinical variation and methodology. The appropriate conclusion is that ASD involves altered neurodevelopmental processes, not that any one scan, blood measure or neuropathological feature establishes the diagnosis.

Peripheral hyperserotonaemia is the most consistently replicated biochemical observation: elevated serotonin in blood and platelets is reported in between 25-50% of children and adolescents with autism. It is peripheral, not a direct measure of cerebrospinal fluid or brain serotonin. A candidate should therefore resist the tempting but invalid inference that it specifies a universal central neurotransmitter abnormality or tells the clinician how to treat an individual child.

Structural findings have focused on development and timing. In the first MRI study, total brain tissue volume in ASD was approximately 6% larger than in controls. **Megalocephaly** may be observable as young as 2 years of age, but was not present at birth in the cited observation. The teaching point is not that all autistic children have enlarged heads. It is that a developmental trajectory may differ after birth, and a cross-sectional image cannot be read as a universal sequence.

Postmortem studies describe increased neural packing, reduced cell size in the limbic system, reduced cerebellar Purkinje-cell number and altered cortical minicolumn organisation, as well as macroencephaly and altered brain-growth trajectories. Such work is constrained by small samples and tissue quality. It must be kept separate from in-vivo imaging. In a voxel-based meta-analysis, grey matter reduction was reported in the bilateral amygdala-hippocampus complex and bilateral precuneus, with a small increase in the middle-inferior frontal gyrus. These are group findings, not a radiological signature for clinical diagnosis.

21.5 Synaptic pruning as a mechanistic example

Synaptic pruning is a useful model for linking cellular findings with developmental circuitry. In the cited postmortem study, typically developing controls lost approximately 40% of dendritic spines across the age span, while individuals with ASD lost half as much as controls. The observation supports a hypothesis of less efficient pruning in at least some ASD tissue. It does not establish that deficient pruning is the sole pathway to ASD, nor that it is measurable in routine practice.

In the linked mechanistic work, **mTOR hyperactivity** was associated with impaired autophagy and disrupted synaptic pruning. In mice, rapamycin, an mTOR inhibitor, corrected pruning deficits and ASD-like behaviours. This is an important translational distinction: a correction in an animal model is not a recommendation for standard ASD treatment. The pathway is being examined in the tuberous-sclerosis subgroup, but the same source cautions that rapamycin is unlikely to become standard treatment for ASD. Mechanism-guided research is valuable precisely because it identifies testable subgroup hypotheses, not because it offers a universal cure.

MNEMONIC

Formulate, do not flatten

family pattern, genomic architecture, developmental brain evidence and exposure history belong in one formulation, but none should be promoted alone into “the cause.”

21.6 Environmental and perinatal associations: how to appraise them

Risk factor means an exposure or characteristic associated with a higher probability of outcome; it is not automatically a necessary or sufficient cause. Obstetric complications have some consistency across reviews, but associated odds ratios tend to be **below 3.0**. This magnitude and the possibility of confounding demand restraint. Complications may be on a causal pathway, may mark an earlier developmental difference, or may share determinants with ASD risk. The clinician should neither dismiss a careful obstetric history nor use it to assign parental blame.

Prenatal valproate exposure is a clinically important exception because it is recognised as a teratogenic exposure. ASD prevalence among those exposed prenatally is between 8-18 times that of the general population. ICD-11 also recognises prenatal valproate as an ASD risk factor. This is a risk statement about prenatal exposure, not permission to alter an individual’s medication without specialist review. In clinical practice, risk communication must balance maternal illness, treatment alternatives and reproductive planning.

Parental age and migration findings illustrate why context matters. Maternal birth abroad is associated with a risk increase of exactly 28% in the general estimate, while the association in immigrant mothers in Nordic countries is a risk increase of exactly 58%. These findings may reflect a complex mixture of migration-related exposures, access to care, social context and ascertainment; they must never be used to stigmatise migrant families.

- The greatest paternal-age risk is reported for fathers over the age of 50, compared with fathers below 30 years.

- For mothers over the age of 30 years, the estimated increased risk is exactly 27%.
- Evidence supports advanced parental age as a risk factor, with a possibly greater paternal contribution. Proposed pathways differ: maternal ageing is linked with chromosomal imbalance, while paternal ageing is linked with point mutation, imprinting, sperm-cell changes, de novo CNVs and epigenetic influences.

The professional response to these associations is prevention-oriented but non-punitive: obtain a sound exposure history, coordinate medication decisions before conception where possible, and avoid retrospective certainty. Most importantly, do not imply that ordinary parental conduct produced the child's ASD.

21.7 Vaccines, parenting and the duty to correct misinformation

This is a safety conversation, not an optional controversy. Claims that vaccines cause autism can lead to delayed or absent vaccination and can damage trust at the point when families need clear guidance. The evidence should be explained calmly, directly and without amplifying the myth through excessive repetition. The same principle applies to blaming parenting: it is inaccurate, harmful and clinically obstructive.

Natural experiment evidence is particularly useful when an exposure changes across a whole population. The Japanese cessation of MMR showed that MMR was not responsible for an epidemic of autism. Separately, Scandinavian cessation of the mercury preservative thimerosal gave the same negative finding. These are distinct questions and should not be blurred: MMR and thimerosal are not interchangeable exposures.

TRAP **Examination trap:** do not write "vaccines are controversial causes." The supported conclusion is that vaccines do not cause autism; withholding routine vaccination can harm the child.

IN INDIA

The Indian guideline, citing the CDC, rejects vaccine causation of autism and cautions that missing routine vaccination can harm the child. It also cites evidence that increasing exposure to vaccine antibody-stimulating proteins and polysaccharides was not associated with autism risk. These statements permit an unambiguous clinical recommendation while still making room for parents' fear to be heard respectfully.

When communicating a diagnosis, frame ASD as a lifelong neurodevelopmental disability with prenatal origins. Explain clearly that neither vaccination nor poor parenting produces it, and that children need not look alike clinically. This framing validates uncertainty without inventing a culprit. It also redirects attention toward assessment of strengths, support needs, associated medical conditions and intervention planning.

21.8 Clinical synthesis and examination answer

A complete aetiology answer begins with multifactorial neurodevelopmental causation and then separates evidence streams. Describe strong familial and twin evidence without treating heritability as individual causation. Explain the range from polygenic liability to rare CNVs,

chromosomal abnormalities and syndromic ASD, while referring genetic-test selection to the ASD medical workup. Use neurobiological observations as developmental correlates, state their limitations, and appraise environmental findings by study design, effect magnitude and confounding. End by explicitly correcting vaccine and parenting myths, because they are clinically consequential errors rather than harmless opinions.

For families, the formulation should be usable. It should say what is known, what remains uncertain, and what can be acted upon now. A syndrome-associated presentation may change surveillance and counselling; a prenatal exposure may affect future reproductive planning; neither changes the need for developmental support. Avoid giving a long list of alleged causes, which often leaves parents with blame rather than understanding.

ASD aetiology is best understood as heterogeneous neurodevelopmental causation: genes and developmental biology predominate, environmental associations require cautious causal inference, and vaccines and parenting do not cause autism.

The clinical picture of autism and how it is recognised

22 · Clinical features and core domains of ASD

The clinical task is to recognise a pattern, not to count isolated oddities. Autism spectrum disorder becomes visible when differences in social communication are understood alongside restricted, repetitive or inflexible patterns of behaviour and experience. A child may be quiet, highly verbal, bright, anxious, disruptive, apparently aloof, or warmly attached to familiar people. None of those impressions settles the question. The useful clinical formulation asks how the person shares attention, uses communication with another mind in view, manages reciprocity, and responds when routine, expectation or sensory input changes.

Recognition matters because the presentation is developmental and contextual. The same behaviour can have different meanings at different developmental levels, and a behaviour that looks unusual in a brief consultation may be an adaptive response to uncertainty. History, direct observation and reports from the settings in which the person lives should therefore be brought together. The diagnostic criteria are addressed separately; this section concerns the clinical phenotype that makes those criteria intelligible at the bedside.

approximately 20%	12-24 months	12-24 months	10-50%
REPORTED REGRESSION OR DEVELOPMENTAL STAGNATION	USUAL RECOGNITION WINDOW	USUAL WINDOW FOR SKILL LOSS, WHEN PRESENT	ESTIMATED RANGE FOR SAVANT OR SPLINTER SKILLS

22.1 Recognising a developmental social-communication difference

Autism is usually recognised through a qualitative difference in how social information is noticed, interpreted and used. The central issue is not whether the person wants company in an abstract sense. It is whether interaction is organised as a reciprocal exchange in which another person's

attention, knowledge, feeling and response alter one's own communication. A person may seek proximity, enjoy affection, or initiate contact for a need, yet still have difficulty sustaining the back-and-forth adjustments that make interaction feel shared.

Social reciprocity includes initiating interaction, responding contingently, sharing interests and affect, and allowing the partner's response to shape the next move. In young children this may be seen as limited showing, bringing, pointing out or checking back after an event. In older children and adults it may appear as a one-sided conversation, a tendency to return rapidly to a preferred topic, or difficulty recognising when the listener is confused, bored or trying to change direction. These are descriptions of the quality of exchange, not moral judgements about empathy, attachment or motivation.

A careful history separates capacity from performance. Some people communicate much less when overloaded, unfamiliar with the examiner, tired, frightened or expected to respond rapidly. Others have learned scripts that make initial interaction appear fluent but that do not readily flex when the conversation departs from the script. The clinician should look for developmental continuity and for the effort required to maintain apparently typical social behaviour. A socially successful encounter does not erase a pervasive developmental difficulty, just as an awkward encounter does not establish one.

RULE **Interpret the social behaviour in its communicative context: the question is how the person shares a mind with another person, not whether eye contact or sociability is simply present or absent.**

GOOD TO REMEMBER

At the bedside, ask the caregiver for ordinary examples of sharing an achievement, reacting to another person's distress, joining group play, managing a misunderstanding or telling a story to a listener who does not already know it. Then observe the response to an unexpected but benign shift in topic or activity: does the person repair communication, seek clarification, withdraw, perseverate or become distressed? This helps distinguish a stable developmental pattern from a situational reaction.

CLINICAL DOMAIN	WHAT TO EXPLORE	HOW IT MAY PRESENT IN CONSULTATION	INTERPRETIVE CAUTION
Reciprocal exchange	Initiation, response, turn-taking and sharing	Conversation may be asymmetrical, unusually passive, or driven by an immediate need	Shyness and anxiety can reduce performance without creating the developmental pattern
Non-verbal integration	Gesture, facial expression, gaze and timing	Signals may be limited, atypical, poorly coordinated with speech, or difficult to read	Do not convert one gaze style into a diagnosis
Relationships	Peer interest, social imagination and adaptation to roles	Rules of friendship may be understood literally; group interaction may be hard to enter or sustain	Solitude may be a preference, a coping strategy, or both
Repetition and inflexibility	Patterns, routines, focused interests and sensory responses	Distress, persistence or repetitive action becomes prominent when expectations shift	Determine function and impairment before labelling a preference pathological

22.2 Non-verbal communication and shared attention

Non-verbal communication is not a decorative adjunct to speech. Gesture, posture, facial expression, gaze, distance, timing and prosody carry much of the meaning of social exchange. In autism, the difficulty may lie in producing these signals, coordinating them with words, noticing those used by others, or inferring the unstated message they convey. The pattern is variable. Some individuals use abundant gesture but in an idiosyncratic or poorly integrated way; others have a relatively neutral facial style yet understand familiar relationships well.

Joint attention is especially useful clinically because it captures the difference between requesting and sharing. A person can point to obtain an object while finding it harder to point simply to make another person notice something interesting. Similarly, a child may follow a hand because it predicts access to a desired item but not because the other person's focus is meaningful in itself. The history should ask about following another's attention and actively directing it. Direct observation can then assess whether the person shifts attention between an object and a partner, checks the partner's reaction, or incorporates the partner into the experience.

Do not reduce this to an eye-contact test. Gaze is influenced by culture, anxiety, visual ability, temperament and the demands of the interaction. Sustained eye contact may be uncomfortable, distracting or consciously performed. Conversely, apparently good eye contact may coexist with marked difficulty using its social meaning. A better formulation is that visual social signals can be used differently, sometimes with little coordination between gaze, gesture and spoken language.

- Explore whether gestures are used to share as well as to request.
- Observe whether facial expression and voice match the intended message.
- Ask how misunderstandings are repaired when the listener does not follow.

- Consider whether social signals are missed, over-read or interpreted literally.

TRAP **Examination trap: neither reduced eye contact nor a preference for solitude is a sufficient clinical shortcut. The developmental pattern across reciprocal communication, non-verbal integration and flexibility is what carries meaning.**

22.3 Language phenomenology: form, use and reciprocity

Language in autism must be described at the level of use, not merely the presence or absence of words. The language phenomenology of autism includes differences in developmental progress, conversational reciprocity, prosody, literal interpretation and the ability to adjust communication for another person's perspective. Language ability is heterogeneous. Some people have very limited spoken language; others have extensive vocabulary and grammatically complex speech while finding the social use of language persistently difficult. Language impairment is considered separately as a specifier and should not be confused with the social-communication phenotype itself.

Pragmatic language concerns what speech does between people. It includes selecting relevant information, recognising implied meaning, taking turns, maintaining an appropriate topic, judging what the listener knows, and repairing breakdowns. A child may answer factual questions accurately but not volunteer information that would make the account coherent for someone else. An adult may speak fluently at length about a preferred interest yet have trouble sensing the reciprocal rhythm of conversation. These patterns are often most evident in unstructured conversation rather than in direct question-and-answer exchanges.

Echolalia refers to repetition of heard language. It may be immediate or delayed, but the clinician should not assume that it is meaningless. Repeated phrases can request, protest, regulate emotion, preserve a familiar sequence, or communicate an association that is not obvious to the listener. The clinical task is to determine the communicative function and the degree to which repetition substitutes for flexible, generative language. Similarly, pronouns may be used in an unusual perspective, and speech may have an atypical rhythm, volume or melody. Such features are useful only when understood as part of the wider developmental pattern.

History taking should locate the change in ordinary life. Ask how the person tells a story, joins a conversation already in progress, copes with jokes and indirect requests, or reacts when someone asks an ambiguous question. A family may report that the person is articulate but seems not to "read the room". That everyday observation can be more clinically revealing than a formal vocabulary performance. Equally, a bilingual environment should not be mistaken for a cause of autism or used to excuse a pervasive social-communication concern. The relevant question is whether the pattern is present across the languages and relationships available to the person.

For the intervention plan, speech and language therapy belongs with the broader support approach described in the relevant section of this chapter. At assessment, the immediate responsibility is more basic: document what communication achieves, what breaks down, and what support makes the person's intention understandable.

22.4 Restricted patterns, insistence on sameness and sensory experience

Restricted and repetitive behaviour is clinically broader than obvious motor stereotypy. It includes repetitive movements or speech, a marked need for predictability, unusually intense or narrowly focused interests, and atypical responses to sensory input. Its common thread is a reduced ease with variation or a distinctive way of regulating attention, arousal and meaning through repetition. The behaviour may be quietly internalised and therefore missed in an articulate adolescent or adult whose outward presentation appears composed.

Insistence on sameness is often best recognised through the consequences of disruption. The person may rely on a fixed route, sequence, object arrangement, conversational script or rule. A change may produce distress, anger, shutdown or prolonged preoccupation, not because the preference is trivial but because predictability is serving an organising function. Obtain concrete examples from home, school, workplace and travel. Then ask whether the routine can be modified with preparation, whether the response is proportionate, and whether the restriction limits participation or causes conflict.

Sensory reactivity may involve unusually strong, weak or seeking responses to sound, touch, light, smell, taste, movement or visual detail. It should be elicited as lived experience rather than treated as a box to tick. A child who covers their ears may be in pain, anticipating noise, avoiding a social demand, or doing more than one of these. An adult who avoids crowded places may be managing sensory overload, social uncertainty, panic, or a combination. The formulation must link trigger, response, function and consequence.

- Ask what the person repeatedly does, says, collects, watches or arranges.
- Ask what must happen in a particular order and what follows if it does not.
- Explore focused interests for intensity, flexibility and impact, rather than judging the topic itself.
- Map sensory triggers, protective strategies and the effect on ordinary participation.

Focused interests can be a route to competence, pleasure, identity and connection. They become clinically relevant when their intensity or inflexibility constrains functioning, blocks reciprocal engagement, or makes transition difficult. This distinction protects against pathologising expertise or temperament. It also enables the clinician to use an interest respectfully as a bridge during assessment rather than treating it only as a symptom.

22.5 Developmental regression and developmental stagnation

Developmental regression means loss of abilities that were previously acquired and used, whereas developmental stagnation refers to a plateau in expected gains. Both deserve a careful timeline. A report may be imprecise because a skill was inconsistent, context-bound or only recently emerging. The clinician should therefore ask for examples of the earlier ability, its ordinary use, the sequence of change, and what else changed around the same period. In autism, regression or stagnation is reported in approximately **20%** of cases.

Autism symptoms are typically recognised between **12 and 24 months**. Where previously acquired social or language skills are lost, the loss itself also typically occurs between **12 and 24 months**. These statements describe distinct clinical questions: recognition concerns when the pattern comes to notice, while regression concerns the timing of actual skill loss. Keeping that distinction prevents a history of late recognition from being incorrectly recorded as regression.

Loss of previously acquired skills is usually described during the second year of life and is rarely observed after **3 years of age**. When it occurs, the loss most often concerns language use and social responsiveness. If the reported course is later or broader, document it precisely rather than forcing it into an autism narrative. If a loss occurs after 3 years of age, it is more likely to include changes in cognitive and adaptive functioning, continence, sleep, language, social ability, emotion and behaviour. Such a presentation needs separate evaluation; the differential diagnosis of regression is addressed elsewhere in this chapter.

Regression is emotionally potent for families. They often remember a before-and-after story, and it is important neither to dismiss that account nor to turn it prematurely into an aetiological explanation. Clarify whether the child lost a functional word, stopped responding to name, ceased sharing interest, became less socially responsive, or simply failed to add new skills. Review contextual changes and establish whether the apparent loss was global or selective. The record should preserve the caregiver's observations in concrete behavioural language, because that is more useful than the label alone.

> A plateau and a loss are not interchangeable: establish the prior skill, its functional use and the sequence of change before calling a course regressive.

22.6 Cognitive style, uneven ability and exceptional islands of skill

There is no single cognitive profile that defines autism. What is clinically common is an **uneven profile of abilities**, including in people whose general intellectual ability is average or high. A person may have striking factual knowledge, rapid pattern recognition or strong rote learning alongside difficulty applying ability flexibly in everyday social and practical contexts. The gap between demonstrated intellectual skill and adaptive functioning can be conspicuous. This is why a superficially impressive verbal or factual performance should not end the assessment of support needs.

Several cognitive accounts have helped clinicians describe aspects of the phenotype: **theory of mind**, weak central coherence, and executive dysfunction. Difficulty representing another

person's perspective can illuminate social misunderstandings. A detail-focused processing style can illuminate difficulty deriving the broader context. Problems with planning, shifting set, organising and inhibiting a habitual response can illuminate inflexibility. None should be used as a universal explanatory key. The cognitive theories do not establish a unitary cognitive origin for all manifestations of autism.

Savant or splinter skills describe competencies that stand out above the individual's general level of ability or above population expectation. Estimates vary with how such skills are defined, ranging between **10% and 50%** of people with autism. Their presence does not negate disability in another domain, and their absence has no diagnostic implication. Clinically, ask what the skill enables, whether it is enjoyable or burdensome, and whether it can be incorporated into education, work, self-advocacy or engagement.

Mental-state, contextual-integration, executive and motor features often discussed in autism are descriptive aids, not a substitute for developmental assessment. They can explain why an individual may know a rule yet fail to use it in a fast-moving social situation, or complete a complex task yet struggle with the unstructured demands around it. The practical lesson is to look for discrepancies: between knowledge and use, verbal expression and reciprocal conversation, performance in a preferred task and performance under change, or stated independence and actual day-to-day functioning.

22.7 A disciplined clinical formulation

A high-quality formulation is developmental, functional and contextual. It anchors current observations to the early pattern, describes what the person can do independently and what becomes difficult, and identifies environmental adjustments that alter performance. Home, educational, occupational and peer settings may reveal different aspects of the same difference. This framing matters when a person camouflages difficulties or when family routines have hidden impairment in consultation.

Use examples rather than labels wherever possible. "Talks at length about one topic and does not notice attempts to change it" is more clinically useful than "poor reciprocity" alone. "Becomes unable to continue when the usual route changes" is more useful than "rigid". Concrete descriptions allow later review, enable communication across disciplines and protect against diagnostic overshadowing. They also help the person and family identify accommodations without requiring the clinician to infer motives from a behaviour.

Changes from the person's usual baseline need particular care. Do not attribute new distress, marked withdrawal, loss of function, self-injury, agitation, sleep change or altered eating automatically to autism. Medical and psychiatric comorbidity, including catatonia, is considered in the medical comorbidities and workup section of this chapter. The clinician's immediate job is to recognise a baseline change and investigate it as a change, rather than accepting it as an inevitable expression of the developmental condition.

The assessment must also leave room for the person's strengths, preferences and account of their own experience. A formulation that records only deficits will miss the conditions in which

communication works, the interests through which rapport can be built, and the strategies that already reduce overload. The aim is not to make every distinctive preference disappear. It is to understand the pattern well enough to distinguish difference from impairment and to identify where support can make participation more possible.

23 · Severity levels and specifiers (with or without ID, language impairment)

Severity is a statement about current help, not a shorthand for ability. In autism spectrum disorder (ASD), a useful formulation has to keep several descriptions in view at once: the intensity of core autistic difficulties, intellectual functioning, language functioning, associated conditions and the person's changing circumstances. Collapsing these into one label makes the record look tidy but makes clinical planning less accurate. The diagnostic formulation should therefore preserve distinctions that matter to the person, family and team.

The immediate examination value is equally practical. A severity level describes the support needed for the core autistic presentation. It does not quantify intelligence, does not replace a language description, and does not exhaust the associated clinical picture. Specifiers make those separations visible. They turn a broad diagnostic name into a clinically communicable account of the individual sitting in front of the clinician.

3	2	3
DSM-5-TR SUPPORT LEVELS	DOMAINS RATED SEPARATELY	ICD-11 FUNCTIONAL-LANGUAGE LEVELS

23.1 What an ASD severity level is intended to convey

Start with the question behind the label. The DSM-5-TR severity framework is a description of **support need in the core autistic domains**. It asks how much assistance is currently required because of social-communication difficulty and because of restricted, repetitive patterns of behaviour. It is thus a functional clinical description, not a global ranking of the person.

There are **three** named support levels: **Level 1, requiring support**; **Level 2, requiring substantial support**; and **Level 3, requiring very substantial support**. The wording is deliberately about the assistance needed. A level should prompt the clinician to ask what supports permit participation, communication, flexibility and safety, rather than being treated as a fixed essence of the person.

RULE **Rule:** Record ASD severity as support need in the core domains, and record intellectual and language impairment separately.

That distinction matters because observed difficulty can be shaped by context. A familiar, predictable setting with effective communication supports may reveal capacities that are obscured in an unfamiliar assessment room. Conversely, a change in demands, sensory load, illness, distress or available support may expose need that was not apparent previously. The severity description must therefore be anchored in current functioning and meaningful participation, not in a superficial impression formed from a brief encounter.

The phrase “severity” can mislead candidates because the same word is used elsewhere in developmental psychiatry. Intellectual disability has its own severity classification, which is dealt with in the severity classification of intellectual disability section. The ASD framework answers a different question. It does not establish the presence of intellectual impairment and it does not substitute for an assessment of adaptive functioning. Keeping the questions separate prevents a common category error.

23.2 Rate the domains separately, not the person globally

DSM-5-TR asks that the level of support be recorded separately for **two** domains. One rating concerns social communication; the other concerns restricted, repetitive behaviour. This is not clerical fussiness. These domains can create quite different practical barriers, and their support requirements may not move together.

A person may need intensive help to manage inflexibility, transitions and repetitive behaviour while communicating more effectively in a structured interaction. Another may have relatively less conspicuous repetitive behaviour in a short consultation yet need extensive support to sustain reciprocal communication across daily settings. A single global level would conceal that pattern and can lead the receiving team to organise support around the wrong problem.

The social-communication rating asks how much support is needed for reciprocal communication. The restricted and repetitive behaviour rating asks how much support is needed for rigidity, repetitive behaviour and related interference. The intellectual-impairment specifier asks whether intellectual impairment accompanies ASD, while the language-impairment specifier asks whether language impairment accompanies it and, if so, what current verbal functioning is like. None of these questions can be answered by simply borrowing the answer to another.

GOOD TO REMEMBER

In a clinical note, record the two domain ratings with the observed barriers and the supports that alter them. A later change in level may reflect a change in support need, setting or the effect of effective intervention; it is not a prognosis.

TRAP **Classic trap:** Do not derive the ASD level from an IQ score. Intellectual impairment is carried by a separate specifier, not by the ASD severity level.

Equally, do not infer the support level merely from speech quantity. Language impairment and social-pragmatic difficulty overlap in everyday presentation but are not interchangeable descriptions. The language phenomenology of ASD belongs with the clinical features of ASD section; here the task is to show how language is captured in the diagnostic formulation without converting it into a core-severity score.

23.3 DSM-5-TR specifiers: add the clinically relevant dimensions

Specifiers prevent the broad ASD diagnosis from becoming clinically empty. They should be stated positively where present and negatively where absent, after assessment rather than by assumption. The first pair addresses accompanying intellectual and language impairment: **with**

or without accompanying intellectual impairment, and **with or without accompanying language impairment**.

The intellectual specifier is not an invitation to re-grade intellectual disability within the ASD note. It flags a co-occurring dimension that changes communication, assessment interpretation, educational planning and the kind of support likely to be required. The underlying assessment and severity classification of intellectual disability should be documented using their own standards. In particular, an autistic person's social difficulty should not be mechanically treated as evidence of global adaptive limitation.

The language specifier is similarly an addition, not a restatement of ASD itself. When language impairment is present, the clinician describes the current level of verbal functioning. This avoids the unhelpful shorthand of treating all language difficulty as equivalent. It also guards against the opposite error: assuming that fluent speech rules out significant social-communication disability. The diagnostic criteria section explains why language impairment is not itself a DSM-5 core criterion; the present specifier tells the reader whether it accompanies the syndrome.

Other specifiers place ASD in its wider clinical setting. The formulation may state that it is associated with a known genetic or other medical condition or environmental factor. This wording records an association or context; it must not be casually converted into a causal conclusion. It may also state that ASD is associated with a neurodevelopmental, mental, or behavioural problem. The full map of co-occurring conditions and how to detect them belongs in the medical comorbidities and workup in ASD section.

- Use the intellectual-impairment specifier to make accompanying intellectual impairment explicit, not to estimate it from presentation.
- Use the language-impairment specifier to record an accompanying language problem and current verbal functioning.
- Use the known-condition wording to state context accurately without claiming causation that the evidence has not established.
- Use the associated-problem wording to ensure that important co-occurring neurodevelopmental, mental or behavioural difficulties do not disappear behind the ASD label.

For the candidate, this is a disciplined form of diagnostic writing. "ASD" alone describes the syndrome but not the clinically relevant modifiers. A complete formulation makes visible which parts of the presentation are core, which are accompanying impairments, and which require parallel assessment or treatment. That distinction also protects against diagnostic overshadowing, where all distress or disability is wrongly attributed to autism.

23.4 Catatonia: a specifier that requires active clinical attention

Do not let a specifier become a footnote. DSM-5-TR permits the specification **with catatonia**. This should prompt careful assessment of a change from the individual's usual state, including

motor behaviour, responsiveness, activity and functional capacity. A diagnostic label should never replace a longitudinal account of what has altered and what the family or carers have observed.

When catatonia accompanies ASD, DSM-5-TR directs use of the additional code **F06.1**. It is a separate diagnostic code, not an ASD severity modifier and not a reason to raise a support level by default. The distinction is clinically important: support-level language describes core autistic support needs, whereas catatonia identifies an associated syndrome that requires its own recognition and management pathway.

The period of greatest risk described in DSM-5-TR is the adolescent years. That fact should sharpen clinical vigilance without turning ordinary developmental change into a diagnosis. When there is concern, document baseline, timing and trajectory, seek collateral from people who know the individual well, and evaluate the wider clinical context. Recognition belongs with the ASD comorbidity assessment; treatment is addressed in the pharmacotherapy in ASD section.

> A support level is not a catch-all label: ASD severity, accompanying intellectual impairment, accompanying language impairment and catatonia each answer different clinical questions.

23.5 ICD-11: characterisation through intellectual development, language and loss of skills

ICD-11 takes a differently structured approach. It does not supply DSM-style support-need severity levels. Instead, ASD is characterised through specifiers relating to **intellectual development, functional language and loss of previously acquired skills**. This is not a minor terminological difference. A clinician transferring information between systems must not invent a support level from an ICD-11 code, nor assume that an ICD-11 language category is a DSM support rating.

The intellectual-development axis is expressed as **with or without disorder of intellectual development**. In ICD-11, a co-occurring disorder of intellectual development is diagnosed separately rather than folded into the ASD diagnosis as an inline descriptor. When assessing this co-occurrence in ASD, greater weight should be given to the intellectual, conceptual and practical aspects of adaptive functioning than to social skills. This protects against mistaking social difficulties intrinsic to autism for evidence of a broader adaptive disorder.

The **functional-language axis** has **three** levels. It distinguishes mild or no functional-language impairment, impaired functional language, and complete or almost complete absence of functional language. The middle category concerns a person unable to use more than very short spoken expressions. These categories primarily describe functional expressive language, including nonverbal expression where relevant; they do not replace assessment of the pragmatic communication difficulty that is central to ASD.

FRAMEWORK	WHAT IT RECORDS	CLINICAL READING
DSM-5-TR ASD severity framework	Current support need in each core domain	Use to communicate the assistance required for core autistic difficulties
DSM-5-TR intellectual specifier	Presence or absence of accompanying intellectual impairment	Keep intellectual impairment distinct from ASD support level
DSM-5-TR language specifier	Presence or absence of accompanying language impairment	Describe current verbal functioning when impairment is present
ICD-11 ASD characterisation	Intellectual-development, functional-language and loss-of-skills specifiers	Do not translate this structure into a support-level rating

ICD-11 also records whether there has been loss of previously acquired skills. The suffixes 6A02.x0 and 6A02.x1 distinguish absence from presence of such loss. This coding distinction should not be used to teach the phenomenology or differential diagnosis of regression, which are considered elsewhere in the chapter. Its value here is to show that ICD-11 preserves a clinically salient developmental course feature within the diagnostic characterisation.

23.6 ICD-11 coding: use the matrix, do not guess it

The ICD-11 code reflects the combination of intellectual-development and functional-language descriptors. It is safer to determine the descriptors first, then select the matching code, rather than attempting to recall a code from an impression of severity. The following are selected, explicitly stated combinations. They are examples for accurate use, not a substitute for the full coding matrix.

DOCUMENTED COMBINATION	ICD-11 CODE	POINT TO RETAIN
Without disorder of intellectual development, with mild or no functional-language impairment	**6A02.0**	This is a coding combination, not a DSM support level.
Without disorder of intellectual development, with impaired functional language	6A02.2	Language description and intellectual-development status are both needed.
With disorder of intellectual development, with mild or no functional-language impairment	6A02.1	Co-occurring intellectual-development disorder is represented in the code.
With disorder of intellectual development, with impaired functional language	6A02.3	Do not infer support need from this code.
With disorder of intellectual development, with complete or almost complete absence of functional language	6A02.5	Use the language descriptor that is actually documented.

ICD-11 provides 6A02.Y for other specified ASD when the parameters do not apply, and 6A02.Z for unspecified ASD when the parameters are unknown. These are not interchangeable expressions of uncertainty. Good documentation reduces unnecessary use of the unspecified category while respecting genuine limits of available information.

23.7 A practical method for writing the formulation

Write the formulation in layers. First establish the diagnosis using the diagnostic criteria. Then describe the current ASD support need in each core domain when using DSM-5-TR. Next state the intellectual and language specifiers, followed by relevant associated-condition and associated-problem specifiers. Finally, record catatonia when present and use the appropriate additional code. This order mirrors clinical reasoning: syndrome, core impact, accompanying impairments, then associated context.

- State the diagnostic system being used so that the reader knows whether a support-level or coding-matrix framework applies.
- For DSM-5-TR, record the two core-domain support ratings separately and add a short functional explanation of each.
- State whether accompanying intellectual impairment and accompanying language impairment are present, without converting either into an ASD level.
- Record associated conditions and associated problems as clinical context, and keep association distinct from causal attribution.
- For ICD-11, establish intellectual-development status and functional-language status before selecting the code and any loss-of-skills suffix.

This layered method also improves communication across disciplines. It tells a speech and language clinician that a language issue is recognised without pretending that language alone explains the autistic presentation. It tells an educational or disability team that intellectual impairment requires its own assessment. It tells the medical team that an associated condition needs parallel attention. Above all, it avoids turning a diagnostic label into a description that is too vague to guide care.

When information is incomplete, state what has and has not been assessed rather than filling the gap with an assumed level. Diagnostic precision is not achieved by false certainty. A provisional formulation can still be useful if it clearly separates observed support needs from unassessed intellectual functioning, language status or associated conditions. The next assessment question then becomes obvious.

23.8 High-yield discriminations

The strongest answers distinguish neighbouring ideas before they list them. ASD severity is a support-need description for the core autistic domains. Intellectual impairment and language impairment are accompanying specifiers. ICD-11 uses a different characterisation system, based on intellectual development, functional language and loss of previously acquired skills rather

than DSM-style support levels. These are complementary ways of making heterogeneity visible, not rival measures of a single latent "severity".

In practice, the formulation should remain revisable. Support needs can change with environment, development, communication access, co-occurring clinical problems and the fit between the person and available services. Revision is not inconsistency when it reflects a better account of current functioning. What should remain stable is the discipline of recording each dimension for what it means, rather than allowing a memorable label to do the work of assessment.

24 · Screening and diagnostic tools (M-CHAT, ADOS, ADI-R, CARS, ISAA, INCLEN)

Tools organise evidence; they do not substitute for clinical judgment. Autism assessment is often difficult not because there is a shortage of instruments, but because instruments answer different questions. A brief parent questionnaire can identify a child who needs closer attention; an observed interaction can make social communication and restricted behaviour more visible; a developmental history can establish whether the pattern has been present across time; and a disability assessment can document functional impact for statutory purposes. Treating all of these as interchangeable produces familiar errors: diagnosing from a screen, or mistaking an administrative score for the diagnostic formulation.

For the candidate and the clinician, the useful organising question is therefore not, "Which scale proves autism?" It is, "What decision is this instrument designed to support?" A positive screen changes the urgency of assessment. A clinician-administered diagnostic measure can sharpen an already careful formulation. An Indian disability instrument serves a further, legally important function after diagnosis. This sequence protects children from delayed support while preserving the clinician's responsibility to weigh developmental history, direct observation, informant accounts, context, and alternatives.

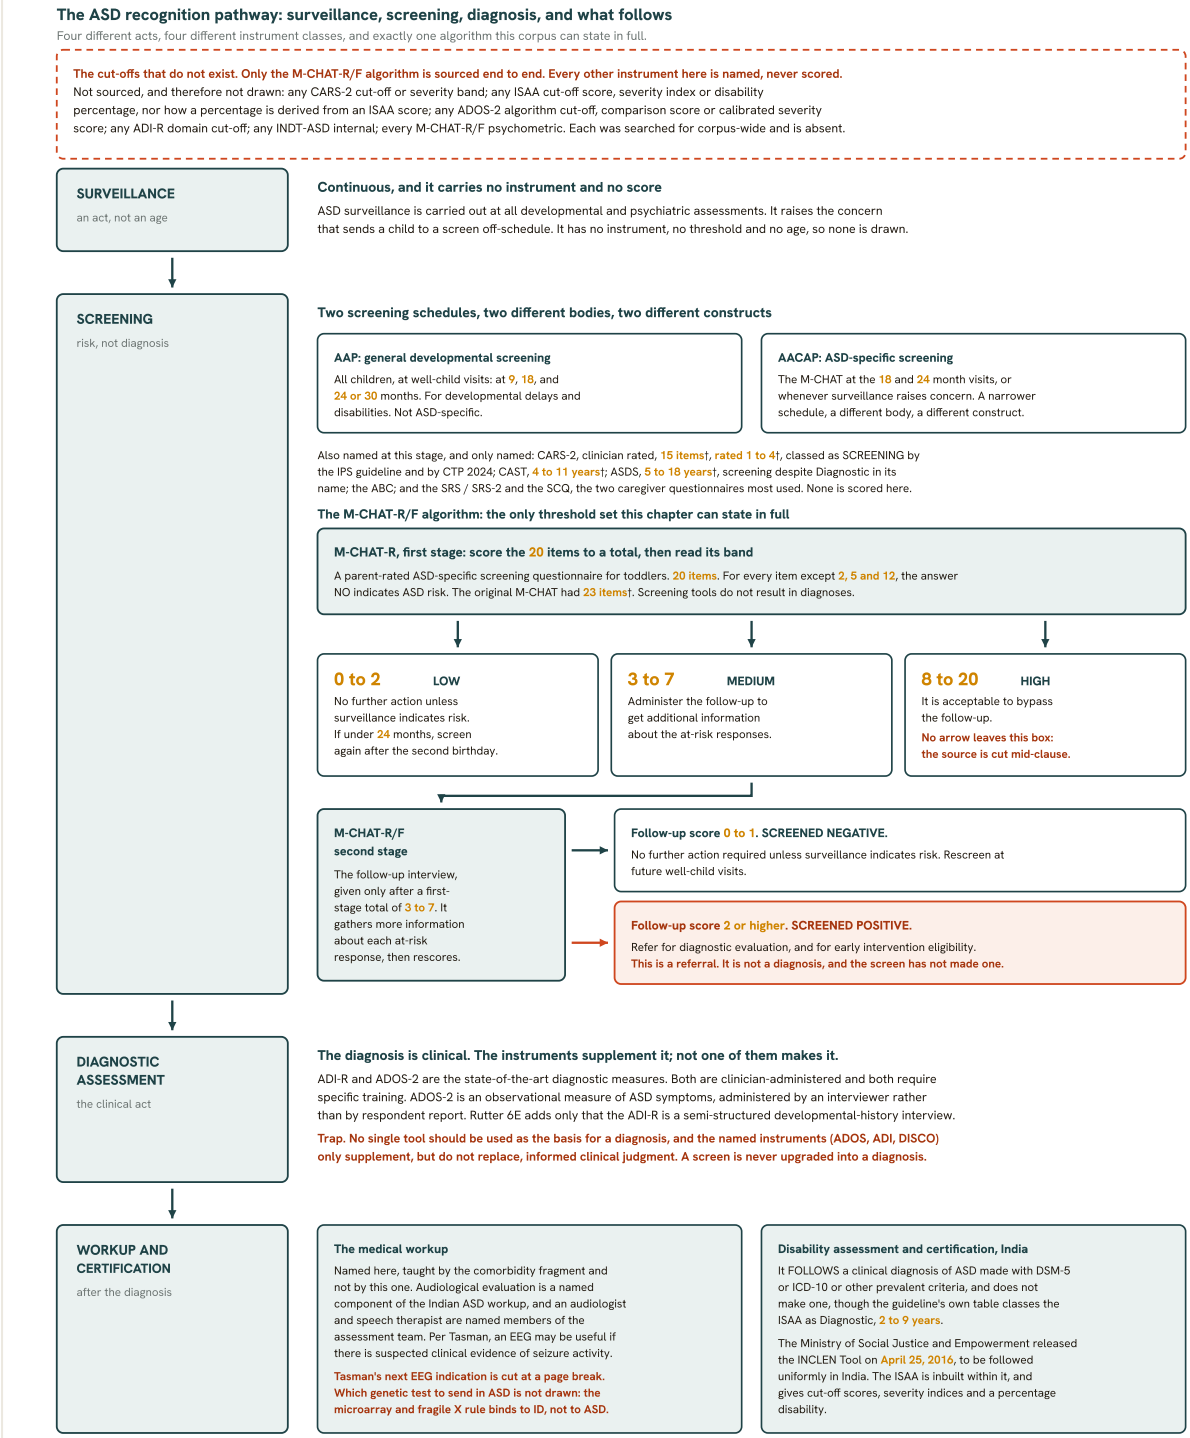

Fig 21.17 **The ASD recognition pathway.** Surveillance raises the concern, screening estimates the risk, the diagnosis is clinical, and both the workup and the Indian certification route follow it. Only the M-CHAT-R/F algorithm is sourced end to end; every CARS-2, ISAA, ADOS-2 and ADI-R cut-off is named on the plate and left undrawn.

24.1 A functional taxonomy of autism instruments

Screening is a process for finding children whose developmental profile warrants further assessment. Its purpose is sensitivity to concern, not a final statement about diagnosis. A screen can be negative when concerns remain clinically persuasive, and it can be positive because another developmental or behavioural difficulty needs assessment. Conversely, the absence of a score should never close a history that is concerning to parents or a clinician. **The M-CHAT-R/F** is a parent-rated, autism-specific toddler screen with a second-stage follow-up interview; it is not a diagnostic instrument.

RULE **Rule:** Match the instrument to its decision, then return the result to a clinical formulation rather than allowing the score to become the formulation.

CLINICAL QUESTION	USEFUL INSTRUMENT CLASS	WHAT THE RESULT SHOULD DO
Is there sufficient concern to escalate assessment?	Parent-rated autism-specific screen	Trigger follow-up questioning, surveillance, or referral according to the algorithm.
Can autism-related behaviour be sampled directly?	Observational assessment	Add direct clinical observations to the history and examination.
What was the developmental course?	Developmental-history interview	Clarify onset, change over time, and examples across settings.
Does a scale indicate concern or quantify observed features?	Clinician-rated screening scale	Support communication and follow-up, without becoming the diagnosis.
What is required for disability documentation in India?	Post-diagnostic disability assessment	Quantify disability and support access to certification-related entitlements.

The distinction is clinically productive. A questionnaire brings the caregiver's longitudinal experience into the consultation. An observation samples what happens under clinical conditions, but cannot by itself reproduce every home, school, or peer context. A history interview may expose a meaningful developmental trajectory, but its interpretation depends on the quality of the informant account and the clinician's questions. Each contributes a different kind of evidence. Diagnostic confidence comes from their convergence with informed judgment, not from collecting the largest possible pile of forms.

Informed clinical judgment remains central: diagnostic instruments supplement it and no single tool should provide the sole basis for diagnosis. This is not a vague appeal to intuition. It means the clinician must decide whether reported and observed features form a coherent autism pattern, whether they are developmentally meaningful, and whether another explanation better accounts for the presentation. The full assessment framework belongs with the Child psychiatry: assessment, treatment, services and protection notes; the present task is to understand what each autism-specific tool can and cannot add.

24.2 M-CHAT-R/F: using a screening algorithm safely

A screen is an invitation to think again. The M-CHAT-R/F is designed for toddlers and is parent rated. The revised checklist contains **20 items**. Its follow-up interview matters because an initial answer may reflect misunderstanding of the question, an unusual circumstance, or a concern that becomes clearer when a clinician asks for examples. In practical terms, the first stage identifies responses needing clarification; the follow-up turns a crude count into a more clinically usable account of risk responses.

0-2	3-7	2 or higher	8-20
LOW FIRST-STAGE BAND	FOLLOW-UP REQUIRED	POSITIVE AFTER FOLLOW-UP	FOLLOW-UP MAY BE BYPASSED

At a first-stage total of **0-2**, the result falls in the low-risk band. No further algorithmic action is required unless surveillance itself indicates risk. For a child younger than 24 months, with repeat screening after the second birthday, the guidance is to screen again. This is a useful reminder that a reassuring questionnaire is not permission to ignore a parent's developing concern, a developmental history, or a change in social engagement.

> **GOOD TO REMEMBER**
>
> A first-stage total of **3-7** is the medium-risk band and calls for the follow-up interview. Do not call this initial score the diagnostic threshold. It is a decision point for gathering better information about at-risk answers. After follow-up, a score of **at least 2** is screen positive and should lead to referral for diagnostic evaluation and consideration of early-intervention eligibility. A follow-up total of 0-1 is screen negative; ongoing surveillance and rescreening at future well-child visits remain appropriate when concerns arise.

At a first-stage total of 8-20, out of a possible **20**, it is acceptable to bypass the follow-up stage. The important interpretive point is that bypassing an interview is a rule within a screening algorithm, not a licence to pronounce a diagnosis from the questionnaire. In any referral, record the informant's examples, what was observed in clinic, and why the referral is being made. This makes the result clinically portable rather than a detached number.

Scoring direction is an easily missed technical trap. On most items, a response indicating risk is “no”; the exceptions are items 2, 5 and 12, where “yes” indicates risk. A clinician should not attempt to reconstruct the scoring from recollection while interpreting a parent form. Use the approved scoring algorithm, check that the correct revised version is being used, and document whether the score is before or after follow-up. That last distinction prevents a medium-risk first-stage score from being misreported as a positive screen.

TRAP **Examination trap:** A positive follow-up screen warrants diagnostic evaluation; it is not itself a diagnostic threshold.

Autism-specific screening is recommended at 18 and 24 months and whenever surveillance raises concern, alongside surveillance at developmental and psychiatric assessments. This differs from the schedule for general developmental screening, which is recommended at 9, 18, and 24 or 30

months during regular well-child visits. The distinction matters because a general screen and an autism-specific screen answer overlapping but not identical questions. The normal developmental context and milestones that make a particular response concerning are developed in the Normal child development and milestones notes.

24.3 Diagnostic instruments: observation, history, and trained use

Diagnostic measures are not simply longer screening scales. The ADI-R and ADOS-2 are described as state-of-the-art diagnostic measures and require specific training for clinician administration. Training is not ceremonial. It is needed to standardise how prompts are given, how behaviours are recognised and coded, and how the resulting information is used without overriding the clinical context. An untrained, improvised administration can create an appearance of precision while reducing the value of the observation.

ADOS-2 is an interviewer-administered observational measure of autism-spectrum symptoms. Its contribution is direct sampling: the assessor sees how communication, reciprocity, play, flexibility, and other relevant behaviours emerge in interaction. That is valuable when caregiver descriptions and clinic impressions diverge, when the child presents differently across contexts, or when the clinician needs well-described behavioural examples for a multidisciplinary discussion. It remains a sample, however. A calm consultation, a familiar caregiver, fatigue, anxiety, unfamiliar language, or the child's strategy for coping with novelty can all influence what is observed.

ADI-R is a semi-structured instrument for obtaining a developmental history. It is particularly useful conceptually because autism is not diagnosed from a single cross-sectional interaction. The interviewer asks the caregiver to move from labels such as “he does not mix” to concrete examples: what the child did, in what situation, whether the pattern was sustained, and how it changed. A good developmental history distinguishes a stable developmental style from a recent change and makes it possible to test whether apparently isolated symptoms belong together. This also protects against treating a questionnaire response as though it were already a clinical observation.

These instruments should be read as complementary rather than competitive. One asks what behaviour can be observed now; the other helps establish developmental meaning through a knowledgeable informant. Neither removes the need to consider communication ability, sensory or physical factors, environmental demands, and alternative developmental formulations. Nor should their absence be used to deny care where an experienced clinician can make a sound diagnosis. Their special value lies in disciplined, reproducible evidence when the assessment is complex, contested, or requires detailed communication across services.

MNEMONIC

H-O-L-D the hierarchy

History, **O**bservation, **L**inkage across contexts, then **D**iagnostic judgment. It is a sequence for thinking, not a substitute scoring rule.

24.4 Rating scales and caregiver questionnaires: useful, but bounded

Rating scales create a compact record of behaviours and can support screening, communication, and longitudinal review. Their apparent simplicity is also their risk. A numerical total can look more authoritative than a detailed narrative, yet a rating depends on who observed the behaviour, what comparison they used, and what setting was captured. The score should lead back to examples. If a scale and the clinical account disagree, investigate the discrepancy rather than automatically privileging either source.

INSTRUMENT	CLASSIFICATION AND RESPONDENT	STRUCTURE STATED IN THE GUIDELINE
CARS-2	Screening, clinician rated	15 items rated 1-4
CAST	Screening, parent rated, ages 4-11 years	37 yes/no items
ASDS	Screening, parent rated, ages 5-18 years	50 yes/no items
Autism Behavior Checklist	Screening, parent rated	57 items rated 1-4

CARS-2 is classified as a screening measure, even though it is clinician rated. That distinction is worth making explicitly because clinician administration alone does not convert a scale into a diagnostic instrument. Likewise, the word "Diagnostic" in the Asperger Syndrome Diagnostic Scale can mislead: the guideline classifies it as screening. Candidates should classify an instrument by its validated clinical role, not by the confidence suggested by its name.

Caregiver questionnaires are especially helpful when clinic behaviour is unrepresentative of home or school. The commonly used instruments include the Social Responsiveness Scale, including SRS-2, and the Social Communication Questionnaire. They can focus the interview and identify domains requiring examples. They do not turn the caregiver into the diagnostician. The clinician's task is to determine the meaning of an endorsed difficulty, its developmental context, its consistency across settings, and the effect of communication level or situational stress.

24.5 ISAA, INCLEN, and the Indian certification pathway

Diagnosis and certification answer different questions. The **Indian Scale for Assessment of Autism** is listed as a diagnostic instrument for children aged 2-9 years. Its stated format is a parent interview with 40 items rated 1-5. It produces cutoff scores, severity indices, and percentage-disability output that can assist certification. These capabilities make it important in Indian practice, but they should not be allowed to collapse the distinction between a clinical diagnosis and the later task of documenting disability for statutory purposes.

The ISAA is inbuilt within the INCLEN Tool; this is a containment relationship, not a claim that the two names are interchangeable. The **INCLEN Diagnostic Tool for Autism Spectrum Disorder** was released for uniform autism assessment in India by the Ministry of Social Justice and Empowerment, Department of Empowerment of Persons with Disabilities on April 25, 2016. In an examination answer, this is best presented as an Indian assessment and certification framework rather than as an alternative to clinical reasoning.

IN INDIA

Clinical diagnosis precedes disability assessment. After an established clinical diagnosis using recognised diagnostic criteria, the INCLEN tools and ISAA are used for disability assessment. It is therefore incorrect to write that a child "has autism because the ISAA is positive." A scale result may support certification-related documentation, but the diagnosis must already rest on a clinical assessment. Conversely, an appropriate clinical diagnosis should not be withheld simply because certification has not yet been completed.

Certification quantifies disability and can facilitate scheme benefits and insurance eligibility. It therefore has material consequences for a family, and careful documentation is part of good clinical care. The required board comprises a paediatrician or paediatric neurologist, a clinical or rehabilitation psychologist, and a psychiatrist. This multidisciplinary composition reinforces the point that administrative assessment should be clinically anchored rather than reduced to a form-filling exercise.

Certificate validity depends on the nature of the disability. For an individual under 18 years of age with temporary disability, validity is 5 years; where a permanent disability has been acquired, the certificate has permanent validity. When discussing this with families, distinguish clearly between the diagnosis, the disability assessment, and the certificate. They are connected steps but not synonymous labels. The statutory context is the Rights of Persons with Disability Act, and the instrument's output should be explained as serving this practical pathway.

TRAP **Examination trap:** Do not use an ISAA or INCLEN disability assessment as though it replaces the clinical diagnosis of autism.

24.6 Integrating results in the consultation

A robust assessment is transparent about the status of each piece of evidence. State whether a result came from a parent screen, a caregiver questionnaire, clinician rating, direct observation, developmental-history interview, or disability assessment. Then state what it adds and what remains uncertain. This simple discipline prevents a referring clinician from reading a "positive" score as definitive and prevents a receiving clinician from discarding valuable information because it is not itself diagnostic.

- When a screen is positive, explain that it identifies a need for thorough diagnostic assessment and does not apply a diagnostic label.
- When a score is negative but surveillance remains concerning, return to the history, settings, and direct observation rather than treating the score as a veto.
- When trained diagnostic measures are used, document that their findings were integrated with clinical judgment rather than reported as a free-standing conclusion.
- When disability documentation is needed, establish the clinical diagnosis first and then proceed through the appropriate Indian assessment pathway.

The practical consequence is a more humane and accurate conversation with caregivers. Rather than saying “the test says autism” or “the test is normal,” the clinician can say what was observed, what the caregiver described, what the instrument contributes, and why further assessment or follow-up is appropriate. This approach also makes room for uncertainty without inaction. Where developmental concerns are real, referral and support planning need not wait for a family to understand every technical distinction among questionnaires, interviews, observation schedules, and certificates.

> A positive autism screen changes the next clinical action; it does not, by itself, make the diagnosis.

25 · Medical comorbidities and workup in ASD (epilepsy, sleep, GI, genetics)

Autism does not protect a person from ordinary illness, and it can make illness harder to detect. A change in behaviour, communication, participation or self-care may be the presenting language of pain, sleep disruption, seizures, anxiety or another co-occurring condition. The assessment therefore has two linked tasks: recognise the developmental autism phenotype and ask what else may be contributing to current impairment. This is especially important when the person has limited spoken language, difficulty describing internal states, or a history in which distress has repeatedly been attributed to autism itself.

Co-occurring conditions are not a miscellaneous appendix to diagnosis. They alter risk, family burden, educational participation and the interpretation of behaviour. A useful formulation begins with the person's usual baseline and asks what has changed, in which setting, with what bodily or emotional correlates, and what reliably relieves or worsens it. The clinician should bring together caregiver observations, the person's own account where possible, developmental history, medication exposure, sleep and elimination history, dietary pattern, and a focused physical and neurological examination. The aim is not indiscriminate testing. It is a hypothesis-led medical workup that can explain a new problem and identify needs that autism alone cannot explain.

ESTIMATED EPILEPSY IN CHILDREN WITH ASD	WITH A FREQUENT SLEEP PROBLEM	WITH SIGNIFICANT CHRONIC GASTROINTESTINAL COMPLAINTS	ESTIMATED TO MEET ADHD CRITERIA IN SOME SAMPLES

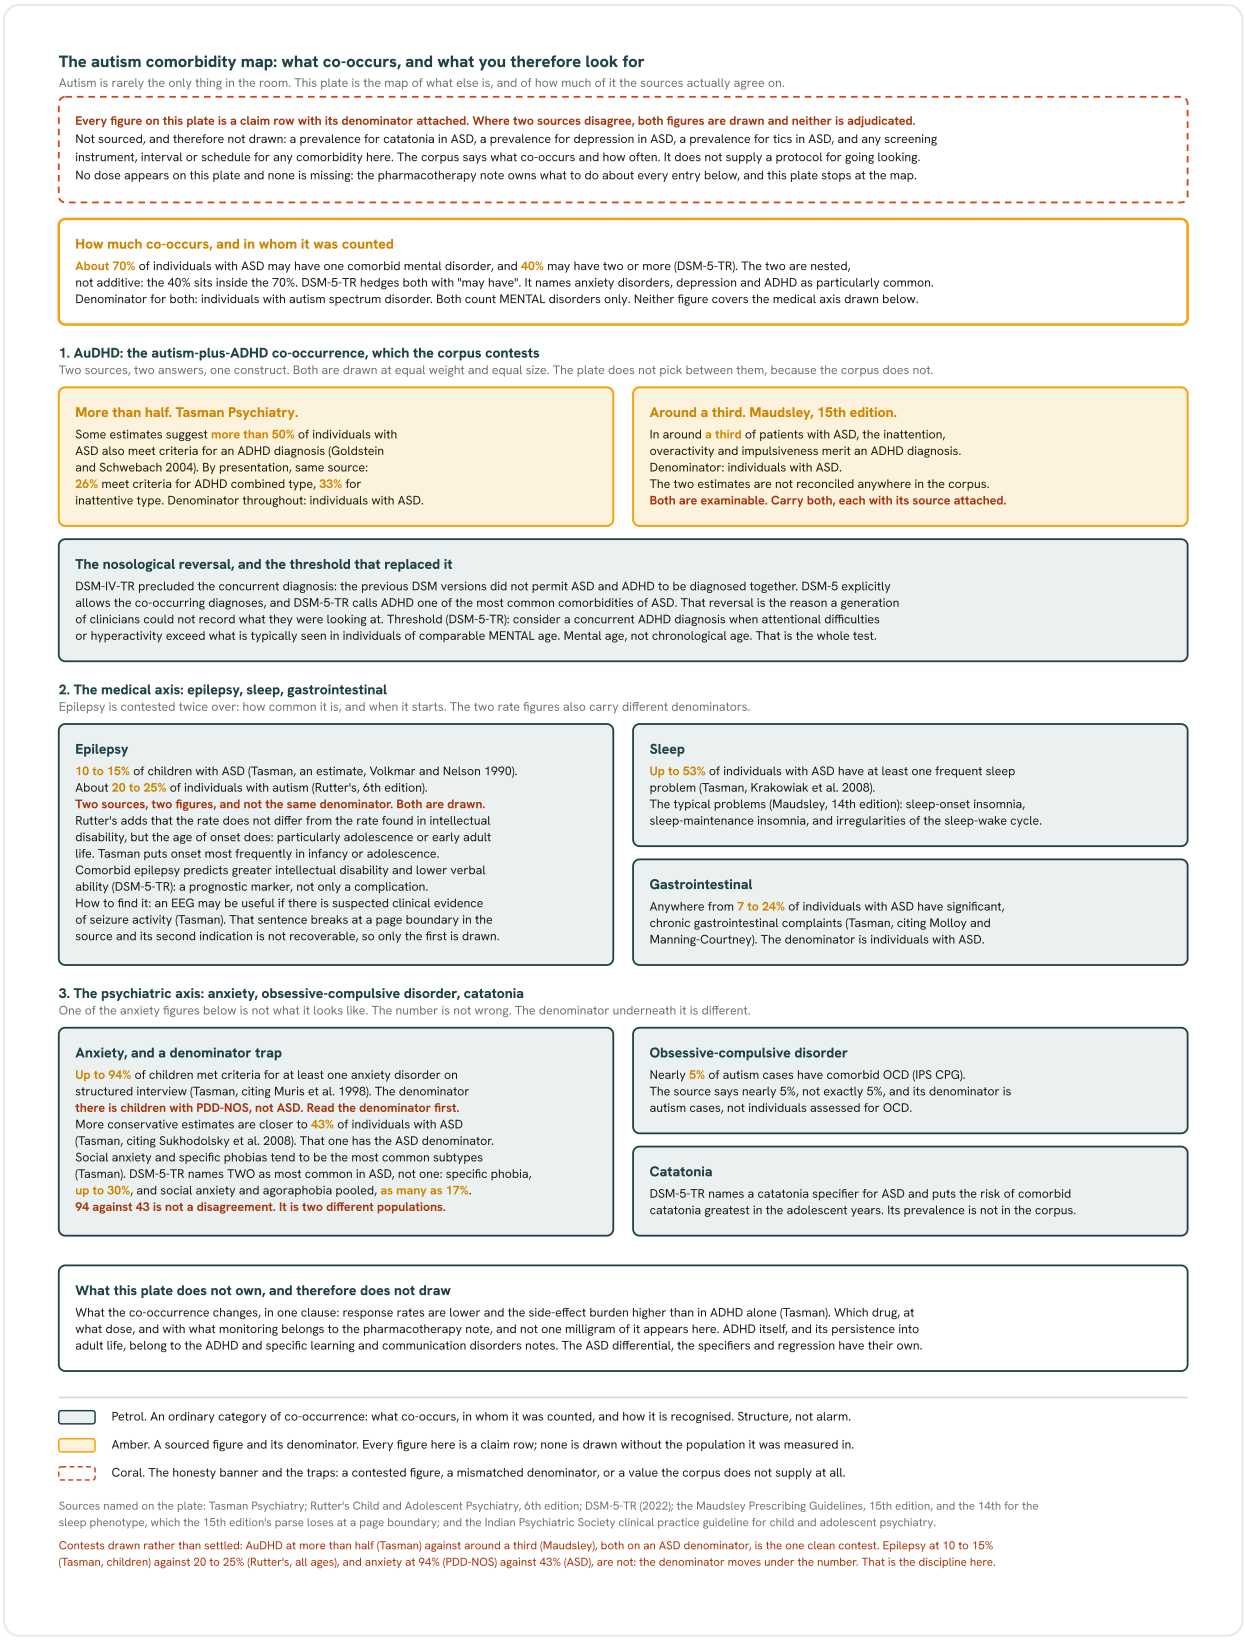

Fig 21.18 **The autism comorbidity map.** What co-occurs with autism, medical and psychiatric, with every figure carried alongside the population it was counted in. AuDHD leads the plate because the sources contest it: more than half of individuals with ASD (Tasman) against around a third (Maudsley), drawn side by side at equal weight rather than reconciled, with the DSM-IV exclusion that DSM-5 reversed and the comparable-mental-age threshold that replaced it. Epilepsy is contested in rate and in age of onset, though its two rate figures also differ in denominator, children against all ages. Anxiety at 94% against 43% only looks contested: the denominators are PDD-NOS and ASD respectively, and telling the two cases apart is the point. Prevalences for catatonia, depression and tics in ASD are not in the sources, so none is drawn.

25.1 A clinical method for finding comorbidity

Start with the referral question, but do not let it narrow the enquiry prematurely. A child described as "more autistic" may in fact be sleeping poorly, constipated, frightened, in pain, having unrecognised seizures, depressed, overwhelmed by a new demand, or experiencing an adverse effect of treatment. An adult who has always required support may develop a new loss of function that deserves the same respect as new loss of function in any other patient. Baseline is therefore a clinical instrument: establish usual communication, mobility, eating, sleep, continence, interests, activity level, self-injury, emotional expression and ability to tolerate ordinary transitions before interpreting change.

Behavioural equivalent is a practical term for a bodily or emotional problem expressed through observable behaviour when direct reporting is limited. It should prompt enquiry, not provide a conclusion. Agitation may reflect discomfort, fear, overstimulation, an interpersonal conflict, a seizure-related event or an emerging psychiatric syndrome. Similarly, apparent non-compliance can be a communication about an inaccessible demand or an aversive physical state. Ask caregivers for a sequence rather than a global adjective: what happens first, what follows, how long it lasts, whether awareness changes, and what restores the person to baseline.

CLINICAL SIGNAL	QUESTIONS THAT SHARPEN THE HISTORY	WHY IT MATTERS	IMMEDIATE ROUTE
New episodic change	Was there altered awareness, a motor event, a fall, a period of confusion, or a return to usual functioning?	Distinguishes a possible neurological event from a behavioural description alone	Document the event carefully and consider neurological assessment
New irritability or self-injury	What has changed in sleep, bowels, eating, activity, medication, demands or sensory load?	Physical discomfort and environmental strain are common explanatory possibilities	Examine, identify urgency, and investigate the leading hypothesis
Functional decline	Which specific skill has changed, how abrupt was the change, and is it present across settings?	Prevents a serious change being absorbed into a static developmental label	Assess medical, neurological and psychiatric contributors in parallel
Internalising distress	What situations are avoided, feared, anticipated or endured with marked distress?	Anxiety may be obscured by shutdown, rigidity, anger or somatic complaint	Make a symptom formulation before assigning a label

RULE **Any marked change from baseline deserves a fresh medical and psychiatric formulation; do not accept autism as its explanation until competing explanations have been considered.**

25.2 Epilepsy: recognise events, assess risk and use EEG selectively

Epilepsy is an important ASD comorbidity, but its clinical relevance lies in more than its frequency. Estimates in children with ASD place comorbid epilepsy between **10% and 15%**.

Another estimate for individuals with autism is about **20% to 25%**. These figures should not be treated as a prediction for an individual patient. They do, however, justify a low threshold for taking a paroxysmal history seriously, particularly when family descriptions include abrupt episodes that differ clearly from the person's usual repetitive behaviour, sensory response or emotional dysregulation.

The age pattern has clinical value. Onset is reported most often in infancy or adolescence, while onset in adolescence or early adult life is particularly distinctive when autism is compared with intellectual disability. The overall epilepsy rate in autism does not differ from that found in intellectual disability; the timing of onset is the more useful discriminating observation. A routine visit should therefore include a longitudinal question about events across development, rather than only asking whether seizures are occurring now.

Paroxysmal event is preferable to the word seizure until the history supports a conclusion. Ask whether the event occurs from sleep, during illness, after a particular trigger, or in a stereotyped sequence. Repetitive movements, staring, withdrawal, panic, dissociation and behavioural shutdown can all be misread if the sequence is not reconstructed.

Explain to families who expect a single investigation to explain autism or every behavioural difficulty that the question for the test is narrow: whether the event pattern raises a neurological concern that the EEG can help clarify. When events are recurrent or the account is unclear, contemporaneous documentation and neurological collaboration are often more informative than retrospective labels.

GOOD TO REMEMBER

When a new event is reported, reconstruct it with a witness before naming it a seizure: onset, behaviour, awareness, responsiveness, colour change, injury, duration, recovery and return to baseline. A caregiver-recorded video can improve phenomenology. An EEG may be useful when there is clinical evidence suggesting seizure activity; it does not replace a careful event history and must be interpreted in its clinical context.

Comorbid epilepsy is associated with greater intellectual disability and lower verbal ability. This association should guide anticipatory support, not deterministic counselling. It signals that communication access, safety planning and caregiver education may need particular attention. It does not mean that every person with epilepsy will follow the same developmental course, nor does it license therapeutic pessimism. Seizure management itself should be coordinated with the relevant neurological service; syndrome-specific seizure teaching belongs to the relevant syndrome sections rather than to a general ASD workup.

TRAP **Examination trap: do not request an EEG merely because a person has ASD. Request it for a clinically credible paroxysmal history, and document the event phenomenology that created that suspicion.**

25.3 Sleep disturbance: make the phenotype visible before treating it

Sleep problems are common enough to merit routine enquiry rather than waiting for a complaint. Up to **53%** of individuals with ASD have at least one frequent sleep problem. The common clinical patterns are **sleep-onset insomnia**, **sleep-maintenance insomnia** and **sleep-wake cycle irregularity**. Naming the pattern matters because a family report of "not sleeping" may refer to a prolonged settling period, repeated waking, a shifted schedule, an early waking pattern, or a combination.

Ask for the sequence around sleep rather than an estimate of total sleep alone. Establish the evening routine, time of attempted sleep, latency, night waking, nocturnal activities, waking time, naps, weekend variation, bedroom conditions, caregiver responses, daytime sleepiness and change from baseline. Ask directly about pain, bowel discomfort, breathing concerns, seizures, itching, medication timing, caffeine exposure, activity, screen use and anxiety. This identifies reversible drivers and clarifies whether the intervention must change the environment, the daytime rhythm, an associated condition, caregiver contingency, or a biological sleep signal.

Melatonin has shown benefit in **17 studies** in children with ASD. The dosing figures come from a narrower base and should be quoted as such: a meta-analysis of five of those studies is what reports good efficacy across doses of **1 and 10 mg**.

IN INDIA

For sleep disturbance in ASD, Indian guidance states a melatonin range between 1 and 10 mg at night.

Treatment periods in the cited evidence ranged from 14 days to over 4 years, which shows that use has not been confined to a single brief interval, not that every patient should receive long-term treatment.

Where epilepsy is also present, the guidance describes melatonin as carrying a low risk of seizure precipitation. This is reassuring but does not remove the need to document the seizure history, current neurological treatment and temporal relation between any new symptom and a medication change. The broader pharmacological management of target symptoms is addressed separately. Here the principle is to treat sleep as a clinical syndrome with contributors, not as an inevitable feature of autism.

For sleep, identify the pattern and its maintaining conditions before adding a treatment. A precise sleep history often prevents both under-treatment of discomfort and over-treatment of behaviour.

25.4 Gastrointestinal symptoms and bodily distress

Gastrointestinal complaint may present as a direct report, altered food intake, agitation around meals, a new sleep problem, avoidance of the toilet, or self-injury. Significant chronic gastrointestinal complaints are reported in between **7% and 24%** of individuals with ASD. It

should encourage active enquiry, not a presumption that every distress behaviour is gastrointestinal.

The clinical history should make eating and elimination discussable without embarrassment. Ask about appetite, food selectivity, texture or smell sensitivity, pain behaviour, swallowing concerns, nausea, vomiting, stool pattern, toileting avoidance, soiling, bleeding, weight change and the relation of symptoms to medication or routine disruption. In a person who cannot describe pain conventionally, a caregiver's recognition of a distinct grimace, posture, guarding, meal-related distress or night waking may be the most useful starting point. Examination and referral should be guided by the symptom pattern and urgency, as in any patient.

It is useful to separate a sensory preference from a medical symptom without making them adversaries. A narrow diet may be a stable sensory accommodation, a consequence of pain, an anxiety-driven avoidance, a learned family adaptation, or several of these together. The same is true of toileting refusal. The formulation becomes clinically useful only when it identifies function, discomfort, nutritional impact and the practical barriers to change. Abrupt dietary restriction, apparent pain, dehydration, bleeding, persistent vomiting or a significant decline in functioning should not be normalised as autism.

- Ask directly about bowel, bladder, appetite and pain at each meaningful change in behaviour.
- Use familiar caregiver observations as data, then test them against a focused history and examination.
- Distinguish a long-standing preference from a new restriction or a new distress signal.

25.5 Genetic and general medical workup: phenotype-led, not reflexive

Phenotype-led genetic evaluation means that genetic assessment is anchored to the individual rather than to a generic autism label. The history should include developmental course, medical events, neurological symptoms, family history and any pattern suggesting a broader developmental condition. The examination should attend to growth, physical features, skin, neurological signs and other findings that may make a syndromic explanation more likely. This approach improves the quality of the referral question and helps the family understand why genetic assessment is being considered.

Genetic testing is part of the ASD medical workup, but its value is not exhausted by producing a laboratory result. A result may refine an aetiological formulation, prompt surveillance for associated medical issues, inform reproductive discussion through an appropriate genetics service, and connect a family with relevant supports. Conversely, an uninformative result does not invalidate the person's autism diagnosis or their need for support. Consent should cover what the investigation can and cannot answer, the possibility of uncertain findings, and the implications of receiving information that concerns relatives.

The psychiatrist's role is to recognise when a broad medical formulation is needed, obtain a careful developmental and family history, coordinate referrals and translate results into a person-

centred plan. It is not to assign a syndrome from a single physical feature or to promise that testing will identify a cause in every case.

- Record the phenotype and the family question that prompted referral.
- Explain what a result may clarify and what it may leave uncertain.
- Coordinate interpretation with genetics and other relevant services.

Hearing and vision concerns, nutritional status, sleep, bowel function, medication effects and neurological symptoms should be considered alongside genetic assessment. This prevents the common error of pursuing an etiological explanation while missing a treatable contributor to day-to-day distress. A medical workup is successful when it makes the clinical picture more intelligible and improves care coordination, even when no single cause is established.

25.6 AuDHD: distinguish co-occurrence from diagnostic substitution

AuDHD refers to the co-occurrence of autism and ADHD. ADHD is one of the most common comorbidities in ASD, and some estimates suggest that **more than 50%** of individuals with ASD also meet criteria for an ADHD diagnosis. The clinical task is not to decide which label "explains everything". It is to establish whether attentional difficulties, impulsivity or hyperactivity represent an additional, impairing syndrome rather than an understandable consequence of overload, anxiety, poor sleep, learning demands or the social environment.

This is a major nosological correction for candidates to understand. DSM-IV-TR did not permit concurrent ASD and ADHD diagnoses; DSM-5 permits co-occurring diagnoses. The earlier exclusion still shapes clinical habits. In one direction, marked activity or distractibility is dismissed as part of autism. In the other, social difficulty is assumed to follow from ADHD alone. Both shortcuts can delay a formulation that makes sense of the person's whole pattern.

Assess attention and activity across settings and against the person's developmental level. A concurrent ADHD diagnosis should be considered when attentional difficulties or hyperactivity exceed what is typical for individuals of comparable mental age. Ask what happens in a low-demand preferred activity, in an unstructured group setting, during a task that is understood but not preferred, and after a poor night of sleep. Gather collateral from the settings where demands differ. This separates sustained regulation difficulty from a problem that appears only under a particular sensory, social or academic load.

The co-occurrence changes management planning because sleep, anxiety, communication demands and environmental predictability can all alter attention and activity. Establish the target impairment, its baseline, the family's priorities and the measures by which benefit and adverse effects would be judged. Pharmacological treatment selection for target symptoms is addressed in the pharmacotherapy section; ADHD itself, including adult persistence, is addressed in the ADHD and specific learning/communication disorders notes. The key point here is that dual diagnosis is clinically permissible and often clinically clarifying.

MNEMONIC

Clinical spine - CHANGE

When behaviour worsens, check **C**ourse from baseline, **H**ealth and pain, **A**rousal and sleep, **N**eurological events, **G**astrointestinal and other bodily symptoms, and **E**motional or attentional comorbidity. It is a sequence for broadening the formulation, not a substitute for assessment.

25.7 Anxiety, obsessive-compulsive phenomena and catatonia

Anxiety disorder is common in ASD, with a more conservative estimate of **43%** in individuals with ASD. Social anxiety and specific phobias tend to be the most common subtypes. The assessment must not mistake all avoidance for autism-related social difference or all insistence on sameness for anxiety. Ask what the person fears will happen, what they anticipate, whether distress appears before the event, what safety behaviours are used, and whether the pattern is new, pervasive or situation-bound.

Obsessive-compulsive symptoms demand a similarly functional distinction. Repetitive acts in autism may be enjoyable, regulating or linked to predictability, whereas compulsions are more often driven by distress and an attempt to reduce a feared outcome. The distinction can blur, particularly when the person cannot easily report intrusive thoughts. Explore the emotional state before and after the act, the consequences of interruption, the degree of choice, and whether the behaviour has acquired a feared meaning. Nearly 5% of autism cases have comorbid OCD, so the possibility should be actively considered rather than hidden within a description of repetitive behaviour.

Catatonia requires recognition because new marked slowing, reduced initiation, mutism, posturing, agitation, loss of previously established function or other conspicuous motor-behavioural change may be misattributed to autism. The core safeguard is temporal: a substantial change from the person's own baseline is a clinical event. Obtain a careful timeline, assess medical and neurological contributors, seek collateral, and involve appropriate specialist services where concern is significant. Do not wait for a person to fit a stereotyped image of catatonia before taking severe change seriously.

TRAP **Examination trap: repetitive behaviour is not automatically OCD, and withdrawal is not automatically autism. Establish the preceding emotion, perceived purpose, degree of distress and change from baseline.**

25.8 Integrating findings into a safe, useful formulation

The completed assessment should answer practical questions: what is longstanding, what is new, what is impairing, what needs urgent medical attention, and which professional needs to act next? Document observations in behavioural language, preserve uncertainty where it remains, and specify the evidence supporting each concern. A formulation such as "new nocturnal waking with apparent abdominal discomfort and daytime irritability" is more actionable than "behavioural problem in ASD". It allows the family, psychiatrist, paediatric or medical colleague, school and therapist to work from the same clinical picture.

Finally, explain the formulation to the person and family without implying blame. Families often arrive after being told either that every problem is autism or that autism explains nothing. Both positions are unhelpful. Autism provides a developmental context. It does not erase the need to recognise pain, epilepsy, sleep difficulty, gastrointestinal symptoms, genetic questions, ADHD, anxiety, OCD or catatonia. Care improves when the clinician can hold both truths at once: the person's baseline neurodevelopmental profile matters, and a real change from that baseline always deserves to be understood.

Managing autism and its outcome

26 · Differential diagnosis of ASD

Differential diagnosis is a longitudinal task. Autism spectrum disorder (ASD) is not established by an isolated socially atypical behaviour, a language delay, or a repetitive act observed in clinic. The clinician asks whether the social-communication pattern is pervasive, whether restricted or repetitive behaviour is present across development, what the child could do before the concern emerged, and whether the proposed alternative explains the whole presentation more parsimoniously. The same exercise determines whether an apparent alternative is instead a co-occurring condition that deserves its own diagnosis and treatment plan.

For examination answers, organise the differential around the **developmental trajectory**: an early and pervasive neurodevelopmental pattern supports ASD; a setting-bound difficulty, a later change after relatively typical development, or a symptom driven by fear, psychosis, sensory loss, neurological illness, or adverse care conditions should redirect assessment. Collateral developmental history, direct observation across settings, and attention to communication without spoken language are often more informative than a checklist answer. The task is not to make every unusual behaviour autistic, nor to deny ASD when another condition is also present.

RULE **Core rule.** Diagnose ASD when its characteristic social-communication and restricted or repetitive pattern is the best account of the developmental presentation; add another diagnosis when that condition independently meets its threshold or requires separate clinical attention.

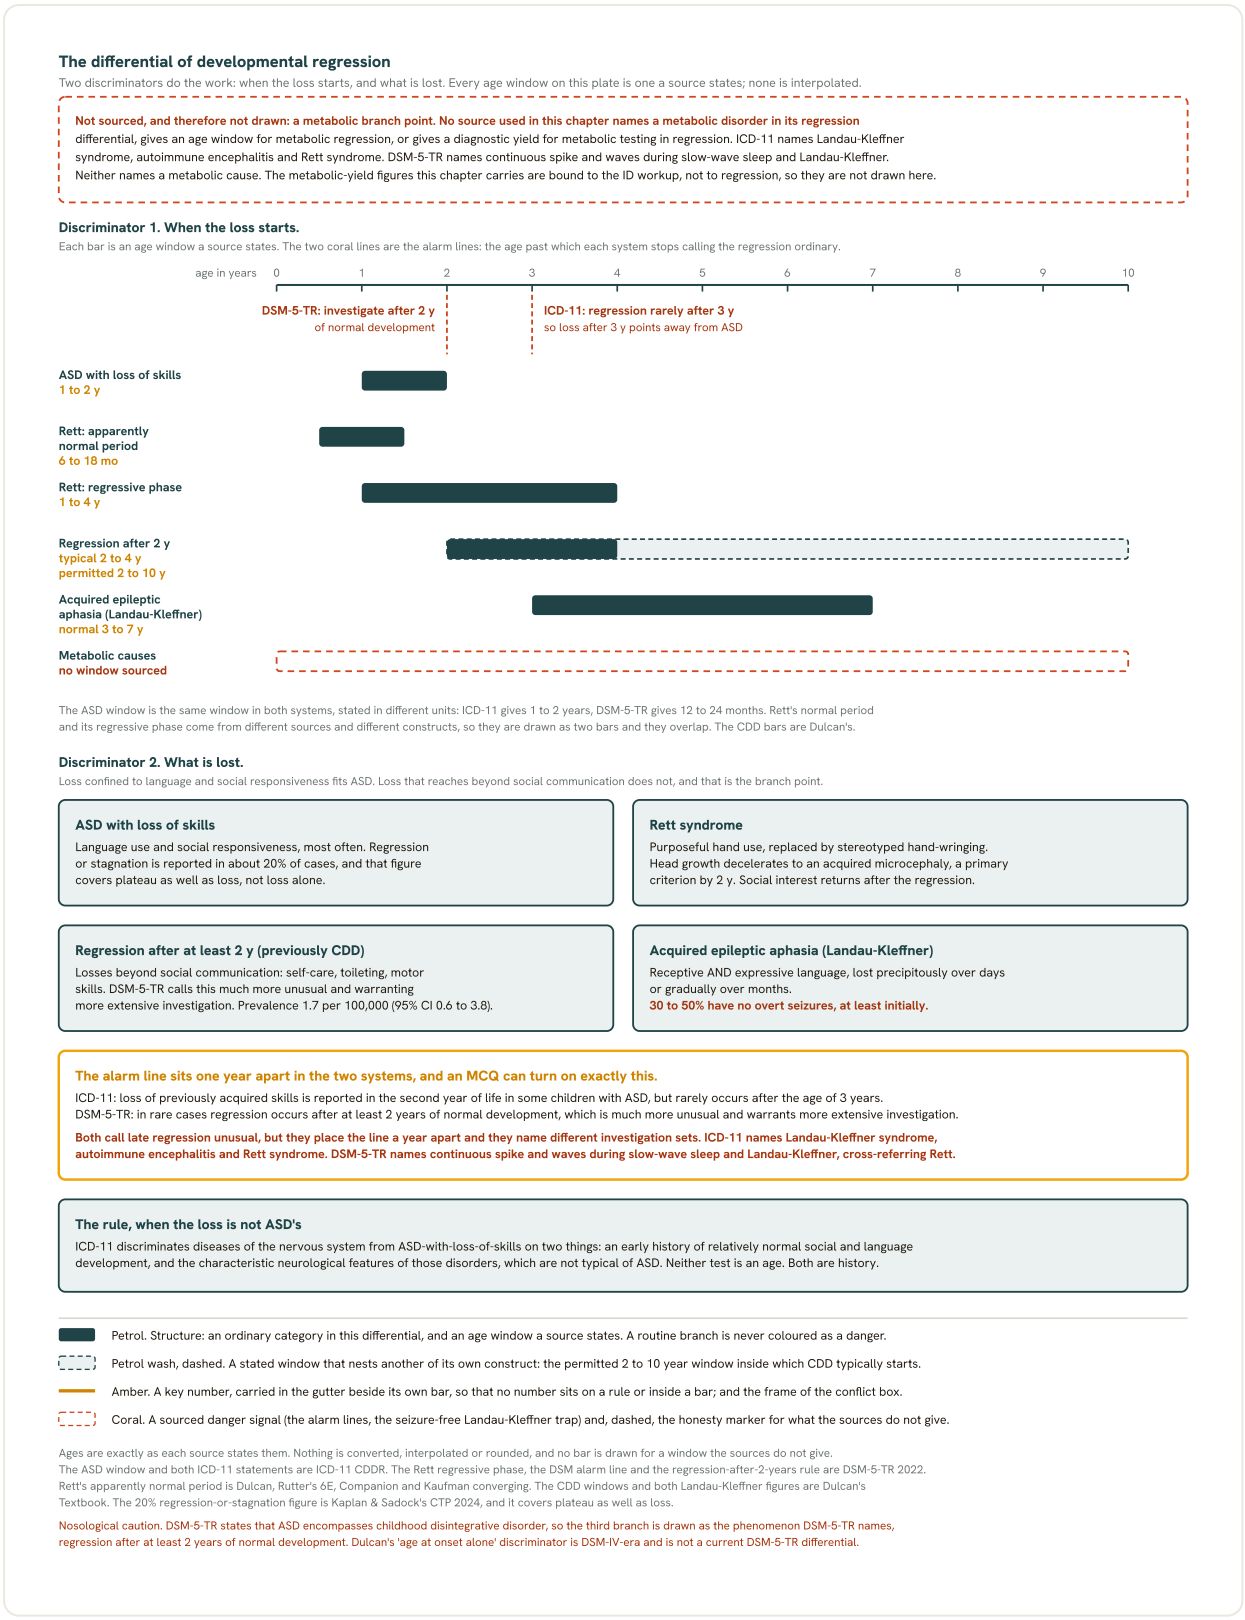

Fig 21.19 **The differential of developmental regression.** The branch points that separate autism with loss of skills, Rett syndrome, regression after at least two years (previously childhood disintegrative disorder) and acquired epileptic aphasia, drawn on the two discriminators that actually do the work: the age at which the loss starts, and what is lost. The ruler carries only age windows a source states, and the alarm lines show ICD-11 and DSM-5-TR placing the boundary of the ordinary a full year apart. A metabolic branch point is named on the banner and left undrawn: no source used here supplies one, and the metabolic yields this chapter carries are bound to the intellectual-disability workup rather than to regression.

26.1 A practical frame for the differential

Start by examining social communication, restricted or repetitive behaviour, pervasiveness across settings, and any loss of acquired capacity. Was early social communication qualitatively atypical, or merely delayed in proportion to overall development? Are repetitive behaviours, unusual interests, inflexibility, or sensory-linked patterns truly present, including historically? Is the pattern evident across relationships and environments? Does the time course suggest ASD or a neurological, psychiatric, or environmental cause? This frame prevents the common error of treating an isolated surface feature as diagnostic.

Use function, not appearance alone. Repetition may be self-organising, enjoyable, anxiety-reducing, an attempt to avoid an aversive demand, or a response to an intrusive thought. Social withdrawal may reflect a pervasive social-communication difference, fear of scrutiny, low mood, psychosis, or an attachment-related adaptation. The meaning of the behaviour, its developmental onset, and what changes it are more discriminating than the behaviour's name.

- Obtain a timeline of social reciprocity, communication, play, interests, daily routines, and any losses of skill.
- Ask about the same behaviour at home, school, and with familiar and unfamiliar people.
- Separate a core ASD feature from a secondary reaction to anxiety, frustration, communication failure, or environmental change.
- Look for independent evidence that an alternative disorder is present, rather than using it as a label for a difficult symptom.

TRAP **Examination trap.** A child who does not speak in a particular setting does not automatically have ASD. Pervasiveness of the social-communication difficulty and the presence or absence of restricted or repetitive behaviour decide the direction of enquiry.

26.2 ADHD and intellectual developmental disorder

ADHD and ASD can be difficult to discriminate. Interrupting, intruding into personal space, excessive volume, impatience, and poorly modulated interaction can create social difficulty in ADHD. These behaviours should not be mistaken for the qualitative reciprocity and communication pattern of ASD. The discriminating history is the developmental course, together with whether restricted or repetitive behaviours and unusual interests are absent. When they are absent and the social difficulty tracks inattention, impulsivity, or hyperactivity, ADHD is the better explanation.

These disorders may also coexist. In a person with ASD, a concurrent ADHD diagnosis should be considered when attentional difficulty or hyperactivity exceeds what is expected at a comparable mental age. This is a clinical comparison against developmental capacity, not a shortcut based on chronological age. Do not use the presence of ASD to explain away disabling inattention, and do not use the presence of ADHD to dismiss a developmental history of restricted interests and pervasive social-communication difference. ADHD itself is covered in the ADHD and specific learning/communication disorders notes.

The boundary with intellectual developmental disorder demands the same developmental comparison. In intellectual developmental disorder without ASD, social-communicative skills generally do not show an apparent discrepancy from other intellectual skills. ASD is justified when social communication and interaction are substantially more impaired than the developmental level indicated by nonverbal abilities. Observe how the child uses gaze, gesture, affect, shared attention, and nonverbal problem solving, rather than equating sparse speech with autism. This distinction is especially difficult before symbolic communication has emerged and when repetitive behaviour occurs in the context of developmental disability.

ICD guidance makes the same point operationally: assign both diagnoses, with the relevant specifier, when social-communication deficits are greater than would be expected from intellectual functioning. In this setting, adaptive assessment should not let ASD-related social difficulty artificially inflate the apparent global developmental impairment. The conceptual and practical evidence, the developmental record, and repeated assessment matter greatly. The full differentiation of intellectual disability, global developmental delay, and borderline intellectual functioning is addressed elsewhere in this chapter.

26.3 Language, pragmatic communication, and selective mutism

A **developmental language disorder** can produce frustration, reduced participation, and secondary social difficulty. It is not usually accompanied by abnormal nonverbal communication or restricted and repetitive patterns. A child with language disorder may therefore show a strong wish to engage, communicative use of gesture and facial expression, and reciprocal response despite impaired spoken language. The assessment should be designed so that social intent can be seen without demanding verbal fluency.

Social (pragmatic) communication disorder is the nearer diagnostic neighbour because social use of communication is impaired. The separator is the absence of restricted or repetitive behaviour and interests. Before making this diagnosis, enquire carefully about such behaviour in both the past and the present. If ASD criteria are met, ASD takes diagnostic precedence; it is not appropriate to divide an ASD presentation into separate social-communication and repetitive-behaviour diagnoses. Conversely, pragmatic language impairment alone does not justify adding developmental language disorder to ASD. Individuals with a primarily pragmatic language disorder may still initiate and respond appropriately to social and emotional cues and share interests, while lacking the typical restricted or repetitive pattern seen in ASD.

Selective mutism is a disorder of context, not a global absence of communication. Early development is not typically disturbed; communication can be appropriate in some settings; and even where the child is mute, reciprocity is not impaired and restricted or repetitive patterns are not present in the way expected in ASD. Ask what the child does at home, with familiar relatives, and in school. Selective mutism shows normal language and social communication in specific environments but not others, whereas ASD-related social-communication deficits and restricted or repetitive patterns are evident across situations and contexts. Anxiety and ASD can coexist, so a clear setting effect should prompt assessment for both rather than a hurried either-or decision.

PRESENTATION	QUESTION THAT RESOLVES IT	PATTERN FAVOURING THE ALTERNATIVE
Developmental language disorder	Can social intent be demonstrated nonverbally?	Reciprocal nonverbal communication without the restricted or repetitive ASD pattern.
Social pragmatic communication disorder	Has restricted or repetitive behaviour ever been present?	Social-communication impairment without that behavioural pattern.
Selective mutism	Does communication become normal in a safe, familiar setting?	Context-specific mutism with preserved reciprocity.

26.4 Attachment-related presentations, deprivation, and disruptive behaviour

Severe social deprivation can produce **quasi-autism**, an autism-like presentation that must not be assumed to establish a lifelong neurodevelopmental diagnosis without careful history. A key discriminating observation is substantial improvement after movement to a more nurturing environment. Where there is no reliable account of earlier social and communicative development, the distinction may remain difficult. Longitudinal observation is then clinically more honest than premature certainty.

Reactive attachment disorder and ASD share social withdrawal and low reciprocity, but their organising patterns differ. ASD shows atypical language development, whereas delayed language in reactive attachment disorder is not stereotyped or otherwise deviant; restricted or repetitive behaviour is not a feature of reactive attachment disorder; and children with ASD can show attachment behaviour with caregivers at least some of the time despite their social-communication difficulty. A history of severe neglect or maltreatment is required for reactive attachment disorder and is very unusual in ASD. The diagnosis should therefore rest on both the caregiving history and the behavioural phenotype, not on either alone.

Disinhibited social engagement disorder may also enter the differential when a child approaches unfamiliar adults indiscriminately. That feature is not decisive, because some children with ASD may also show it. Restricted, repetitive, and inflexible patterns are not typical of disinhibited social engagement disorder, and a marked reduction in symptoms after a nurturing environment is provided supports that diagnosis. The clinical task is to avoid a false split between adversity and neurodevelopment: adversity may be clinically crucial whether or not ASD is ultimately present.

Oppositional behaviour needs a functional formulation. In oppositional defiant disorder, the social-communication and restricted or repetitive pattern characteristic of ASD is absent. Explosive rages in ASD are often linked to a specific trigger - a disruption of routine, aversive sensory input, anxiety, or interruption of a rigid sequence - rather than a wish to be provocative or spiteful as required for an oppositional account. Ask what occurred immediately before the outburst and what the child was trying to preserve, escape, or communicate. Demand avoidance

may be prominent in ASD, but it should not be mistaken automatically for a separate disruptive disorder.

26.5 Repetitive behaviours: OCD, stereotypies, and tics

The same act can look repetitive while serving very different psychological functions. In **obsessive-compulsive disorder**, compulsions are performed in response to intrusive thoughts, commonly to relieve anxiety. In ASD, repetitive motor acts, insistence on sameness, or ordering behaviour may be experienced as pleasurable and reinforcing. Ask the person, in developmentally appropriate language, what happens if the behaviour is interrupted: is there fear of a feared consequence, a drive for relief or completeness, sensory regulation, enjoyment, or distress at change? The answer is informative but not self-sufficient, because insight and the ability to report internal experience vary.

Resistance is another useful but imperfect axis. People with OCD more often consciously resist compulsive urges, whereas the characteristic social-communication deficits of ASD are not features of OCD even when repetitive behaviour is prominent. Adolescents and adults with ASD may nevertheless attempt to suppress behaviour they know is socially unwelcome. Therefore, neither resistance nor lack of resistance should be converted into an isolated diagnostic test. Evaluate the cognitive antecedent, emotional consequence, developmental context, and the rest of the ASD phenotype.

Stereotypic movement disorder is not added merely because repetitive movements are visible in someone with ASD. A separate diagnosis is not made when the movement is better explained by ASD; it can be appropriate when stereotypy causes self-injury and becomes a specific treatment focus. The practical point is to describe the movement carefully, assess injury and impairment, and decide whether it needs additional clinical attention rather than multiplying labels.

Differentiate stereotypies from **tic disorders** by phenomenology. Tics tend to be less stereotyped, briefer, later in emergence, and associated with premonitory sensory urges; unlike ASD repetitive behaviours, they are not generally experienced as soothing. Direct questioning about an urge, temporary suppression, fluctuation, and relief is useful when language permits. Co-occurrence remains possible, so the aim is accurate description and not forced diagnostic exclusivity.

MNEMONIC

Meaning before movement

For any repetitive act, ask: what precedes it, what does it achieve, what happens if it is blocked, and does the broader social-developmental pattern support ASD? This is a reasoning sequence, not a diagnostic acronym.

26.6 Anxiety, psychosis, and personality pathology

Anxiety disorders overlap with ASD because social withdrawal and repetitive behaviours can be core ASD features but can also express anxiety in either presentation. The central question is

whether social functioning becomes broadly intact when anxiety is low and the context is familiar. In **social anxiety disorder**, interaction with familiar people or in non-anxiety-provoking situations does not show the pervasive impairment expected in ASD; persistent restricted, repetitive, or inflexible patterns are also not features of social anxiety alone. A patient may have both conditions, and avoidant behaviour should then be formulated in terms of both developmental style and fear.

Childhood-onset **schizophrenia** is usually preceded by normal or near-normal development, and hallucinations and delusions are defining features that do not belong to ASD. Its prodrome can nonetheless resemble ASD through social impairment, unusual interests, or odd beliefs. Questions about psychotic symptoms require concrete follow-up: an affirmative literal answer may refer to ordinary media rather than a perceptual experience. Establish the source, location, controllability, conviction, and functional consequence of the reported experience. If ASD and schizophrenia each meet criteria, diagnose both rather than making one erase the other.

In adults without major language or intellectual impairment, personality disorder can resemble ASD through detachment, eccentricity, unusual preoccupations, or restricted affect. The most helpful discriminator is the early developmental course: lack of imaginative play, restricted or repetitive behaviour, and sensory sensitivity in childhood point toward ASD rather than a personality-based explanation. Adult social style alone is an unreliable retrospective diagnostic shortcut. Seek informant history and records where available, and distinguish a lifelong developmental pattern from interpersonal adaptations that emerged later.

26.7 Regression and neurological red flags

Regression changes the diagnostic posture. Loss of skills can occur in ASD. The syndrome-specific accounts belong with their dedicated discussion.

> **GOOD TO REMEMBER**
>
> In ASD, loss of skills is reported in the **second year of life** in some children and rarely occurs after the age of **3 years**. A later loss, especially after a relatively normal early social and language history, should trigger a differential that includes acquired epileptic aphasia, autoimmune encephalitis, Rett syndrome, and other neurological causes.

Medical causes are distinguished from ASD with loss of skills through the history of relatively normal development and the neurological features that are not typical of ASD on their own. Look beyond social communication. Loss of self-care, toileting, motor ability, or other acquired competence makes an encephalopathic process more concerning and warrants more extensive medical investigation than an uncomplicated ASD assessment. Where autistic features are attributable to a medical condition, ICD guidance allows a secondary neurodevelopmental syndrome diagnosis rather than ASD. The distinction matters because immediate management and prognosis can change.

Landau-Kleffner syndrome is an important mimic when apparent autism follows loss of receptive and expressive language after a period of normal development. That period may be **3 to**

7 years. An absent seizure history does not exclude it: **30 to 50%** of affected children may initially have no overt seizures. A careful neurological history and appropriately directed investigation are therefore essential in acquired language regression.

30 to 50%
LANDAU-KLEFFNER SYNDROME MAY INITIALLY LACK OVERT SEIZURES

26.8 Sensory impairment and closing clinical synthesis

Severe hearing impairment, severe visual impairment, maltreatment, developmental coordination disorder, epileptic encephalopathy, mood disorder, conduct disorder, and other behavioural conditions belong in a broad ASD differential when the presentation requires it. Their presence should slow diagnosis rather than become a reason to abandon developmental assessment. Hearing assessment is a named component of ASD workup, and audiology with speech and language expertise belongs in the multidisciplinary team for this reason. The technical differentiation of hearing impairment from developmental language disorder should not be imported uncritically as an ASD rule.

End with a positive formulation: which features establish ASD, which features point to a differential, which conditions may coexist, and what further observation or investigation is required before certainty is justified. This separates a thoughtful assessment from a list of labels. It also protects families from both diagnostic delay and diagnostic overreach. The full child psychiatric assessment battery, services and protection are covered in the Child psychiatry: assessment, treatment, services and protection notes.

> In ASD differential diagnosis, developmental course, pervasiveness across settings, the function of repetitive behaviour, and evidence of neurological regression are more useful than any isolated symptom.

27 · Rett syndrome and childhood disintegrative disorder

Why these conditions matter. Both **Rett syndrome** and childhood disintegrative disorder can present to the psychiatrist as a child who has lost development and now appears autistic. That surface resemblance is clinically consequential but diagnostically incomplete. Rett syndrome is a distinctive genetic and neurological condition with a characteristic course and physical phenotype. Childhood disintegrative disorder is a historical diagnostic construct describing unusually marked regression after a prolonged period of apparently typical development. A careful longitudinal history prevents the error of treating every regression as simply another presentation of autism.

The exam task is not merely to recall labels. It is to identify the pattern of loss, look for the accompanying neurological signs, understand what has changed in current classification, and arrange a proportionate medical assessment. The broader differential diagnosis of developmental regression is addressed in the differential diagnosis of ASD section; here the emphasis is on the two named entities and on the clinical reasoning that separates them from ASD.

RETT CASES DUE TO SPORADIC MUTATION	REPORTED PREVALENCE IN GIRLS	CLASSIC RETT COURSE PHASES	CDD PREVALENCE ESTIMATE

27.1 Rett syndrome: identity, genetics and diagnostic stance

Rett syndrome was first described by Andreas Rett, an Austrian paediatrician, in Austria in 1966. It is an X-linked dominant condition caused by pathogenic change in MECP2, located at Xq28. MeCP2 binds methylated DNA and participates in the regulation of gene expression and chromatin structure. Its loss disrupts neuronal maturation and synaptogenesis. This mechanistic framing is useful because it explains why the syndrome is not just a behavioural regression syndrome: its evolution includes motor, autonomic, skeletal and epileptic manifestations.

Most cases arise anew rather than being inherited. The proportion attributed to a **99%** sporadic mutation is a memorable genetic fact, while the wider clinical point is that family history may be unrevealing. The syndrome is reported chiefly in females. A hemizygous mutation has been described as incompatible with life in a male fetus, but this should not be recited as an unqualified explanation for the sex distribution because the literature contains a contrary account of that mechanism. The clinically safer formulation is that rare affected males may have severe neonatal encephalopathy, and rare male cases have been reported with a concomitant XXY abnormality.

The syndrome is a major cause of intellectual disability in girls, described as the second most important cause after Down syndrome. Frequency figures require care because sources use different denominators and epidemiological constructs. A reported prevalence is **about 1 per 10,000 girls**; an incidence estimate is approximately 1 per 10,000 female live births. These should never be swapped in an answer. In practice, their shared message is rarity combined with high clinical importance.

RULE **Rett syndrome remains a clinical diagnosis.** Consensus clinical criteria establish the syndrome; genetic testing supports the diagnosis but does not establish it in isolation.

This principle avoids two errors. First, a compatible molecular result does not replace phenotype and developmental trajectory. Secondly, a negative or non-diagnostic result must not cause a clinician to abandon a convincing clinical syndrome. Variant forms exist, including a very rare preserved speech variant in which mutation carriers may communicate well and have mild intellectual disability; asymptomatic carriers have also been reported. Such variation makes clinical synthesis more important, not less.

27.2 The Rett developmental trajectory

The diagnostic spine is a period of apparently ordinary early development followed by loss of acquired skills and a changing neurological phenotype. The early apparently normal period is reported as **6-18 months**. Delays may become apparent around 6 months, but this is not a substitute for listening closely to the parents' account of the developmental sequence. In the

regressive phase, typically between ages 1 and 4 years, a child may look strikingly autistic. The key question is what happens next, and what accompanies the loss.

The course is conventionally understood as **four** classic phases. Rather than forcing stage labels onto a history, describe the sequence: an early apparently normal period, a short plateau, rapid deterioration of motor and speech abilities, a later plateau that can last for years, and subsequent deterioration of the motor system. This sequence is more clinically useful than a list of labels because it connects the family narrative to examination findings and anticipates changing care needs.

Loss of **purposeful hand use** is particularly discriminating. It is replaced by stereotyped hand-wringing, hand-washing, hair-pulling, clapping, flapping or twisting movements. These movements are not an incidental repetitive behaviour. They represent the substitution of a stereotypy for previously functional manual activity, and therefore should be elicited with a before-and-after history. Hand stereotypies first appear at about 18 months. Bruxism, mouthing and body twisting can accompany the hand movements.

Head growth is also informative. Head circumference can be normal at birth, then head growth decelerates, producing **acquired microcephaly**. The adjective matters: it distinguishes a postnatal deceleration from a head that was already small at birth. Significant microcephaly has been stated to emerge by 2 years of age, although head-growth slowing is not universal. A normal head-growth record therefore does not by itself dispose of the diagnosis; it makes the whole pattern, rather than one sign, more important.

TRAP **Examination trap.** Do not call a child autistic solely because she has social withdrawal, language loss and stereotypies during Rett regression. Ask specifically about loss of purposeful hand use, slowing of head growth, gait change and the later social course.

There is a further reason this distinction matters. Social interest often diminishes during the regressive period but later improves; many affected individuals develop an intense eye gaze or staring. Thus, an early autistic appearance need not remain the dominant social phenotype. In the current manual, ASD should be considered in Rett syndrome only when all ASD diagnostic criteria are independently met. This is a disciplined use of co-diagnosis, not a reflexive relabelling of the syndrome.

27.3 Neurological, autonomic and systemic phenotype

The neurological examination should deliberately seek a pattern, rather than recording isolated abnormalities. Gait dyspraxia or apraxia, truncal ataxia, gait and trunk movement apraxias, muscle wasting and dystonia are described in Rett syndrome. These features change the clinical question from “is this autism?” to “what neurological disorder is producing regression and autistic-appearing behaviour?” A child who can no longer use her hands purposefully and develops an abnormal gait demands this broader formulation.

Breathing abnormalities are another helpful clue. Episodes of hyperventilation and breath-holding can alternate. Their importance is practical as well as diagnostic: they should not be

assumed to be wilful behaviour or anxiety without a careful clinical account. Reflux and swallowing problems may reflect autonomic pathology. Acrocyanosis and trophic skin changes of the feet add to the autonomic and vascular phenotype. These physical features often explain why a narrowly psychiatric interview is insufficient.

Epilepsy is a frequent complication, but numerical statements in this area differ between sources. One source reports over 90% of girls with Rett syndrome having epilepsy, with seizures usually beginning around 4 years; another reports a lower range beginning at a different age. The defensible clinical learning point is that seizure history must be actively sought and that later changes in behaviour, alertness or function should not automatically be attributed to the developmental disorder. The Rett-specific seizure burden belongs in the medical formulation, not as a generic ASD comorbidity statistic.

Scoliosis is common over the course of the syndrome, reported in about 87% of females by 25 years of age. Sleep disturbance also deserves direct inquiry: 85% of preschool children have been reported to have disturbed sleep with night waking and paroxysmal or continuous laughter. These are not peripheral details. Sleep disruption, immobility, seizures, feeding difficulty and spinal deformity can each alter daily function, caregiver strain and the safety of medication choices.

Cardiac risk requires particular prescribing attention. There is an increased risk of arrhythmias associated with a **prolonged QT interval**. In Rett syndrome, avoid prokinetic agents, antipsychotics, tricyclic antidepressants, certain antiarrhythmics, anaesthetic agents and certain antibiotics where this risk is relevant. This is not an instruction to leave distressing symptoms untreated. It is a reminder that a psychiatric prescription belongs within a medical plan that considers cardiac conduction and concurrent treatment.

Despite the apparent downhill trajectory, Rett syndrome is **not a neurodegenerative disorder**. The neuropathological account is one of developmental arrest in infancy rather than progressive inflammatory, demyelinating or degenerative destruction. That distinction protects against a common conceptual mistake: later motor deterioration is real, but it does not prove a conventional neurodegenerative process.

27.4 Classification and the autism boundary

Rett syndrome is no longer included as an ASD or pervasive developmental disorder subtype in DSM-5. This differs sharply from childhood disintegrative disorder, which was absorbed into ASD. The historical placement of Rett beside autistic disorders should therefore be taught as classification history, not current nosology. The separation has validating evidence: MeCP2 mutation is not found in other autism spectrum disorders, making Rett a distinct genetic and neurological entity rather than simply a severe ASD subtype.

The current ASD diagnosis nevertheless contains a useful documentation route. The specifier **associated with a known genetic or other medical condition or environmental factor** can be applied when the individual has a known genetic condition, with Rett syndrome named as an example. The specifier does not itself claim that every aspect of the autistic presentation is

caused by the genetic condition. It documents clinically relevant context while preserving the requirement to establish ASD on its own criteria.

In ICD-11, Rett is named as a boundary or differential condition rather than as an ASD category. Diseases of the nervous system with regression are distinguished from ASD with loss of skills by an early history of relatively normal social and language development and by characteristic neurological features. This is exactly the clinical distinction the psychiatrist should make at the bedside. The legacy codes are F84.2 in ICD-10 and 299.80 in DSM-IV or DSM-IV-TR; do not use them as current ASD subtype labels.

> A child with regression and autistic-appearing behaviour needs a syndromic neurological formulation: in Rett syndrome, social interest may later improve, whereas the hand, head-growth, motor and autonomic phenotype remains diagnostically central.

27.5 Childhood disintegrative disorder: the historical construct

Childhood disintegrative disorder is also known as Heller syndrome or Heller's disease and was originally termed dementia infantilis. It described a child with a substantial period of apparently normal development followed by marked loss of skills and the emergence of an autistic clinical picture. The eponym is worth recognising because older examinations, case records and ICD-10 terminology may use it, but current clinical reasoning should not mistake a legacy label for a separate contemporary ASD category.

The historical criteria required at least **2 years** of apparently normal development before regression. Regression begins no earlier than 2 years and no later than 10 years; the most typical onset is between 2 and 4 years. These constructs are easy to confuse. The first specifies the preceding normal developmental interval, the second the permitted boundaries for regression, and the third the modal onset. In a vignette, establish the timing before deciding that the term fits.

Under the legacy DSM-IV-TR criteria, loss had to occur in two or more domains. The domains were expressive or receptive language; social skills or adaptive behaviour; bowel or bladder control; play; and motor skills. This breadth of loss is clinically important. A history that includes toileting and motor loss cannot be reduced to a narrow social-communication account. It should trigger medical evaluation alongside developmental and psychiatric assessment.

- Ask what the child could actually do before decline, using concrete examples rather than global parental labels.
- Establish whether language, social or adaptive abilities, continence, play and motor skills were all affected, and in what sequence.
- Seek neurological and systemic symptoms alongside the behavioural change, then pursue the regression differential described in the differential diagnosis of ASD section.

Following the regression, **autistic symptomatology** emerges, with impairments in socialisation and communication together with restricted, repetitive patterns of behaviour. The clinical

features are otherwise quite similar to autistic disorder, and age at onset is the principal distinguishing feature. This is why a prolonged normal developmental period makes the distinction easier, while a shorter apparently normal period makes it less secure.

27.6 Rett syndrome and childhood disintegrative disorder compared

CLINICAL AXIS	RETT SYNDROME	CHILDHOOD DISINTEGRATIVE DISORDER
Core framing	MECP2-related neurological syndrome	Historical syndrome of regression after apparently normal development
Typical developmental timing	Apparently normal early period of 6-18 months	Regression most typically between 2 and 4 years
High-yield clues	Loss of purposeful hand use with hand stereotypies; acquired microcephaly and motor signs	Loss across language, social or adaptive, continence, play and motor domains
Current DSM position	Not an ASD subtype	Subsumed within ASD
Expected outcome	Long-term neurological disability with changing motor and medical needs	Generally more severe intellectual disability and poorer outcomes than autism

The table should be used as a reasoning aid, not as a substitute for a history. Rett syndrome has a biologically distinctive phenotype, while childhood disintegrative disorder is defined by its temporal pattern of broad regression. In both cases, apparent autism is a clinical presentation that must be interpreted in context. The most hazardous mistake is diagnostic closure after observing social withdrawal or repetitive behaviour.

27.7 Current status, intervention and outcome in childhood disintegrative disorder

Childhood disintegrative disorder is not a separate diagnosis in DSM-5 or DSM-5-TR; it is encompassed within ASD and referred to as a disorder previously described as childhood disintegrative disorder. There is no CDD category in ICD-11 CDDR. Its legacy codes are F84.3 in ICD-10 and 299.10 in DSM-IV or DSM-IV-TR. These codes are useful for interpreting older records, but they should not be presented as current parallel diagnostic categories.

DSM-5 absorption should not make the regression clinically bland. A child with the pattern formerly called CDD requires extensive medical investigation, because regression warrants a search for neurological and medical explanations. The detailed regression differential belongs in the differential diagnosis of ASD section, and the broader ASD medical workup is addressed in the medical comorbidities and workup section. The psychiatrist's immediate contribution is to preserve the chronology, document the breadth of lost skills and ensure that an autistic formulation does not truncate investigation.

Intervention methods for CDD are identical to those used for autism. This statement does not mean the clinical task is identical: marked functional loss often changes the family's practical needs and the level of support required. The named behavioural programmes, speech and

occupational interventions, and family support are dealt with in their respective sections of this chapter. Here, the key point is that a historical CDD label does not exclude access to ASD-focused intervention.

Outcome is generally more severe than in autism. CDD has been described as having a much worse prognosis, with more severe intellectual disability and poorer outcomes than autism. This is why it is important to be honest with families without becoming deterministic: outcome language should describe present support needs, continuing medical assessment and the need to revise the formulation if the course changes. It should never be used to imply that rehabilitation, communication support or family partnership are futile.

27.8 Practical clinical synthesis

GOOD TO REMEMBER

When a child with possible ASD has lost skills, establish the developmental baseline and order of loss. Ask about purposeful hand use, continence, play and motor ability; then examine for acquired microcephaly, stereotypies, gait or trunk abnormalities, breathing changes and other neurological signs. Decide whether this is ASD with loss of skills, a known syndrome such as Rett syndrome, or a regressive disorder requiring a broader medical differential.

- For Rett syndrome, preserve the distinction between a clinical diagnosis and a supportive molecular result.
- For any psychiatric prescription in Rett syndrome, incorporate the arrhythmia and QT-risk context into the medical review.
- For historical CDD, document the prolonged normal period and the domains of loss before applying a legacy label; in either presentation, communicate that regression deserves explanation, not merely classification.

These two conditions are therefore important not because they add obscure eponyms to ASD, but because they teach a general clinical discipline. Developmental regression is a temporal event with neurological and functional meaning. Recognising its pattern protects the child from premature diagnostic closure and gives the family a more coherent account of why assessment, treatment and support must extend beyond a behavioural description.

28 · Behavioural interventions (ABA, TEACCH, PECS, ESDM)

Behavioural intervention is a clinical method, not a branded package. In autism spectrum disorder, the psychiatrist's task is to translate a broad concern - communication, participation, learning, distress around change, or a behaviour that has become difficult to manage - into an observable target and a coherent programme. The useful question is not which acronym is fashionable. It is which learning opportunity, environmental support, communication route and review process are most likely to help this person participate more effectively in ordinary life.

Behavioural intervention means planned alteration of the conditions in which a skill is taught or a behaviour occurs, with observation of whether the planned change helps. It is not

synonymous with making a child compliant, and it must never be framed as a contest of wills. Good work begins with strengths, interests, communication needs and the burden placed on the person and family. It then turns a vague wish such as “behave better” into a target that can be observed, practised and reviewed. This fragment concerns named behavioural and educational programmes; the service model of early intervention belongs in the management of intellectual disability, while speech and occupational therapy and family support are addressed separately.

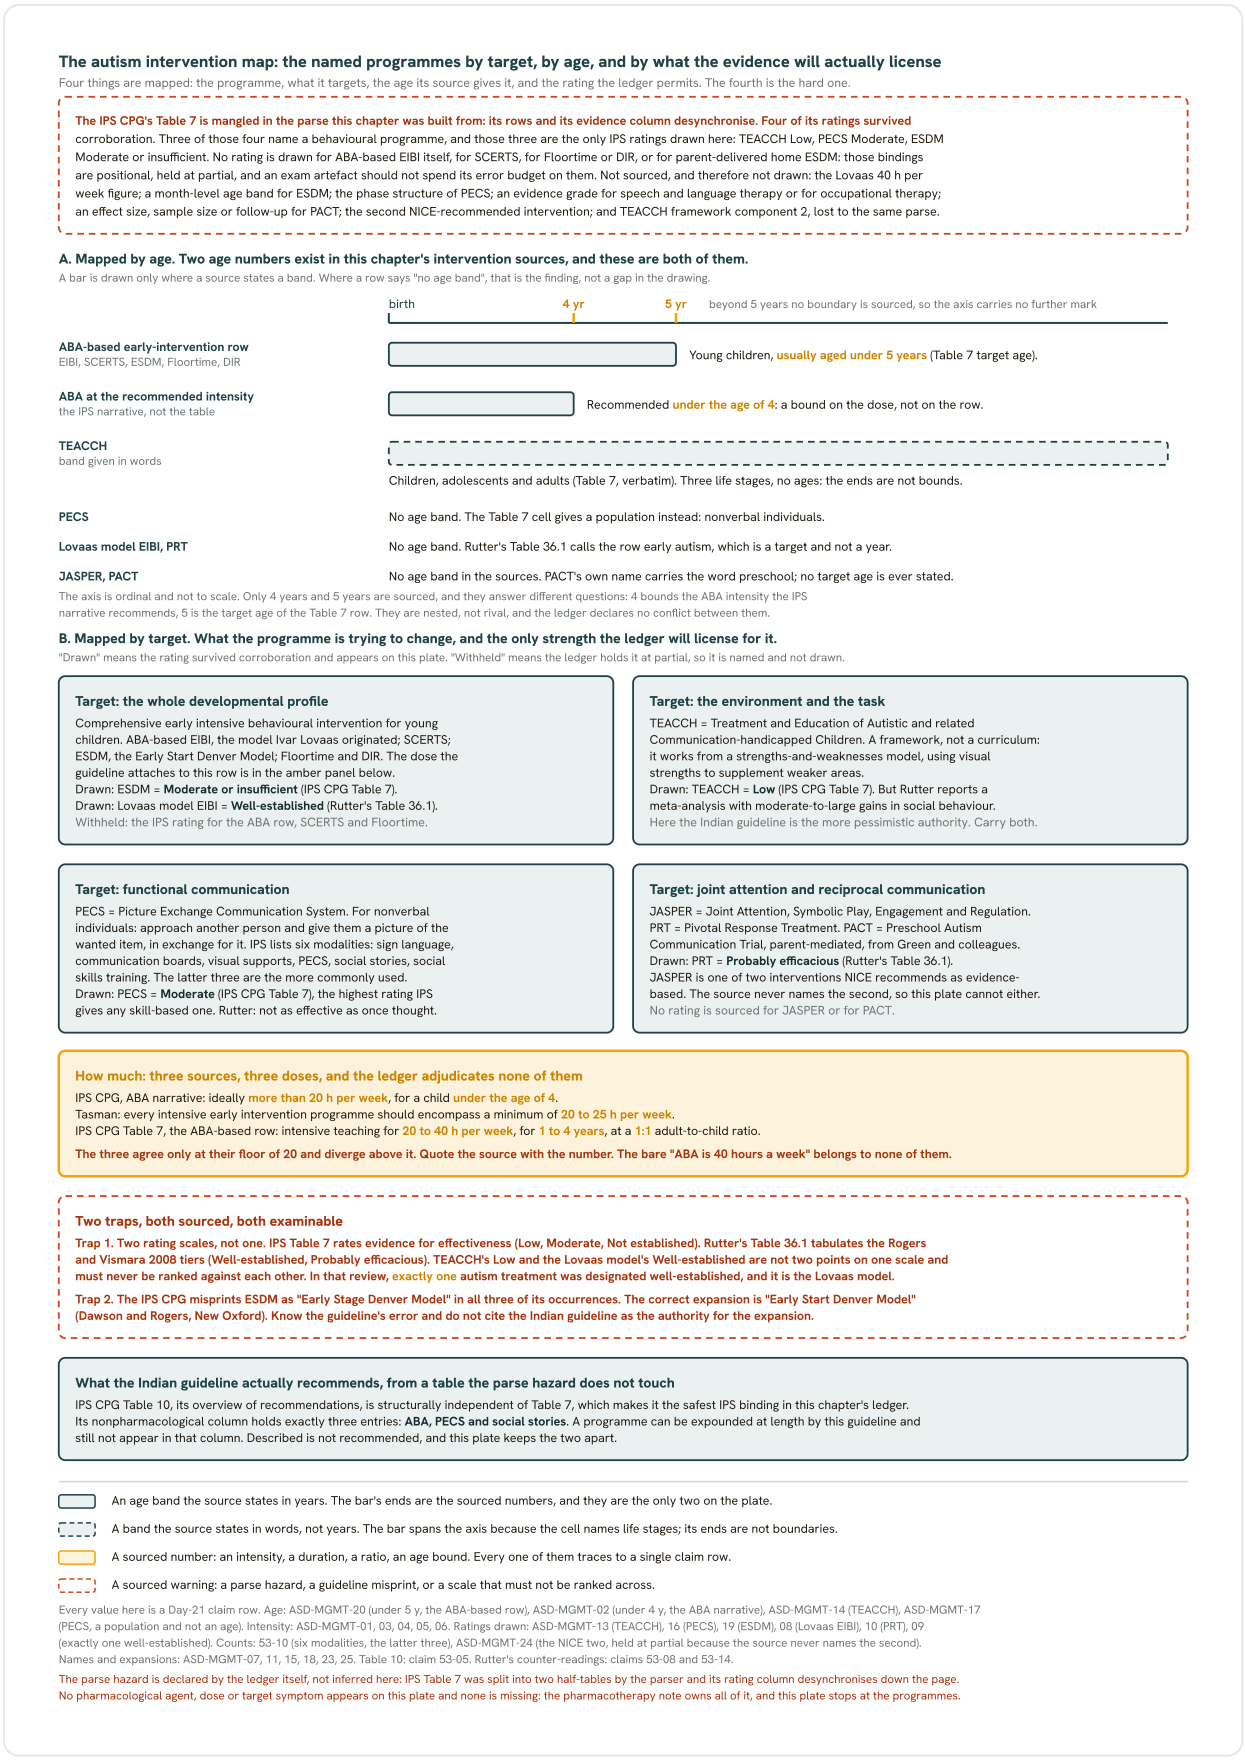

Fig 21.20 **The autism intervention map.** The named behavioural programmes placed by age and by target, carrying only the evidence ratings that survived corroboration: the IPS guideline's Table 7 is mangled in the parse behind this chapter, so TEACCH Low, PECS Moderate and ESDM Moderate-or-insufficient are drawn while the ratings for ABA-based EIBI itself, SCERTS, Floortime and parent-delivered home ESDM are named and withheld.

28.1 Clinical logic before programme selection

A programme label does not replace formulation. The clinician should first establish what is happening, where it happens, what tends to precede it, what follows it, and what the person may be communicating through it. The same outward behaviour can call for quite different changes. This is why copying a technique from another child's plan is poor practice.

Functional formulation links a target behaviour to its context and probable purpose. It makes the intervention humane and testable. Behavioural reasoning should reduce avoidable distress, not explain it away.

> **GOOD TO REMEMBER**
>
> When a child leaves a task, ask what the behaviour may be communicating before choosing a response. It may reflect an incomprehensible demand, a need for a break, an attempt to obtain an item, sensory overload or distress needing medical or psychiatric assessment. The plan may need a communication response, a better-matched task, clearer cues, a smaller step or a predictable way to ask for help.

RULE **Treat the function of a behaviour and the person's communication need, not merely its visible form.**

When the target and its context are explicit, family members, teachers and therapists can work towards the same practical outcome. When they are not explicit, adults often respond inconsistently and the plan becomes a series of reactions rather than treatment.

Targets should be meaningful to the person's daily life. They may concern requesting, tolerating a transition, joining a routine, sharing attention, completing a manageable activity, or reducing a barrier to participation. Progress must be interpreted in context: a newly learned response that occurs only in a training room has not yet become a dependable everyday skill. The clinician should ask where a skill is expected to occur, who can prompt it, what support makes it possible, and how the support will be reduced or adapted when appropriate. This keeps the programme connected to participation rather than to worksheet performance.

- State the target in observable language and identify why it matters in daily life.
- Record the setting, likely antecedents, consequences and communication context.
- Choose a teaching route that matches the person's current access to communication and learning.
- Review benefit, burden, generalisation and acceptability with the family and educational team.

28.2 Applied behavioural analysis and intensive behavioural teaching

Applied behavioural analysis is a framework for using behavioural principles to define targets, arrange teaching opportunities, record response and alter the plan in the light of observed learning. Its strength is not a rigid script. It is disciplined attention to what is being taught, what cues are available, what response is expected, what consequence makes a response worth repeating, and whether the skill transfers outside the teaching situation. A plan can be systematic without being mechanical, and it can be individualised without becoming unmeasurable.

Teaching may be organised into brief, clearly cued learning opportunities or embedded in meaningful activity and routine. The clinical distinction is useful: a more structured format can help when a new discrimination needs clarity, whereas opportunities in ordinary activity are important when a response needs to become useful beyond a formal session. In either case, prompting should help the person succeed rather than repeatedly expose failure. The team should watch for prompt dependence, because an apparently learned response may actually be a response to an adult's familiar cue.

Early intensive behavioural intervention is an ABA-based programme organised around a broad developmental teaching plan rather than an isolated target. The model is associated with **Ivar Lovaas**. A historical evidence review reported that only one autism treatment met its well-established category, namely that EIBI model, classified as well-established. That classification is useful for understanding the evidence history; it should not be turned into a promise about any individual child or into a reason to disregard individual goals and feasibility.

Intensity is often discussed as though it alone determines quality. It does not. The relevant question is whether there is enough repeated, purposeful teaching for a child to learn and use skills, while preserving play, rest, family life, education and responsiveness to distress.

IN INDIA

The IPS guidance recommends, ideally, more than **20** hours per week of ABA for children below 4 years. A broader intensive-programming statement sets a minimum of **20-25** hours per week. These are programme-intensity statements, not a prescription to fill every waking hour with adult-led drills.

20-40	1-4	1:1	<5
ABA-BASED EIBI TEACHING, WEEKLY HOURS	ABA-BASED EIBI PROGRAMME, YEARS	ADULT-TO-CHILD RATIO STATED FOR THE EIBI ROW	USUAL TARGET AGE IN THE EARLY-INTERVENTION ROW, YEARS

More specifically, the ABA-based EIBI row describes teaching between **20-40** hours per week over between **1-4** years, with an exactly 1:1 adult-to-child ratio for that EIBI row. The same early-intervention row is directed at young children, usually below 5 years. These details describe an intensive programme architecture. They do not mean that every component, or every teaching moment, must be delivered in an identical format.

The psychiatrist should make the architecture clinically workable. Ask who delivers each part, how parents understand the aim, whether the educational setting can reinforce the same communication route, and what data will trigger a change in plan. A programme can be intensive on paper but ineffective if targets are poorly chosen, staff turnover is high, the child is distressed, or skills never leave the treatment room. Conversely, a lower-resource setting can still use a disciplined behavioural formulation when it selects priorities carefully and trains the adults who share the person's routine.

TRAP **Examination trap.** Do not equate ABA with a single teaching technique, or assume that a stated adult-to-child ratio applies only to one teaching format. The cited ratio belongs to the ABA-based EIBI row as a whole.

28.3 Structured TEACCHing

TEACCH expands to **Treatment and Education of Autistic and related Communication-handicapped Children**. Its clinical contribution is the deliberate use of structure so that expectations are legible. Rather than assuming that verbal explanation will organise behaviour, the environment, task presentation and sequence are made easier to interpret. This can reduce ambiguity for a person who finds open-ended social or practical demands difficult to process.

Structured TEACCHing is best understood as a way of making the environment do some of the organising work. The framework is described as having exactly four components. In clinical use, the central question is whether the arrangement helps the person see what is happening now, what is expected next, how much is involved, and when an activity is complete. A visual or physical cue is not therapeutic merely because it has been produced; it is useful only if it reduces uncertainty and supports a meaningful response.

Visual structure can be incorporated into home, school or adult settings without reducing the person to a timetable. It may clarify transitions, make materials easier to locate, distinguish work from leisure, or show the endpoint of an activity. The clinician should avoid turning structure into inflexibility. If a plan is imposed without attending to preference and communication, it can become another demand. The better aim is predictable access to activity and choice, with room for the person to signal refusal, need for help, or a wish to change course.

The evidence-for-effectiveness rating listed for TEACCH is low. This should prompt honest discussion rather than dismissal. A low rating does not prove that a structured environment is useless for an individual; it says that confidence in an effect from the cited evidence base is limited. TEACCH is listed for children, adolescents, and adults, which is clinically important because environmental clarity can remain relevant across settings and stages of life. The decision should be based on a specific participation problem, a clearly described support, and observable review.

28.4 PECS and functional communication

PECS means **Picture Exchange Communication System**. It is a communication intervention in which pictures or symbols can provide an accessible route for an individual to initiate an exchange. Its relevance is not that pictures are inherently superior to speech. Its relevance is that a person who cannot reliably use speech may still have a clear reason to communicate, and should have a practical means of doing so.

Functional communication is the clinical aim: a response that changes the person's access to something meaningful in a socially understandable way. When an individual can request, refuse, seek help or indicate a preference, adults need not infer every need from distress or behaviour. This is why communication planning belongs in behavioural formulation. It may reduce conflict

by replacing an ineffective route with a more reliable one, but it should never treat communication as a device for suppressing autonomy.

PECS is listed for nonverbal individuals, with a moderate evidence-for-effectiveness rating. In assessment, establish whether the person notices the visual representation, can physically manage the exchange, understands what will follow, and has communication partners who will respond consistently. The picture, book or display is not the intervention by itself. The intervention is the repeated, successful experience that an intentional act reaches another person and has a meaningful consequence.

Clinical review should include whether the communication route is available where it is needed, not just during planned teaching. A system that stays in a cupboard or depends on one trained adult can produce a misleading appearance of non-response. Equally, the clinician should not make a symbolic system a compulsory endpoint. The right question is whether it expands the person's agency and participation. The separate discussion of speech and language therapy addresses broader communication assessment and therapy; the present focus is the behavioural logic of an accessible communicative exchange.

MNEMONIC

MAP the communication plan

Meaningful need, **A**ccessible response, **P**artner who responds. If any part is missing, the plan risks becoming a display rather than communication.

28.5 ESDM within early behavioural programmes

ESDM is the **Early Start Denver Model**. In a clinical plan it should be named accurately and then linked to a specified developmental and behavioural target, rather than invoked as a generic synonym for good early care. It appears in the same ABA-based early-intervention row as EIBI and other named programmes. That placement helps the candidate remember that programme labels are not competing diagnoses: they are organised approaches whose usefulness depends on the individual's needs, the quality of delivery and the fit with family and educational contexts.

The evidence rating listed for ESDM is **moderate or insufficient**. This wording requires restraint. It should not be simplified into a claim of established benefit for every outcome, nor used to imply absence of any possible benefit. When discussing it with a family, be precise about the proposed targets, the opportunity cost, the support required of caregivers and the plan for reviewing whether the programme is helping. In a fragmented service system, a recognisable model may be less important than a coherent, respectful plan that can actually be delivered and monitored.

The early-intervention row is directed to young children usually below 5 years. This is a description of the target age for that programme row, not a rule that support ceases after that threshold. Across the lifespan, the psychiatrist still identifies barriers to participation and coordinates a plan appropriate to the person's current setting. The form of teaching, the

communication route and the environmental adaptation may change, but the principle of setting meaningful goals and reviewing their effect remains constant.

28.6 Comparing programmes without false equivalence

Named programmes overlap in their concern with learning and participation, but they do not answer precisely the same clinical question. The accompanying table is a way to hold the distinction in mind. It is not a menu from which a family should be asked to choose unaided. The psychiatrist's role is to identify the main barrier, explain what a proposed approach is intended to change, and ensure that claims about evidence are communicated with their stated limits.

APPROACH	CLINICAL ORGANISING IDEA	EVIDENCE OR SCOPE STATED IN THE SOURCE	QUESTION FOR REVIEW
ABA-based EIBI	Planned behavioural teaching across meaningful targets	Between 20-40 hours per week over between 1-4 years	Are skills becoming useful outside teaching?
TEACCH	Environmental and task structure that makes expectations clearer	Low evidence rating; listed for children, adolescents, and adults	Does the support reduce ambiguity and improve participation?
PECS	Accessible symbolic exchange for communication	Moderate evidence rating; listed for nonverbal individuals	Can the person initiate a meaningful exchange in daily settings?
ESDM	Named early behavioural programme linked to individual goals	Moderate or insufficient evidence rating	Are proposed goals, burden and observed benefit explicit?

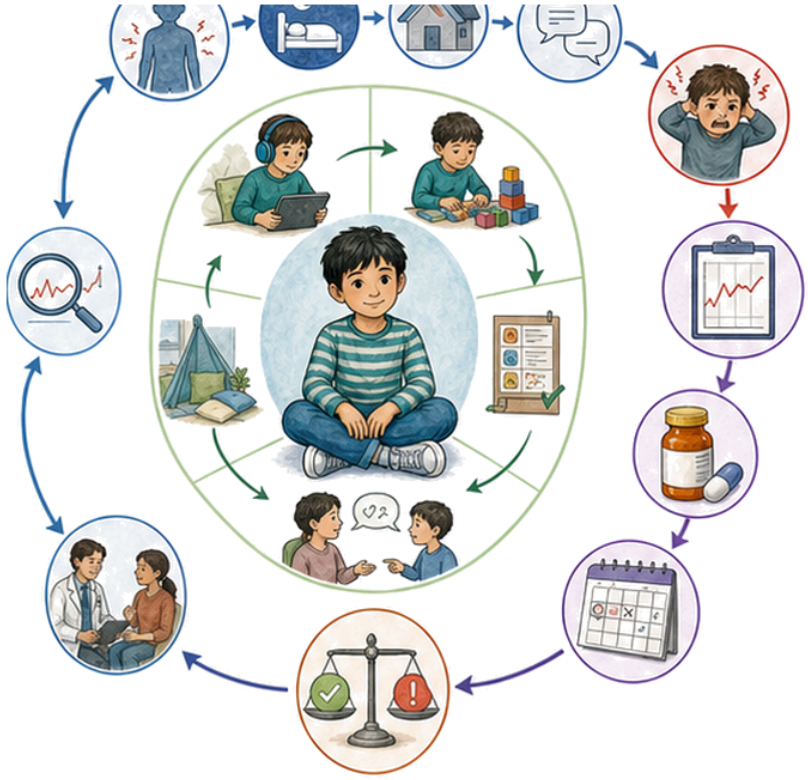
The comparison also guards against a familiar clinical error: treating an evidence rating as a property of the child. It is not. Ratings describe a body of evidence for an intervention as studied and categorised. The individual question remains whether a carefully specified, feasible intervention is improving a valued outcome. A programme with a stronger evidence classification may still be poorly delivered or poorly matched; a supportive adaptation with limited evidence may be reasonable when it has a clear rationale, low burden and observable benefit. Neither statement licenses therapeutic drift. Every plan needs a target, a responsible team, a way to observe change and a point at which it will be reconsidered.

28.7 Monitoring, ethics and the psychiatrist's coordinating role

Treatment fidelity means that the agreed intervention is actually being delivered in a recognisable and consistent way. It is an ethical as well as a methodological issue. Families are often asked to commit time, effort and money. If the target is vague, adults use incompatible prompts, or records are collected without changing the plan, the family carries the burden while nobody can say what is being tested. Clear documentation protects both the person and the team.

Monitoring should be practical. It can include the frequency or context of a target response, the level of assistance needed, the settings in which it occurs, the person's affect and signs of distress, and the views of family and staff. The record is not an end in itself. It should answer whether the

intervention is helping, whether the goal remains meaningful, and whether a different explanation of the difficulty is now more plausible. A plateau is not a moral failure by the child or caregiver. It is a prompt to re-examine the formulation, access to learning opportunities and competing sources of distress.



The psychiatrist also has a boundary-setting role. Behavioural work must preserve dignity, assent where it can be expressed, choice, and access to communication. It should not make the suppression of harmless difference its central aim. Concerns about pain, sleep, seizures, anxiety, mood change, trauma, bullying, family stress or adverse effects of medication require appropriate assessment rather than escalation of a behavioural plan. The wider assessment and care system is covered in the Child psychiatry: assessment, treatment, services and protection notes.

What the candidate should be able to defend. A sound answer does more than expand acronyms. It explains why a target was chosen, how the proposed method fits the observed barrier, what the evidence statement does and does not justify, and how progress will be judged in ordinary settings. The best intervention plan is not the most elaborate one. It is the one that gives the autistic person a more understandable environment, a more usable route to communication and participation, and a team capable of learning from the result.

> **Remember:** Select ABA, TEACCH, PECS or ESDM by the clinical problem and delivery context, then judge the programme by meaningful everyday change rather than by its acronym.

29 · Pharmacotherapy in ASD (target symptoms, risperidone, aripiprazole)

Medication in autism is symptom-directed. It is not a treatment for the autistic condition as a whole. No medicine is established to alleviate the **core features of autism spectrum disorder**. This distinction is the conceptual anchor for a safe prescription: the clinician is treating a disabling, observable target and its consequences, not attempting to medicate autistic identity or to substitute a drug for developmental, environmental, or family work.

- Define the target
- Check context
- Measure baseline
- Time-limited trial
- Review benefit and harm
- Never for autism itself

Fig 21.21 Medication in autism is directed at a severe, observable target behaviour and measurable impairment, not at autism itself. Context is assessed first, outcomes are defined before prescribing, and benefit and harm are reviewed as a time-limited clinical trial.

The marks in this area come from clinical precision. A good answer begins by naming the target behaviour, judging its severity and impact, and stating why medication is justified now. It then selects a medicine whose evidence fits that target, starts conservatively, monitors benefit and harm with the same discipline, and plans review from the outset. The prescription is therefore a time-limited clinical experiment with explicit outcomes, rather than an automatic response to a diagnosis.

29.1 The target-symptom framework

Irritability in autism is a clinical cluster, not merely a description of a child who is difficult to manage. In the regulatory construct for risperidone, it includes aggression towards others, deliberate self-injury, tantrums, and rapidly changing moods. These behaviours may cause injury, exclude the person from ordinary settings, exhaust carers, or make education and communication

impossible. They deserve active treatment, but the treatment target must be stated in behavioural language that can later be reviewed.

RULE **Prescribe for a defined target behaviour and measurable impairment, never for autism itself.** A medication trial is defensible when the target is severe, persistent, and associated with meaningful risk or loss of function, after the immediate context has been understood. It is not defensible simply because a person is autistic, has repetitive behaviour, or causes concern to others.

Before calling a presentation psychiatric, reconstruct its function. Consider what precedes the behaviour, what follows it, whether pain, fear, sensory overload, communication failure, a demand that exceeds capacity, or a change in routine is maintaining it, and whether the behaviour has become a reliable route out of an intolerable situation. This is not an argument against medication. It is what prevents a medicine from being used to silence the only available signal of distress. The wider assessment of co-occurring medical and psychiatric conditions belongs with the medical-comorbidity discussion; here the practical point is that an unexplained new target should be assessed before it is medicated.

Agree in advance what improvement would look like: fewer episodes, less intensity, less injury, better participation, or greater ability to use supports. Also agree what would make the trial unsuccessful: no clinically meaningful change, unacceptable adverse effects, or a target that turns out to have been incorrectly formulated. Carer observations are valuable, but must be joined to direct clinical enquiry and the person's own communication wherever possible.

TRAP **Examination trap.** Do not write that antipsychotics treat the social-communication differences or restricted interests of autism. Their established role in this section is management of severe irritability and associated dangerous behaviour.

29.2 Deciding whether medicine is needed

A target-symptom formulation protects against diagnostic overshadowing. The question is not whether the behaviour appears dramatic; it is whether there is a sufficiently clear syndrome of irritability, a serious consequence, and a realistic opportunity to judge change. It also protects the person from prolonged exposure to a drug when its intended benefit was never specified.

- Describe the target in observable terms and identify the harm, distress, or loss of access that makes it clinically important.
- Seek a working explanation for the behaviour, including communication and environmental contributors, before interpreting it as a medication-responsive syndrome.
- Record a baseline and choose a small set of outcomes that matter to the person and carer.
- Discuss the expected trade-off openly: reduction of dangerous behaviour may be valuable, but sedation, appetite change, movement effects, endocrine effects, and weight change may alter quality of life.

This approach also clarifies the place of non-drug intervention. Environmental adaptation, communication support, behavioural work, and carer support remain necessary even when

medication is appropriate. A drug may lower the intensity of a crisis enough for those measures to become usable; it does not replace them. The detailed programmes and therapies are addressed elsewhere in this chapter.

Shared decision-making is particularly important where the observable benefit is reported mainly by adults around the child. Ask what has changed for the person: comfort, participation, sleepiness, appetite, mobility, alertness, and ability to engage. A quiet child is not necessarily a better child. The therapeutic objective is improved safety and access to life, not convenience for a system that has failed to adapt.

29.3 Evidence base and place of risperidone

Risperidone and aripiprazole are the **two FDA-approved atypical antipsychotics** for irritability in children and adolescents with autism. For risperidone, the approved wording is irritability associated with autistic disorder. The listed age range is **5-16 years**. These regulatory facts should not be converted into an indiscriminate rule that every distressed autistic young person requires an antipsychotic. They identify a well-studied target, not a substitute for formulation.

Risperidone has the clearest short-term evidence when severe irritability is the dominant target. In a controlled trial, **69%** of participants receiving risperidone showed substantial reduction in irritability, compared with 12% receiving placebo. Across additional trials, short-term response generally lay between 57% and 72%. The clinical reading is not that response is guaranteed. It is that a clearly observed trial can be worthwhile where the presenting problem is dangerous, severe, and recognisably within this target cluster.

69%	12%	2.7 kg	5.6 kg
SUBSTANTIAL IRRITABILITY REDUCTION WITH RISPERIDONE	CORRESPONDING PLACEBO RESPONSE	MEAN WEIGHT GAIN IN SHORT-TERM LARGE TRIALS	MEAN WEIGHT GAIN AT FOLLOW-UP IN THE CITED STUDY

Evidence must be interpreted alongside burden. In the discontinuation phase of a risperidone study, 62.5% relapsed when switched to placebo. This makes abrupt, reflexive withdrawal after a response unwise. It does not mean that treatment must continue indefinitely. It means that the earlier formulation and the conditions that supported improvement should be revisited before tapering, and that the family needs a plan for recognising recurrence.

A meta-analysis of 46 randomised controlled trials found risperidone and aripiprazole the most effective agents for irritability, with moderate to large effects relative to placebo. This supports their priority over speculative polypharmacy. It also explains why an answer that simply lists psychotropics loses the clinical point: the evidence concerns a particular target, not a general drug treatment of autism.

29.4 Risperidone: practical dosing and titration

Start low and make each change interpretable. Weight-sensitive paediatric dosing is designed to reduce avoidable adverse effects while allowing time to judge the direction of change. The smaller-weight schedule begins at **0.25 mg/day** and then moves to 0.5 mg/day. Subsequent

increases are 0.25 mg at intervals of 2 weeks or more, within a licensed range of 0.5-3 mg/day whose upper end is not a target for a small child: therapeutic benefit plateaus at **1 mg/day**, and only patients over **45** kg may require more. Read the range as the outer bound of the licence and the plateau as the clinical ceiling. That plateau applies to both weight schedules rather than to the lighter one alone; escalation beyond a useful response should therefore not be routine.

For the higher-weight schedule, the initial dose is 0.5 mg/day, followed by 1.0 mg/day. Further increases are 0.5 mg at intervals of 2 weeks or more, with a total range of 1.0-3 mg/day. The 1 mg/day plateau applies to this schedule too. Only those weighing more than **45** kg may require higher doses, and it is in that subgroup alone that the effect plateaus at 3 mg/day. Reading the higher plateau as licence for every child on this schedule is the error the weight bands exist to prevent. Below **15 kg** there is no paediatric dosing data at all, and the source's instruction is caution for that reason rather than caution about data that exist. The distinction is the whole point: an absent evidence base is not a cautious one.

CLINICAL SITUATION	STARTING AND EARLY DOSE	LATER ADJUSTMENT	INTERPRETIVE POINT
Lower body-weight schedule	0.25 mg/day, then 0.5 mg/day	Increase by 0.25 mg at intervals of 2 weeks or more	Licence 0.5-3 mg/day, but benefit plateaus at 1 mg/day: the top of the range is not a target at this weight
Higher body-weight schedule	0.5 mg/day, then 1.0 mg/day	Increase by 0.5 mg at intervals of 2 weeks or more	Licence 1.0-3 mg/day, but benefit plateaus at 1 mg/day: the 3 mg/day ceiling belongs to patients over 45 kg alone, so a lighter child on this schedule is not titrated toward it

GOOD TO REMEMBER

The table is a dosing aid, not permission to chase the top of a range. At each step, ask whether the pre-agreed target has changed enough to justify further exposure. A partial response may be clinically important if it prevents injury or restores access to school and family life. Conversely, an apparently calmer presentation accompanied by marked sedation may represent harm rather than success. Avoid simultaneous medication changes where possible, obtain information from the settings in which the target occurs, and resist adjunctive psychotropics before the initial trial has become interpretable.

29.5 Risperidone: adverse effects, monitoring, and review

Weight gain is the adverse effect that most often changes the risk-benefit balance over time. In the larger short-term trials, mean gain was 2.7 kg. In a follow-up study it was 5.6 kg, an increase of 16.7% from baseline body weight. A paediatric estimate over a year was 7.5 kg, compared with expected annual gain of 3-3.5 kg/year. These figures make routine measurement clinically necessary rather than an administrative formality.

Prolactin elevation is another important adverse effect. Reported rates in paediatric risperidone users range from 49% to 87%, compared with 2% to 7% on placebo. Galactorrhoea has been reported in 0.8%, and gynaecomastia in 2.3%, of paediatric users. These are not simply laboratory concerns: enquire sensitively about symptoms, pubertal concerns, and distress, and interpret any abnormality in the whole clinical context.

Movement effects require active questioning and observation, especially when altered posture, restlessness, or behavioural change might otherwise be attributed to autism. Tardive dyskinesia was reported in 0.1% of paediatric participants in industry-sponsored risperidone trials, while an annual estimate for young people receiving antipsychotics was 0.3% per year. Transient somnolence after initiation had a median duration of 16 days. The numbers are low enough to tempt omission and important enough to make that unsafe: movement phenomena and sedation may be difficult to elicit from a person with limited speech.

Monitoring must therefore connect directly to the indication. At every review, revisit the original behaviour, weight trajectory, appetite, alertness, movement symptoms, endocrine symptoms, and the person's capacity to participate. If benefit is marginal, adverse effects should carry more weight in the decision. If benefit is substantial, monitoring is still not optional, because an initially acceptable trade-off can become unacceptable as exposure continues.

29.6 Aripiprazole: alternative evidence and dosing

Aripiprazole is the other approved antipsychotic for autism-related irritability in children aged 6-17 years; the FDA approval was granted in 2009. It is an alternative when the same target syndrome is present and risperidone is unsuitable, not a drug for core autism. Its initial dose is 2 mg/day. The usual range is 5-15 mg/day, the maximum is 15 mg/day, and titration proceeds by 5 mg/day at intervals of no less than 1 week.

Across the pivotal trials, active-arm responder rates were 52.2% and 55.8%, while placebo rates were 34.7% and 14.2%. The trial-to-value pairing is not reliable and should not be asserted. The defensible conclusion is that the medicine has evidence of benefit for irritability, but the size of individual benefit and the placebo contribution need careful reading rather than slogan-level certainty.

At short-term follow-up, aripiprazole-associated weight gain was 1.3-2 kg, somewhat lower than that reported with risperidone in the cited trials. It was not associated with prolactin elevation. These differences may matter when choosing between agents, especially where weight or endocrine effects have already shaped the discussion. They do not make aripiprazole benign: treatment-emergent extrapyramidal symptoms and vomiting were reported more often than in the risperidone studies. Moreover, aripiprazole may be ineffective for self-injurious behaviours. The target behaviour, rather than an imagined universally preferable drug, should drive selection.

The comparative choice is therefore a conversation about the individual target and anticipated trade-offs. Risperidone offers a strong evidence base with substantial concerns about weight and prolactin. Aripiprazole offers a distinct adverse-effect pattern, including movement effects and vomiting, and may have limitations where self-injury is the central target. Both require the same

disciplined baseline, follow-up, and willingness to stop if the promised benefit does not materialise.

29.7 Restricted and repetitive behaviour and the limits of extrapolation

Restricted and repetitive behaviours and interests are often distressing, but they should not be treated as a single undifferentiated drug target. A Cochrane review found no evidence of effect and emerging evidence of harm for selective serotonin reuptake inhibitors in children with autism. This is an important corrective to the tempting, but unsound, analogy that repetitive behaviour in autism should automatically be treated as though it were an obsessive-compulsive symptom.

The negative citalopram trial illustrates the point: responder rates were 33% with citalopram versus 34% with placebo. Evidence should be allowed to overrule pharmacological intuition. If an SSRI is being considered for another clearly formulated indication, that decision requires its own assessment; it should not be presented as treatment of core repetitive behaviour in a child with autism.

Where fluoxetine is used in the paediatric regimen cited for repetitive behaviours, the starting schedule is 2.5 mg/day for 1 week and the maximum is 0.8 mg/kg/day. These dosing details do not overturn the negative child evidence. In an examination answer, that distinction earns more credit than listing a drug without stating the weakness of its indication.

29.8 Duration, discontinuation, and the longitudinal plan

Planned discontinuation belongs in the initial prescription, not only after adverse effects emerge. For irritability in autism, antipsychotic treatment appears beneficial for **6-12 months**, after which discontinuation should be considered. This is a prompt to review, not a rigid deadline. The clinician should ask whether the original syndrome persists, whether the environment and communication supports have changed, whether adverse effects have accumulated, and whether a carefully observed reduction is now feasible.

> The success of medication in autism is not a quieter person. It is a safer, less distressed person with greater access to ordinary life, at an acceptable cost in adverse effects.

When a person has improved, explain that withdrawal is also a clinical test. A gradual, monitored reduction allows the team to distinguish continuing need from inertia. If the target returns, reconsider the formulation rather than simply restoring medication without thought: relapse may identify a genuine medication-responsive syndrome, an environmental trigger, loss of support, or an insufficiently prepared taper. If the target does not return, the successful outcome is not merely drug cessation but a person spared unnecessary exposure.

For the MD or DNB candidate, the mature answer is consequently structured rather than encyclopaedic: state that core autism is not medicated, define the target, justify either risperidone or aripiprazole for severe irritability, give cautious dosing, name the adverse-effect trade-off, and

make review and discontinuation part of treatment. That sequence shows pharmacological knowledge and, more importantly, clinical judgement.

30 · Speech and occupational therapy and family support in ASD

The practical aim is participation, not performance. Speech and language work, occupational therapy and family support translate an autism formulation into a plan that can be used during ordinary communication, play, self-care, learning and community life. They are not interchangeable therapies, and they should not be presented to families as a menu of equally established options. The useful clinical question is: which barrier is limiting this person's participation now, and what change can the child, family and communication partners realistically carry across settings?

A good plan makes communication more available, adapts demands and environments, and gives carers a role that is sustainable. It also makes uncertainty explicit. This matters especially where an intervention has an appealing explanatory story or a memorable label: plausibility, popularity and individual preference do not by themselves establish effectiveness. The psychiatrist's contribution is to hold the formulation together, protect the family from exaggerated promises, and ensure that therapy goals remain linked to daily function rather than to a fashionable technique.

30.1 Speech and language therapy: from language form to functional communication

Speech and language therapy begins with an account of how the person currently communicates, what communication partners understand, and where breakdown occurs. The assessment is broader than spoken output. It asks what the person can initiate, how they show choice or refusal, whether they can repair a misunderstanding, and which routines make communication easier or harder. The resulting targets should be concrete enough for a caregiver and teacher to recognise in ordinary life. A target that cannot be seen outside the therapy room is difficult to generalise and difficult to judge honestly.

RULE **Treat communication as access to agency.** The person needs a reliable way to request, refuse, share attention and participate, whether or not speech is the route.

This framing prevents a common drift towards making speech itself the sole outcome. Spoken language may be an important goal for some people, but clinical work should not postpone access to communication while waiting for it. The therapist therefore works with the person's existing signals and with the adults who respond to them. The psychiatrist should ask whether the proposed therapy has identified a meaningful communication function, a communication partner, and a setting in which the new skill will be practised.

A **communication partner** is not merely a helper standing nearby. The partner notices an attempt, allows time for a response, interprets it cautiously, and creates repeated opportunities for the person to communicate. This is why family and classroom work cannot be an afterthought to individual sessions. A technically correct target can fail if the adults around the person repeatedly anticipate needs, change the routine without warning, or respond inconsistently.

Conversely, a modest target can become powerful when it is recognised in the home, school and clinic.

Clinical review should distinguish a communication goal from a behavioural label. For example, a difficult moment may represent an unmet need, an inaccessible instruction, an intolerable demand, or an ineffective means of protest. The response is not to assume intent from the behaviour alone, but to test whether a clearer route for communication and a changed interaction pattern reduce the impasse. This keeps speech and language work tied to formulation without turning every difficulty into a speech problem.

- Specify the everyday situations in which communication fails.
- Agree on the response expected from communication partners.
- Choose a visible marker of change that families can recognise without specialist scoring.
- Review whether the skill appears outside the session, not only during prompted practice.

30.2 Augmentative and alternative communication in the therapy plan

Augmentative and alternative communication covers every route that supplements or replaces speech: gesture, signing, objects of reference, picture and symbol systems, and speech-generating devices. The named manualised picture-exchange programme is described with the other manualised interventions in the behavioural-interventions section of this chapter; the question here is the one the speech and language therapist actually answers, which is what the person needs a communicative route *for*, and how that route is chosen, taught and kept available.

The clinical decision is not which system is best in the abstract. It is which communicative acts are currently impossible for this person, and what would make them possible. A route is worth introducing when there is a real need to request, refuse, seek help, comment or indicate a preference; when the person can physically and perceptually manage it; and when the people around them will respond to it consistently. Assessment therefore examines comprehension as carefully as expression, because a system chosen for output alone will be abandoned by a person who cannot follow what it is being used to negotiate.

The practical discipline is to decide what communicative act the route is meant to make possible and whether the family can keep it available in the settings that matter. A picture system that remains in a folder at school is not a functional communication system at home. Equally, the introduction of a symbol system should not lead adults to stop attending to gesture, vocalisation, movement toward an item, or any other communicative attempt. The method should widen the person's options, not narrow adults' attention.

TRAP **Examination trap.** Do not present augmentative communication as a last resort that follows failed speech therapy, and do not describe it as a substitute for therapeutic formulation. It is offered alongside speech and language work from the outset, because an accessible route now does not foreclose speech later; the evidence does not show that a symbol route suppresses talking.

Review asks whether the selected communicative functions have become more available in daily routines, whether the person initiates them with multiple partners, and whether the route itself has become a barrier through poor access, excessive prompting or inconsistent adult response. A system that only works in the therapy room has not yet done its job.

30.3 Occupational therapy: participation, adaptation and sensory questions

Occupational therapy addresses participation in the occupations of ordinary life. Its clinical value lies in observing the fit between a person, a task and an environment, then changing the part of that fit that can be changed. This may involve simplifying a routine, preparing a transition, altering materials, building a practicable self-care sequence, or helping adults recognise what makes an activity inaccessible. The emphasis is not on a universal profile of autism; it is on the particular activity that has become difficult for this person and family.

Sensory integration therapy, associated with Jean Ayres, requires sharper evidence literacy. The IPS narrative frames sensory integration as challenge within a purpose-designed sensory environment, intended to support adaptation in daily activity. It assumes that a child may be receiving too much or too little environmental stimulation. That description explains why the intervention can sound intuitively compelling to families: it connects a visible response to a tangible environment. It is a rationale, however, not an outcome demonstration.

CLINICAL QUESTION	CONSTRUCTIVE RESPONSE	BOUNDARY THAT PROTECTS THE FAMILY
What activity is difficult?	Describe the task, setting, demand and response in functional terms.	Do not infer a single cause from the label “sensory”.
What can change now?	Adapt the routine, materials or adult response and observe participation.	Keep goals visible outside the therapy room.
Is sensory integration proposed?	Discuss its rationale and agree a time-limited, functional review.	Explain the uncertain evidence before commitment.
Are sound-based treatments offered?	Ask what is delivered and what safety safeguards are in place.	Do not treat a sensory rationale as evidence of benefit.

The IPS evidence rating for sensory integration is **Not established, but potentially effective**; its overview also places sensory integration outside the guideline’s recommended nonpharmacological group. This is not a contradiction to be concealed from parents. It is a reason to state the uncertainty plainly, define a functional outcome in advance, and avoid allowing an expensive or time-consuming programme to displace communication, education, family support or medical review.

30.4 Sensory integration and auditory integration: explaining contested evidence safely

A sympathetic explanation is not an endorsement. Sensory distress can be real and can interfere substantially with participation. The clinical response should be respectful observation, environmental problem-solving and a careful search for what the person is communicating

through their response. It should not convert an observation into a certainty that a particular branded intervention will correct an assumed underlying deficit.

Systematic reviews find the evidence base for sensory integration inadequate for recommendation as an evidence-based ASD treatment, with poor study design a central concern. A different textbook account reports **an absence of controlled efficacy studies**. Rather than pretending these summaries are identical, the clinician should communicate their common practical implication: controlled evidence does not establish sensory integration as a treatment for autism. The source-level tension reinforces, rather than weakens, the need for transparent uncertainty.

Auditory integration training needs an even firmer boundary. Reviews do not support a conclusion that it is effective in ASD, and they identify a potential hearing risk from loud sound exposure. The distinction between occupational adaptation and a sound-based treatment matters. A clinician who hears "sensory therapy" should ask what is actually being proposed, what outcome is promised, and whether a potential harm is being minimised in the sales language.

For sensory interventions, validate the difficulty, adapt the environment, define a functional outcome, and state the evidence limit before recommending a programme.

30.5 Family support and parent-mediated work

Family support is clinical work, not a polite adjunct after referral. Families need a coherent formulation, clear goals, practical help in negotiating settings, and space to describe what a proposed programme costs them. A plan that depends on constant availability, specialised materials or flawless delivery may be technically elegant but clinically unsustainable. The psychiatrist should make the burden visible early, especially when multiple services each prescribe home tasks without coordination.

GOOD TO REMEMBER

Before adding a parent-mediated task, ask whether it can be carried across the family's routines. Engaging parents as **co-therapists** can help maintain treatment effects and generalise learned responses across settings, but the same therapeutic tasks can increase parental stress when they become an added burden. Protect capacity: the parent is a partner whose knowledge of routines is indispensable, not an untrained therapist to be judged for poor adherence.

Preschool parent-mediated social-communication interventions teach parents, carers or teachers strategies that increase **joint attention** and reciprocal communication, often through interactive play and action routines. Their evidence should be read with precision. Improvements are usually found in proximal measures closely related to what was trained or in broader developmental measures; autism behaviours are rarely assessed and longer-term outcomes remain unstudied. This does not make the work pointless. It tells the clinician what result may reasonably be expected and what result should not be promised.

JASPER expands to Joint Attention, Symbolic Play, Engagement and Regulation. It is one of **two** evidence-based ASD interventions recommended by NICE in the cited account. The remaining intervention is not named in that source, so it should not be guessed. **PACT** means Preschool Autism Communication Trial and illustrates the same broad clinical principle: the adult-child interaction is a treatment context that needs skilled support, realistic goals and review of burden.

2
NICE-RECOMMENDED EVIDENCE-BASED INTERVENTIONS IN THE CITED ACCOUNT

NICE found too little evidence to recommend a programme for parental stress, mental health or quality of life, and directs practical intervention towards behaviours that challenge. This is a statement about the evidence base, not permission to ignore carers. Clinicians should still listen to strain, coordinate demands, make plans understandable, and reassess whether the family can live with the regimen. Where family distress requires assessment or treatment in its own right, that work belongs within the broader child psychiatric care framework, including the Child psychiatry: assessment, treatment, services and protection notes.

30.6 Matching expectations to developmental stage and setting

RULE **Match the intervention to the functional target.** The target must survive in the setting where it actually matters, not only in the therapy room.

Home, clinic and educational settings each reveal different demands. The point is not to prescribe identical practice everywhere, but to make sure that the adults in those settings understand the same goal and respond in compatible ways. This is particularly important when a child is taught a new communication act in a setting but encounters a different routine, material or response elsewhere.

Social-communication programmes can have a role where social isolation is the therapeutic target. Their evidence does not justify comparable claims for restricted, repetitive behaviours or sensory sensitivities. Candidates should avoid claiming that a communication programme treats every domain of autism. It may improve an interactional pathway while leaving another source of difficulty unchanged. That is not a failure of the child or family; it is an instruction to keep the formulation plural and to revise the plan.

For older school-aged children and young people, the evidence for social-skills and peer-mediated work is methodologically limited. A possible signal in favour of more intensive and longer work is not enough for firm conclusions. In clinical practice, this calls for proportionate claims, collaboratively chosen goals and regular review of whether a group or peer-based format is producing meaningful participation rather than merely attendance.

- Write a shared functional aim in language that family and school can use.
- Identify the adult responses that will support that aim in each setting.
- Ask what new burden the plan creates before adding another home task.
- Review benefit, feasibility and unintended effects together.

30.7 The psychiatrist's synthesis and review

The psychiatrist need not deliver every therapy to lead the treatment plan. The task is to ensure that referrals answer a clinical question, that different professionals are not pursuing incompatible goals, and that the family is not asked to carry an impossible programme. At review, ask what has changed in the specified activity, who has observed the change, where it is seen, and what has become harder. A vague report that therapy is "going well" should be translated into observable participation and weighed against burden.

This approach also guards against false choices. It is not speech therapy versus occupational therapy versus family work. Communication access, environmental fit and caregiver capacity are linked, but each needs a distinct assessment and an honest account of evidence. When an intervention is uncertain, the ethical response is neither contempt nor uncritical referral: explain the rationale, disclose the limitation, agree a meaningful review point and retain interventions with clearer functional value. Document the family's own priorities and the practical barriers that may prevent follow-through. At the next review, revise the plan rather than interpreting an unworkable intervention as a failure of motivation.

31 · Prognosis and outcome in ASD

Prognosis is not a single endpoint. In autism spectrum disorder (ASD), outcome has to be described across the abilities and circumstances that make adult life workable: communication, adaptive functioning, education and employment, relationships, autonomy, mental health, safety, and the fit between a person's needs and the support actually available. A child may make striking developmental gains yet continue to need help in daily life; another may meet fewer diagnostic features over time but remain vulnerable at transitions. The useful clinical question is therefore not whether autism will "go away", but what trajectory is emerging, what risks can be anticipated, and what support will allow the person to participate as fully and safely as possible.

For examination answers, separate the course of autistic features from functional outcome and from service outcome. They overlap but are not interchangeable. A reduction in visible autistic symptoms does not itself prove independence, and a constrained adult outcome may reflect a poor transition environment as much as the person's intrinsic abilities. Prognosis should be communicated as an individual formulation: it recognises uncertainty while identifying practical levers for surveillance, preparation and support.

31.1 The longitudinal frame

Autism is developmental, not a progressive neurological decline. ASD is **not a degenerative disorder**. Learning, adaptation and compensation can continue across the life course, which is why adult outcome cannot be inferred simply from the severity of a child's presentation at one assessment. Development may be uneven: a person can gain language, practical routines or self-awareness while continuing to have substantial difficulty with reciprocity, flexibility, sensory demands or social judgement. Clinical review must therefore look for new demands as well as changes in core features.

At the population level, many people show a **gradual reduction in autistic symptoms** alongside improved adaptive abilities. The most important qualification is the breadth of individual variation. The same diagnostic label includes people whose adult lives are relatively autonomous and people who require continuing intensive support. That variation is not a reason to abandon prognosis. It is a reason to make prognosis descriptive, revisable and grounded in function rather than in a label alone.

RULE **State prognosis as a trajectory of function and support needs, not as a promise of cure or a verdict based on diagnosis alone.**

A minority have a more difficult behavioural course in adolescence, whereas improvement is the more usual direction overall across the long run. This distinction is clinically useful. It prevents the erroneous reassurance that developmental progress eliminates later risk, while avoiding the equally damaging assumption that autism inevitably worsens. Behavioural deterioration requires assessment of change in context, physical health, seizures, psychiatric symptoms, environmental demands and the adequacy of support. It should not be dismissed as an unavoidable feature of ASD.

31.2 Diagnostic stability and its meaning

Diagnostic stability is one strand of outcome research, not a complete outcome measure. A systematic review brought together 23 longitudinal studies of children diagnosed using earlier diagnostic categories. Such work asks whether a later profile still crosses a diagnostic threshold. It does not by itself answer whether the person is communicating well, participating in education, safe from exploitation, or living with a satisfying degree of autonomy. A resident should explicitly make this distinction in a long-answer question.

Within the earlier category of **DSM-IV autistic disorder**, the diagnosis was generally stable. At follow-up, however, approximately **15%** no longer met criteria for that earlier category. This should not be translated into a claim that a corresponding proportion of people with present-day ASD lose the diagnosis. The denominator, diagnostic system and question are different. It is better understood as evidence that developmental profiles can change sufficiently for some individuals to cross a categorical boundary.

Earlier labels of Asperger syndrome and pervasive developmental disorder not otherwise specified showed a **more variable diagnostic course**. Follow-up could move in either direction: some profiles no longer met criteria for a pervasive developmental disorder, whereas others became more consistent with autistic disorder. That finding illustrates a broader teaching point. Categories are useful clinical shorthand, but development is dimensional and context-sensitive. A later reassessment should be based on the current developmental history and functional picture, rather than treated as an administrative confirmation of a childhood label.

TRAP **Do not equate a change in diagnostic threshold with normalisation.** Diagnostic status, symptoms, adaptive functioning and participation must be reported separately.

31.3 What adult outcome studies actually show

Adult outcome studies are difficult to compare because they use different samples, eras of diagnosis, follow-up methods and definitions of a good outcome. Some use a common classification ranging from very good to very poor, while others emphasise schooling, work, living arrangement or social inclusion. These are related outcomes, but they are not synonyms. The evidence base also contains relatively few prospective studies that follow children from early childhood into adult life. That limitation matters when counselling families: precise-sounding estimates may conceal a very particular cohort and a very particular endpoint.

23	approximately 15%	between <5% and 25%
LONGITUDINAL STUDIES IN ONE STABILITY REVIEW	LATER BELOW AN EARLIER AUTISTIC-DISORDER THRESHOLD	VERY-GOOD RATING ACROSS PROSPECTIVE COHORTS

Using that common outcome classification, the proportion rated as having a **very good outcome** lay **between <5% and 25%** across prospective childhood-to-adulthood studies. This is not an employment rate, a school-attendance rate or a prevalence estimate. It is a rating on a particular outcome tool. The correct interpretation is that very favourable adult outcomes occur, but their frequency varies substantially by cohort and definition.

Another older, narrower set of estimates concerns children with **childhood autism**, not the contemporary whole ASD spectrum. Around **10% to 20%** improved from early childhood and subsequently attended an ordinary school and obtained work. A further 10% to 20% could live at home but could not work and required special schooling or a training setting. At least **60%** improved little and could not lead an independent life. These figures are worth knowing only with their boundaries intact: they are historical, category-specific outcome tiers, not a universal prediction for all persons now diagnosed with ASD.

OUTCOME QUESTION	WHAT IT CAPTURES	WHY IT MUST NOT BE SUBSTITUTED FOR ANOTHER OUTCOME
Diagnostic status	Whether current features meet a specified threshold	It does not establish independence or quality of life.
Symptom trajectory	Change in autistic features over time	Improvement can coexist with persistent support needs.
Functional outcome	Communication, practical autonomy, participation and work	It depends on both personal skills and opportunity.
Living arrangement	Where and with what support a person lives	Family resources and service availability influence it greatly.
Outcome classification	A study-defined global rating	It should not be relabelled as a single attainment figure.

Improvement is also not synonymous with the disappearance of autistic traits. People with childhood autism who improve may continue to have language problems, emotionally detached interpersonal style, and unusual behaviour. The clinical implication is respectful realism:

celebrate gains without withdrawing supports prematurely, and assess the person's own goals rather than judging success only against a conventional adult template.

31.4 Predictors: useful, but never deterministic

The strongest recurring predictors are markers, not destiny. Better long-term outcome is associated with **higher intellectual ability** and the presence of useful speech before **5 years of age**. A second account places useful speech at age 5 years. The slight difference in wording should not be forced into a false precision. Both formulations identify the early emergence of functional language as a favourable marker, while preserving the fact that people with similar apparent strengths can have very different adult outcomes.

Why are these predictors clinically plausible? Intellectual ability and functional speech can broaden the routes through which a child learns, signals distress, understands rules, uses education and later negotiates environments. They may also make it easier for carers and teachers to recognise strengths and tailor demands. Yet this is interpretation, not a reason to reduce prognosis to a score or a language milestone. Social understanding, emotional regulation, daily living skills, family circumstances, educational fit, co-occurring conditions and adult services can each alter what those strengths mean in real life.

There is also an **optimal outcome** literature describing a minority whose later presentation no longer meets diagnostic criteria. In observational comparisons, this group had four distinguishing features four:

- milder social impairment at baseline, despite comparable early communication and restricted or repetitive difficulties;
- earlier access to intervention;
- more intensive behavioural intervention services; and
- a greater likelihood of receiving applied behaviour analysis rather than pharmacological intervention.

These observations are important but do not prove that any one service caused the outcome. Baseline social differences may themselves influence both eventual outcome and access to an intervention. Service intensity may also be a proxy for family resources, local provision or a clinician's perception of need. This is the distinction a mature answer should make: observational association can guide hypotheses and service planning, but causal claims require a design able to separate treatment effects from pre-existing differences.

RULE **Use prognostic markers to individualise support and follow-up, never to ration intervention or forecast an individual's ceiling.**

That caution is especially necessary when discussing earlier identification. There has been **no randomised combined screening-and-treatment trial** demonstrating that screening and an earlier age at diagnosis itself lead to better long-term outcome. This does not make timely recognition unimportant. It means that the causal chain should be stated honestly: earlier

recognition may allow access to help sooner, but the long-term benefit of a screening-and-treatment pathway has not been established by that trial design. The detailed approach to early intervention belongs with the management sections of this chapter.

31.5 Adolescence: where trajectories can diverge

Adolescence increases both opportunities and strain. New educational settings, changing social expectations, bodily changes, growing self-management demands and the approach to adult roles can expose a mismatch between a person's coping strategies and their environment. A previously manageable pattern may become more visible when routines change or supports recede. It is therefore good practice to establish a functional baseline and to ask what has changed before assuming a deterioration reflects the autism itself.

Some studies describe a **deterioration in functioning during adolescence** that may coincide with the development of epilepsy or with the onset of psychiatric disorders. The occurrence of epilepsy in ASD, its assessment and medical management are covered in the medical-comorbidity section. In this prognosis section, its relevance is as a warning that a loss of functioning needs active medical review rather than passive observation.

Similarly, the onset of **co-occurring anxiety or mood disorder** may accompany adolescent deterioration. A changed presentation may be behavioural rather than verbal: withdrawal, irritability, sleep change, avoidance, increased rigidity, loss of skills in familiar routines or escalating distress can all be clinically meaningful. Do not presume that every change is a core autistic feature. The map of psychiatric and medical comorbidity, including how to detect it, is addressed in the medical-comorbidity section; pharmacological treatment of target symptoms is addressed separately.

Regression should also be handled carefully in prognostic discussion. A developmental history of regression may shape a family's fear about future loss, but it is not a licence to make a numerical prediction. When there is new loss of function, the clinician must revisit the differential diagnosis and investigate the current change. The differential of regression is considered in the differential-diagnosis section of this chapter.

31.6 Mortality and preventable risk

Mortality in ASD appears **slightly increased** relative to the general population, but the available evidence is limited and no numerical rate should be implied where one has not been established. Prognostic counselling should avoid alarmist language. The clinical value of raising this issue is not to frighten families; it is to focus attention on preventable hazards and on continuity of medical care.

One proposed pathway concerns medical events such as status epilepticus or accidental death associated with epilepsy. This makes seizure monitoring during adolescence a potentially preventable part of risk reduction when seizures emerge or change. The point is not that every deterioration is epileptic, nor that epilepsy explains all excess mortality. It is that a new seizure history, impaired recovery after an event, or a change in functioning deserves prompt clinical attention.

A change in function in an adolescent or adult with ASD is a clinical event: reassess health, mental state, environment and support before attributing it to autism.

31.7 Transition to adulthood is a prognostic intervention point

Services shape outcome. The exit from school can be profoundly stressful and may slow overall progress. The move into adulthood often reveals gaps in adult mental-health care, social care and developmental-disability provision. This is a service problem as well as a developmental challenge. A young person's competence can appear to fall when familiar structures disappear, travel demands increase, family carers become exhausted, or no one coordinates education, work, benefits, healthcare and daily support.

Transition planning should begin with an account of the person's present strengths, communication preferences, sensory and behavioural needs, health risks, decision-making support, family capacity and preferred adult roles. It should identify what the young person can increasingly manage independently and what assistance remains necessary.

GOOD TO REMEMBER

Make the transition plan concrete: who will notice deterioration, who will coordinate appointments, what happens when routine breaks down, and how meaningful daytime activity will be maintained. This protects dignity while avoiding a sudden and unrealistic withdrawal of care.

The evidence for specific transition-planning interventions remains limited, so clinical reasoning matters. Build continuity wherever possible, prepare the receiving service, and make the handover understandable to the person and family. The broader assessment battery, service organisation and safeguarding framework are set out in the Child psychiatry: assessment, treatment, services and protection notes. The detailed discussion of adult ADHD belongs in the ADHD and specific learning/communication disorders notes.

31.8 A practical way to communicate prognosis

A useful prognostic conversation starts with what is already known and names uncertainty without retreating into vagueness. Describe the person's trajectory in domains: communication, adaptive skills, learning, participation, mental health, physical health, safety and support network. Then identify favourable capacities, current barriers and foreseeable transition points. Families often need help distinguishing a realistic plan from a deterministic prediction. The clinician can say that development may continue, that outcomes vary markedly, and that progress is strengthened when demands and support are matched over time.

In a written formulation, avoid a bare phrase such as "poor prognosis". Instead state the active issues and the plan for each. This gives the team a framework for review and gives the family an intelligible account of why monitoring continues even when the person is doing well.

FORMULATION DOMAIN	QUESTION FOR FOLLOW-UP	CLINICAL USE
Developmental trajectory	What has improved, plateaued or changed?	Separates expected variation from a clinically significant loss of function.
Functional participation	What can the person do with the available support?	Prevents symptom counts from standing in for real-world outcome.
Communication and cognition	How are strengths being used in education and daily life?	Uses prognostic markers without turning them into ceilings.
Health and mental state	Has there been a new seizure, distress pattern or behavioural change?	Prompts review of potentially modifiable contributors.
Transition and supports	What will change when current structures end?	Turns a predictable risk point into a planned intervention point.

The final examination-quality conclusion is balanced. ASD usually permits ongoing learning and adaptation, but outcome is highly heterogeneous. Better intellectual ability and early useful speech are favourable markers, not guarantees. Co-occurring epilepsy or psychiatric illness, and failures at major transitions, can worsen functioning and require active review. The best clinical response is sustained, person-centred planning that measures meaningful function and keeps support available as needs change.

Discriminate, apply and consolidate

32 · Differentiation of intellectual disability from autism, GDD and borderline intellectual functioning

The discriminative task. A developmental presentation is not solved by attaching the most visible label to the child. Intellectual disability, autism spectrum disorder, global developmental delay and borderline intellectual functioning may all come to attention through slow learning, school difficulty, communication concerns or behaviour that unsettles adults. They answer different clinical questions. The useful formulation asks what the person can do in everyday life, how development has unfolded, whether social communication is qualitatively atypical for that developmental level, and whether the current assessment is a valid account of ability.

The marks are usually in the reasoning, not in reciting a checklist. Start by separating a broad developmental profile from a distinctive pattern of social-communication and behavioural difference. Then decide whether the profile has reached the threshold for intellectual disability or is better recorded as **borderline intellectual functioning**. This avoids opposite errors: calling every child with delayed language autistic, and using a reassuring test score to overlook everyday limitations that require support.

32.1 Begin with a developmental formulation, not a label

A **developmental formulation** is a map of strengths, difficulties and their context. It is more useful than an early diagnostic label because the same presenting complaint can arise from very different pathways. Slow acquisition of school skills may reflect a generally low level of functioning, a sensory or language barrier, missed learning opportunities, emotional distress, a neurodevelopmental condition, or an assessment that did not capture the child's usual capacity. The clinician therefore compares domains rather than treating a single complaint as the whole phenotype.

History supplies the frame. Establish the tempo of acquisition and whether abilities have continued to accrue, plateaued, or been lost. Ask how the person communicates needs, joins shared activity, copes with ordinary demands, learns from modelling, and manages changes in routine. Observe the same questions in the interview. A score is evidence, but not an explanation. It must be interpreted with language, sensory, motor, educational and behavioural context in view. This is especially important when the interview setting is unfamiliar or the person is anxious, overactive, shut down, oppositional, exhausted, or unable to understand the task demands.

RULE **Rule.** Diagnose the pattern of functioning and its real-world consequences; never let a conspicuous developmental symptom decide the diagnosis by itself.

The comparison must be made against **developmental level**, not merely chronological expectation. This prevents a common false positive for autism. A person with broadly delayed development may use simpler language, play, social approaches and coping strategies than peers. The pivotal question is whether social communication is more impaired, qualitatively different, or oddly uneven even when compared with that person's overall developmental level. Conversely, apparently sociable behaviour does not by itself settle the issue: the clinician asks whether contact is reciprocal, flexible, shared and meaningful, rather than simply frequent.

- Define the referral problem in ordinary functional terms before translating it into a diagnostic question.
- Seek convergent information from the person, family, school and direct observation.
- Describe strengths as carefully as limitations, since unevenness often carries the diagnostic clue.
- Record factors that could have distorted the assessment before treating its result as trait-like ability.

32.2 Comparison at the bedside

The table is a reasoning aid, not a substitute for assessment. Intellectual disability concerns the established diagnostic construct and its functional consequences. Autism spectrum disorder concerns a characteristic social-communication and behavioural pattern. Global developmental delay is a developmental description used when a stable intellectual-disability formulation cannot yet be made with confidence. Borderline intellectual functioning identifies a clinically relevant

zone near the boundary, where careful assessment and context matter more than an automatic diagnostic conclusion.

CLINICAL QUESTION	INTELLECTUAL DISABILITY	AUTISM SPECTRUM DISORDER	GLOBAL DEVELOPMENTAL DELAY	BORDERLINE INTELLECTUAL FUNCTIONING
Central task	Establish the intellectual and adaptive profile	Identify a characteristic social-communication and behavioural pattern	Describe developmental delay while the profile is still evolving	Judge a boundary presentation and its clinical relevance
Pattern of difficulty	Broad functional limitations are central	Qualitative difference may coexist with any intellectual level	Delay is described across development rather than presumed permanent	Difficulties may be real without establishing intellectual disability
Key comparison	Everyday function alongside intellectual assessment	Social reciprocity and behaviour relative to developmental level	Current abilities, opportunities and developmental trajectory	Intellectual and adaptive findings, including their mismatch
Common error	Equating a test result with the whole diagnosis	Calling global delay autism without qualitative evidence	Forcing a permanent label before adequate assessment	Using an obsolete numerical rule as a current diagnosis

Use the table dynamically. A person can occupy several categories in a clinically meaningful sense. Autism can occur with intellectual disability, and developmental delay can be the initial description before the later formulation becomes clearer. The task is not to make the categories mutually exclusive. It is to avoid using a category as an explanation for every feature and to state clearly what each diagnosis contributes to care planning.

> The decisive comparison is qualitative pattern against developmental level, interpreted alongside everyday functioning, not the presence of delay alone.

32.3 Intellectual disability and autism spectrum disorder

When intellectual disability is being considered, autism must be established by a characteristic qualitative pattern beyond the effects of broad developmental limitation, rather than inferred from delayed performance alone.

GOOD TO REMEMBER

Observe how the person uses the abilities they do possess. Do they seek another person for comfort, enjoyment, help or shared attention? Can they respond to a familiar social bid when demands are low? Is there flexibility in the way people and objects are used? Interpret the answers in the context of communication ability and the environment, not as isolated signs.

In autism, the important finding is a disproportionate alteration in **relative social reciprocity** and in the behavioural pattern, rather than delayed performance alone. A person may have very limited speech yet show clear social interest and shared enjoyment that are consistent with their overall developmental level. Another may have fluent speech but persistently atypical reciprocity, difficulty using communication socially, inflexible interests or restricted patterns that cannot be explained by general developmental delay. The latter pattern warrants an autism assessment even when intellectual ability is not clearly impaired.

Do not set up a false contrast in which one diagnosis excludes the other. When autism and intellectual disability coexist, the formulation should state both and then show what observations support the autism diagnosis beyond global delay. That discipline protects against diagnostic overshadowing in either direction. It prevents clinicians from attributing all behaviour to intellectual disability, while also preventing an autism label from obscuring practical support needs, communication limitations or safeguarding concerns associated with intellectual disability.

TRAP **Examination trap.** Delayed language, poor eye contact in an unfamiliar interview, repetitive play at a low developmental level, or behaviour under stress is not by itself evidence of autism. The question is whether the social-communication and behavioural pattern is qualitatively atypical for that person's developmental level.

Clinical interviews should therefore include situations that lower performance pressure. Watch what happens when the examiner follows the person's lead, offers a familiar object, pauses for a response, or involves a caregiver. A narrow clinic observation can overread anxiety, sensory discomfort or communication mismatch as autism, especially when the person has intellectual disability. Equally, a warm greeting or brief eye contact cannot rule autism out. Longitudinal history and reports across settings are what convert an impression into a defensible formulation. Detailed diagnostic criteria and assessment methods for autism belong in the relevant sections of this chapter; here the practical point is to ask whether autism adds a distinctive explanatory pattern beyond general developmental difficulty.

32.4 Intellectual disability and global developmental delay

Global developmental delay is best understood as a developmental description, not as a shortcut to a lifelong conclusion. It communicates that delay is evident across the developmental profile while acknowledging that the available evidence may not yet support a stable intellectual-disability formulation. The distinction matters because a child's observed performance is shaped by opportunity, health, communication access and the feasibility of formal assessment. A label that is too final can close inquiry prematurely; a label that is too vague can fail to communicate support needs.

The key concept is **developmental trajectory**. Ask whether the profile is broadly delayed or strikingly uneven, whether new skills are being acquired, and whether the child's functioning is being assessed under conditions that permit a fair estimate. Repeat assessment may be more informative than forced precision when a child cannot engage with formal tasks, when communication access is poor, or when the environment has substantially limited experience.

The clinician should explain uncertainty plainly: uncertainty is not indecision when it accurately reflects the developmental state of the evidence.

This distinction also changes the conversation with families. The immediate work is to describe present strengths and needs, arrange appropriate developmental and functional assessment, and review change over time. It is not to promise a future intellectual level or to use a temporary descriptive term as a euphemism for a diagnosis that has not been established. The normal developmental framework should be read alongside the *the Normal child development and milestones notes*; assessment, services and protection are addressed in *the Child psychiatry: assessment, treatment, services and protection notes*.

- Use global developmental delay when it accurately describes the current developmental evidence and its limits.
- Do not assume that a broad early delay proves a fixed intellectual-disability formulation.
- Do not assume that later identification of intellectual disability was predictable from one early observation.
- State what must be clarified on follow-up: developmental course, everyday function, communication access and validity of assessment.

The distinction is therefore practical rather than semantic. It determines how confidently the clinician communicates prognosis, how the record represents uncertainty, and why follow-up must revisit the formulation rather than merely repeat a label. It also keeps the assessment open to alternative or coexisting explanations when the profile is not globally uniform.

32.5 Borderline intellectual functioning: category, boundary and limits

Borderline intellectual functioning is not a milder synonym for intellectual disability. In the DSM-5-TR, it is coded **R41.83** and appears in Section II among conditions that may warrant clinical attention. That location is clinically useful: it permits recognition of a relevant cognitive vulnerability without converting every such presentation into a formal mental disorder.

The nosological boundary must be stated accurately. Borderline intellectual functioning is a **condition**, rather than a formal DSM-5 disorder. It should not be treated as a clear-cut disability category or as proof of definite deficits across intellectual and adaptive domains. The category is appropriate when the cognitive profile is itself the focus of clinical attention, or when it materially shapes treatment or prognosis. In practical terms, it can alert the clinician to adjust explanations, consent processes, expectations of independent follow-through, and the format of psychological or pharmacological care, while continuing to assess the actual person rather than acting on a label.

A psychometric zone may be described as **about 70 to 85**, or as one to two standard deviations below the mean, but this is not a current definitional rule. The current DSM-5 approach does not use a numerical IQ criterion to define the category. The older DSM-IV-TR definition explicitly used **IQ 71-84**; importing that band into current diagnostic reasoning is a category error. A

numerical result can prompt a closer look. It cannot replace clinical assessment of function, context and discrepancy.

R41.83	about 70 to 85	71-84	no numerical criterion
CURRENT CODE	DESCRIBED PSYCHOMETRIC ZONE	OLDER DEFINITIONAL BAND	CURRENT DEFINITION

Why this boundary matters. A person can have modest cognitive efficiency yet function capably in familiar, well-supported settings. Another may appear competent until demands increase, language becomes technical, routines change, or treatment requires planning and self-monitoring. Neither observation alone settles whether the person has intellectual disability, borderline intellectual functioning, another condition affecting performance, or a mixture of these. The clinician must avoid both minimisation and overpathologising.

32.6 Separating borderline intellectual functioning from mild intellectual disability

This is the boundary at which disciplined assessment matters most. The current DSM-5 framing expressly compares borderline intellectual functioning with mild intellectual developmental disorder, rather than making a broad contrast with intellectual disability in general. The assessment requires careful appraisal of intellectual and **adaptive functions**, including the **discrepancies** between them. This is not a mechanical exercise. A discrepancy may signal uneven opportunity, a co-occurring disorder, an invalid test session, a skill that is context-bound, or a genuine pattern requiring further understanding.

Work in both directions. If a test result lies near the boundary but everyday functioning is more limited than expected, ask what accounts for the gap before deciding that it demonstrates intellectual disability. Consider communication barriers, educational experience, emotional state, psychiatric symptoms, physical illness, sensory difficulty, family scaffolding and the actual demands of the setting. If everyday functioning appears stronger than a test result, ask whether the person has learned routines exceptionally well, receives extensive unobtrusive support, or had a poor-quality testing experience. The aim is not to rescue a preferred diagnosis. It is to identify the most credible account of the data.

Test validity is central to this judgement. The DSM entry specifically cautions that co-occurring disorders can affect adherence to standardised testing, including schizophrenia and ADHD with severe impulsivity. A low score obtained when attention, motivation, comprehension or behavioural regulation has collapsed is not automatically evidence of stable intellectual ability. Nor should a clinician dismiss all low performance as psychiatric. Reassess the conditions of testing, use collateral evidence, and formulate whether the observed score is likely to represent the person's usual functioning.

The practical record should make the reasoning visible. State the referral question, the data sources, their limitations, the relation between assessed ability and everyday functioning, and what alternative explanation has been considered. Then state why the conclusion is intellectual disability, borderline intellectual functioning, or a provisional formulation. This is kinder to families and more defensible clinically than an unsupported categorical assertion. Intelligence

testing itself and the instruments used for it are addressed in the assessment section of this chapter; do not confuse such testing with a complete functional evaluation.

32.7 Coding, language and the historical trap

The current label has a complicated historical trail, which explains why outdated terminology still appears in records and teaching material. In DSM-II, the 1968 entry used the label "borderline mental retardation" and the code 310. In 1973, the American Association on Mental Deficiency, now AAIDD, eliminated that name in favour of "borderline intellectual functioning".

The coding location also shifted. DSM-III placed it on Axis I with V62.89 in 1980. DSM-III-R moved it to Axis II with V40.00 in 1987; DSM-IV later used Axis II V62.89 in 1994. Axes were removed in DSM-5 in 2013, which used R41.83.

This history should sharpen, not confuse, current practice. It shows why an old numerical band, an old axis placement, or stigmatising terminology is not a substitute for a contemporary formulation. Use language that describes the person's current functioning and support needs. When older records are encountered, translate their meaning cautiously and verify what assessment was actually done before carrying a label forward.

Finally, "borderline" in borderline intellectual functioning has no relationship with borderline personality disorder. Similar wording is not shared aetiology, shared diagnosis or a reason to infer one condition from the other. Keeping this distinction explicit is particularly important when a patient has emotional dysregulation or interpersonal difficulty, because such features can tempt clinicians into semantic rather than phenomenological reasoning.

32.8 A defensible conclusion and its clinical use

Clinical attention is the right frame for borderline intellectual functioning. The category may be recorded when it changes how treatment is delivered or how prognosis is understood, not as a casual descriptor of anyone who struggles academically. Explain information plainly, check comprehension through the person's own account, anticipate difficulties with abstract instructions, and involve supports appropriately while respecting autonomy. These are good clinical practices because they respond to observed needs, not because a code has replaced assessment.

In a written answer, a strong conclusion follows a consistent sequence. Identify whether the central issue is broad functional limitation, a distinctive autism pattern, an evolving developmental profile, or a boundary cognitive presentation. State the observations that support that judgement. Name any coexisting diagnosis separately. Finally, state what must be reassessed and how the formulation changes communication, support and follow-up. This makes the differential useful at the bedside rather than a set of mutually exclusive examination labels.

Diagnostic humility is not vagueness. It means using a provisional developmental description when the evidence is still developing, making an autism diagnosis only when its qualitative pattern is established, recognising intellectual disability through the established formulation rather than a score alone, and using borderline intellectual functioning accurately when it is

clinically relevant without overstating its status. For associated attention and learning questions, use the ADHD and specific learning/communication disorders notes.

33 · Four worked cases

Vignettes test clinical organisation, not label recognition. A short stem rarely gives a complete developmental history, a valid cognitive assessment, an adaptive profile and a collateral account. The candidate's task is to recognise what the available pattern supports, state what remains uncertain, and choose the next discriminating enquiry. The same discipline protects clinical practice from premature labelling.

Use each vignette as a **developmental formulation**: place the person's trajectory, everyday function, social-communication pattern, repetitive or restricted behaviour, medical context and environment alongside each other. A diagnostic label is the conclusion of that process, not a substitute for it.

Trajectory	Function	Pattern	Context
DEVELOPMENTAL COURSE	EVERYDAY INDEPENDENCE	SOCIAL COMMUNICATION AND BEHAVIOUR	MEDICAL, FAMILY AND EDUCATIONAL SETTING

33.1 Read the stem before naming the diagnosis

The useful first question is not “Which disorder is this?” but “What is impaired, in which settings, and since when?” Separate a person's learning and problem-solving capacity from **adaptive functioning**, and separate both from the quality of social reciprocity and the behavioural pattern. School difficulty, delayed language, disruptive behaviour and poor self-care are findings. None is diagnostic in isolation.

RULE **Rule.** Diagnose the pattern of impairment, then test whether the pattern is global, autism-specific, developmental but still evolving, or below expected ability without the pervasive functional deficits required for intellectual disability.

- **Trajectory:** establish whether development has been delayed, uneven, static or marked by loss of previously acquired abilities.
- **Current function:** ask how the person manages communication, self-direction, daily routines, safety and participation in ordinary settings.
- **Pattern and context:** seek social-communication differences, restricted or repetitive behaviour, sensory concerns, physical clues, medical symptoms and the accounts of people who know the person well.

33.2 The central discrimination

Intellectual disability remains an assessment question when a stem describes broad difficulty with learning and everyday function. An autism-spectrum formulation depends on its characteristic social-communication and behavioural pattern. These formulations may coexist. The presence of autism does not answer the question of intellectual functioning, and global learning difficulty does not by itself establish autism.

FINDING IN A STEM	WHAT IT SUGGESTS	WHAT PREVENTS AN OVERCALL
Broad difficulty learning and carrying out everyday tasks	Consider a global impairment formulation	Clarify adaptive functioning and the developmental course
Qualitative difference in reciprocal social communication with a restricted or repetitive pattern	Consider an autism-spectrum formulation	Do not infer intellectual disability from the autism label alone
Developmental concerns in an early developmental presentation without a stable assessment picture	Use **global developmental delay** as a working developmental formulation where appropriate	Plan review as developmental information becomes clearer
Academic or occupational struggle with relative preservation of everyday adaptive competence	Consider **borderline intellectual functioning** and competing explanations	Do not convert a low score, poor scholastic performance or social disadvantage directly into intellectual disability

TRAP **Exam trap.** "Delayed speech" is not a shortcut to autism, and "poor school performance" is not a shortcut to intellectual disability. The discriminating evidence is the whole developmental and functional pattern.

33.3 Vignette: broad developmental difficulty without an autistic pattern

A child is brought because progress across learning, communication and self-care has been slow. The family describes a steady developmental course and needs help across ordinary routines. In the consultation, the child seeks shared engagement in a manner that is proportionate to developmental level, with no clear history of a restricted or repetitive behavioural pattern.

The defensible formulation is that the stem raises concern for intellectual disability or, when developmental assessment remains incomplete, a developmental-delay formulation. The point is not to exclude autism because the child is friendly, nor to diagnose autism because language is delayed. Ask for formal assessment of ability and adaptive behaviour, collateral accounts across settings, developmental history, physical and neurological review, and an aetiological evaluation guided by the wider presentation.

Why the distinction matters. The intervention plan must address the actual pattern of support needs. If autism is added without its defining pattern, families may be diverted from the assessment and supports that explain the person's everyday difficulty.

33.4 Vignette: autism with an uneven profile

An adolescent has intense, narrow interests, inflexible routines and marked difficulty interpreting reciprocal social interaction. Academic achievement is strong in selected areas, while practical independence and social judgement are variable. The stem offers no valid basis to conclude that intellectual functioning is globally impaired.

The appropriate formulation is autism spectrum disorder with a separate assessment of intellectual and adaptive functioning. Uneven strengths do not cancel clinically important disability, but neither do social difficulty and inflexibility prove intellectual disability. Document

the areas of competence as carefully as the areas of difficulty, because support planning follows function rather than assumptions about a diagnostic label.

- Ask which difficulties are intrinsic to social communication and behavioural flexibility.
- Ask whether practical dependence reflects limited capacity, limited opportunity, anxiety, environmental mismatch or a combination.
- Describe co-occurring attention, mood, anxiety, sleep, neurological and medical concerns without attributing all distress to autism.

33.5 Vignette: the apparent boundary case

A young person has struggled academically for years and has been described as "slow." At home and in the community, the person manages familiar routines, relationships and responsibilities with little extra help. An isolated test result is quoted in the referral note, but its validity, context and relation to everyday functioning are not described.

This stem is designed to expose **score determinism**. Consider borderline intellectual functioning, specific learning or communication disorders, attention problems, educational deprivation, sensory impairment, emotional disorder and contextual barriers. For the detailed assessment battery, see the Child psychiatry: assessment, treatment, services and protection notes; for attention and learning differentials, see the ADHD and specific learning/communication disorders notes.

GOOD TO REMEMBER

Do not diagnose from a number or a pejorative description. Interpret formal assessment alongside adaptive function and developmental history.

33.6 Vignette: change after an established developmental course

A caregiver reports that a child who had acquired skills is no longer using them in the same way. The current presentation includes communication difficulty and repetitive behaviour. The temptation is to treat the current surface pattern as sufficient for an autism diagnosis.

Here the clinical priority is a careful account of **regression**, its tempo, the affected skills, associated neurological or medical symptoms, and the possibility of an alternative developmental or neurological condition. Autism may remain part of the formulation, but loss of skills changes the workup and makes a broad differential essential. Do not reassure, diagnose or narrow the enquiry before establishing the trajectory.

MNEMONIC

MAPS

Map the developmental trajectory. **A**ssess everyday adaptive function. **P**attern-match social communication and restricted or repetitive behaviour. **S**earch for syndromic, neurological, psychiatric and contextual signals. This is a retrieval map, not a substitute for assessment.

33.7 Turning a vignette into a clinical answer

A strong answer starts with a provisional formulation, gives the positive findings that support it, then names the information required to distinguish nearby alternatives. It states comorbidities and safety or medical concerns as possibilities to assess, rather than presenting them as conclusions not contained in the stem. A developmental diagnosis does not make new distress, behaviour change or physical symptoms self-explanatory: assess each reported change on its merits.

When asked for management, link recommendations to the person's identified functional needs and family priorities. Do not leap from a label to a named programme, medication or legal entitlement. The relevant chapters provide the detailed intervention, medical-workup, disability-certification and family-support pathways.

> In every developmental vignette, the diagnosis must explain the whole pattern of trajectory, function and behaviour better than its nearest alternative.

34 · Consolidate: the master mnemonic, the retrieval prompts and the synthesis map

Consolidation is a clinical discipline, not a list of labels. Intellectual disability, autism spectrum disorder, developmental delay and borderline intellectual functioning can overlap in a referral, yet each answers a different clinical question. The task is to preserve that distinction while building a single account of the person's abilities, difficulties, context and needs.

A high-quality answer therefore moves from the presenting concern to a **developmental formulation**. It does not let a test result, a screening result, a certificate or a diagnostic label substitute for the history, observation and functional account. The chapter's component sections supply the detail; this closing section shows how to hold them together without flattening them.

MAP	READ	CHECK	PLAN
THE DEVELOPMENTAL COURSE	THE FUNCTIONAL PROFILE	CO-OCCURRENCE AND CONTEXT	MEANINGFUL SUPPORT

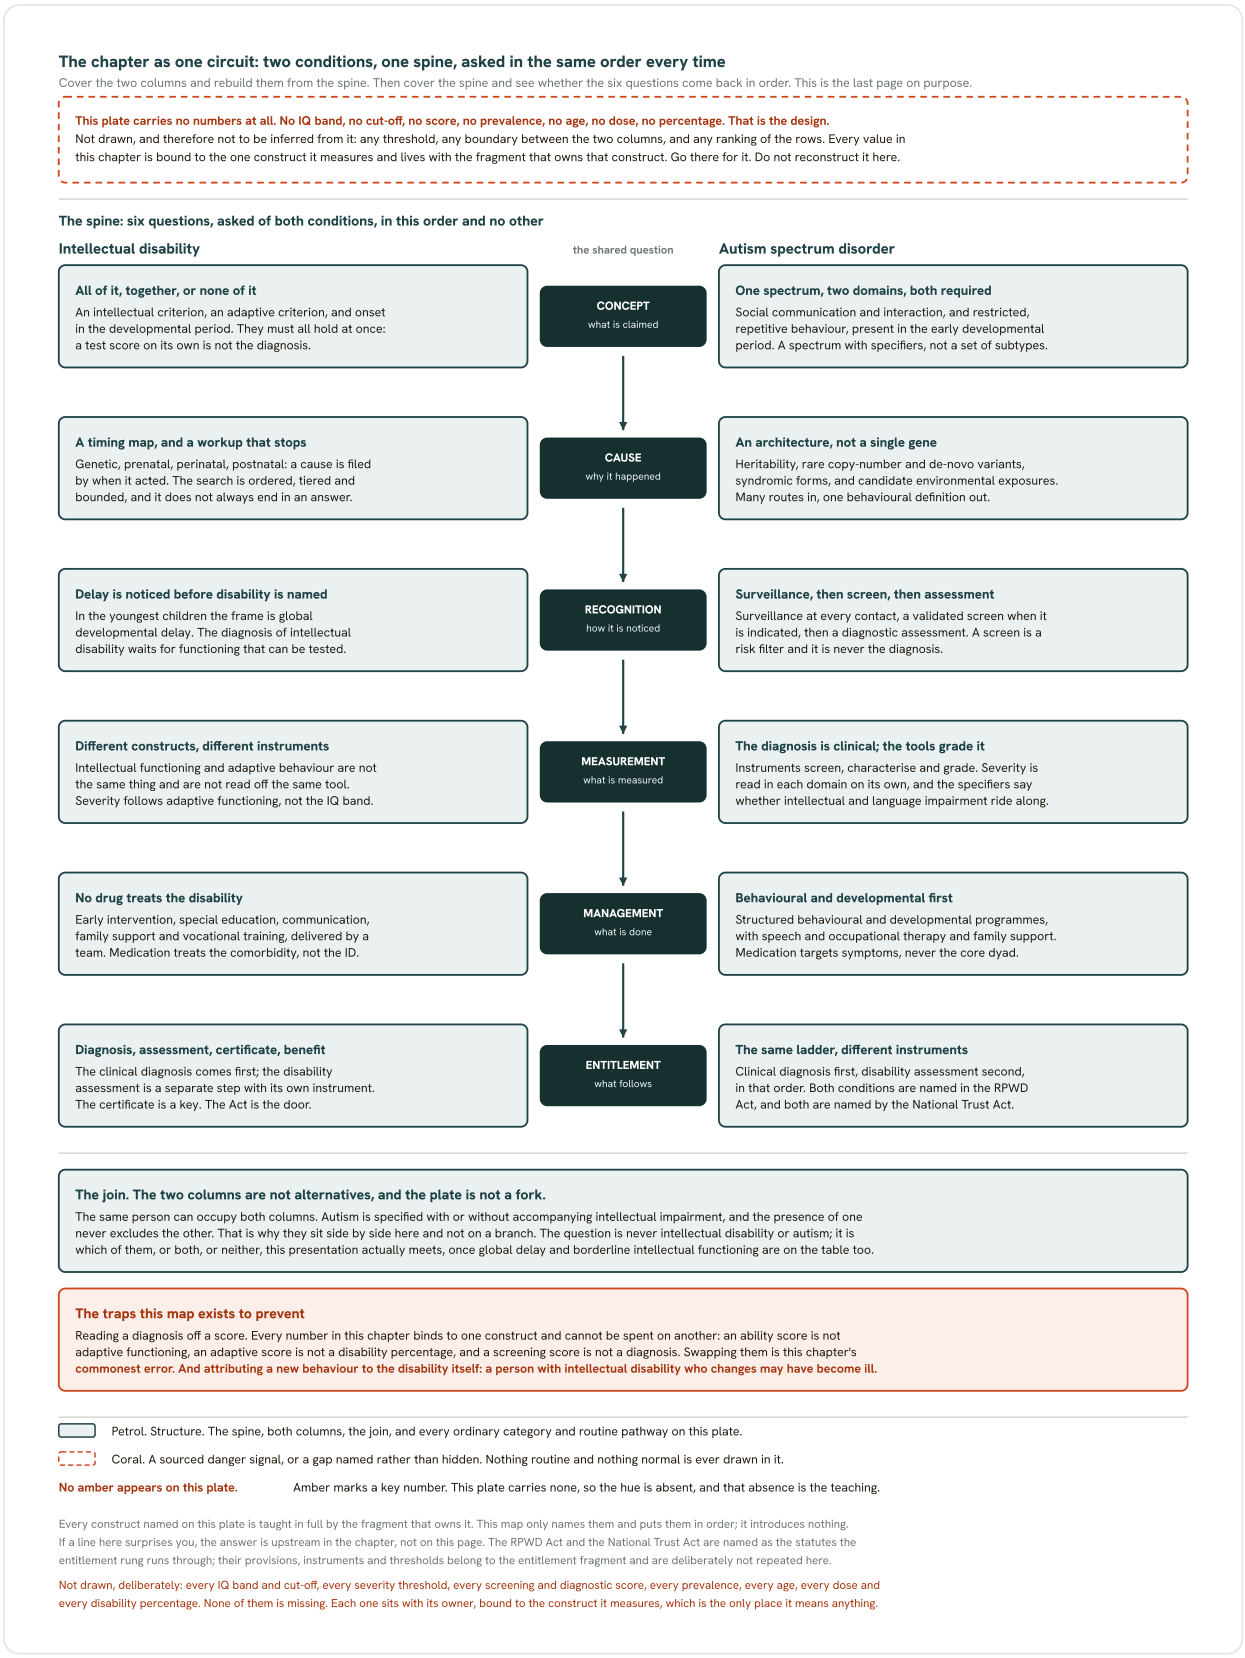


Fig 21.22 **The chapter as one circuit.** Intellectual disability and autism spectrum disorder set side by side across a shared spine of six questions, concept to cause to recognition to measurement to management to entitlement, asked of both conditions in the same order. The plate carries the shape of the chapter and no numbers at all, because every number in this chapter binds to the one construct it measures and lives with the fragment that owns that construct. The join band states the thing the side-by-side layout is there to teach, that the two columns are not alternatives and the same person can occupy both.

34.1 Start with the developmental question

The starting task is to establish the **developmental trajectory**: what was acquired, what is currently difficult, whether skills have been lost, and how the pattern affects everyday life. This makes the assessment developmental rather than merely behavioural. It also keeps current symptoms in relation to the person's communication, cognitive and social capacities.

Developmental history should be interpreted alongside the account in the Normal child development and milestones notes. If the presentation includes regression, unusual episodic events, altered sleep, pain, sensory difficulty or a change from baseline, the formulation must remain open to medical and psychiatric contributors rather than assuming that all change belongs to the neurodevelopmental condition.

RULE **Rule.** Begin with the person's developmental course and present functioning; use diagnostic categories to clarify the pattern, not to replace the formulation.

34.2 Separate constructs before combining them

Intellectual functioning, **adaptive functioning**, developmental level and the autism phenotype are related but not interchangeable. A cognitive assessment addresses an aspect of ability. Adaptive functioning asks what the person manages in ordinary settings. Autism assessment asks whether a characteristic pattern of **social communication** differences and **restricted and repetitive behaviour** is present. Each finding changes the meaning of the others, but none can be inferred from another alone.

CLINICAL TASK	QUESTION TO KEEP SEPARATE	WHERE TO RETURN FOR FULL TEACHING
Describe ability	What can the person understand, learn and do?	Intellectual disability definition, clinical assessment and IQ testing
Describe everyday function	What support is needed in usual environments?	Adaptive behaviour assessment and intellectual disability severity
Describe autism features	Is the social-communication and behavioural pattern characteristic of autism?	Autism diagnostic criteria, clinical features and diagnostic tools
Describe developmental concern	Is the available profile sufficient for a stable diagnostic conclusion?	Global developmental delay and differentiation of intellectual disability from autism, GDD and borderline intellectual functioning
Describe participation	What changes at home, in education, in work and in the community are required?	Management, family support, disability certification and benefits

TRAP **Examination trap.** Do not use an intelligence score as a synonym for adaptive functioning, or use either as proof for or against autism. They are different clinical constructs.

34.3 Read the profile, not only the label

A useful formulation gives a profile of strengths and vulnerabilities. It asks how communication is used, how social reciprocity is experienced, how routines and sensory demands affect participation, and how demands change behaviour. It records what helps the person engage, learn and regulate. This profile is often more useful for care planning than a diagnostic word alone.

- Describe the person's effective means of communication and the situations in which communication breaks down.
- Identify abilities that can be recruited for learning, self-care, relationships and participation.
- Notice environmental triggers, including mismatch between demands and capacity.
- Ask whether behaviour is communicating distress, pain, fear, overload, confusion or an unmet need.

This approach protects against **diagnostic overshadowing**: the error of attributing every new symptom or behaviour to an established developmental diagnosis. A change from baseline still deserves ordinary clinical curiosity. The full child psychiatric assessment battery, services and protection are set out in the Child psychiatry: assessment, treatment, services and protection notes.

34.4 Look actively for co-occurrence

Co-occurrence is clinically important because it can alter presentation, risk, family burden and the practical plan. Medical conditions, sensory problems, sleep disturbance, emotional symptoms, behavioural disturbance and psychiatric syndromes may make a familiar developmental profile look suddenly more difficult. The right response is not diagnostic proliferation; it is a disciplined search for treatable contributors and an account of how they interact.

When autism and intellectual disability coexist, describe each profile explicitly. When attentional symptoms or social difficulties raise the possibility of ADHD, use the ADHD and specific learning/communication disorders notes for the full assessment framework. Do not treat social difficulty as automatically explained by either condition.

MNEMONIC

FIND

is a practical closing mnemonic: **F**unction in daily life; **I**nteraction and communication profile; **N**eurodevelopmental course; **D**rivers of change, including co-occurring conditions and context.

34.5 Convert formulation into support

The endpoint of assessment is a plan that is intelligible to the person and family and usable across settings. State the priority difficulty, the strengths that can be used, the support required, the contributors that need treatment or further assessment, and the follow-up question. A plan framed around **support needs** is more clinically honest than one framed around a label alone.

- Link recommendations to a named functional difficulty rather than to diagnosis alone.

- Make family partnership part of the formulation, not an afterthought.
- Coordinate educational, communication, occupational, behavioural and mental-health input around shared goals.
- Review change over time, especially after a new stressor, treatment or transition.

Intervention models, speech and occupational support, family support, pharmacotherapy and prognosis are considered in their respective sections.

GOOD TO REMEMBER

Keep statutory processes separate from clinical formulation: certification may help access entitlements, but it does not replace an individualised account of function and care.

34.6 The final answer in practice and in examination

For a case discussion, write the problem representation before writing the diagnosis: developmental course, current profile, functional impact, possible co-occurrence, contextual modifiers and priority supports. This structure prevents the common drift from a complex clinical presentation into a label-led answer.

The must-remember synthesis is simple: diagnose carefully, describe function clearly, search for change and co-occurrence, then plan support around the person rather than the label.

Previously asked

Genuine past questions from this chapter's territory, with their board of origin. Only two examination questions in the catalogue fall inside intellectual disability and autism, and both are printed here. No question is reconstructed, paraphrased into a new one, or invented to pad the list.

QUESTION	TYPE	ASKED
Describe the etiology, clinical features and management of Fragile X syndrome	Long essay	MUHS 2013
Asperger's syndrome	Short note	MUHS 2012

TRAP **Asperger's syndrome no longer exists as a diagnosis.** A question asked under the older nomenclature still expects you to know where the construct went and why it was absorbed, not to defend it as a current category. The historical topic in this chapter carries that story.

The quick review

One table, read down the left column, cover the right. Every line is taught in full somewhere above; nothing here is new. Where the sources disagree, the disagreement is the answer.

ASK	HOLD
WHAT MAKES INTELLECTUAL DISABILITY	All three criteria: intellectual deficits, adaptive deficits, onset in the developmental period. Not an IQ score on its own.
WHAT GRADES ITS SEVERITY	Adaptive functioning across the conceptual, social and practical domains. IQ is supporting evidence, not the grade.
WHAT GRADES AUTISM SEVERITY	Support needs, rated separately for the two domains. Never IQ. Grading autism by IQ is the classic error.
GLOBAL DEVELOPMENTAL DELAY	The under-fives placeholder for a child too young or too impaired for a valid standardised assessment. It is a holding position, not a diagnosis to keep.
THE FOUR INSTRUMENTS ROUTINELY CONFUSED	They measure four different constructs: intelligence, development, social maturity, adaptive behaviour. Being asked for adaptive scales and listing all four is the exam error this chapter exists to prevent.
THE STATUTORY INSTRUMENT FOR INTELLECTUAL DISABILITY IN INDIA	Not the mental-illness disability scale. The routes are separate, and the chapter shows which is which.
THE AUTISM DYAD	Social communication, all of its sub-criteria; restricted and repetitive behaviour, the stated minimum of its four. Language is a specifier, not a criterion.
WHERE ASPERGER'S WENT	Absorbed into the spectrum. A past question under the old name still expects you to know why.
THE COMMONEST PSYCHIATRIC CO-OCCURRENCE IN AUTISM	ADHD. DSM-IV forbade the joint diagnosis; DSM-5 permits it. The frequency is contested and the chapter gives both figures.
DIAGNOSTIC OVERSHADOWING	A new behaviour in intellectual disability gets blamed on the disability and the treatable illness is missed. It is a reasoning failure, not a knowledge failure.
WHAT NO DRUG DOES IN AUTISM	Treat the core features. The licensed agents target irritability, and the monitoring burden is the price.
WHAT THE SOURCES REFUSE TO TELL YOU	Several cut-offs, several band tables and several Indian figures are simply not in the literature consulted. The chapter says so where it happens rather than inventing them.

References

Every specific in this chapter is bound to one of the sources below, and the count is the number of claims each carried. Books and guidelines are cited author, title and year in the house convention; no PMID is asserted for a book. Where two sources disagreed, the chapter shows both rather than choosing, and those disagreements are named in the text where they fall.

ADHD: the concept, the criteria and the mechanism

1 · The neurodevelopmental frame

Why this chapter matters clinically. A child described as inattentive, restless, struggling at school, difficult to understand, or unable to keep up may be presenting with a disorder, an environmental mismatch, a response to distress, a developmental difference, or more than one of these at once. The useful question is therefore not simply whether a symptom can be recognised. It is whether a coherent developmental pattern is affecting the child's participation in ordinary life, and what evidence is needed before that pattern is named. This chapter provides the framework for approaching attention-deficit/hyperactivity disorder, specific learning disorder, communication disorders and selected motor disorders without turning a referral complaint into a premature conclusion.

These conditions are grouped because they frequently enter clinical care through the same doors: concern from home, a report from school, conflict around work, behavioural escalation, or a child's growing sense of failure. Their mechanisms, diagnostic boundaries and interventions are not interchangeable. A good clinician holds both truths at once: the presenting difficulties need to be understood together, while each possible disorder must be assessed on its own terms. The chapter therefore moves from recognition to assessment, then to management and longer-term planning, while keeping the child's actual functioning at the centre.

Child	Family	School	Clinic
DEVELOPMENTAL CONTEXT	DAILY FUNCTIONING	PARTICIPATION DEMANDS	INTEGRATED FORMULATION

1.1 A shared neurodevelopmental frame

A **neurodevelopmental frame** asks how a child acquires and uses capacities over time, rather than treating each behaviour as a free-standing symptom. Attention, activity regulation, communication, motor coordination and academic skill are expressed in relation to the tasks a child is expected to manage. The same observable difficulty can have a different meaning when the demand changes, when support is added, or when the child moves from a familiar setting to one that makes the weakness more visible. This is why a chapter on these disorders must begin with development and function, not with a checklist.

The frame also protects against a false split between biology and context. A developmental vulnerability does not make family life, teaching conditions, language exposure, sleep, adversity, peer experience, or emotional state irrelevant. Conversely, the presence of contextual stress does not by itself explain away a persistent developmental difficulty. Clinical work is the disciplined

task of deciding which influences are central, which are amplifiers, and which are consequences of the child's struggle. A child who is repeatedly corrected, excluded, or unable to demonstrate competence may understandably become anxious, angry, avoidant or demoralised. Those reactions deserve care, but they should not obscure the developmental question that brought the child to attention.

A **developmental expectation** is therefore a clinical comparator, not a demand for uniformity. Children develop unevenly. Strength in one area does not cancel a marked problem in another, and a difficulty does not define the whole child. The clinician looks for a pattern that has enough persistence, breadth and consequence to require explanation. The formal diagnostic discussion later in the chapter supplies the criteria for particular disorders. The orientation point is more basic: diagnosis is an act of pattern recognition constrained by evidence, not a label attached to inconvenience.

RULE **Start with development in context, then decide whether a disorder best explains the pattern.** The referral label is a hypothesis. It becomes clinically useful only after the child's capacities, demands, supports and impairment have been considered together.

1.2 From complaint to clinical question

Referral language is usually compressed. "Not listening," "poor concentration," "slow work," "bad handwriting," "talks too much," "does not speak clearly," or "cannot sit" are observations made by an adult under pressure. They are worth taking seriously, but none is a diagnosis. Each must be translated into a clinical question: What exactly happens? In which tasks? What precedes it? What follows it? What can the child do when the task, setting, support or motivation changes? This translation prevents the clinic from inheriting the assumptions already embedded in a referral.

The key distinction is between a behaviour and a **functional impairment**. Behaviour is what another person sees. Impairment concerns what the child cannot reliably do, participate in, learn, communicate, organise, or sustain in the situations that matter. A child may be conspicuous yet functioning adequately, or quiet yet carrying a substantial burden that is visible only in lost learning, exhausted family routines, social withdrawal, or a fragile sense of competence. Asking about function makes assessment fairer to both children: the child whose activity is disruptive and the child whose difficulty is hidden because it causes little trouble for adults.

Clinical questions should also distinguish capacity from performance. A child may understand an instruction but fail to hold it in mind long enough to act on it. Another may remain engaged but lack the academic skill the task assumes. Another may have the skill but become overwhelmed by language, motor demands, anxiety, sensory discomfort, conflict, or fear of error. The chapter's later sections sort these possibilities systematically. At orientation, the discipline is to resist collapsing all failed performance into a single explanatory category.

- Describe the behaviour before interpreting its cause.
- Identify the task and demand in which the difficulty becomes visible.

- Ask what the difficulty costs the child in participation and relationships.

CLINICAL QUESTION	PURPOSE	WHAT MAY CHANGE THE INTERPRETATION
What is the observed difficulty?	Separates description from explanation.	The task, the adult response and the child's own account.
Where does it occur?	Locates the demand on the child.	Structure, language, pace, familiarity and available support.
What is the functional cost?	Establishes why the concern matters clinically.	Participation, learning, relationships and self-concept.
When does performance improve?	Identifies strengths and possible supports.	Interest, reduced load, clearer communication or adapted expectations.

GOOD TO REMEMBER

The stated referral problem and the clinical target are often different. A family may seek help for disruptive evenings, while the most useful formulation concerns an unrecognised learning or communication burden that makes each school-related demand a conflict.

1.3 The logic of cross-setting formulation

A **cross-setting formulation** asks whether a difficulty is present across the child's life and, if it is not, what the pattern of variation means. Home and school are not duplicate testing sites. They make different demands, provide different structure, reward different behaviours and tolerate different levels of support. A child can appear settled in one setting because an adult has quietly adapted the environment, because the task is intrinsically engaging, or because the child has withdrawn from challenge. A difficulty that is most apparent in a particular setting is not thereby unreal. It may tell the clinician where demands and vulnerabilities meet.

This is the reason collateral information is indispensable. The caregiver sees routines, transitions, play, sleep-related strain and the emotional aftermath of demanding days. School staff see sustained group demands, pace, written work, peer comparison and the supports already being improvised. The child can describe effort, embarrassment, boredom, worry, confusion, unfairness and the private strategies used to cope. Each account is partial. The clinician's job is not to award one informant the status of truth, but to integrate accounts into an explanation that can survive contact with the child's everyday life.

An **informant discrepancy** is often data rather than noise. If adults disagree, explore the conditions under which they observe the child. The disagreement may reveal a highly structured classroom, a home routine with little academic load, a language mismatch, different thresholds for concern, or a relational pattern that changes behaviour. It can also reveal that an adult has seen a meaningful change over time while another is describing a longer baseline. Prematurely averaging such accounts destroys the very clinical information that makes formulation possible.

PITFALL

Do not convert a school report into a diagnostic verdict. Educational observations are essential evidence, but they are observations made within a particular curriculum, classroom culture and set of available supports. They need to be placed alongside history, direct clinical work and the child's own account.

1.4 ADHD within the chapter's map

ADHD is approached here as a developmental disorder of regulation whose diagnosis requires more than recognising a lively child or a poor worker. The diagnostic section addresses the formal structure of the diagnosis. The clinical-features section gives the lived expression of its core symptom domains. Epidemiology, sex differences, mechanisms and neurobiology are then considered separately so that the reader does not mistake a statistical association or a mechanistic model for a diagnostic criterion.

This separation is deliberate. In practice, attentional and behavioural complaints commonly travel with other difficulties. A child may have problems with academic acquisition, language, mood, anxiety, sleep, behaviour, tics, family stress or school fit. Sometimes these are concurrent conditions; sometimes they are competing explanations; sometimes they are consequences of repeated failure. The assessment and differential sections show how to sort this without treating every overlap as proof of comorbidity. Management follows only after that work, because an intervention should be matched to the formulation rather than to the loudest symptom.

The reader should keep an **ecological formulation** in view. It links the child's regulatory style to actual environments: an unstructured transition, a long verbal instruction, independent written work, a crowded classroom, an inconsistent routine, or a conflictual homework interaction. This does not reduce ADHD to an environmental problem. It ensures that clinical recommendations alter the conditions in which impairment occurs, instead of relying solely on exhorting the child to try harder. Medication, behavioural support, parent work, school intervention and psychosocial care each have a place only when they address a defined part of the formulation.

TRAP **Do not diagnose ADHD from a complaint of poor attention alone.** Attention can be disrupted by many developmental, emotional, medical, educational and relational processes. The clinical task is to establish the full pattern and then test alternatives, not to rename a common complaint.

1.5 Why learning, communication and motor concerns sit beside ADHD

Academic underperformance can be the consequence of difficulty regulating attention and effort, but it can also arise because a child has not acquired a particular academic skill in the expected way. This distinction matters because a child who repeatedly fails at a task may look inattentive, avoidant or oppositional even when the primary obstacle lies in learning. Conversely, a child with ADHD may underperform inconsistently despite having the relevant skill. The chapter later defines and assesses specific learning disorder, while the discrimination section brings the relevant possibilities into direct comparison. At this stage, the clinician should retain the question rather than force an early choice.

Communication difficulties can similarly alter the apparent meaning of behaviour. A child who cannot efficiently understand, formulate or express language may disengage from verbal teaching, respond slowly, interrupt, rely on action rather than words, or become distressed during rapid social exchanges. Motor coordination difficulties may make written tasks, self-care routines, games or classroom production disproportionately effortful. The communication and motor sections describe these disorders in their own right. In an initial formulation, their importance is that they can shape performance, self-esteem, relationships and behavioural presentation.

This is not an argument for indiscriminate diagnostic multiplication. It is an argument for **diagnostic humility**. A clinician should be able to say what is known, what remains to be clarified, what needs collateral evidence, and what support is justified even before every boundary question is settled. Children do not need to wait for conceptual perfection before adults reduce avoidable strain. At the same time, an accommodation should not be used as a substitute for careful assessment when persistent impairment needs explanation.

- Consider whether the task is exposing a regulation difficulty, a skill deficit, a communication barrier, a motor burden, or a combination.
- Ask whether avoidance is protective behaviour in the face of repeated failure.
- Separate immediate support needs from the longer diagnostic enquiry.

1.6 The child as participant, not a collection of deficits

Good developmental psychiatry does not ask only what is wrong. It asks where the child can participate, who understands the child well, what the child enjoys, what supports already work, and how the current difficulty has affected identity. A **strengths-based formulation** is not a reassuring add-on. It improves diagnostic accuracy because it shows the conditions under which abilities emerge. It also changes management: a plan that ignores interests, relationships and existing competence is unlikely to be sustained.

Listen directly to the child whenever communication and developmental level allow. Adults often report observable disruption more readily than internal experience. The child may describe constant effort to keep up, shame about reading aloud, fear of being called on, exhaustion after school, anger at being misunderstood, or relief when a particular adult gives help without humiliation. Such accounts do not independently establish a diagnosis, but they reveal the burden of impairment and the meaning of interventions. They also protect against plans designed for adult convenience that worsen the child's exclusion.

Family work begins with explanation, not blame. Caregivers may be exhausted, divided about what is happening, worried about labels, or understandably sceptical after receiving conflicting advice. Teachers may feel they have already tried every practical adjustment available to them. The clinician's role is to replace moral language with a shared working model: identify the difficulty, identify the demand, identify the support, and review what changes. This preserves accountability without implying that the child's struggle is wilful or that adults caused it by insufficient effort.

IN INDIA

School information may come from settings that differ markedly in teaching language, class routines, resources, assessment style and access to remedial support. Ask what the child is being asked to do in that particular school before treating academic performance as a stable measure of ability. A useful plan must be intelligible to caregivers and feasible for the educational setting, not merely ideal on paper.

1.7 Working across systems without losing the formulation

These disorders sit at the boundary of home, school and health care. Each system has a legitimate concern, but each also sees a different slice of the problem. The clinic must avoid becoming an isolated site that issues labels without understanding the child's day-to-day ecology. Equally, it must not hand all responsibility back to school or family with vague advice to be more patient. A useful **longitudinal formulation** is revised as the child's demands, supports and difficulties change. It records not simply what diagnosis was considered, but why the current explanation remains the best fit.

Coordination is most helpful when recommendations are concrete and linked to a stated functional problem. "Support attention" is too vague to guide anyone. A better plan identifies the demand that breaks down, the environmental modification or skill support being tried, the adult who can implement it, and the sign that it is helping. Later sections of the chapter give disorder-specific approaches. The orienting principle is that recommendations should be testable in ordinary life. If they cannot be implemented or reviewed, they are not yet a clinical plan.

The same principle applies to referral. Speech and language input, educational assessment, occupational support, paediatric review, psychological intervention or specialist psychiatric management may each be appropriate depending on the formulation. Referral should answer a question, not merely distribute responsibility. The broader assessment battery and service approach are set out in the Child psychiatry: assessment, treatment, services and protection notes. Developmental history should be interpreted alongside the Normal child development and milestones notes, while conditions that lie outside this chapter's main focus are addressed in the Child behavioural, emotional and other disorders notes and the Intellectual disability and autism spectrum disorder notes.

1.8 A practical route through the chapter

Use the chapter in the order a careful assessment unfolds. Begin with the concept and diagnostic boundaries of ADHD, then learn the clinical pattern well enough to recognise it without overcalling it. Move next to comprehensive assessment, rating scales, co-occurring conditions and differential diagnosis. Treatment sections should then be read as components of a formulation-led plan rather than as an isolated drug list or a menu of generic advice. The later discussion of adolescence, adulthood and outcomes keeps the initial consultation connected to the child's future functioning.

The specific learning disorder material follows the same logic: definition before assessment, assessment before remediation, and educational provisions after the clinical basis is clear.

Communication and motor disorders require the same restraint. Learn the boundaries of each disorder, then ask how that disorder changes a child's participation and what intervention is realistic. The closing discrimination and vignette material is intended to consolidate clinical reasoning, not to reward pattern matching based on a few memorable clues.

MNEMONIC

MAP: Meaning, Across settings, Participation

Use **M**eaning to translate a complaint into a clinical question; ask what is seen **A**cross settings and why it varies; then judge the effect on **P**articipation. MAP is a guardrail against both premature diagnosis and dismissing a child whose difficulty is real but quiet.

Formulate the child in context before naming the disorder, and let the diagnosis lead to support that changes participation.

2 · Diagnostic criteria of ADHD (DSM-5 presentations, ICD-11 hyperkinetic disorder)

Why the criteria matter. Attention-deficit/hyperactivity disorder is not diagnosed by recognising a lively child, a poorly organised student, or an adult who reports distractibility. The diagnostic task is to decide whether a developmentally inappropriate pattern has persisted, is evident beyond a single relationship or environment, produces impairment, and is not better accounted for by another condition. The criteria make that judgment reproducible. They also protect against the opposite errors of dismissing clinically important inattention because overt overactivity is absent, and labelling a situational response as a neurodevelopmental disorder.

For the postgraduate candidate, ADHD criteria are best learnt as a sequence rather than as a loose symptom list: establish the relevant symptom pattern, establish persistence, establish developmental onset, establish pervasiveness, establish impairment, and then consider exclusionary explanations. The symptom descriptions themselves are discussed with the core clinical features. This section concerns the diagnostic architecture: what must be shown before the label is applied, how the current **presentation** is specified, and why the older term **hyperkinetic disorder** should not be used as though it were simply a synonym.

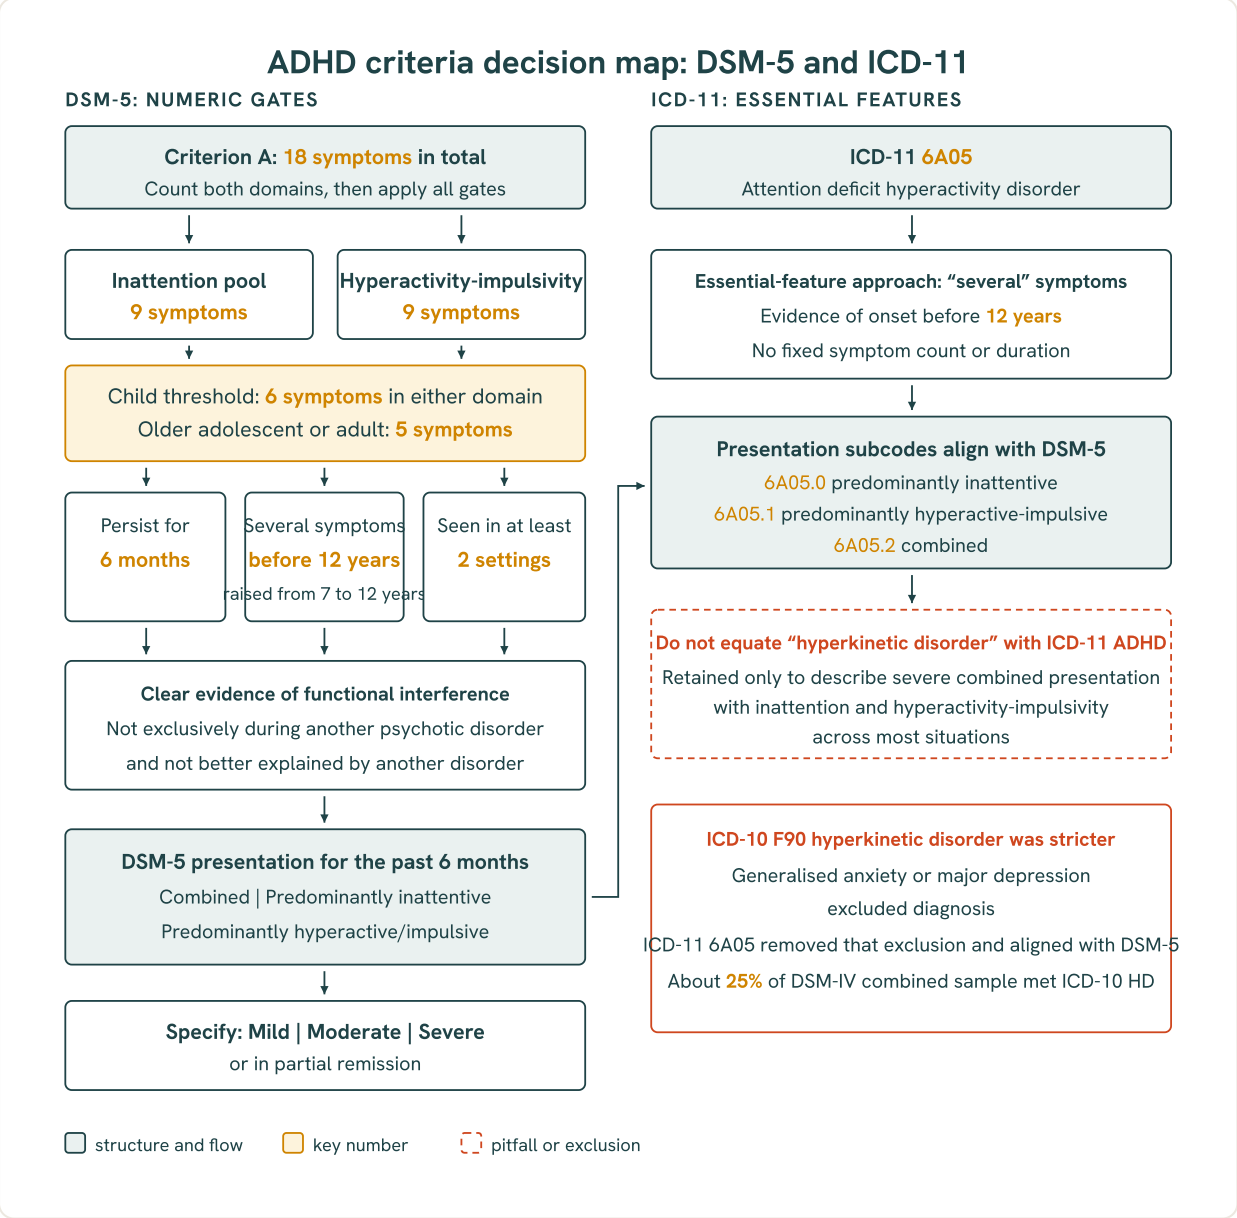

Fig 22.1. DSM-5 ADHD presentation thresholds and gates contrasted with ICD-11 ADHD essential features and the narrower ICD-10 hyperkinetic-disorder legacy.

2.1 The diagnostic task: pattern plus consequence

ADHD diagnosis begins with a pattern of symptoms drawn from the inattention list and the hyperactivity-impulsivity list. Neither list is a personality inventory. Each item has to represent a behaviour that is persistent, clinically meaningful, and incongruent with the person's developmental level. A symptom count without clinical interpretation is therefore insufficient. Conversely, a persuasive clinical narrative cannot substitute for the required structure of the criteria.

The two lists are deliberately balanced in their construction. The inattention list contains 9 symptoms, and the hyperactivity-impulsivity list contains 9 symptoms. Together they make up the full diagnostic set of 18 symptoms. This matters because the clinician should ask separately about each domain rather than use a global impression such as "attention problems" or "overactive behaviour". A person may meet the required pattern through one domain, or through both; the later presentation specifier communicates that distribution.

9	9	6	5
INATTENTION ITEMS	HYPERACTIVITY-IMPULSIVITY ITEMS	CHILDHOOD THRESHOLD	OLDER-AGE THRESHOLD

In children, the threshold is **at least 6 symptoms** from the inattention list when that domain is being met, and at least 6 symptoms from the hyperactivity-impulsivity list when that domain is being met. For older adolescents and adults, the threshold in either relevant domain is at least 5 symptoms. The change acknowledges that the same disorder need not appear as a childhood-level tally of overt behaviours throughout later life. It does not mean that a lower count alone establishes the diagnosis. The other diagnostic requirements retain their force.

RULE **ADHD is diagnosed from a structured pattern of symptoms with demonstrable developmental and functional significance, not from a single striking behaviour.** The count opens the diagnostic question; persistence, onset, setting and impairment determine whether the threshold has clinical meaning.

There is a useful discipline in recording the evidence alongside each domain. State which symptoms are supported, where they occur, who observed them, and how they interfere with the person's responsibilities or relationships. This makes the formulation auditable and prevents an apparently precise number from concealing vague evidence. It also leaves room for a later review if the pattern changes, collateral information changes the picture, or another disorder proves to be the better explanation.

- Separate the evidence for the inattention domain from the evidence for the hyperactivity-impulsivity domain.
- Record concrete examples rather than relying on a global adjective such as "careless" or "restless".
- Identify the settings in which the pattern is evident and the functional consequence in each.
- State any competing explanation that remains clinically plausible and why it is or is not primary.

2.2 Persistence and developmental appropriateness

The symptom pattern must have persisted for **at least 6 months**. This requirement distinguishes an enduring pattern from a transient deterioration during a stressful school term, a disrupted home environment, a medical illness, or an episode of another mental disorder. Duration is not a clerical detail. It asks whether the behaviour has acquired the stability expected of a disorder rather than remaining an understandable response to circumstances.

Persistence must be read together with developmental appropriateness. A behaviour can be inconvenient to adults and still be ordinary for a particular developmental stage. The clinical question is whether the frequency, intensity, and consequences are out of keeping with what is expected for that individual's developmental level. The question is comparative, but it is not a demand for a false precision. The resident should integrate the developmental history with reports from daily settings and avoid treating a single complaint as evidence of pervasive

pathology. The Normal child development and milestones notes provide the wider developmental frame needed for that comparison.

This criterion is also a guard against retrospective simplification. A family may recall a recent escalation more readily than a long-standing, lower-grade pattern. Conversely, a current crisis may make every past act of restlessness seem diagnostic. The appropriate approach is to reconstruct the course carefully, ask for concrete examples from earlier periods, and separate chronic traits from changes in intensity. The criteria require persistence of symptoms, but clinical reasoning must still decide whether the account is coherent and whether the behaviours have the same meaning across contexts.

TRAP **Do not convert a period of poor concentration into ADHD merely because it has lasted for the minimum duration.** The duration criterion confirms persistence; it does not establish developmental inappropriateness, pervasiveness, impairment, or diagnostic primacy.

In practice, this distinction is especially important when school demands have changed or when conflict, sleep disruption, emotional distress, substance use, or illness has altered functioning. Such factors may coexist with ADHD, amplify its expression, or account for the presentation altogether. They should be explored as explanations, not treated as inconvenient exceptions to a symptom tally. The full child psychiatric assessment battery and services are set out in the Child psychiatry: assessment, treatment, services and protection notes.

2.3 Developmental onset

The criteria require that several inattentive or hyperactive-impulsive symptoms were present before **12 years**. The wording is important. It does not require a complete diagnosis before that point, nor does it require that the disorder was recognised at the time. It requires credible evidence that several relevant symptoms had already emerged in the developmental period. This distinction is clinically useful because many people reach assessment only after educational, occupational, or relational demands reveal the functional cost of a long-standing vulnerability.

Developmental onset is a test of continuity, not a demand for perfect recall. Retrospective reports may be incomplete, coloured by current distress, or limited by absent records. A careful clinician therefore looks for convergence: the person's account, family recollection, old school comments where available, and a developmental narrative that makes sense across settings. If the evidence is weak, the uncertainty should be acknowledged rather than covered by a confident label. The criterion is designed to preserve the neurodevelopmental identity of ADHD while allowing the ordinary reality that recognition can be delayed.

The present onset requirement is a broader developmental threshold than the earlier DSM formulation. It should not be misread as permission to dispense with developmental evidence. The criterion still asks whether the history supports symptoms in the developmental period, rather than whether current impairment can be given a retrospective label.

Do not mistake later impairment for later onset. A person may have managed adequately while demands were modest and then struggle when independent organisation, sustained work, or

complex role responsibilities increase. That change in visibility can be real without implying that the underlying symptoms began only then. At the same time, a genuinely new attentional syndrome requires a broader search for psychiatric, medical, sleep-related, substance-related, and situational explanations. The diagnosis should follow the developmental history, not rescue an attractive explanation for a recent decline.

GOOD TO REMEMBER

When evidence from the early developmental period is uncertain, document both the supporting history and its limits. Diagnostic confidence should track the quality of the onset evidence rather than the examiner's wish to make the record look decisive.

2.4 Pervasiveness, impairment and exclusion

Symptoms must be present in **at least 2 settings**. This is the **pervasiveness** requirement. It prevents the diagnosis from being based solely on a conflictual classroom, an unstructured workplace, one difficult relationship, or one setting whose demands are mismatched to the person. The settings need not be identical in their demands or in the exact behaviour they reveal. What matters is that the underlying pattern is evident beyond a single local explanation.

Pervasiveness is not a mechanical search for the same symptom in every place. Different environments expose different demands on attention, activity regulation and impulse control. A quiet child may struggle most when tasks require sustained self-organisation; another may show overt difficulty chiefly where waiting, turn-taking, or behavioural restraint is required. The clinician's task is to identify whether these observations cohere as manifestations of the same pattern, while remaining alert to setting-specific stressors that explain them better.

There must also be clear evidence that symptoms interfere with, or reduce the quality of, social, academic, or occupational functioning. This is the **functional impairment** requirement. The diagnosis is not a reward for endorsing enough familiar behaviours. It is a clinical conclusion that the pattern matters in the person's life. Impairment may involve underachievement, missed responsibilities, relationship strain, unsafe impulsive acts, or a disproportionate effort required to maintain ordinary functioning. The precise form of impairment varies with age, role and environmental support.

Finally, the presentation must not occur exclusively during a psychotic disorder and must not be better explained by another mental disorder. This exclusion requirement obliges the clinician to consider whether the apparent ADHD symptoms belong instead to an alternative syndrome, or whether they are secondary to another disorder. It does not turn differential diagnosis into a ritual list. The central question is explanatory priority: does ADHD best account for the enduring, cross-situational developmental pattern and its impairment? The differential diagnosis of ADHD is addressed in the later differential section of this chapter.

PITFALL

School difficulty alone is not proof of pervasiveness or impairment due to ADHD. The clinical error is to let one setting define the disorder before asking whether the pattern is present elsewhere and whether another explanation better accounts for the difficulty.

2.5 Presentations, severity and course language

DSM uses the term presentation rather than a fixed subtype because the balance of symptoms can change over time. The recognised presentations are **combined, predominantly inattentive, and predominantly hyperactive/impulsive**. The current presentation is determined by which symptom-domain requirements have been met over the recent period. This terminology is clinically preferable to implying that each person has an immutable biological category. It describes the current configuration of the diagnostic evidence, while the underlying developmental history may be broader and more changeable.

The combined presentation is used when the requirements are met in both domains. Predominantly inattentive presentation is used when the inattention requirement is met but the hyperactivity-impulsivity requirement is not, and the converse applies to predominantly hyperactive/impulsive presentation. The labels should not be used to infer personality, intelligence, prognosis, family functioning, or treatment response. They are descriptive specifiers, not complete formulations. The lived phenomenology of the symptom domains belongs to the clinical-features section of this chapter.

Current severity is specified as **mild, moderate, or severe**. Severity should communicate the burden represented by the symptom load, the intensity of symptoms, and the degree of functional impairment. It is not a substitute for a formulation and should never obscure a major environmental stressor, coexisting condition, or protective support. The criteria also permit the course description of partial remission when the full current requirements are no longer met but clinically relevant difficulties remain. Such language helps the record explain the current state without erasing the earlier course.

MNEMONIC

Pattern - Persistence - Past - Places - Performance - Primary explanation

Use this as a recall spine for the criteria: identify the symptom pattern, confirm persistence, establish developmental onset, demonstrate more than one setting, show functional consequence, and consider whether another disorder is the primary explanation.

ADHD requires a developmentally inappropriate, persistent symptom pattern with developmental onset, cross-setting evidence, functional impairment, and no better explanation.

2.6 ICD-11 ADHD and the meaning of hyperkinetic disorder

In ICD-11, attention deficit hyperactivity disorder is coded 6A05 and sits within neurodevelopmental disorders. Its clinical organisation aligns closely with the presentation-based approach: 6A05.0 denotes predominantly inattentive presentation, 6A05.1 predominantly hyperactive-impulsive presentation, and 6A05.2 combined presentation. The shared language helps when records move between classification systems, but the diagnostic descriptions should not be assumed to be word-for-word interchangeable.

CLINICAL QUESTION	DSM APPROACH	ICD-11 APPROACH
Symptom threshold	Uses a specified count from each listed domain.	Uses several symptoms rather than a fixed tally.
Duration	Requires a stated period of persistence.	Describes essential features without a fixed duration rule.
Developmental onset	Uses a stated developmental threshold.	Seeks evidence of significant symptoms before the same developmental threshold.
Presentation language	Specifies the current presentation.	Uses corresponding clinical-presentation specifiers.
Hyperkinetic disorder	Does not use it as the principal category.	Reserves it as a descriptor for a more severe combined pattern.

The important difference is that ICD-11 describes essential features rather than applying the DSM machinery of a fixed symptom count and stated duration. The **essential-features approach** requires clinical judgment rather than arithmetic substitution. Nevertheless, ICD-11 asks for evidence of significant symptoms before 12 years. A clinician should therefore avoid the simplistic claim that one system is merely "strict" and the other merely "loose". They organise the evidence differently, while both require a developmental, impairing and pervasive pattern.

Within ICD-11, hyperkinetic disorder is retained to describe a severe combined presentation, with marked inattention and hyperactivity-impulsivity evident across most situations. It is not the primary name for the whole category. This distinction is clinically and examination-relevant: calling every person with ADHD "hyperkinetic" imports an older and narrower clinical image, particularly when overt motor activity is not the dominant current presentation.

IN INDIA

When preparing a clinical record, referral letter, or certification-related document, state the classification system being used and write the full diagnostic formulation rather than relying on a legacy label alone. This reduces ambiguity when services, schools, and clinicians use different diagnostic vocabularies.

2.7 The older ICD-10 category: why the distinction persists

The historical ICD-10 category of **hyperkinetic disorder**, coded F90, was more restrictive than the current ICD-11 ADHD category. It excluded the diagnosis when generalised anxiety or major depression was present. ICD-11 removed that exclusion and brought its category closer to the

DSM approach. The practical lesson is not that comorbidity should be assumed, but that the presence of another disorder does not automatically settle the question against ADHD. Each syndrome must be evaluated on its own evidence and explanatory value.

The earlier stringency had visible consequences. In a comparison of children meeting the combined ADHD pattern, only **about 25%** also met the ICD-10 hyperkinetic-disorder threshold. This figure should be used as an illustration of diagnostic narrowness, not as a prevalence estimate and not as a shortcut for individual diagnosis. It explains why older literature, older records, and older teaching may appear to describe a more uniformly severe and overtly hyperactive group than current ADHD classifications do.

For a resident, the safe wording is precise: ICD-11 names the overall category attention deficit hyperactivity disorder; hyperkinetic disorder denotes a severe combined pattern within that framework; and the former ICD-10 category was narrower. This protects the reader from treating nomenclature as mere semantics. Classification language changes the threshold for whom a service identifies, the populations represented in older studies, and the continuity of a person's clinical record.

3 · Clinical features and core symptom domains

The clinical task is to recognise a pattern, not to count a collection of irritating behaviours. Attention-deficit/hyperactivity disorder is expressed through **three** interacting symptom domains: **inattention**, **hyperactivity** and **impulsivity**. They are useful clinical lenses rather than labels to be applied to any child who is busy, forgetful, or impatient. The marks lie in recognising how these domains work together in everyday activity. The formal diagnostic framework addresses threshold questions. This section addresses the lived picture: what the domains look like, how they change in their outward form, and why a brief apparently reassuring encounter can mislead.

The domains often travel together, but they should be described separately before they are assembled into a formulation. That discipline prevents a familiar error: calling every difficulty with schoolwork "poor attention", or calling every interruption "hyperactivity". A careful phenomenological account makes the later diagnostic judgement more defensible and gives parents and teachers language for observations that otherwise seem unrelated.

Inattention	Hyperactivity	Impulsivity
ENGAGEMENT AND ORGANISATION	ACTIVITY REGULATION	PAUSE BEFORE ACTION

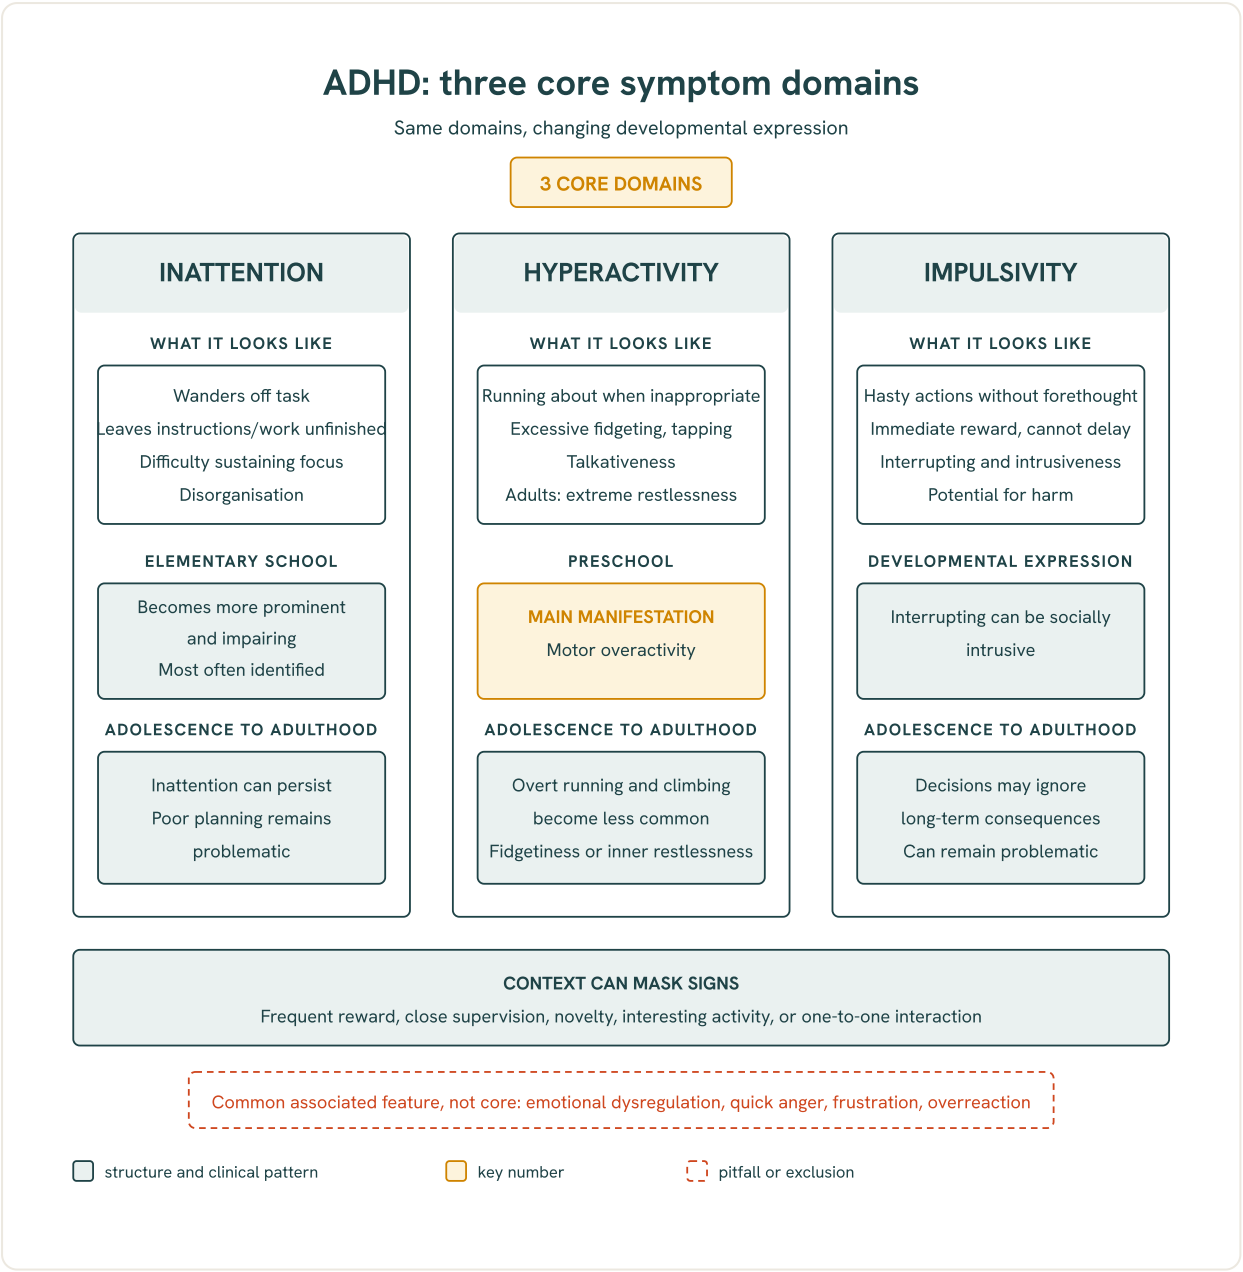

Fig 22.2. ADHD has three core symptom domains whose observable expression changes from preschool through adulthood.

3.1 The clinical architecture of the symptom domains

The domains overlap in ordinary life because a person must sustain attention, regulate activity, and pause before responding during the same task. A child who leaves a written exercise unfinished may have lost the task set, been pulled away by an attractive stimulus, become restless while seated, or answered before reading the instruction. The surface event is one event; the clinical work is to identify the process that repeatedly produces it. This is why a useful history preserves sequence and context instead of accepting an umbrella description such as “does not study”.

Phenomenology means staying close to the observable pattern and to the person's experience of it. It asks what occurs just before the task is abandoned, what happens while demands are sustained, and what follows an interruption or rash response. It does not require a moral explanation. In particular, the central symptoms should not be translated into laziness, poor

upbringing, or deliberate opposition. Such translations close enquiry prematurely and make the informant defend either the child or the family rather than describe the difficulty.

The distinction between activity and impulse is especially useful. Hyperactivity concerns the regulation of movement and verbal output. Impulsivity concerns the failure to insert a sufficient pause between urge and action. A person may be physically restless yet wait appropriately, or may sit quietly while repeatedly blurting, intruding, buying, deciding, or acting before considering the likely result. Clinically, the domains remain separable and can have different consequences and examples.

RULE **Describe the domain first, then infer its effect.** A behaviour becomes clinically informative when it is linked to the attentional, activity-regulation, or response-inhibition process that repeatedly precedes it.

This formulation also protects against circular reasoning. “He cannot complete work because he has ADHD” is not a description. It merely repeats the conclusion in another form. “He begins work, drifts from it, misses parts of the instruction, and has difficulty organising the steps needed to return” is a clinical description. The latter allows competing explanations to be considered later without making this section into a differential-diagnosis exercise.

3.2 Inattention: failure to keep the task online

Inattention is not simply an absence of attention. It is a difficulty in regulating attention in relation to a task, especially when the task demands sustained engagement, orderly follow-through, and retention of its goal. The person may begin with genuine intention and adequate comprehension, yet **wander off task**, lose the thread of what is being done, or shift to a more immediately available stimulus. The result may be mistaken for lack of effort because the work is visibly incomplete, even though the difficulty arose while trying to maintain the task rather than from a decision to refuse it.

The ordinary presentation can include **disorganisation**: misplaced materials, an unclear sequence of work, trouble keeping track of multiple instructions, or a chaotic transition between activities. It can also include a pattern of initiating work but failing to follow through. The important clinical distinction is that the person may understand the instruction and wish to comply, yet not maintain the task sufficiently to complete it. This is different from a strategic refusal, and it is different from not understanding what has been asked.

- Difficulty sustaining focus can leave an otherwise ordinary task only partly processed.
- Following an instruction may break down at the stage of carrying it through, rather than at the stage of hearing it.
- Work may be left unfinished after the person has moved away from the original task.

At the desk, this domain is often visible in the pathway rather than the final product. A notebook with gaps tells little by itself. Ask whether the child loses place while copying, starts before the full instruction is heard, repeatedly requires redirection, abandons one component for another, or cannot reconstruct where the task was left. The same pathway can appear outside academic work:

routine preparation, household responsibilities, conversation, and paperwork all require a goal to remain active while distractions compete.

> **GOOD TO REMEMBER**
> "Can focus on preferred activities" does not by itself negate an inattentive presentation. The useful question is how reliably attention is regulated when a task is repetitive, delayed in reward, or requires self-organisation.

Inattention should therefore be recorded in action language: loses track, does not return, omits a step, needs the task restated, or cannot organise the next move. This makes the account falsifiable. It also avoids collapsing a symptom domain into an academic outcome. Academic difficulty may be the consequence that brings the family to care, but the clinical domain is the repeated difficulty in sustaining and directing attention.

3.3 Hyperactivity: activity out of proportion to the setting

Hyperactivity involves **movement that is excessive for the setting**. Its significance lies in the mismatch between activity and context, not in whether a child is energetic or enjoys play. It may be expressed through running about when remaining nearby is expected, leaving a place repeatedly, conspicuous fidgeting, tapping, or a level of talking that disrupts the shared activity. The clinical description should specify what was expected in that setting and why the observed activity was difficult to regulate.

Movement may be small and continuous rather than dramatic. Feet may move beneath a desk, hands may tap or manipulate objects, and speech may fill pauses that others can tolerate. Such behaviour is easily dismissed as a habit if its cost is not explored. The relevant questions are whether it repeatedly disrupts work, disturbs others, makes waiting difficult, or continues despite a clear environmental cue to settle. The same person may appear calm in a stimulating or closely structured interaction and much less regulated when independent stillness is required.

It is useful to separate the observation from its social interpretation. "Running around" is an observation. "Naughty" is an interpretation. The first can be placed beside other data and tested against setting. The second is often a frustrated adult's shorthand, and it may obscure both the child's difficulty and the demands that provoke it. A respectful account also asks the person what the body state feels like, rather than assuming that outward movement is chosen for attention or disruption.

TRAP **Do not equate high energy with hyperactivity.** The symptom is dysregulated activity in a situation where that degree of movement is inappropriate, not a temperament judgement about an active child.

With development, the external form can become less obvious. The clinician should not require running or climbing in order to recognise the activity domain. In later developmental periods, overt activity may become **fidgetiness** or an internal experience of restlessness and impatience.

The change in form matters because informants often report that the person has "grown out of hyperactivity" when the visible expression has simply become more contained.

3.4 Impulsivity: action before adequate forethought

Impulsivity refers to **acting before enough thought has been given** to the situation. The central problem is not merely speed. It is a reduced capacity to pause long enough to consider information, social boundaries, likely consequences, or the possibility of waiting. The action may be minor and frequent, such as interrupting before another person has finished. It may also carry greater risk when a decision is made without allowing long-term consequences to influence the immediate response.

A useful formulation distinguishes impulse from intention. A child who calls out may genuinely know the answer and genuinely want to participate; the difficulty is waiting for the appropriate turn. A young person who agrees, spends, leaves, or reacts quickly may later recognise the consequence clearly; the difficulty was insufficient delay at the point of decision. This is why retrospective remorse does not exclude impulsivity. It may instead reveal the gap between what the person values after the event and what could be brought to bear in the moment.

- Interrupting can express social intrusiveness rather than simple enthusiasm.
- A strong pull toward immediate reward can make delay difficult to tolerate.
- Actions taken without adequate forethought may create potential for harm.

Why it matters clinically. Impulsivity often creates the most visible interpersonal consequences because it enters other people's space: it cuts across conversation, queues, shared rules, and family routines. Yet it should not be reduced to rudeness. The clinical account asks what the person did, what opportunity there was to pause, what consequence was foreseeable, and whether the same rapid-response pattern appears elsewhere. This preserves accountability without treating the symptom as a character defect.

MNEMONIC

Focus - Activity - Response

Use this simple spine when eliciting the domains: how the person keeps **focus** on a task, regulates **activity** to the setting, and pauses before a **response**.

3.5 Development changes the form, not the need for description

Symptom domains must be read through developmental demands. In the preschool period, the activity domain is usually the most conspicuous feature. This is clinically awkward because active movement is also common in ordinary early development. The task is therefore not to pathologise exuberance, but to notice whether activity is persistently difficult to contain when the setting requires containment and whether it creates a recurring burden for the child or those around the child.

As school demands become more sustained and organised, the inattentive domain comes to the foreground and creates clearer difficulty, and ADHD is often identified during the elementary-

school period. The developmental shift is intelligible: a setting that requires listening through instructions, maintaining place in work, organising materials, and completing sequences exposes failures of task regulation more clearly than a setting built around brief, adult-led activity. The change is not proof that inattention suddenly began. It may be that the demand has made an existing vulnerability visible.

DEVELOPMENTAL CONTEXT	CLINICAL EMPHASIS	HOW TO HEAR THE ACCOUNT
Preschool	Activity is the feature most likely to stand out.	Ask whether movement can be regulated when regulation is expected.
Elementary school	Difficulties in sustaining and organising attention become clearer.	Trace the pathway from instruction to completed work.
Adolescence	The large visible forms of activity recede.	Ask about fidgetiness, restlessness, impatience, and rash responding.

In adolescence, obvious running or climbing becomes less common and activity may be confined to fidgetiness or an **inner feeling of restlessness**. This is a change in presentation, not a licence to stop asking about the activity domain. The clinician should use the informant's developmental language rather than forcing childhood examples onto a person whose difficulty is now experienced more privately.

IN INDIA

In an Indian clinical record, preserve an everyday phrase such as “does not sit”, “forgets instructions”, or “answers without waiting”, then translate it into an observed sequence before attaching a symptom-domain label. This prevents a culturally familiar complaint from being mistaken for a complete clinical formulation.

3.6 Context dependence: why the consultation may look deceptively calm

Context-dependent expression is a central clinical fact. Signs may be minimal or absent when there is frequent reward, close supervision, novelty, an especially interesting activity, or a **one-to-one** interaction. This is not inconsistency in the pejorative sense. It shows that external structure, immediate reinforcement, and intrinsic engagement can temporarily carry regulatory work that the person struggles to sustain alone.

Office observation must therefore be interpreted modestly. A brief interaction is novel, adult-led, and often personally engaging. It may provide rapid feedback and a clear structure. A child who sits appropriately during it has demonstrated that regulation is possible under those conditions; the observation does not settle how regulation functions during ordinary demands. Conversely, a restless encounter should also be understood in its setting, rather than treated as a self-explanatory demonstration of the disorder.

PITFALL

A calm, cooperative consultation can become falsely reassuring when it is allowed to outweigh a consistent history of difficulty in less structured settings. Observation is valuable, but it is one context among several.

The same principle improves clinical conversations with families. Rather than treating apparently good performance during a preferred activity as a contradiction, ask what is different there: who is nearby, how quickly reward arrives, whether the activity is new, how much structure is supplied, and what happens when the task becomes routine. The answer may show why the family has experienced the behaviour as selective or puzzling without implying that the difficulty is fabricated.

3.7 Emotional reactivity as an associated clinical feature

Emotional dysregulation and emotional impulsivity are commonly encountered alongside ADHD. The person may be quick to anger, easily frustrated, and overreactive. These experiences deserve careful description because they can dominate the family's account and shape peer, school, and household consequences. They are not, however, an additional core diagnostic domain. Treating them as one blurs the boundary between the required symptom architecture and a clinically important associated feature.

The link with impulsivity is clinically intuitive: when delay, frustration, or interruption is difficult to tolerate, emotion may be expressed quickly and at high intensity. That explanation should remain a hypothesis in the individual case, not a shortcut that dismisses other contributors to distress. Describe triggers, sequence, recovery, and impact. Then decide whether the emotional pattern is best understood as associated reactivity, as part of another condition, or as both. The assessment and comorbidity sections take up those broader questions.

For bedside practice, the aim is a coherent narrative: the person loses the task, becomes active when stillness is required, responds before sufficient pause, and may react intensely when blocked or frustrated. Such a narrative is more useful than a symptom tally because it tells the clinician where everyday impairment is likely to arise and where apparent exceptions may be generated by context.

ADHD is recognised clinically by the patterned regulation of attention, activity, and response, interpreted in developmental context rather than by any single behaviour.

4 · Epidemiology and sex differences in ADHD

Epidemiology is not a decorative preface to diagnosis. It tells the clinician what a reported frequency can and cannot mean, and it explains why a child who is struggling may be missed when local expectations have been shaped by a narrow stereotype. In attention-deficit/hyperactivity disorder, the useful question is not whether a survey produces a definitive figure. It is whether the population examined, the route by which participants were identified, and the diagnostic method used make that figure applicable to the clinical question at hand.

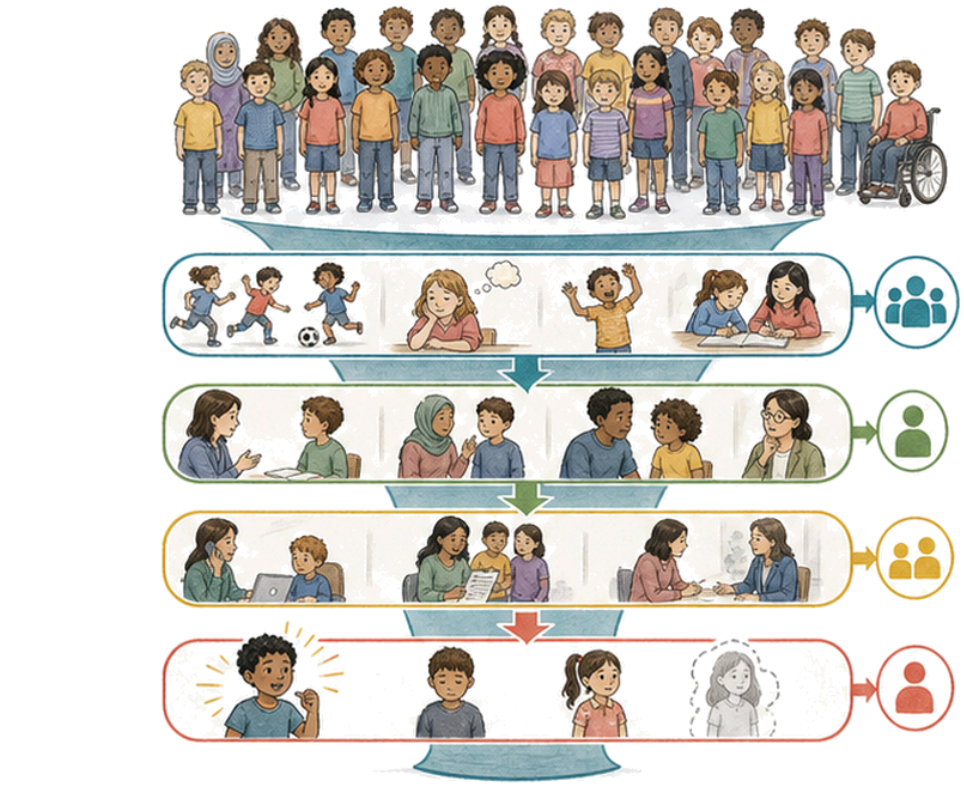

Fig 22.3 Observed ADHD caseloads pass through filters of presentation, recognition, access and referral. Disruptive behaviour is noticed earlier than quieter organisational or attentional difficulty, so clinic sex ratios cannot be read as population prevalence.

The epidemiological account also has a corrective function. ADHD is encountered across cultural settings and across the lifespan, but referral pathways do not select people neutrally. Behaviours that disrupt a classroom usually attract attention sooner than quieter difficulties with organisation or sustained mental effort. Sex differences in the observed caseload must therefore be read alongside sex differences in presentation and recognition. For a postgraduate answer, report the estimate, then explain the method and the clinical implication. That sequence demonstrates epidemiological reasoning rather than recital.

4.1 What prevalence means in ADHD

Population prevalence is the proportion of a defined population that meets the relevant diagnostic standard at the time and in the setting studied. It is not the same as the proportion already attending a clinic, receiving treatment, identified by a school, or labelled in administrative records. Each of those groups has passed through filters of recognition, help-seeking, access,

referral, and assessment. Their frequencies may be clinically useful, but they cannot simply be substituted for a community estimate.

For children worldwide, the current manual reports a frequency of **about 7.2%**. This is best used as an orienting benchmark, not as a shortcut to diagnosis in an individual child. A diagnosis still depends on the clinical assessment described elsewhere in this chapter. Prevalence provides a prior expectation that the condition is common enough to be actively considered when the presentation fits; it never converts an isolated complaint of distractibility or activity into a disorder.

In adults, the corresponding cross-national estimate is **about 2.5%**. This figure establishes that ADHD remains relevant beyond child services, while detailed adult presentation, persistence, and transition are addressed in the adult ADHD section of this chapter. The practical point here is modest but important: an epidemiological estimate should not be misread as either a developmental prognosis for an individual or a statement that every person identified in childhood will have the same clinical course.

7.2%	2.5%	2:1	1.6:1
WORLDWIDE CHILDHOOD ESTIMATE	ADULT ESTIMATE	CHILD MALE:FEMALE RATIO	ADULT MALE:FEMALE RATIO

RULE **Read every ADHD prevalence figure as an estimate produced by a particular method in a particular population.** The number is the beginning of interpretation, not its conclusion.

4.2 Why published estimates differ

A **cross-national range** is expected when studies do not use the same sampling frame or diagnostic process. Across nations, reported childhood and adolescent frequencies range from **0.1% to 10.2%**. A range of this width should prompt scrutiny of method before claims are made about culture, parenting, schools, or biology. The critical issue is comparability: are investigators asking the same question of populations selected in the same way and deciding caseness through an equivalent procedure?

Several features can shift the observed estimate without necessarily altering the underlying occurrence of ADHD. A survey based in schools begins with children who are present and observable in that setting. A community survey must locate families and achieve participation outside it. A clinic sample begins after referral, which is itself shaped by local awareness, resources, and the threshold at which difficulty is considered to require help. The informants available, the extent of collateral information, and the distinction between screening symptoms and a diagnostic assessment also influence who is counted. These are not technical footnotes. They determine whether figures from different studies can be compared at all.

It is also worth distinguishing measurement from service visibility. A community may have few recorded diagnoses because assessment is difficult to obtain, because school concerns do not reach health services, or because families frame the difficulty in non-medical terms. The inverse problem can occur where referral systems are highly responsive to classroom concerns. Neither

pattern can be interpreted without knowing the pathway from difficulty to identification. Epidemiology is strongest when it makes this pathway visible rather than concealing it behind a single headline percentage.

Diagnostic procedure has a particularly large effect. A symptom questionnaire can identify children who warrant fuller assessment, but it is not identical to a clinical diagnosis. Conversely, a restrictive procedure may miss children whose impairment is less visible to the informant or whose difficulties are interpreted through another frame. The examiner should therefore avoid treating a low estimate as proof that a disorder is rare, or a high estimate as proof of overdiagnosis, without first examining how the estimate was generated.

- Ask who was sampled and who was left outside the sampling frame.
- Ask whether the setting selected children before assessment.
- Ask how symptoms, impairment, and alternative explanations were evaluated.
- Ask whether the reported figure is a screening yield, a clinical rate, or a population estimate.

This discipline protects against a familiar error in viva discussion: explaining a numerical difference immediately as a cultural difference. Culture matters to recognition, report, and service access, but a difference between studies may be methodological before it is cultural. The answer should retain that uncertainty rather than inventing a causal story the data have not established.

MNEMONIC

MAP the estimate

Method asks how diagnosis was made; **A**scertainment asks how participants entered the study; **P**opulation asks who the result represents. Use this before comparing figures from different reports.

4.3 Culture, setting, and interpretation

The appropriate inference from the available international evidence is **cross-cultural comparability**: ADHD is seen broadly across cultures, and regional variation in reported prevalence is better understood primarily through diagnostic procedures and study methodology than as evidence of genuine regional differences in occurrence. This matters because the idea that ADHD is restricted to a particular cultural setting can lower diagnostic vigilance and make families feel that a formulation is imported rather than clinically grounded.

At the same time, cross-cultural comparability does not authorise cultural blindness. The clinician still has to establish what a behaviour means within the child's home, school, language, and daily demands. A child's difficulties can be obscured when educational expectations are inconsistent or when a family has had little opportunity to describe concerns in mental-health language. They can also be amplified when the referral is driven by a conflict with a particular environment. Epidemiology supports the possibility of ADHD; it does not replace contextual formulation.

IN INDIA

The **pooled estimate in Indian children** is **about 63.2 per 1000**. This is useful evidence against dismissing ADHD as uncommon in Indian practice. It should not be used as a local clinic target or as a substitute for a full developmental, educational, and psychiatric assessment. Differences between school-based and community-based estimates are especially instructive because they show how the place of recruitment changes the population being counted.

INDIAN STUDY CONTEXT	POOLED ESTIMATE	HOW TO USE THE FINDING
Children overall	About 63.2 per 1000	A broad pooled reference, not an individual diagnostic threshold.
School-based studies	About 75.1 per 1000	Interpret in light of school selection and school visibility of difficulty.
Community-based studies	About 18.6 per 1000	Interpret in light of household sampling and participation outside schools.

The lower community-based pooled estimate than the school-based pooled estimate is a methodological lesson, not a contradiction requiring a single winner. Schools concentrate observation of task demands and may make concerns more visible; community sampling reaches a differently selected population. Neither setting alone captures every child whose needs deserve attention. In clinical work, school information remains essential, but it is part of assessment rather than a population survey in miniature.

PITFALL

Do not compare a school-derived figure with a community-derived figure as though they measure identical populations. The apparent difference may arise before the assessment begins, through the route by which children entered the study.

4.4 Sex ratio is a finding, not a diagnostic rule

In the general child population, the male:female ratio is **about 2:1**. In the general adult population it narrows to about 1.6:1. These ratios describe observed population distributions. They do not mean that ADHD is a male disorder, that a female patient requires a different standard of evidence, or that a ratio can decide the probability of diagnosis for an individual.

The distinction between population and clinic is particularly important here. Referral services are shaped by whether concerns have been noticed, how they have been understood, and whether help has been sought. A clinic ratio can therefore reflect both underlying distribution and the selection pressures that precede referral. It should not be presented as a direct estimate of the frequency in the general population. Similarly, a clinician should not lower suspicion simply because a patient does not resemble the locally familiar referral pattern.

The change in the reported ratio across age groups invites thoughtful interpretation but does not, by itself, tell us why it occurs. A complete explanation could involve differences in recognition,

referral, symptom expression, service contact, or other features of study design. The epidemiological data in this section establish the pattern of ratios; they do not license a simple causal account. In a written answer, separating observation from explanation is a mark of clinical maturity.

TRAP **Do not turn a sex ratio into an exclusion criterion.** The ratio describes groups. Diagnosis concerns the individual's symptoms, impairment, developmental context, and differential diagnosis.

4.5 Female presentation and under-recognition

Females are more likely than males to present chiefly with **inattentive features**. This statement has direct clinical consequences. Difficulties that are less outwardly disruptive can be interpreted as poor motivation, anxiety, low confidence, or a personality style rather than as possible ADHD. The error is not that these alternative formulations never apply. The error is failing to consider ADHD because the presentation does not match an expectation built around conspicuous overactivity or impulsive behaviour.

Under-recognition is not solved by applying a lower threshold to girls and women. It is solved by asking a better question and gathering better evidence. Explore whether the reported concentration, organisation, task completion, and regulation difficulties are persistent, present in relevant settings, impairing, and better explained by another condition or circumstance. Seek collateral wherever feasible, and ask how the demands of school, work, family life, and social roles have exposed or concealed the difficulty. The core symptom domains and the formal diagnostic approach are set out in the relevant sections of this chapter.

Questions should be phrased so that a patient is not required to recognise their experience as ADHD before it can be described. Ask for situations in which work was abandoned despite intention, responsibilities were managed only through elaborate reminders, or attention failed under ordinary demands. Then ask what happened when external structure was removed. Such enquiry is not a symptom checklist in disguise. It is a way to understand function, context, and adaptation before deciding whether the broader diagnostic formulation is supported.

A less disruptive presentation may produce a quiet trajectory of burden. A patient can compensate by overpreparing, avoiding demanding tasks, relying heavily on relatives, or restricting opportunities. Such adaptation can make impairment harder to see in a brief consultation. It should not be mistaken for absence of impairment. The task is to identify the cost of maintaining functioning as well as the visible failures of functioning, while avoiding retrospective certainty where the history is unclear.

Why it matters clinically. Sex-sensitive assessment improves accuracy in both directions. It reduces missed ADHD in patients whose difficulties have been normalised or misattributed, and it guards against premature attribution when another formulation better accounts for the presentation. A careful history should neither presume ADHD from a stereotype nor exclude it because of one.

GOOD TO REMEMBER

When a patient reports a long history of effortful organisation or concentration without a disruptive referral history, ask what supports, avoidance strategies, and role demands have kept the difficulty out of view. The absence of a dramatic school narrative is not, by itself, reassuring.

4.6 From epidemiology to clinical judgement

Epidemiological data should change the clinician's calibration, not replace clinical judgement. A common condition deserves active consideration in an appropriate presentation; it does not deserve automatic attribution. The same discipline applies to sex differences. They should broaden the clinician's recognition of possible presentations, but should not encourage speculative diagnosis without evidence of clinically meaningful difficulty and a careful differential diagnosis.

In practice, keep separate the question of how often ADHD is identified in a population sampled by a given method, the question of who may have been missed or preferentially included before assessment, and the question of whether the individual in front of the clinician meets the required clinical formulation after relevant alternatives have been considered. Conflating these questions creates both overdiagnosis and under-recognition. Keeping them separate makes prevalence genuinely useful.

Documentation benefits from the same clarity. When recording epidemiological information, state whether it is a population benchmark, a school-based finding, a community estimate, or a service figure. When recording sex-related considerations, describe the observed presentation and the assessment undertaken rather than writing a stereotype as though it were an explanation. This produces records that are easier for colleagues, families, and future services to interpret.

For the examination candidate, an epidemiology answer should move from broad frequency to heterogeneity, then to clinical consequence. State the worldwide and Indian evidence where relevant, explain why estimates vary across settings, give the child and adult sex ratios, and finish with the implication that inattentive presentations in females may be under-recognised. Avoid expanding this section into diagnostic criteria, neurobiology, comorbidity, or treatment. Those topics require their own evidence and their own clinical reasoning.

Prevalence describes populations; careful assessment decides diagnosis, and sex differences should widen recognition rather than narrow it.

4.7 A concise examination framework

A high-quality short answer can be organised around interpretation. Begin with the worldwide childhood estimate and the adult estimate, making clear that these are population figures. Next, note the wide cross-national range and state that differing diagnostic procedures and methodology account for much of the apparent regional variation. Then add the Indian pooled figure and the contrast between school-based and community-based studies to show that setting

changes estimates. End with the male:female ratios and the greater likelihood of inattentive presentation among females.

The final sentence should carry the clinical point: prevalence and ratios should guide recognition and service planning, but they do not diagnose an individual. This ending prevents a fact-heavy answer from becoming detached from patient care. It also avoids opposite errors: using epidemiology to minimise ADHD in a setting where it is under-recognised, and using a familiar epidemiological figure as a substitute for careful assessment.

5 · Etiology and neurobiology (genetics, dopamine-noradrenaline, executive dysfunction)

Why it matters clinically. ADHD is best understood as a developmental disorder of regulation, not as a failure of will, parenting, or intelligence. Its aetiology is therefore neither a discrete lesion nor an isolated adverse experience. The useful clinical question is not "what caused this child's ADHD?" but how inherited liability, brain development and context have combined to produce the present pattern of impairment. This formulation gives the clinician a coherent explanation for families while keeping diagnosis anchored in clinical assessment.

The biology is examined because it explains several otherwise puzzling features: clustering within families, variation in the balance of inattentive and hyperactive-impulsive difficulties, inconsistent performance across settings, and the characteristic difficulty in converting intention into organised action. It also prevents common errors: genetic evidence must not be mistaken for genetic determinism, and a brain-based account must not be used to erase the child's environment, strengths, or need for practical support.

5.1 A multifactorial model, not a single cause

ADHD is a **multifactorial vulnerability**: multiple inherited and environmental influences of small effect can converge in an individual. This is a more accurate model than searching for a decisive biological abnormality. The causal pathways are heterogeneous. Children may meet the same clinical diagnosis through partly different combinations of familial liability, developmental exposures, neural organisation and compensatory strengths.

This matters for formulation. A family history can make an inherited contribution plausible, while a prenatal or early developmental history can identify circumstances relevant to vulnerability. Neither alone establishes the diagnosis, explains every current difficulty, or tells the clinician what a particular child will become. The phenotype is the clinical end point of development, not a direct read-out of a gene or an exposure.

RULE **Heritability describes variation in a population; it does not measure how inevitable ADHD is for an individual child.** It supports a substantial inherited contribution while leaving room for developmental context, individual differences and change over time.

For the same reason, a high heritability estimate does not license blame directed at a parent. It is compatible with shared family traits, with parents who have developed effective adaptations, and with a child whose support needs are different from those of relatives. The clinician should use

biological explanation to reduce moral judgement, not to convert a complex developmental problem into fatalism.

At the bedside, the formulation can be kept orderly without pretending to be exhaustive:

- identify the developmental pattern and current functional difficulty;
- ask whether familial liability is likely to be relevant;
- consider developmental circumstances that may have added vulnerability; and
- look for the present demands and supports that determine how severely the difficulty is expressed.

This sequence is deliberately formulation-led rather than cause-hunting. It acknowledges uncertainty honestly. It also gives the family a practical narrative: some contributors cannot be changed, but the child's current environment, routines and supports can be altered. A neurobiological explanation earns its place only when it makes this conversation clearer and less blaming.

5.2 What family and twin evidence establishes

Family aggregation and twin research provide the strongest starting point for the genetic account. The DSM estimate is displayed in the evidence strip above. Across family, twin and adoption designs, the reported heritability index ranges from **0.6 to 0.98**. Such estimates indicate that inherited differences make an important contribution to variation in ADHD in the populations studied; they do not identify an individual cause.

The pattern within twin pairs makes the inference intuitively clear. Reported concordance is **MZ 59-92%; DZ 29-42%**, with the more genetically similar pairs showing greater concordance. The twin-study estimate of genetic contribution is displayed in the evidence strip. The residual difference within genetically similar pairs is clinically important. It cautions against treating genes as a complete explanation and directs attention to development and context.

The first-degree relative estimate is displayed in the evidence strip. In practice, this means that the history should be taken broadly. Ask about lifelong distractibility, disorganisation, impulsive decisions, school difficulties and coping styles in close relatives, rather than asking only whether a relative carries a diagnostic label. A parent's account of childhood experience may illuminate the family context, but it must never substitute for an assessment of the child.

Evidence of familiality answers a population question: whether inherited factors contribute meaningfully to variation in the condition. It does not answer the individual question of why one sibling is more impaired than another, why a child has difficulties in one setting but not another, or whether a current school problem is due to ADHD. Those questions require the longitudinal, contextual assessment described elsewhere in the chapter. This distinction protects the clinician from making a statistical association carry more clinical meaning than it can bear.

GOOD TO REMEMBER

Family history has complementary uses: it strengthens the developmental formulation and it helps identify practical supports within the family. It is not a diagnostic shortcut, and it should not be presented as proof that a child cannot improve.

5.3 Polygenic architecture and candidate-gene findings

ADHD is **polygenic**; there is no single ADHD gene. Candidate-gene work has concentrated on systems relevant to catecholamine signalling and synaptic regulation. The **DAT1 (dopamine transporter gene)** has been associated with ADHD, particularly with hyperactive-impulsive or combined clinical presentations. Its biological interest lies in its relation to synaptic dopamine reuptake, which offers a plausible bridge between molecular variation and regulation of neural signalling.

Another repeatedly studied candidate is the **DRD4 seven-repeat allele**, linked in this literature with novelty seeking, impulsivity and the inattentive subtype. Other reported candidates include **DRD5, DBH, COMT, SNAP25, SLC6A2 and ADRA2A**. These names are useful for understanding why dopamine, noradrenaline and synaptic processes recur in mechanistic accounts. They are not a clinically actionable genetic panel for routine diagnosis.

The candidate-gene story also teaches an important scientific lesson. Many early associations have not been consistently reproduced. Known candidate genes account for below **5%** of genetic variation. Broad genomic association work identified **12 independent loci**, reinforcing the conclusion that liability is distributed across many variants of small effect rather than concentrated in one explanatory gene.

For an examination answer, distinguish levels of evidence. Family and twin findings support heritability. Molecular findings ask which biological pathways may carry part of that liability. Neither level reduces ADHD to a Mendelian disorder, and neither makes molecular testing a replacement for phenomenology, developmental history and impairment. This distinction is often more valuable than memorising a long list of gene symbols.

TRAP **Do not answer "DAT1 causes ADHD" or "DRD4 is the ADHD gene."** Candidate associations are part of a distributed liability model. The exam-safe conclusion is polygenic vulnerability, with individual variants contributing limited and sometimes inconsistently replicated effects.

LEVEL OF EXPLANATION	WHAT IT CONTRIBUTES	CLINICAL INFERENCE
Familial liability	Explains aggregation across relatives	Take a developmental family history without assuming destiny
Polygenic variation	Distributes liability across many small effects	Do not seek a diagnostic gene
Neural signalling	Links molecular systems to regulation of behaviour	Use it to explain mechanisms, not to label a child biologically
Developmental context	Shapes vulnerability and adaptation	Build a formulation that remains individualised

5.4 Dopamine, noradrenaline and state regulation

The central neurotransmitter account concerns **dopamine and norepinephrine (noradrenaline), with epinephrine**, within a broader catecholamine imbalance. These systems are relevant because efficient attention and purposeful behaviour require the brain to regulate salience, arousal, effort and response selection according to the demands of the moment. A child may know what should be done yet fail to sustain the regulated state required to do it consistently.

Dopamine is especially helpful as a conceptual link to reinforcement, motivation and the selection of responses; noradrenergic signalling is helpful as a link to alertness and the allocation of attention. These are not separate boxes. They work within connected circuits, so an apparent problem of "motivation" may actually reflect inefficient regulation of attention, timing and response control. This helps the clinician move beyond the simplistic contrast between "can do" and "will not do."

The important idea is state regulation. Effective performance depends on bringing attention and effort to the task, maintaining them despite distraction, and readjusting when the task changes. Catecholamine-linked systems are plausible contributors to these transitions. When they are inefficient, the child's output may fluctuate sharply with task structure, novelty, feedback and competing stimulation. Such fluctuation can look oppositional or careless if the clinician observes only the finished work rather than the regulatory demands imposed by the situation.

This account should not be used to collapse all difficulties of attention into ADHD. Attention can be disrupted by many developmental, emotional, cognitive and environmental conditions. The neurobiological model explains why ADHD is a plausible formulation after diagnostic work has been done; it does not establish the diagnosis before that work.

A proposed noradrenergic mechanism is reduced inhibition of **locus coeruleus neurons**. This could account for inattention, cognitive difficulty and gross motor activity by impairing the regulation of arousal and attention. The wording is deliberately mechanistic rather than deterministic: the finding is a model of how a symptom pattern may arise, not a laboratory test that confirms the disorder in an individual patient.

IN INDIA

When families ask whether ADHD is "chemical" or "because of upbringing," avoid forcing a false choice. Explain that biology and developmental context jointly shape vulnerability, then return to the child's observable impairment and the supports that can be put in place at home and school.

5.5 Circuit-level account and cortical development

The circuit model locates ADHD in **cortico-basal ganglia-thalamo-cortical (fronto-striatal) circuitry**. Hypoactivation has been reported in frontostriatal, frontoparietal and ventral attention networks. These systems support goal-directed executive processes and decision making. The clinical relevance is that regulation requires a coordinated network: maintaining a

goal, filtering competing input, selecting a response, monitoring its consequence and adjusting course are connected operations.

Network language is preferable to a crude "frontal-lobe deficit" formulation. It explains why ADHD can affect the organisation of behaviour across tasks without implying a fixed global intellectual deficit. It also explains why performance may improve markedly when structure, novelty, immediate feedback or external scaffolding reduces the regulatory load. Such variability is not evidence that the difficulty is fabricated; it is often the clinical signature of context-sensitive control.

Developmental imaging work describes the maturational delay displayed in the evidence strip, particularly in frontal and temporal regions. This should be read as a developmental timing account. It does not mean that every child follows one anatomical timetable, nor does it permit prediction of outcome from a scan. The useful inference is that symptoms arise during an evolving developmental process, which is consistent with the importance of developmental history and longitudinal review.

Important safeguards apply when interpreting circuit findings. Group-level differences do not create a diagnostic signature for an individual, and a network description is not an excuse to overlook psychosocial formulation. Neural systems operate in a child who is learning, relating, sleeping, attending school and responding to expectations. A mature formulation holds both levels in view without falsely setting them against each other.

> **PITFALL**
>
> Do not present group-level circuit findings as though they explain an individual child completely. They are useful for formulation, but they do not replace careful clinical reasoning about that child's developmental history, context and impairment.

5.6 Executive dysfunction: the clinical bridge from circuit to behaviour

The most clinically useful bridge from neural systems to daily impairment is **behavioural (response) inhibition**. In the executive-function model, a central weakness in pausing or withholding an immediate response has downstream effects on self-regulation and executive functioning. The point is not that every person with ADHD is constantly disinhibited. Rather, when rapid response, delay, distraction or competing reward increases demand, the person may have less reliable capacity to stop, hold a goal in mind and choose a more adaptive next action.

Executive functions are therefore best conceptualised as control processes that allow behaviour to be organised over time. They include maintaining task goals, monitoring performance, shifting strategy, resisting a dominant response and regulating effort. The accompanying figure can be used to connect the neural network account with this control problem. It should not be confused with the descriptive account of core symptoms, which is covered separately in the clinical-features section of this chapter.

This model makes sense of the everyday paradox of an able child who starts with intention but does not complete work, gives a quick answer before considering alternatives, or needs repeated

external prompts to return to a task. The difficulty is often not lack of knowledge of the rule. It is inefficient use of the internal control processes required to apply that rule at the relevant moment. External organisation can therefore be therapeutic because it temporarily supplies structure that the child cannot yet generate reliably.

Executive dysfunction is a mechanism, not a synonym for the diagnosis. The clinician should not infer it from an isolated messy notebook, an isolated impulsive act or a parent's understandable frustration. Its explanatory value lies in a coherent pattern across contexts and over time: the child repeatedly struggles to regulate action when independent planning, sustained monitoring or delayed response is required. The model then guides a practical question: which external prompts, routines and task structures reduce the control load enough for the child to show existing competence?

MNEMONIC

PAUSE

Pause the response, **A**im at the goal, **U**pdate the plan, **S**can for competing input, **E**xecute deliberately. This is a memory aid for the executive-control sequence, not a diagnostic checklist.

5.7 Environmental contributors and a usable formulation

Environmental associations include **very low birth weight, prematurity, prenatal smoking exposure, in-utero alcohol and lead exposure**. These should be approached as contributors to vulnerability, not as a list of proven causes for every patient. The distinction matters both scientifically and ethically. Retrospective history can identify a relevant developmental context, but it cannot establish that one exposure caused one child's ADHD.

In a clinical history, exposures should be recorded accurately and without accusation. The question is whether they contribute to the developmental formulation, not whether a parent can be assigned responsibility for a disorder that has complex origins. It is equally important not to let an exposure history eclipse evidence of familial liability or current contextual stressors. The biological and environmental strands are most useful when they are integrated rather than made to compete.

A good formulation brings levels together. Start with familial and developmental vulnerability; consider whether attentional arousal, reward sensitivity and response regulation offer a plausible mechanism; then identify current contexts that expose or buffer the executive-control difficulty. This produces practical, non-blaming language: the child has a difficulty regulating behaviour across demands, and the environment can either overload that system or make success more likely.

Mechanism should guide empathy and intervention planning, not become an explanation that eclipses the child. Ask what demands are being placed on self-regulation, what supports already work, and where the mismatch between capacity and expectation is greatest. For the wider assessment framework, see the Child psychiatry: assessment, treatment, services and protection

notes. For developmental context outside ADHD, see the Normal child development and milestones notes.

ADHD is a multifactorial, polygenic developmental disorder in which catecholamine-linked control networks and executive dysfunction help explain the clinical phenotype.

Recognising ADHD: assessment, scales, comorbidity and differential

6 · Comprehensive assessment of ADHD (history, school reports, observation)

Assessment is the diagnostic intervention before treatment is considered. A convincing assessment of ADHD does not arise from a child's behaviour in the consulting room, a single checklist, or an anxious parent's account taken in isolation. It is a deliberate reconstruction of patterns over time, across demands and relationships, followed by an appraisal of their consequences. The task is not to decide whether the child is lively, distractible, or difficult on a particular afternoon. It is to decide whether the reported pattern is developmentally inappropriate, persistent in the child's ordinary life, and sufficiently impairing to require a clinical formulation.

The assessment has a diagnostic purpose and a formulation purpose. It establishes whether ADHD is the best account of the presenting difficulties, and it identifies the factors that will change the meaning of those difficulties for this child and family. A good assessment makes the later management plan more precise because it has already mapped the child's strengths, the settings in which problems emerge, the adults who can observe change, and the obstacles that may be mistaken for the disorder itself.

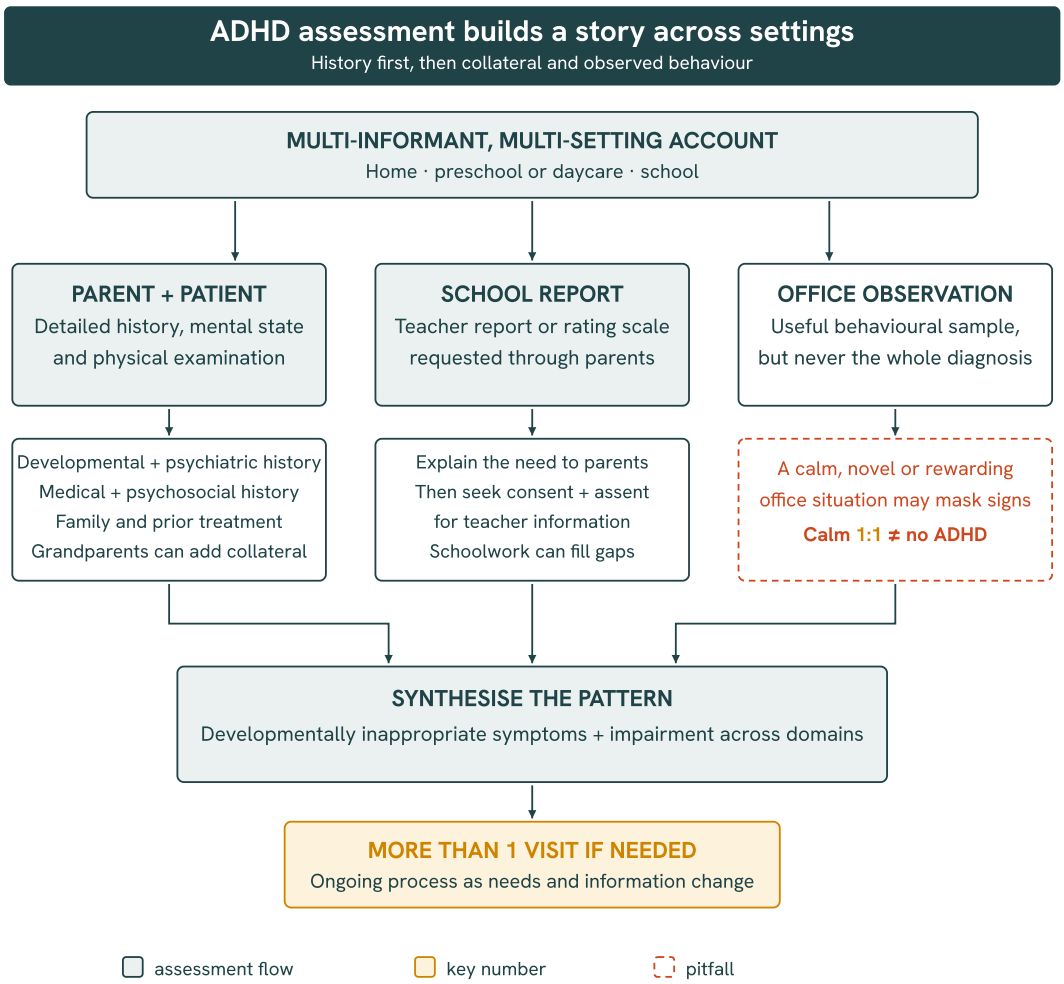

Fig 22.6. ADHD assessment pathway: history-led, multi-informant evidence across settings.

6.1 Architecture of a comprehensive assessment

A **comprehensive ADHD assessment** rests on detailed history, mental state examination, and physical examination. These are not separate bureaucratic stations. Each corrects a limitation in the others: history supplies the longitudinal and contextual picture, the examination tests the immediate clinical impression and alternative explanations, and physical assessment detects medical issues that may alter interpretation or subsequent care.

The **three** pillars should be gathered with a single clinical question in mind: what does the child actually do, where does it occur, what demand exposes it, who is affected, and what follows? This turns global labels such as “not listening” or “very naughty” into observable, comparable information. It also prevents the clinician from treating every report of poor work, conflict, or restlessness as if it carried the same diagnostic weight.

- Describe the behaviour in concrete terms before naming it.
- Place it in the setting and demand in which it occurs.
- Establish the consequence for the child and the people around them.
- Record what remains uncertain and needs corroboration.

History	School	Observation
PATTERN OVER TIME	ORDINARY PERFORMANCE	CLINICAL CONTEXT

RULE **ADHD assessment is a synthesis of converging accounts, not a verdict from a single encounter.** The clinical interview remains the organising method: it decides what needs corroboration, where information is missing, and whether apparent agreement between informants reflects the same behaviour in comparable circumstances.

Use the assessment to construct a formulation rather than merely to fill a diagnostic template. Begin with the presenting concern in the family's own language, then translate it into concrete examples. Ask what has already been tried, what has helped, and what has worsened the problem. This sequence preserves rapport and produces information that can later be shared with parents and school without implying blame. It also reveals whether the referral question is diagnostic uncertainty, functional decline, conflict around expectations, concern about safety, or a request for documentation.

6.2 Multi-informant and multi-setting enquiry

The core strategy is **multi-informant assessment** across settings. Parents or caregivers know the child's routine, transitions, sleep, self-care, conflict, and unstructured time. Teachers witness performance under group instruction, sustained work, peer demands, rules, and academic expectations. The child's own account may clarify internal experience, efforts to compensate, distress, and the meaning attached to repeated criticism. These accounts are complementary rather than competitors in a courtroom.

A **caregiver history** is central because ADHD is diagnosed primarily through history and caregiver report; a brief office sample is rarely adequate to detect the relevant pattern. Ask each informant for examples rather than asking only whether a symptom is present. "What happens when homework begins?" is usually more useful than "Is attention poor?" The first question elicits sequence, triggers, adult responses, and consequences. The second often elicits an interpretation already shaped by frustration or stigma.

Discrepancies deserve curiosity, not premature resolution. A child who appears settled in one environment may be supported by a structure, a relationship, or a task that reduces the relevant demand. Conversely, a report of difficulty in one setting may point to a contextual mismatch, a learning demand, peer difficulty, or a relational strain that needs separate assessment. The clinician should identify what is different about the setting before deciding what the discrepancy means. Agreement is helpful; carefully understood disagreement can be even more informative.

MNEMONIC

Listen, Locate, Link, Look again

Listen for concrete examples; **locate** them in ordinary settings; **link** them to their functional effects; and **look again** when accounts conflict. This is an interviewing spine, not a diagnostic shortcut.

IN INDIA

Collateral need not be restricted to parents. In joint or extended households, **extended-family collateral**, including from grandparents, may add a useful account of routines and behaviour. The clinician should still establish who has regular, direct knowledge of the child rather than treating kinship alone as evidence of reliability.

Interview quality improves when the clinician makes the purpose of collateral explicit. Explain that the aim is to understand the child's functioning in ordinary environments, not to recruit adults to prove that the child is problematic. This framing reduces defensiveness and helps informants offer examples that include strengths, successful situations, and environmental supports. Collateral from other caregivers may be useful when it concerns a setting they know directly, but it should be recorded as an account rather than elevated automatically above the child's or parent's report.

6.3 History: developmental anchoring and clinical context

The history should establish the course of concerns, the situations in which they are most visible, the child's capacities, and the family's explanatory model. **Developmental and psychiatric history** is taken to support differential diagnosis and identify comorbidity. Its value lies in anchoring current concerns in the child's broader developmental trajectory, rather than interpreting behaviour only through the immediate school complaint. For developmental context beyond this focused assessment, consult the Normal child development and milestones notes.

The essential anchor is **developmental appropriateness**. Behaviour must be judged against the child's developmental level, not against an abstract expectation that every child of similar chronological age will behave identically. When intellectual subnormality is suspected, the relevant question is whether the difficulty is inappropriate for the child's mental age; this is why developmental history and a working impression of mental age belong in the assessment. The point is clinical fairness: a behaviour can be challenging for adults yet still be developmentally expected for that particular child.

Build the developmental account around function. Clarify communication, play, self-regulation, adaptive demands, and the child's response to routine changes or increasing expectations, without turning the history into a catalogue. Ask how the current concern differs from the child's usual style and whether it is experienced similarly by the child and adults. A timeline is useful when it links difficulties to transitions in demands or contexts, but it should not be mistaken for proof by itself. The history is an interpretive tool, not a chronology contest.

Medical history searches for comorbidity and identifies issues relevant to medication planning. It should include relevant physical disorders and a focused account of symptoms that may change the safety assessment. When pharmacotherapy may later be considered, obtain family history of ADHD and, specifically, family history of sudden cardiac death **under 40 years**. Baseline sleep and appetite are also worth recording because later change cannot be interpreted well if the starting state was never established.

The wider history includes prior interventions, substance-use history where relevant, psychosocial context, and family experience of the problem. It is tempting to regard family history as a confirmatory box to tick. Instead, treat it as a clue whose meaning is contextual. A history of relatives with ADHD can support the formulation, whereas absent affected relatives in the context of traumatic stress or a family history suggestive of a mimicking condition should prompt renewed diagnostic caution. The detailed differential is addressed elsewhere in this chapter; this is the moment to keep the differential open rather than to settle it too early.

GOOD TO REMEMBER

Baseline sleep, appetite, prior treatment, and family concerns are not "background." They make later follow-up interpretable and help distinguish a new treatment effect from a pre-existing difficulty or a changing environmental demand.

6.4 School reports and the educational record

School is usually the setting in which the gap between capacity and performance becomes most visible, but the school report must be requested and interpreted with care. A **teacher report** may be an unstructured account of observed behaviour or a teacher rating on a structured scale. It is sought through the parents after explaining why information from school is needed and obtaining consent and assent. The explanation matters: parents may fear stigma, blame, or adverse treatment of the child, and a request that feels like surveillance can damage collaboration.

Ask the teacher to describe the learning environment rather than simply to endorse a label. Useful observations concern how the child begins work, sustains it, responds to instruction, handles transitions, completes tasks, interacts with peers, and functions when supervision changes. Ask what appears to help, not only what fails. Schoolwork, notebooks, report cards, and patterns of incomplete or inconsistent work can provide a concrete record of the educational impact, but none is diagnostic in isolation. They need to be read alongside the developmental history and the child's opportunities to learn.

CLINICAL QUESTION	WHAT THE SCHOOL RECORD CAN CONTRIBUTE	HOW TO INTERPRET IT
Where does difficulty arise?	Examples from instruction, independent work, transitions, and peer situations	Locate the difficulty in a real demand rather than in a global judgement
How stable is the pattern?	Observations across routine school tasks and records over time	Compare patterns, not isolated incidents
What supports functioning?	Teacher accounts of structure, prompts, seating, reinforcement, or task format	Identify conditions under which impairment is reduced
What is the impact?	Work completion, classroom participation, relationships, and educational progress	Separate functional consequence from a diagnostic label
What remains uncertain?	Gaps, conflicting accounts, or records that lack context	Return to parent, child, and teacher for clarification

If parents remain reluctant to approach the school, do not convert reluctance into non-cooperation. Elicit the reasons, revisit consent, and make the best assessment possible from parent and child accounts together with schoolwork and report cards. The limitation should be documented honestly. A missing teacher report reduces one source of corroboration; it does not make thoughtful clinical assessment impossible.

Rating scales can help obtain structured teacher information and later monitor response. Their role is supportive; diagnostic judgement rests on clinical assessment. The selection, structure, and interpretation of specific rating scales are covered in the section on rating scales.

6.5 Observation, mental state and physical examination

Direct observation is useful when it is treated as a sample with a known context. The clinician can note engagement, activity level, communication, response to structure, separation from caregiver, frustration tolerance, and the fit between observed behaviour and the history. Observation may also show the child's competencies, which matter when explaining the formulation to family and school. It cannot, however, be allowed to overrule a carefully gathered longitudinal account merely because the interview was calm.

The office is a particularly poor place to infer absence of ADHD from absence of obvious signs. Features may be minimal or absent in **one-to-one** interaction, in a novel setting, under close supervision, with frequent rewards, or during especially engaging activity. These are not loopholes in assessment. They are reminders that behaviour is shaped by the demand and support available at the time it is observed.

TRAP **"The child sat quietly in my room, so the history must be wrong."** A short, structured, novel encounter may be far less demanding than the environments from which the referral arose. Use the observation to refine the formulation, not to dismiss collateral evidence.

The **mental state examination** is especially valuable because it can rule out another mental disorder that better explains the symptoms. It should be developmentally adapted and integrated with the interview rather than reduced to an adult-style checklist. Affect, thought content, anxiety, mood, perception, communication, insight appropriate to development, and risk are considered insofar as they clarify the presenting pattern. This is a screen for explanatory alternatives, not a duplicated teaching of the differential diagnosis.

The **physical examination** and medical history help rule out mimicking disorders and detect comorbid developmental coordination disorder. There are no diagnostic physical signs of ADHD. Abnormal findings therefore require their own clinical interpretation rather than being treated as evidence for ADHD. Examination also establishes a sensible baseline for care and may reveal a reason to broaden the assessment beyond the referral label.

PITFALL

Do not write “normal examination” as if it were a positive diagnostic test for ADHD. A normal examination narrows some concerns; it does not confirm the diagnosis. Equally, an abnormal finding should prompt explanation rather than diagnostic drift.

6.6 Impact, selective tests and the adolescent interview

Symptoms acquire clinical importance through their consequences. Assess **functional impairment** across academic, family, social, interpersonal, peer, and occupational domains as relevant, and ask how the difficulty affects the patient and caregivers. This prevents severity from being equated with how disruptive an adult finds the child. A quietly struggling child may have substantial educational or internal burden, while a highly visible behaviour may have limited impact once the context is understood.

Discuss impact concretely. What activities are avoided? What interactions repeatedly deteriorate? What does the child believe about their own abilities? What is the cost to caregivers in supervision, conflict, time, or distress? The answers guide priorities for follow-up and create a baseline against which meaningful improvement can be judged. They also make it easier to distinguish a symptom count from the lived burden that justifies intervention.

Routine psychological testing and specific physical investigations are not indicated solely to establish ADHD. Cognitive assessment is reserved for suspected intellectual subnormality, and investigations are selected when the history or examination indicates them. This restraint is good clinical method: testing should answer a question generated by the assessment, not substitute for the assessment that should have generated the question.

For older children and adolescents, make space for a **confidential adolescent interview** separate from parents. This acknowledges autonomy and confidentiality and creates an opportunity to elicit mood-related risk, substance use, and high-risk behaviour that may not emerge in a family interview. Explain the limits of confidentiality in language the young person can understand, and then return to shared discussion only to the extent that safety and care require.

6.7 Integrating and revisiting the formulation

End the first assessment by making the reasoning visible. Summarise the reported pattern, the settings represented, the degree and type of impairment, the corroborating evidence, the unresolved discrepancies, and the factors that require further assessment. This is more useful than a bare conclusion because it tells the family why a diagnosis is being considered and tells the clinician exactly what must be clarified at follow-up.

Assessment is not necessarily concluded in a single visit; it may require **at least** a further visit and remains an ongoing, multi-informant process across settings. Follow-up is not an administrative afterthought. New school information, changing demands, treatment response, and family circumstances can sharpen the formulation or reveal that an initial explanation was incomplete. The clinician should preserve uncertainty where the evidence is incomplete, rather than forcing a premature categorical answer.

> The diagnosis is made from a developmentally anchored, multi-setting history of impairment, interpreted with school collateral and examination - never from a quiet consulting-room encounter alone.

7 · Rating scales (Conners, Vanderbilt, SNAP-IV)

Rating scales make behaviour discussable across settings. They convert an informant's observations into a structured record, but they do not convert a questionnaire result into a diagnosis. Their proper contribution is to show which concerns are being endorsed, by whom, how much functioning is affected, and whether the pattern merits clinical synthesis with the history, collateral information and examination. A scale is therefore evidence from an informant, not a substitute for clinical judgement.

The marks in this area usually turn on a more precise distinction: the instruments share an ADHD focus but do not share the same raters, age bands, score metric, thresholds or reproduction permissions. Treating them as different versions of one test produces errors in both interpretation and documentation. The accompanying figure separates the instruments by the question each actually answers.

3	6 to 12	26
CONNERS RATER FORMS	VANDERBILT AGE BAND	SNAP-IV ITEMS

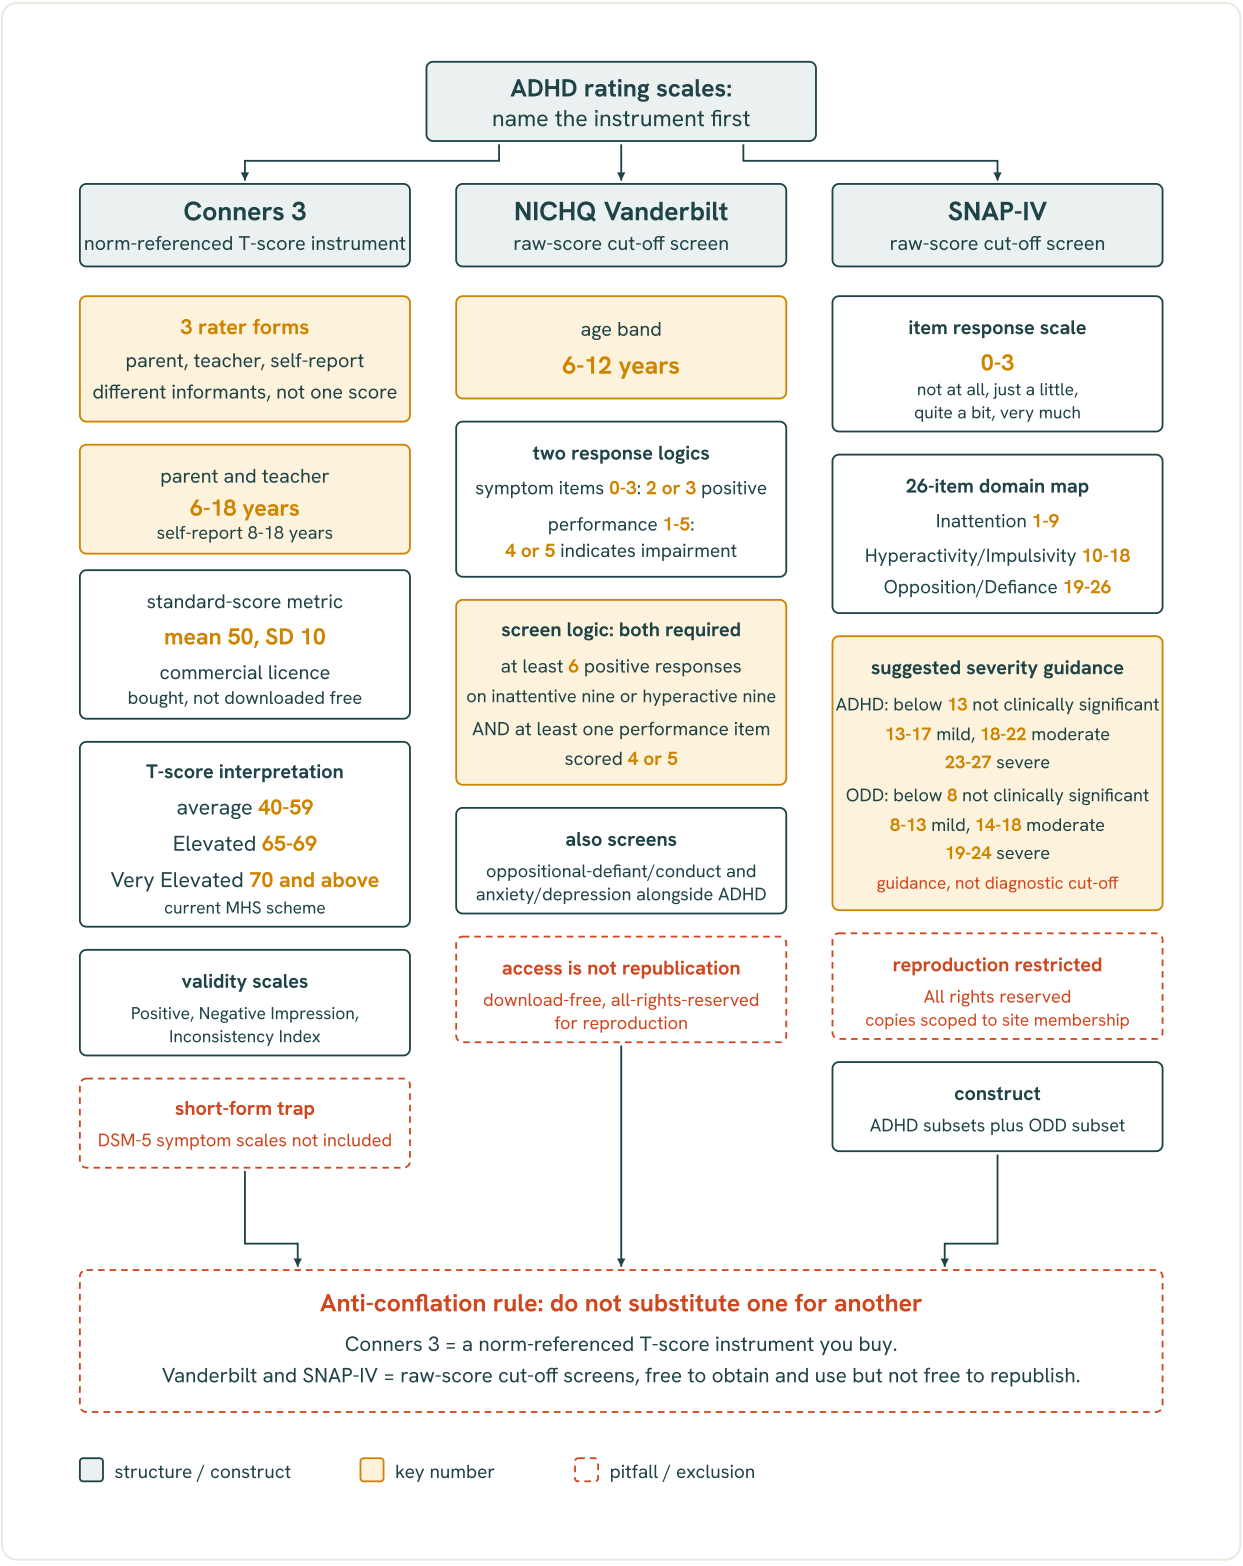

Fig 22.7. ADHD rating-scale split: match the instrument to its rater, age band, scoring construct and cut-off logic before interpreting it.

7.1 What a rating scale adds

A **rating scale** is a structured informant report. It is most useful when the clinician needs a disciplined account of behaviour in the contexts in which it is observed, rather than a retrospective global impression. The form does not observe the child directly. Its value lies in making the informant's frame visible: a teacher may describe demands in a classroom, a parent may describe routines and transitions, and the young person may add an account of internal

experience. Concordance may strengthen confidence in a pervasive difficulty; disagreement is information to explore, not a technical nuisance to average away.

Before choosing any form, decide what is needed from it. A clinician may need an age-appropriate informant report, a profile relative to a reference group, a transparent symptom-and-impairment screen, or a repeatable raw score for monitoring. These are different purposes. A high score may arise from genuine difficulty, context-specific strain, a rater's threshold for concern, misunderstanding of the item, or a response style that needs checking. Conversely, a modest score cannot erase a coherent clinical history. Scale data must be read with the informant's opportunity to observe the behaviour and the demands of that setting in mind.

RULE **Interpret the instrument that was completed, not the instrument you wish it had been.** Its rater, age range, score metric and threshold determine what its result can mean.

This principle also prevents a common shortcut: extracting a number from one scale and applying a cut-off remembered from another. The three named instruments are deliberately **not interchangeable**. Their scores carry meaning only within the rules of their own form and scoring system.

7.2 Conners 3: a norm-referenced profile

Conners 3 provides three rater forms: parent, teacher and self-report. The parent and teacher forms apply from 6 to 18 years; the self-report form applies from 8 to 18 years. This is clinically useful because different raters have access to different parts of the child's life. It does not license a mechanical vote-count. A discrepancy should lead to questions about setting demands, support, structure, relationships and the informant's actual observation window.

The important technical distinction is that it is a **norm-referenced T-score instrument**, supplied under a commercial licence rather than as a freely downloadable form. The score describes the respondent's report relative to the instrument's reference framework. It is not a raw symptom total that can be transferred into another scale's rules. The T-score metric has a mean of 50 and a standard deviation of 10. On the current interpretive scheme, 40 to 59 is the average band, 65 to 69 is Elevated, and 70 and above is Very Elevated.

These bands describe the position of a scale score, not a diagnostic verdict. An elevated profile should focus the interview: which reported behaviours are impairing, are they developmentally unexpected in that context, do they occur across relevant settings, and what alternative explanation might account for them? The result is most helpful when it sharpens questions rather than ends them. Equally, an average score should prompt review of who rated, what period they had in mind, and whether protective structure is masking difficulty in that setting.

Conners 3 also has **validity scales**: Positive Impression, Negative Impression and the Inconsistency Index. These are not accusations of dishonesty. They are prompts to consider whether the response pattern may be unusually favourable, unusually unfavourable or internally inconsistent. The correct response is clinical clarification, including a careful discussion with the informant, rather than discarding the person or treating the profile as self-explanatory.

The choice of form matters. In particular, the **short form** does not include the DSM-5 symptom scales. A short form may be appropriate for the limited question it was designed to answer, but it cannot be read as though it supplied information that it omits. This is a small technical detail with disproportionate consequences in a written answer and in a clinic note.

PITFALL

Do not call a Conners 3 result a "positive screen" and then apply a raw-score rule. Its clinical language is a norm-referenced profile and interpretive band. A high T-score signals a report that needs synthesis; it does not dispense with the rest of the assessment.

7.3 Vanderbilt: symptom screen with impairment built in

The **NICHQ Vanderbilt** scales are intended for children aged 6 to 12 years. Their practical attraction is transparency: the clinician can see the endorsed symptom responses, the associated performance ratings and the additional screening sections. Unlike a norm-referenced profile, this is a **raw-score cut-off screen**. It is free to obtain and use, but reproduction remains rights-protected; free access is not permission to republish the form in a handout, case sheet or digital product.

Its symptom items are **scored from 0 to 3, with 2 or 3 treated as positive responses**. Performance items are scored from 1 to 5, with 4 or 5 indicating impairment. This design teaches a useful clinical discipline: symptom endorsement and functional impact must be considered together. A behaviour may be frequent yet not show the impairment pattern required by the form's screening logic; impairment without the relevant symptom pattern requires a broader explanation.

For its ADHD screen, Vanderbilt requires **at least 6 positive responses in the inattentive nine or the hyperactive nine, or both, plus at least one performance item scored 4 or 5**. This is a form-specific decision rule, not a universal conversion key for other questionnaires. The phrase "or both" is important: a clinician should not force a report into a single neat category when the form records concerns in both symptom groupings.

The form also **screens oppositional-defiant/conduct and anxiety/depression concerns alongside ADHD**. These sections are an invitation to widen the interview, not a replacement for assessment of those conditions. They protect against the narrow habit of treating every difficulty in a child with attentional complaints as merely another expression of ADHD. A screen can identify a direction of inquiry; diagnosis requires the clinical work that follows.

GOOD TO REMEMBER

When using Vanderbilt results, document both sides of the screen: the symptom pattern and the performance information. This makes the reasoning visible and avoids the misleading shorthand of reporting only a symptom total.

7.4 SNAP-IV: transparent raw-score monitoring

SNAP-IV is another raw-score screen. Each item is **scored from 0 to 3: not at all, just a little, quite a bit or very much**. The response anchors are clinically helpful because they make the informant's judgement of frequency or intensity explicit. They do not establish a diagnosis by themselves, and a change in raw score should be interpreted alongside what has changed in the setting, the informant and everyday functioning.

The common form has 26 items, organised as items 1 to 9 for inattention, 10 to 18 for hyperactivity/impulsivity, and 19 to 26 for opposition/defiance. The domain labels can guide scoring and interpretation without reproducing protected item wording. In an answer, state the domains and the scoring structure rather than attempting to recite questionnaire items from memory. That approach is both safer and clinically more useful.

Suggested guidance for each ADHD subscale is **below 13 not clinically significant, 13 to 17 mild, 18 to 22 moderate and 23 to 27 severe**, from a possible total of 27. These are suggested severity bands, not a validated diagnostic cut-off. That distinction matters: a severity label may help describe a rating pattern or monitor it over time, but it should not be presented as proof that a diagnostic threshold has been met.

For the opposition/defiance subset, suggested guidance is **below 8 not clinically significant, 8 to 13 mild, 14 to 18 moderate and 19 to 24 severe**, from a possible total of 24. This section can bring disruptive interaction patterns to attention, but it does not establish a disorder in its own right. Where this screen is clinically salient, the relevant differential and comorbidity assessment belongs in the wider child psychiatric formulation and in the Child behavioural, emotional and other disorders notes.

SNAP-IV is a **raw-score screen with reproduction rights reserved**. It may be available for use, but copying it into an unapproved clinic template, online portal or teaching booklet is a separate permission question. The same distinction applies to Vanderbilt: availability to obtain is not a blanket republication licence.

7.5 The examination contrast: metric, logic and permissions

INSTRUMENT	WHAT THE SCORE REPRESENTS	INTERPRETIVE LOGIC	ACCESS AND REPRODUCTION
Conners 3	Norm-referenced T-score instrument	Interpret the profile and its T-score band in clinical context.	Commercially licensed and purchased
NICHQ Vanderbilt	Raw-score cut-off screen	Read symptom responses together with impairment.	Free to obtain and use, but not free to republish
SNAP-IV	Raw-score cut-off screen	Use its stated scoring guidance without converting it into a diagnostic proof.	Free to obtain and use, but not free to republish

The table captures the distinction worth writing before any detail. Conners 3 is the norm-referenced T-score instrument that is bought; Vanderbilt and SNAP-IV are raw-score screens that may be obtained and used without charge but may not be freely reproduced. This is not mere administration. The metric tells the clinician whether the output is a standard-score profile or a form-specific raw-score screen. The licence tells the clinician whether a familiar form may lawfully be copied into routine materials.

A norm-referenced score and a raw score answer different descriptive questions. A T-score locates a scale result on the instrument's standard-score metric; it is especially useful when the profile and its interpretive band are the clinical focus. A raw score preserves the form's own endorsed responses and scoring rule; it is especially useful when the clinician wants to see exactly how the rule was met and whether the form also requires evidence of impairment. Neither metric is intrinsically more diagnostic. The error is to pretend that they have the same denominator, the same reference frame or the same implication for clinical formulation.

For the same reason, do not compare a numerical change on one scale with a numerical change on another as though the amounts were equivalent. A change has meaning only against the metric, rater, context and scoring method that generated it. In follow-up, the most defensible comparison is usually within the same instrument and informant, with a narrative account of what changed in the child's daily functioning. If a different form is required, record the transition clearly rather than constructing a false trend line.

MNEMONIC

SCALE

Source of report, **C**onstruct measured, **A**ge range, **L**ogic of the score, **E**xceptions and permissions. Use this spine before interpreting any named scale.

TRAP **"All ADHD scales are screening tools, so their cut-offs are interchangeable" is wrong.** Similar subject matter does not make scores comparable. The instrument's own metric and decision logic must be retained.

7.6 Reading rater differences clinically

Rater difference is often where a scale becomes most valuable. The question is not which respondent is "correct" in the abstract, but what each report reveals about the interaction between the child and an environment. A child may appear settled in a highly structured setting and struggle where organisation is self-directed. Another may show difficulties mainly when tasks are boring, socially threatening, confusing or beyond current academic capacity. Such patterns should trigger contextual questions rather than an attempt to manufacture agreement.

- Check whether each rater has enough opportunity to observe the behaviour in the relevant context.
- Clarify the situations the rater used as a reference when responding to the form.
- Ask what supports, supervision or environmental adaptations were already in place.

- Explore whether a discrepancy reflects different demands rather than unreliable reporting.

This interpretive stance protects against two opposite errors. One is to dismiss a school report because the parent does not see the same pattern at home. The other is to accept a concordant report uncritically without asking whether the same developmental, emotional, academic, sensory or relational burden is producing the behaviour. Rating scales help organise the question. They cannot answer it in isolation.

The same caution applies to self-report. It can add a perspective that an adult observer cannot supply, particularly when effort, distress or internal distraction shape the reported problem. Yet self-report too is an informant account, affected by insight, language, current mood and the meaning the young person assigns to the questions. A mature interpretation neither privileges one respondent automatically nor averages away a clinically meaningful discrepancy. It places each response beside the context from which it came.

7.7 Documentation, repeat measurement and Indian practice

When a scale contributes to the record, document the instrument, informant, version used, date, scoring method, salient result and the clinical interpretation. Record whether the result was consistent with the rest of the assessment and what uncertainty remains. This is preferable to writing "ADHD scale positive", a phrase that erases the difference between a T-score profile, a symptom-and-impairment screen and a raw-score severity guide.

Repeat measurement can be useful when the same instrument, rater and scoring method are retained, because it makes change easier to follow. But it should not be mistaken for a simple outcome score. A shift may reflect a changed school context, a different respondent, altered expectations, a new stressor or better understanding of the questions. Clinical improvement must therefore be anchored in functioning and the account of the child and family, not only in a numerical movement.

IN INDIA

Clinic teams often build reusable parent and teacher packs. Keep the scoring sheet, consent process and clinical interpretation separate from the copyrighted instrument itself. Conners 3 requires commercial licensing; Vanderbilt and SNAP-IV may be obtained for use but their reproduction is rights-protected. This small administrative discipline prevents a routine template from becoming an unauthorised republication.

Name the scale, then state its rater, age range, score metric and decision logic before interpreting the result.

8 · Comorbidities of ADHD (ODD, learning disorder, anxiety, tics)

Comorbidity is the rule, not a footnote. In ADHD, the presenting complaint may be distractibility, restlessness, poor homework completion, temper outbursts, school refusal, or an apparently simple behavioural problem. The clinical task is to decide which difficulties belong to

ADHD, which represent a co-occurring disorder, and which arise from the interaction between the two. **Comorbidity** is common, and a child may have multiple additional disorders. That fact changes formulation, the sequence of intervention, and the way the family understands apparent treatment failure.

A diagnostic formulation that stops after identifying ADHD often explains only part of the impairment. Co-occurring externalising symptoms may make conflict the most visible problem; anxiety may make inattention look situation-bound; a learning difficulty may turn ordinary classroom demand into daily demoralisation; and tics may complicate the history of movements and medication concerns. The point is not to turn every difficulty into another label. It is to test whether the additional pattern has its own persistence, context, developmental meaning, and functional consequence.

Common	Externalising	Learning	Anxiety
COMORBIDITY BURDEN	MAY DOMINATE REFERRAL	MAY AMPLIFY IMPAIRMENT	MAY ALTER PRESENTATION

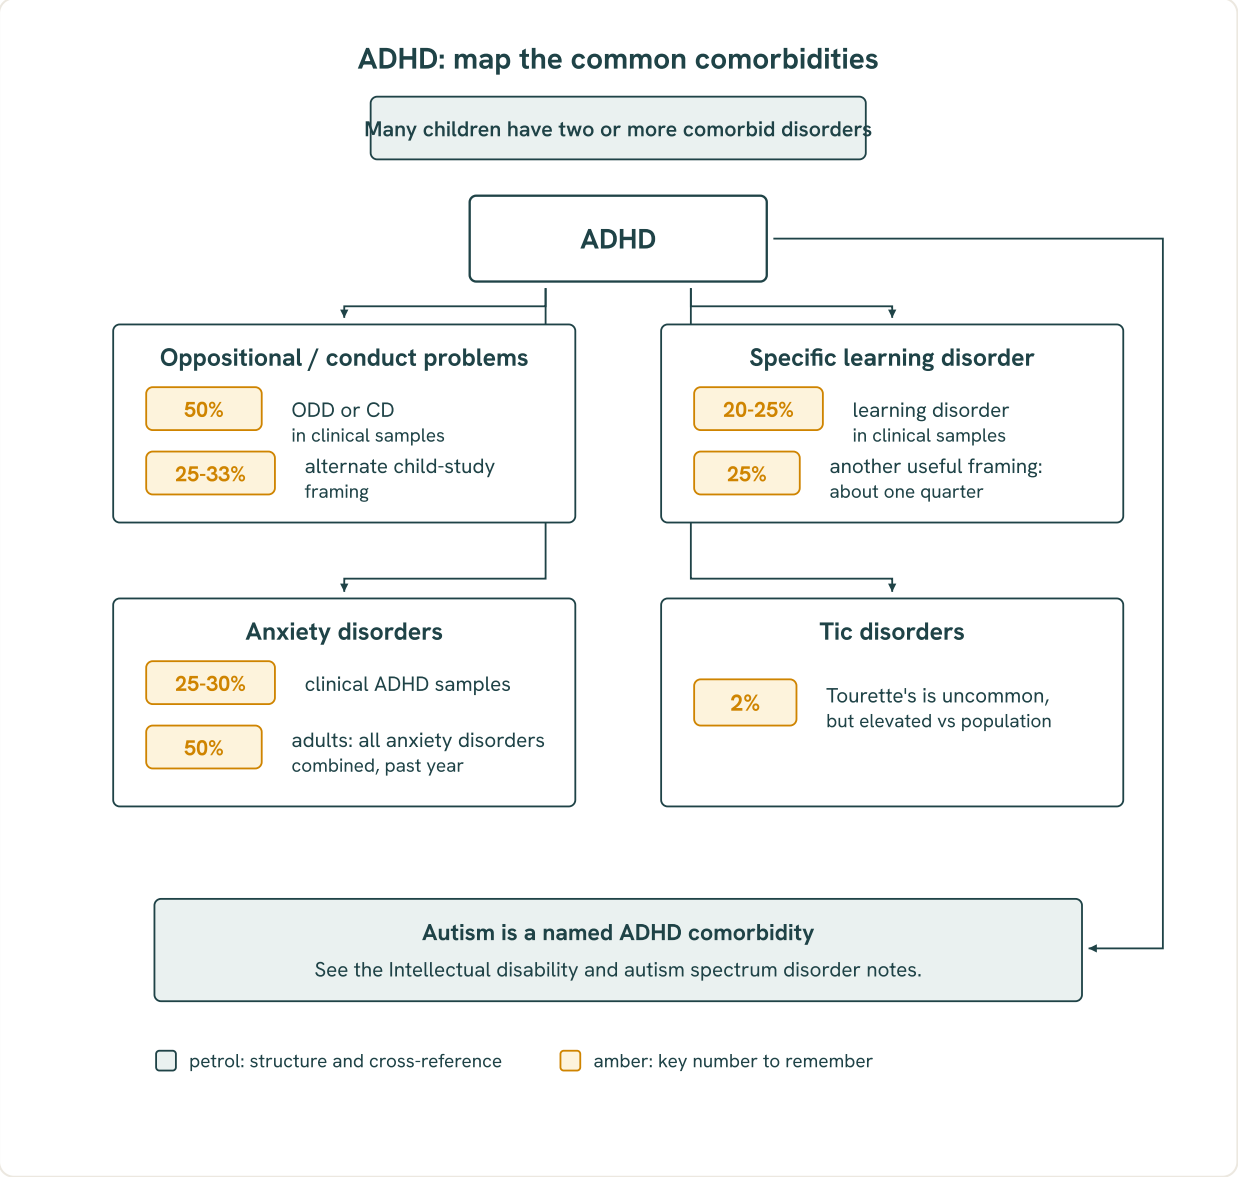

Fig 22.8. ADHD comorbidity map: high-yield associations and the autism cross-reference.

8.1 The comorbidity formulation

Think of the assessment as an effort to separate a *shared consequence* from a *second syndrome*. Poor concentration can follow worry, boredom, repeated academic failure, conflict at home, inadequate sleep, or a primary attention disorder. Irritability can be a reaction to repeated correction, an externalising pattern, an affective symptom, or a child's depleted response to chronic demand. The clinician therefore asks not only, "Is this symptom present?" but also, "When does it occur, what reliably evokes it, and what remains when the immediate trigger is absent?"

This is especially important because impairment is cumulative. A child with ADHD may be able to compensate in a supportive environment, yet become markedly dysregulated when faced with a reading task, peer conflict, fear of failure, or a prolonged bedtime struggle. Conversely, a symptom that appears to be a comorbidity may recede when the core ADHD-related demands are understood and the environment is adjusted. The formulation should preserve this uncertainty rather than prematurely converting every association into a separate diagnosis.

RULE **Diagnose a comorbidity when it adds a coherent pattern of symptoms and impairment, not merely because ADHD is severe.** Ask what the additional formulation explains that ADHD alone does not explain, and whether it persists across the situations in which it would be expected to appear.

For practical work, make a problem list before making a diagnostic list. Record the child's attention and activity difficulties, then separately map academic functioning, oppositional interactions, mood and worry, motor or vocal phenomena, sleep, peer functioning, and the family response. A problem list prevents a familiar error: allowing the loudest complaint to erase quieter but clinically decisive difficulties. It also gives a sensible way to revisit the formulation after intervention, when the relative contribution of each difficulty may become clearer.

- Identify the complaint that brought the family or school to attention.
- Ask which setting makes the difficulty most obvious and which setting protects against it.
- Clarify the sequence between demand, emotion, behaviour, and consequence.
- Determine whether the additional symptoms have a pattern independent of immediate frustration.
- Link each problem to a concrete domain of impairment rather than to diagnostic language alone.

8.2 Externalising comorbidity: opposition, conduct problems, and the referral trap

Oppositional defiant disorder and conduct disorder are frequent companions of ADHD in clinical practice. In clinical ADHD samples, oppositional defiant disorder or conduct disorder together occur in **about 50%**. This estimate is sample-dependent and should never substitute for an assessment: referral pathways and the way disorders are grouped both influence what a clinic reports.

The central clinical distinction is between *reactive non-compliance* and a broader oppositional pattern. A child with ADHD may refuse when a task is lengthy, poorly structured, humiliating, or delivered after a chain of reprimands. That behaviour calls for analysis of antecedents, expectations, and support. A co-occurring oppositional disorder is considered when the pattern extends beyond isolated task frustration and contributes its own recurring interpersonal impairment. Conduct problems require similarly careful separation from impulsive acts, developmental immaturity, and behaviour that is primarily retaliatory or peer-mediated.

ADHD can increase the speed with which an interaction escalates. The child acts before considering consequences; adults become more directive; correction becomes frequent; and both parties can enter a coercive loop. That mechanism does not by itself establish a disruptive-behaviour disorder. Equally, it must not be used to minimise persistent aggression, deceitful behaviour, serious rule violation, or marked hostility. These have their own clinical and safeguarding implications and should be assessed directly.

CLINICAL QUESTION	ADHD-LINKED DIFFICULTY	POSSIBLE ADDITIONAL EXTERNALISING FORMULATION	WHY THE DISTINCTION MATTERS
What precedes refusal?	Demand, boredom, delay, or disorganisation may be prominent.	The pattern may continue beyond task demands and occur within many relationships.	It directs attention toward structure and relational context, not labels alone.
What is the emotional tone?	Frustration may follow repeated failure or correction.	Persistent angry, defiant, or hostile interactions may require their own formulation.	It avoids mistaking understandable distress for wilful misconduct.
What is the behavioural pattern?	Acts may be rapid, poorly considered, and followed by regret.	More organised or recurrent conduct concerns need a fuller risk assessment.	It affects the urgency and breadth of intervention.
Where is the impact?	Impairment may centre on task completion and classroom regulation.	Conflict may be pervasive across home, school, and community settings.	It clarifies whose report and which settings need close scrutiny.

PITFALL

Calling every angry refusal "opposition" hides the function of the behaviour. Before naming an externalising comorbidity, ask whether the child is escaping an impossible task, responding to shame, protecting against anticipated failure, or reacting to an interaction that has already become adversarial. This does not excuse harmful behaviour; it makes the intervention more accurate.

The disorders themselves, their diagnostic boundaries, and their management are covered in the *Child behavioural, emotional and other disorders notes*. Here, the practical message is narrower: ADHD plus an externalising pattern often creates more impairment than either presentation

appears to create in isolation, so the clinical formulation must include both the child's self-regulation difficulty and the interpersonal system in which it repeatedly unfolds.

8.3 Specific learning disorder: when academic failure is more than inattention

Specific learning disorder is a clinically important comorbidity in ADHD. Clinical ADHD samples report it in the **20-25%** range, while another source describes learning and language disorders in **about 25%** of children with ADHD. The educational impact is often disproportionate because the child must manage both the task-specific difficulty and the organisational demands of schoolwork.

Do not infer a learning disorder solely from poor marks, unfinished work, careless mistakes, avoidance of homework, or a parent's report that the child "does not study." These can arise from ADHD, an unsuitable learning environment, emotional distress, inconsistent attendance, or an unrecognised language-related difficulty. Equally, do not assume that ADHD accounts for all academic underachievement. A child who performs poorly despite interest, support, and adequate attention to a particular academic task may need a focused learning assessment.

The useful question in an ADHD clinic is not "ADHD or learning disorder?" but "What is the contribution of each?" Attention problems can reduce the quantity and consistency of practice. A specific learning difficulty can make effort inefficient, expose the child to repeated failure, and generate avoidance that resembles inattention. Once a task becomes associated with humiliation, the child may appear restless, oppositional, anxious, or disengaged only in that context. The formulation should therefore connect symptom pattern to the actual work the child is asked to do.

Obtain examples of the child's work, identify whether the difficulty clusters around particular academic demands, and compare performance under ordinary classroom conditions with performance when the task is broken down and attention is supported. Reports from school are most useful when they describe the task, the error pattern, the help offered, and the child's response to help. A global judgement such as "weak student" provides little clinical information and often imports stigma into the case formulation.

IN INDIA

School records, notebooks, examination history, and teacher observations can be exceptionally informative, but they must be read in context. Medium of instruction, changes in schooling, access to remedial support, family resources, and the child's opportunity to practise may all shape the record. Treat school labels as prompts for inquiry rather than as diagnostic conclusions. The definition, formal assessment, and educational route for specific learning disorder are addressed in the learning disorder sections of this chapter.

The full ADHD-versus-learning-disorder discrimination belongs in the chapter's dedicated comparative section. At this point, preserve both possibilities in the formulation and avoid a false either-or conclusion. That protects the child from being described as simply inattentive when

remedial needs are missed, and from being described as simply learning-disabled when support for ADHD-related regulation is also required.

8.4 Anxiety: quiet suffering behind apparent inattention

Anxiety disorders are also common in ADHD. Clinical samples report any anxiety disorder in the **25-30%** range. Anxiety may be conspicuous through avoidance, reassurance seeking, somatic complaints, tearfulness, or distress around separation and performance. It may also be quiet: the child sits still, appears to daydream, postpones tasks, and is interpreted as inattentive when the active mental process is worry.

The phenomenology matters. ADHD-related inattention is often variable with interest, novelty, structure, and competing stimulation. Anxiety-related concentration difficulty may be most evident when the child is preoccupied by threat, anticipated criticism, uncertainty, or a feared task. These patterns can coexist in the same child, and their interaction can be self-reinforcing. Disorganisation creates missed deadlines or negative feedback; these experiences increase apprehension; apprehension consumes working attention; and the child then performs even less effectively.

Ask what the child is thinking during the period described as "not concentrating." A report of worry, dread, fear of error, or mental rehearsal points the assessment toward anxiety. Ask also about avoidance, bodily sensations, sleep-related fears, and the meaning of school or social situations. Do not rely on the child's direct denial of anxiety alone. Children may have limited language for internal states, may fear disappointing adults, or may describe their experience through behaviour rather than words.

> **GOOD TO REMEMBER**
> An anxious child with ADHD may look less overtly hyperactive in a formal consultation than in daily life. Quietness in the room is not evidence that the attention disorder has disappeared, and activity at home is not evidence that all school avoidance is ADHD. Reconcile reports by examining the emotional demands of each setting.

Clinical priorities follow impairment, risk, and the child's capacity to engage. When anxiety is driving avoidance, a plan that only demands better organisation can feel punitive and may fail. When ADHD-related disorganisation is feeding anxiety, practical scaffolding may reduce anticipatory distress. Families benefit from hearing that both processes can be real at once. This explanation shifts the conversation away from blame and toward a shared map of the child's difficulties.

8.5 Tics, sleep, developmental coordination, and autism: name the association, assess the child

Tourette's disorder is uncommon but clinically relevant in ADHD, occurring in **about 2%** of affected children. The practical issue is not to make an assumption from a single observed movement or sound. Clarify the phenomenology with the child and family, the temporal pattern, the settings in which it occurs, and the degree of distress or interference. The assessment should

also distinguish tics from restlessness, habitual movements, medication concerns, anxiety-linked behaviours, and other repetitive phenomena.

Tics and Tourette's disorder as disorders in their own right are covered in the *Child behavioural, emotional and other disorders notes*. In an ADHD formulation, document the movement or vocal history carefully enough that later change can be interpreted meaningfully. A family may attribute every fluctuation to ADHD treatment, while a clinician who does not establish the baseline may be unable to decide whether a reported change reflects the natural course, heightened observation, stress, or an intervention-related concern.

Sleep disorders have a high prevalence in children with ADHD. Sleep can be both a co-occurring problem and a source of symptoms that resemble ADHD, so it deserves a direct history rather than a perfunctory question about bedtime. Establish the family's account of sleep opportunity, sleep routine, nocturnal disturbance, waking, daytime sleepiness, and the relationship between sleep quality and daytime regulation. The differential diagnosis of sleep-related attentional symptoms is addressed in the ADHD differential diagnosis section.

Developmental coordination disorder is a common ADHD comorbidity. Notice when the child's functional difficulties include everyday motor demands, handwriting burden, sports participation, self-care tasks, or avoidance of activities that expose clumsiness. The purpose at this stage is to recognise that these difficulties may not be explained by inattention alone. The disorder's definition and assessment belong in the communication and motor disorders section.

Autism spectrum disorder may also be named in an ADHD formulation. Do not use this brief comorbidity note to collapse the two developmental histories into one or to make assumptions about prevalence, diagnostic rules, or treatment response. For that discussion, see *the Intellectual disability and autism spectrum disorder notes*.

TRAP **Do not let a recognised comorbidity become a diagnostic shortcut.** A tic does not explain every movement, a learning concern does not explain every unfinished task, and anxiety does not automatically replace ADHD. Each requires its own history, observed impact, and place in the overall formulation.

8.6 Mood symptoms and the longitudinal formulation

Children with ADHD have an increased risk of mood disorders, which may emerge later. In practice, this calls for a longitudinal rather than purely cross-sectional formulation. A child's irritability today may be tied to conflict, anxiety, sleep disruption, demoralisation, environmental stress, or a mood disorder. The clinician should avoid treating the word "mood" as an explanation in itself. Describe the emotional state, its triggers, the change from the child's usual functioning, its relationship to activity and sleep, and the consequences for safety and functioning.

This part of assessment is often more useful when conducted across contacts. Families may initially prioritise disruptive behaviour and disclose hopelessness, withdrawal, or self-critical thinking only after they feel understood. Teachers may notice a decline in engagement rather than verbal sadness. The child may frame the experience as anger, boredom, or physical

discomfort. A careful formulation welcomes these different descriptions and asks whether they fit one process or several.

Where significant mood symptoms are present, assess immediate risk and the supports available to the child. Do not attribute serious distress to ADHD merely because ADHD is already established. At the same time, do not assume that every tearful or irritable period establishes a mood disorder. The useful clinical stance is active curiosity: identify the pattern, obtain collateral, review change over time, and decide what needs attention now while diagnostic certainty develops.

8.7 Turning recognition into a workable plan

The plan follows the formulation, not the order in which diagnoses were noticed. Begin by stating, in plain clinical language, the contribution of ADHD and each suspected or established comorbidity to the child's current impairment. This makes priorities visible. A family can then understand why academic support, emotional work, sleep assessment, behavioural intervention, school liaison, or risk management may be needed alongside ADHD treatment.

MNEMONIC

PAUSE

Problem list, **A**ntecedents, **U**nique pattern, **S**ettings, **E**xtra impairment. Use it to slow down before deciding that a difficult behaviour is either "just ADHD" or automatically a new disorder.

Prioritisation is clinical rather than ideological. Address urgent risk, severe suffering, major barriers to participation, and the factors most likely to prevent the child from benefiting from care. Revisit the formulation after support is introduced. Improvement in one domain can reveal another more clearly: a child whose attention becomes easier to support may then show a specific academic need; a child whose anxiety reduces may provide a more reliable account of attention; a child whose home conflict diminishes may show that apparent defiance was closely tied to coercive interactions.

- Share a formulation that separates symptoms, settings, triggers, and impairment.
- Agree which problem needs action now and which needs observation or further collateral.
- Coordinate with caregivers and school around functional goals rather than labels alone.
- Review whether the working formulation still explains the child's difficulties after intervention.

Comorbidity is therefore not an add-on to an ADHD assessment. It is the reason the clinician must remain both structured and humble: structured enough to look beyond the core syndrome, and humble enough to revise an early explanation when the child's developmental, emotional, academic, and relational pattern says more is happening.

In ADHD, identify the additional pattern of impairment before deciding the additional diagnosis, then let the combined formulation determine what must be addressed first.

9 · Differential diagnosis of ADHD

The diagnostic task is explanatory, not merely descriptive. Inattention, activity and impulsive behaviour are common final presentations in child psychiatry. ADHD is diagnosed only when its core pattern is the best account of the child's difficulties, rather than a label applied to any restless, poorly performing or hard-to-manage child. Differential diagnosis therefore asks what the behaviour means in its developmental, emotional, social and medical context.

The practical stakes are substantial. A false ADHD diagnosis can obscure distress, a communication difficulty, a sleep problem or a treatable medical contributor. The converse error is **diagnostic overshadowing**: dismissing developmentally inappropriate ADHD symptoms as inevitable within another disorder. Good differential work protects against both errors and leaves room for more than one diagnosis when the evidence supports it.

Developmental	Psychiatric	Medical
CAPACITY AND PHENOTYPE	COURSE AND EXPERIENCE	CONTRIBUTORS AND MIMICS

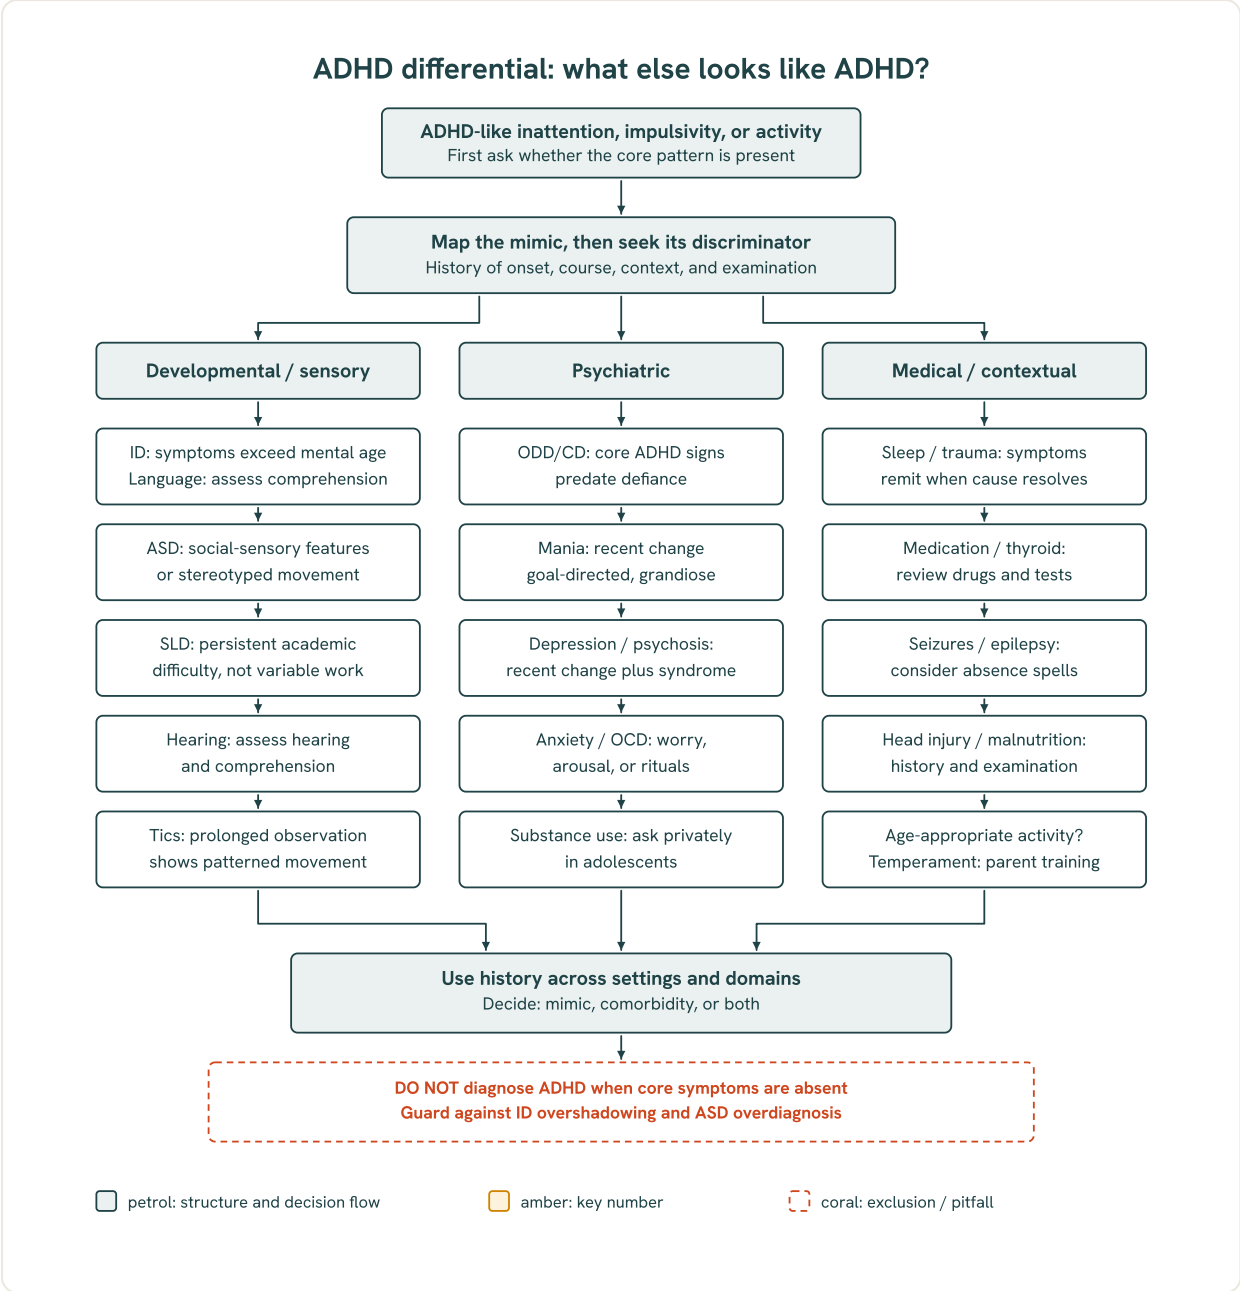

Fig 22.9. ADHD differential tree: common mimics and the short clinical clues that exclude them.

9.1 A structured way to think about the differential

Begin with a broad **developmental, psychiatric and medical differential**, rather than moving immediately from a parent's description to a syndrome label. The **three** groupings organise the possibilities: developmental presentations include intellectual disability, speech and language disorders, learning disorders, motor coordination disorders, autism spectrum disorder and tic disorders; psychiatric presentations include oppositional defiant disorder, conduct disorder, mood and anxiety disorders, psychotic disorders and substance use; medical presentations include epilepsy, tics, seizures, malnutrition and thyroid abnormalities. They are a map for enquiry, not a claim that every child requires every investigation.

At each branch, ask a small set of linked clinical questions.

- Has the behaviour always been characteristic, or does it represent a change from the child's usual state?

- Does the apparent failure to attend arise because the child cannot understand, is preoccupied, is exhausted, or is responding to an internal experience?
- Is movement purposeless and diffuse, patterned and repetitive, or directed toward a particular aim?
- Is the pattern best explained by one condition, by coexisting conditions, or by a contextual stressor?

These questions translate a parent's accurate observation into clinically usable data. They prevent the common mistake of treating a symptom word as though it were a diagnosis. They also make contradictory reports useful: a child who is distractible only in one kind of demand may be telling the clinician more about task capacity or context than about a pervasive attentional problem. The aim is analytic economy: each proposed explanation should account for the observed pattern without making the remainder of the history unintelligible, and should remain compatible with all available collateral. This discipline keeps the formulation honest.

Developmental history, school observations and the mental-state examination supply different parts of this answer. The assessment process itself belongs in the Child psychiatry: assessment, treatment, services and protection notes. Here, the central interpretive discipline is to compare the observed behaviour with the child's developmental capacities and with its temporal course.

RULE **Diagnose ADHD only when its core pattern explains the presentation better than a mimic or contributor.** A symptom such as poor concentration has little diagnostic value until its developmental meaning, onset, context and accompanying features have been established.

9.2 Developmental and educational presentations

Intellectual disability may look like ADHD when a child fails to follow instructions, abandons tasks or appears inattentive. The decisive question is whether the child understood what was asked. In intellectual disability, apparent inattention may be better accounted for by limited comprehension; ADHD should be added only when the symptoms are clearly **developmentally inappropriate for the mental age**. This is not a semantic nicety. It distinguishes failure at a task beyond the child's capacity from a regulatory difficulty at a task the child can perform.

Do not allow a global developmental diagnosis to end the enquiry. Establish the child's usual level of understanding, then examine behaviour in tasks matched to that level. A child who remains markedly distractible or impulsive despite clear, comprehensible demands may have ADHD in addition to intellectual disability. Conversely, repeated demands that exceed comprehension can create frustration, escape behaviour and apparent non-compliance without demonstrating ADHD. For the wider framework, see the Intellectual disability and autism spectrum disorder notes.

Speech and language disorders, hearing impairment and specific learning disorder may also surface through classroom inattention or failure to follow instructions. Undetected hearing impairment deserves active consideration when this is the presentation. Specific learning disorder should be named as a differential. Its academic difficulty tends to be persistent, whereas

ADHD performance can be strikingly variable. See Differentiating SLD from intellectual disability, ADHD and slow learner for the complete comparison.

High activity in a young child is not, by itself, pathology. In preschoolers, supposed symptoms may reflect normal development or temperament; in that circumstance, refrain from an ADHD diagnosis and offer parent training rather than converting an ordinary developmental challenge into a disorder. The developmental and temperament framework is set out in the Normal child development and milestones notes.

IN INDIA

The IPS clinical guidance supports a deliberately broad developmental, psychiatric and medical differential. In busy school-referral practice, "does not listen" is often a presenting complaint rather than a diagnosis. Clarify whether the instruction was heard, understood and developmentally achievable before interpreting the behaviour as inattentiveness.

9.3 Autism, motor phenomena and the form of activity

Autism spectrum disorder can produce behaviours that resemble ADHD, but their form and context matter. In autism, increased motor activity may be **repetitive and stereotyped**, unlike the broader hyperactivity of ADHD. Some apparently ADHD-like behaviours are better understood through sensory difficulties or atypical socio-emotional reciprocity. The question is not whether the child is active, inattentive or difficult to engage; it is what precipitates the behaviour, what function it serves, and whether it is embedded in the autism phenotype.

There are errors in both directions. It is wrong to call sensory-driven avoidance, a difficulty reading a social demand, or repetitive movement "hyperactivity" without further analysis. It is equally wrong to assume that a child with autism cannot also have ADHD. The task is to decide whether developmentally inappropriate ADHD symptoms are present beyond what autism explains. The wider autism framework and the co-occurrence discussion are in the Intellectual disability and autism spectrum disorder notes.

Tic disorders require observation over time rather than a snapshot at one interview. Prolonged observation helps separate complex motor tics in Tourette's disorder from ADHD-associated fidgetiness and increased activity. This is especially useful when the movement is intermittent, complex or embarrassing, because the child may suppress it briefly in a clinic. The phenomenology and management of tics belong in the Child behavioural, emotional and other disorders notes.

TRAP **Do not equate every visible movement with hyperactivity.** Repetitive movement, a tic, sensory-related distress and diffuse ADHD overactivity may all look "restless" from a distance, but they imply different questions and different formulations.

9.4 Disruptive behaviour and emotional disorders

Oppositional or conduct symptoms can dominate the consultation and tempt the clinician to infer ADHD from poor behaviour alone. **Chronology** is the useful discriminator: ADHD symptoms usually predate defiant or conduct symptoms. Defiance without the core ADHD

pattern is not a basis for diagnosing ADHD. In very severe ADHD, oppositional behaviour may arise soon after the attentional and activity difficulties begin, so chronology must be interpreted carefully rather than applied mechanically.

With mood disorders, ask whether the child has changed from their usual state. **Mania** has a relatively recent onset and a definite change from premorbid functioning; its activity is goal-directed, and inflated self-esteem or grandiosity points away from uncomplicated ADHD. The contrast is particularly important when a previously manageable child becomes overactive. Chronic activity alone does not establish mania, and episodic change alone should not be mistaken for a lifelong neurodevelopmental pattern.

Depression can be masked by irritability, agitation and poor concentration. It too is marked by relatively recent onset and a change from the prior state, with features such as decreased interest in pleasurable activities that exceed simple irritability. The clinician should not treat concentration as an isolated cognitive symptom. It belongs to an affective pattern, and the timing of that pattern is often more informative than the intensity of the classroom complaint.

Anxiety commonly brings poor concentration, distractibility and generalized hyperarousal. Worry and autonomic arousal support anxiety as the explanation. Explore the child's thoughts as well as their behaviour: the child whose attention is repeatedly captured by threat or worry may appear inattentive, yet the mechanism is preoccupation rather than the core ADHD pattern. Severe anxiety, including post-traumatic stress disorder, and distress after life events can mimic ADHD; when symptoms remit after the stressor is removed, that course weighs against true ADHD.

PITFALL

Calling a distressed child "ADHD" because the behaviour is disruptive can delay recognition of a new affective or anxiety state. The discriminating work lies in establishing change from baseline, accompanying experience and the relationship of symptoms to stressors.

9.5 Psychosis, compulsions and substance use

Psychosis can include behavioural disorganisation and apparent distractibility, but it generally represents a relatively recent change from premorbid functioning and is accompanied by delusions or hallucinations. The interview should make room for the child or adolescent to describe unusual perceptions and beliefs in language they can use. Such enquiry should be calm and direct; it is not made unnecessary by an existing ADHD diagnosis.

Obsessive-compulsive disorder may also be mistaken for overactivity when the child repeatedly performs acts, cannot move on from routines, or seems slow to begin work. The behaviour in obsessive-compulsive disorder is goal-directed and ritualistic, and concurrent obsessions may be present, unlike the non-goal-directed overactivity of ADHD. Ask what the child fears would happen if the act were not completed. That question clarifies the function of repetition without requiring the clinician to infer it from appearance alone.

Substance use belongs in the psychiatric differential, particularly among older children and adolescents, and must be discussed with privacy. The practical aim is not a moral interrogation but a credible account of when symptoms occur and what may be contributing to them. A private, developmentally appropriate conversation gives the young person a better chance of disclosing use or related risk. It also prevents the clinician from attributing a change in concentration or behaviour automatically to ADHD.

9.6 Sleep, physical illness and medication effects

Sleep disorders can present with inattention, poor impulse control, mood change and daytime sleepiness that resemble ADHD. Sleep-disordered breathing deserves particular attention because suspicion of it warrants sleep evaluation. The value of sleep enquiry is not confined to excluding a mimic: a sleep problem may coexist with ADHD and amplify the functional presentation. Establish the pattern of sleep and daytime alertness before deciding that poor classroom concentration is purely attentional.

Medical history should actively seek acquired and physiological contributors. ADHD-like problems may follow head injury and may be secondary to thyroid disorders or absence seizures; genetic syndromes such as fragile X are rare possibilities. The history should be directed by the presentation rather than reduced to a routine list. A new or fluctuating pattern, altered awareness, physical symptoms or a temporal link to illness makes a medical explanation more plausible and requires appropriate evaluation.

Medication review is equally part of differential diagnosis. Bronchodilators, thyroxine, neuroleptics through akathisia, and isoniazid can be associated with ADHD-like symptoms. Map the timing of behavioural change against medication exposure and distinguish a drug-related restlessness from the child's baseline pattern. This is especially important when a family reports that a previously settled child became restless after treatment began.

> **GOOD TO REMEMBER**
>
> When a child has ADHD-like behaviour plus sleepiness, altered awareness, physical symptoms or a clear medication temporal association, pause before escalating an ADHD formulation. These clues redirect the clinical interview toward a potentially remediable contributor.

9.7 Resolving uncertainty without premature closure

Many referrals contain both a genuine ADHD pattern and another source of impairment. Differential diagnosis should not be treated as a contest in which one label must eliminate every other possibility. The better formulation identifies which phenomena are explained by ADHD, which are explained by another condition, and which require observation over time. This preserves diagnostic precision without denying comorbidity.

When the history is incomplete, resist the pressure to convert uncertainty into certainty. Reconstruct the child's baseline, the sequence in which concerns emerged, and the circumstances in which they improve or worsen. Repeated reports across home and school are useful because they test whether a proposed explanation has coherent reach. A stress-related presentation, for

example, is less convincing as ADHD when it lifts after the stressor is removed; a developmental explanation is weaker when behaviour is plainly disproportionate to the child's capacity.

The overdiagnosis error is particularly instructive: labelling autism-related social or sensory features as ADHD. Its mirror image is diagnostic overshadowing in intellectual disability. These **two** failure modes are corrected by detailed interviewing and by collecting information across situations and domains. The goal is not maximal diagnostic complexity. It is the smallest adequate explanation that remains open to revision when new information appears.

Use the table as a prompt for hypothesis testing, not as a shortcut to diagnosis. No row is intended to work in isolation. A recent change, for example, gains meaning when it is linked to the quality of activity, the child's account of inner experience, and corroboration from those who know the child well. Conversely, the absence of a conspicuous alternative does not by itself prove ADHD. A coherent longitudinal account remains more useful than a checklist of isolated signs.

CLINICAL SIGNAL	INTERPRETATION THAT SHOULD BE TESTED	REASONING CONSEQUENCE
Recent change from usual functioning	mania, depression or psychosis	Seek the new syndrome rather than assume a longstanding neurodevelopmental pattern.
Failure to follow directions	lack of comprehension or hearing impairment	Match the demand to capacity and establish whether it was heard.
Repetitive or intermittent movement	repetitive, stereotyped movement or complex motor tics	Describe form, trigger and persistence before calling it hyperactivity.
Worry, fear or bodily arousal	Anxiety	Explore the cognitive and physiological context of poor concentration.
Sleepiness or altered awareness	Sleep disorder or absence seizures	Redirect the history toward sleep and medical causes.
Clear relation to treatment exposure	Medication effect	Map symptom timing against medication use before changing the psychiatric formulation.

MNEMONIC

Course, Capacity, Context, Character of movement

Use this as a compact differential spine. Ask whether the course is longstanding or changed, whether the demand matches the child's capacity, whether context supplies worry, stress, sleep loss or exposure, and what kind of movement is actually being described.

The differential diagnosis of ADHD is settled by developmental appropriateness, course, context and accompanying phenomena - not by the mere presence of inattention or restlessness.

Treating ADHD

10 · Stimulant pharmacotherapy (methylphenidate, amphetamines, mechanism, dosing)

Stimulants are a prescribing exercise in precision, not a generic trial of "ADHD medicine". Their value lies in matching a clearly defined target problem to a preparation whose exposure pattern fits the child's day, then adjusting from observed benefit and tolerability. The examination answer should therefore distinguish mechanism, formulation, starting regimen, titration and ceiling. A dose without its formulation and population is not a safe answer.

Within pharmacotherapy, a stimulant is best understood as one component of an individual treatment plan. Medication can make attention and behavioural regulation more available to the child; it does not substitute for the assessment of learning, family context, classroom demands or coexisting difficulties. Those elements determine what a meaningful improvement looks like. Adverse effects, physical monitoring and the wider multimodal plan are considered in their respective sections.

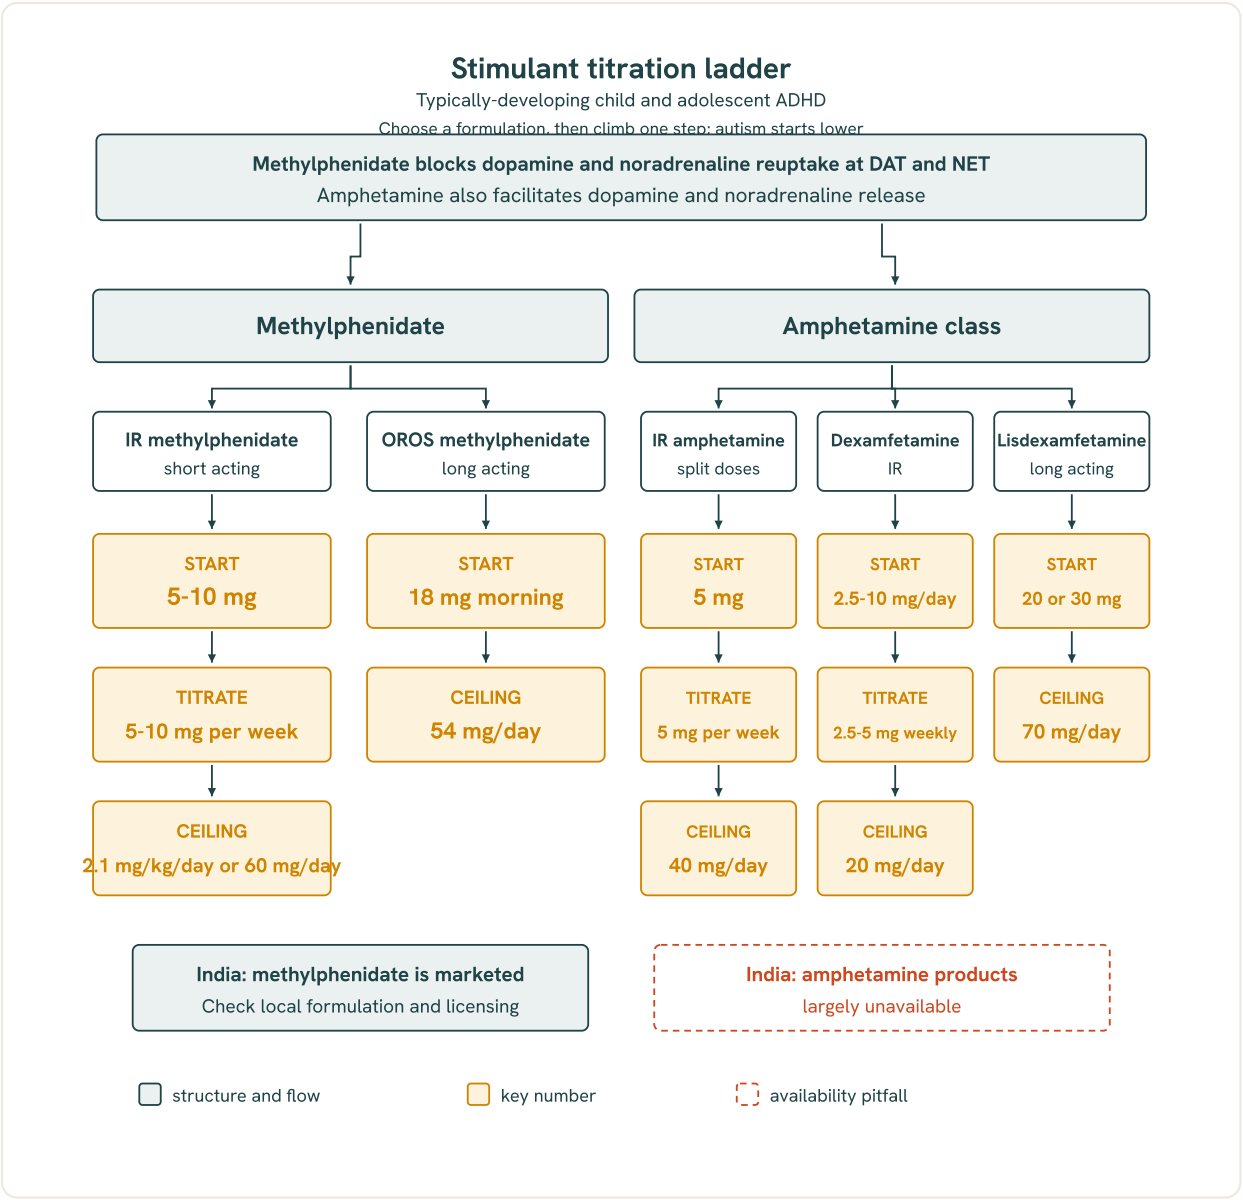

Fig 22.10. Stimulant formulation and titration ladder for ADHD.

10.1 Pharmacological logic of stimulant treatment

Methylphenidate works by reducing reuptake of dopamine and noradrenaline through the relevant transporters. The clinical inference is not that it simply "activates" a child. Rather, it changes catecholamine signalling in circuits that support the allocation and maintenance of attention, response selection and behavioural control. The desired outcome is more usable self-regulation in ordinary settings, not a sedated or compliant appearance.

The pharmacological contrast with **amphetamine** is worth stating precisely. Amphetamine both impedes reuptake and facilitates release of noradrenaline and, particularly, dopamine. Thus the classes overlap in their transporter-level targets but are not mechanistically interchangeable. This distinction helps the candidate explain why a child's response to one preparation cannot be assumed to settle the question of response to every stimulant preparation.

RULE **Prescribe the formulation, not merely the molecule.** The molecular mechanism explains the class effect; the release pattern determines when that effect is available in the child's real daily life.

The prescriber first defines the functional window that needs help. A short-acting preparation is useful when a brief, observable period is needed to establish the relation between dose and effect, or when different parts of the day require different exposure. A long-acting preparation may better suit a continuous school and home routine and can reduce the practical burden of dosing away from home. Neither formulation is intrinsically "stronger"; they solve different timing problems.

It is equally important to decide in advance what will count as benefit. Descriptions such as "more settled" are too vague to direct a dose change. A useful target is concrete and shared with caregivers and school: sustaining a task, completing work, following an instruction, reducing impulsive interruption, or participating without repeated redirection. The target must be observable across the settings in which impairment was established. If the target has not been specified, apparent non-response may actually be a failure of measurement or a mismatch between the chosen exposure window and the relevant demand.

Mechanism should therefore be used to reason, not to over-promise. Transporter actions describe a plausible pharmacological route to clinical change, but they do not tell the clinician which domain will improve most for a particular child or whether a chosen delivery pattern will fit the family's routine. The prescription remains a testable clinical decision. Its interpretation depends on the target behaviour, the setting, the timing of administration and collateral observation, rather than on a theoretical account of catecholamines alone.

GOOD TO REMEMBER

A calm child is not automatically a well-treated child. Ask whether attention, impulse control and participation have become more available in the setting that mattered to the family and school.

10.2 Methylphenidate preparations: translating mechanism into a regimen

Immediate-release methylphenidate is a practical formulation when the clinician needs a clear and adjustable relation between administration and the period of clinical benefit. It requires the family to understand that the formulation and the child population define the instruction. An immediate-release schedule should never be copied mechanically into a modified-release product, even though the active molecule is the same.

For a typically developing child with ADHD, the cited immediate-release starting regimen is **5-10 mg** orally each day, with subsequent divided administration as clinically indicated. This is a start point, not a target achieved by a calendar. It creates room to see whether the intended functional change appears during the desired period before moving further. The child's context matters: a preparation that seems ineffective may simply have its useful interval outside the school or home situation being judged.

In the same population and formulation, titration proceeds in increments of **5-10 mg per week**. Weekly adjustment gives enough clinical space to distinguish an emerging benefit from a transient impression, while preserving the principle that the regimen is adjusted purposefully. The instruction is formulation-specific and should be documented as such. Recording only

"methylphenidate increased" obscures the information needed for a later clinician to understand what has actually been tried.

The ceiling has two dimensions. For immediate-release methylphenidate in a typically developing child with ADHD, keep the weight-based total **below 2.1 mg/kg/day** in divided doses, and the licensed total **below 60 mg/day**. These are boundaries, not goals. A child who has not shown worthwhile functional benefit should not be pushed towards a numerical ceiling merely because that ceiling exists. Conversely, a partial response should prompt a disciplined question about timing, target and formulation before it is labelled a failure of the drug class.

Immediate-release prescribing is also a useful teaching model for the general principle of dose interpretation. A change in daily total, a change in the timing of administration and a change in release profile are different interventions. If they are all altered together, the subsequent response is hard to interpret. Where possible, make one purposeful alteration and record why it was made. This preserves a coherent treatment history and prevents the next decision from being based on recollection rather than clinical evidence.

The family's account should be sought in language that separates effect from expectation. Ask what the child can now do with less prompting, whether the benefit appears during the intended functional period and whether the demand itself changed. A report that the child is "fine at home" may not answer a school-time question; a school report may not answer an evening homework question. This is not a reason to demand perfect measurement. It is a reason to match the question to the formulation being assessed.

5-10 mg	5-10 mg per week	below 2.1 mg/kg/day	below 60 mg/day
IR START	IR TITRATION	IR WEIGHT CEILING	IR LICENSED CEILING

TRAP **Do not quote a methylphenidate dose without saying immediate-release or modified-release.** The molecule alone does not identify the regimen, its timing or its ceiling.

10.3 Modified-release methylphenidate and the school routine

OROS modified-release methylphenidate is designed to provide a morning-administered exposure pattern rather than a simple repetition of an immediate-release dose. Its clinical attraction is organisational as much as pharmacological: it can align medication delivery with a longer functional period while avoiding a school-time administration decision. The practical question is whether this exposure pattern fits the child's own demands, not whether a longer preparation is automatically preferable.

For child ADHD, the cited OROS starting dose is **about 18 mg** in the morning, titrated upward at weekly intervals. It should be communicated as an OROS-specific regimen. "Modified release" is not a licence to infer equivalence across products; the release design is clinically material. When a family reports that a medicine works at one point in the day and not another, the prescriber should think first about the relation between the preparation's delivery pattern and the child's functional timetable.

The licensed ceiling for this OROS preparation in child ADHD is below 54 mg/day. The word licensed matters in a textbook answer because it distinguishes an established product limit from an informal dose escalation. It also reinforces the basic discipline of identifying the exact product before discussing a maximum. A treatment review is then about whether the selected formulation has created a meaningful and durable improvement, not about chasing a number.

QUESTION	IMMEDIATE-RELEASE METHYLPHENIDATE	OROS MODIFIED-RELEASE METHYLPHENIDATE
Prescribing aim	Flexible, observable exposure periods	Morning-administered exposure across a longer functional period
How to write the order	Name the immediate-release formulation and divided administration plan	Name the OROS product and morning administration plan
Interpretation of response	Relate benefit to each intended period	Relate benefit to the child's day-long demand pattern
Common error	Treating a daily total as if timing did not matter	Assuming it is dose-for-dose interchangeable with immediate-release treatment

This formulation distinction has a wider teaching value. Medication decisions should be reversible hypotheses: "this release profile may cover this part of the child's day." A good review can confirm, refine or reject that hypothesis using collateral observations. It does not turn an imprecise prescription into a better one by attaching a diagnostic label to it.

A request for a long-acting preparation may arise from a genuine access problem, a wish to avoid medicine administration during the school routine, or a belief that a longer formulation is inherently superior. These possibilities are clinically different. The prescriber should identify the actual problem first, because the answer may be a different release profile, a clearer administration plan, or recognition that the target period itself has been defined too broadly. Formulation choice is therefore part of case formulation, not a purely administrative afterthought.

10.4 Amphetamine preparations: related class, distinct pharmacology

Amphetamine preparations require the same formulation discipline. Their additional release-facilitating action means that one should not describe them as merely another brand of methylphenidate. Clinically, the useful comparison is between a child's target window, the preparation's delivery pattern and the observed outcome, rather than an abstract hierarchy of "mild" and "strong" stimulants.

For immediate-release mixed amphetamine salts in child ADHD, the cited starting regimen is about 5 mg, given once or twice daily. The associated titration is about 5 mg per week, with a total kept below 40 mg/day in split doses. These statements belong together: drug, immediate-release formulation, child ADHD population, regimen and ceiling. Separating the number from that tuple is how a technically correct figure becomes an unsafe instruction.

Dexamfetamine immediate-release is another amphetamine-class option. In child ADHD, the cited regimen is to start 2.5-10 mg/day, increase by 2.5-5 mg weekly, and use a usual maximum of 20 mg/day in divided doses. The source permits occasional use up to 40 mg/day, but this should never be presented as the routine maximum. The key teaching point is that a regimen belongs to a named preparation, not to "amphetamine" in the abstract.

Lisdexamfetamine is a long-acting prodrug of dexamfetamine. For child ADHD, its cited regimen is 20 or 30 mg in the morning, titrated at weekly intervals, with a maximum below 70 mg/day. The distinction between this prodrug and immediate-release dexamfetamine should be explicit in an answer. The molecule ultimately delivered does not erase the different formulation design, dosing instruction or clinical timing.

PITFALL

Do not convert between methylphenidate and amphetamine products by a remembered "equivalent dose". The supplied evidence establishes formulation-specific regimens, not a universal conversion rule.

10.5 Indian prescribing context

Methylphenidate is marketed in India, making it the stimulant whose local prescribing details deserve particular familiarity. A commonly cited Indian paediatric methylphenidate approach starts at 0.25 mg/kg/day and may be increased in weekly steps up to 1 mg/kg/day, with morning and afternoon administration. This is not the same numerical ceiling as the cited immediate-release framework for a typically developing child with ADHD. The discrepancy must be acknowledged, not silently harmonised.

IN INDIA

State the source framework when documenting a weight-based methylphenidate regimen. The Indian paediatric approach and the cited immediate-release ceiling are not interchangeable. Non-stimulant pharmacotherapy is considered separately.

Local availability changes what can be prescribed, but it should not collapse pharmacological distinctions. Where a cited amphetamine preparation is not locally available, it may still be examined as an international pharmacotherapy option. The answer should say what preparation is being discussed and avoid implying that a regimen can be implemented locally without confirming the product and regulatory setting. Brand names are especially poor substitutes for this discipline because they can obscure formulation and release profile.

The Indian clinical task also includes making the prescription intelligible to the family. Explain the medicine by its purpose and its timing rather than by promising a personality change. Give caregivers a concrete target to observe and a clear instruction not to improvise a different formulation or schedule. When treatment is reviewed, place caregiver and school observations alongside the stated target. This keeps the medication decision connected to function rather than to a vague global judgement that the child is "better" or "worse".

In an examination, this local context is best handled with restraint. State the preparation and regimen that the source supports, then state the population and source framework. Do not imply availability from a foreign dosing table, and do not turn a locally marketed medicine into an assertion that every release form is available in every setting. Precision here is clinically respectful: it prevents an answer from sounding comprehensive while leaving the actual prescriber with an unusable instruction.

10.6 A disciplined sequence for choosing and adjusting a stimulant

Stimulant prescribing becomes safer when it follows a clinical sequence. First, confirm the target impairment and identify the part of the child's routine in which change is sought. Next, choose a molecule and release pattern that can plausibly address that period. Then begin with the cited formulation-specific starting regimen, explain the intended observation and adjust only against the agreed target. Finally, decide whether apparent non-response represents inadequate exposure at the relevant time, insufficient benefit despite an adequate trial, a practical problem with the regimen, or a need to reconsider the treatment plan.

- Write the drug, formulation and administration plan in full.
- State the population to which the dose schedule applies.
- Define the functional target before changing a dose.
- Use the cited titration interval rather than reacting to a single impression.
- Interpret a ceiling as a safety boundary, not as an efficacy target.

This sequence guards against an easy but consequential error: treating dose adjustment as the main therapeutic act. In fact, dose adjustment is only informative when the target, formulation and timing have been kept stable enough to interpret the result. If school information is unavailable, family observation remains useful, but its question must still be specific. If the family cannot feasibly deliver the intended regimen, that is a prescribing problem rather than a failure of adherence or motivation.

At review, distinguish a poor result from an uninterpretable result. A poor result means that the child received the intended formulation during the relevant demand period and the agreed functional target did not improve sufficiently. An uninterpretable result means that one does not know whether the preparation reached the relevant period, whether the target was observed, or whether a practical obstacle disrupted the regimen. The first finding may support a change in treatment strategy. The second requires clarification before a pharmacological conclusion is drawn.

This distinction prevents both over-treatment and premature abandonment. It also makes communication with families more honest. The clinician can say that a medication plan is being assessed against a shared functional question, not against an expectation that every difficulty will disappear. Such framing keeps the child's abilities, school needs and relationships central while still allowing pharmacotherapy to be used with technical rigour.

MNEMONIC

Target - Formulation - Start - Observe - Titrate

Before every stimulant change, name the functional target, name the release profile, begin with the relevant schedule, observe in the intended setting and titrate only when that observation can be interpreted.

A stimulant dose is safe and meaningful only when the drug, formulation, child population, schedule, titration plan and ceiling are stated together.

11 · Non-stimulant pharmacotherapy (atomoxetine, alpha-2 agonists)

Non-stimulants are not merely substitutes for stimulants. They offer a different pharmacological route to treating ADHD, and therefore require a different conversation with the child, family and school. The important distinctions are mechanism, the pace at which benefit is judged, formulation, and the safety issue that must be made explicit before treatment begins. A sound prescription is not a drug name followed by a dose: it is a deliberately scoped plan that states who the regimen is for, how it will be advanced, what response is being sought, and when the plan will be reconsidered.

Atomoxetine and the adrenergic agonists are the principal non-stimulant options considered here. Their place is clinical rather than ideological. A child may need an alternative route because the treatment plan, co-occurring difficulties, family priorities, prior experience, or practical feasibility make that route more appropriate. The prescriber should avoid presenting non-stimulant treatment as passive or lesser treatment. It is active pharmacotherapy, but its logic is slower, more longitudinal, and especially dependent on a shared expectation of what early treatment can and cannot show.

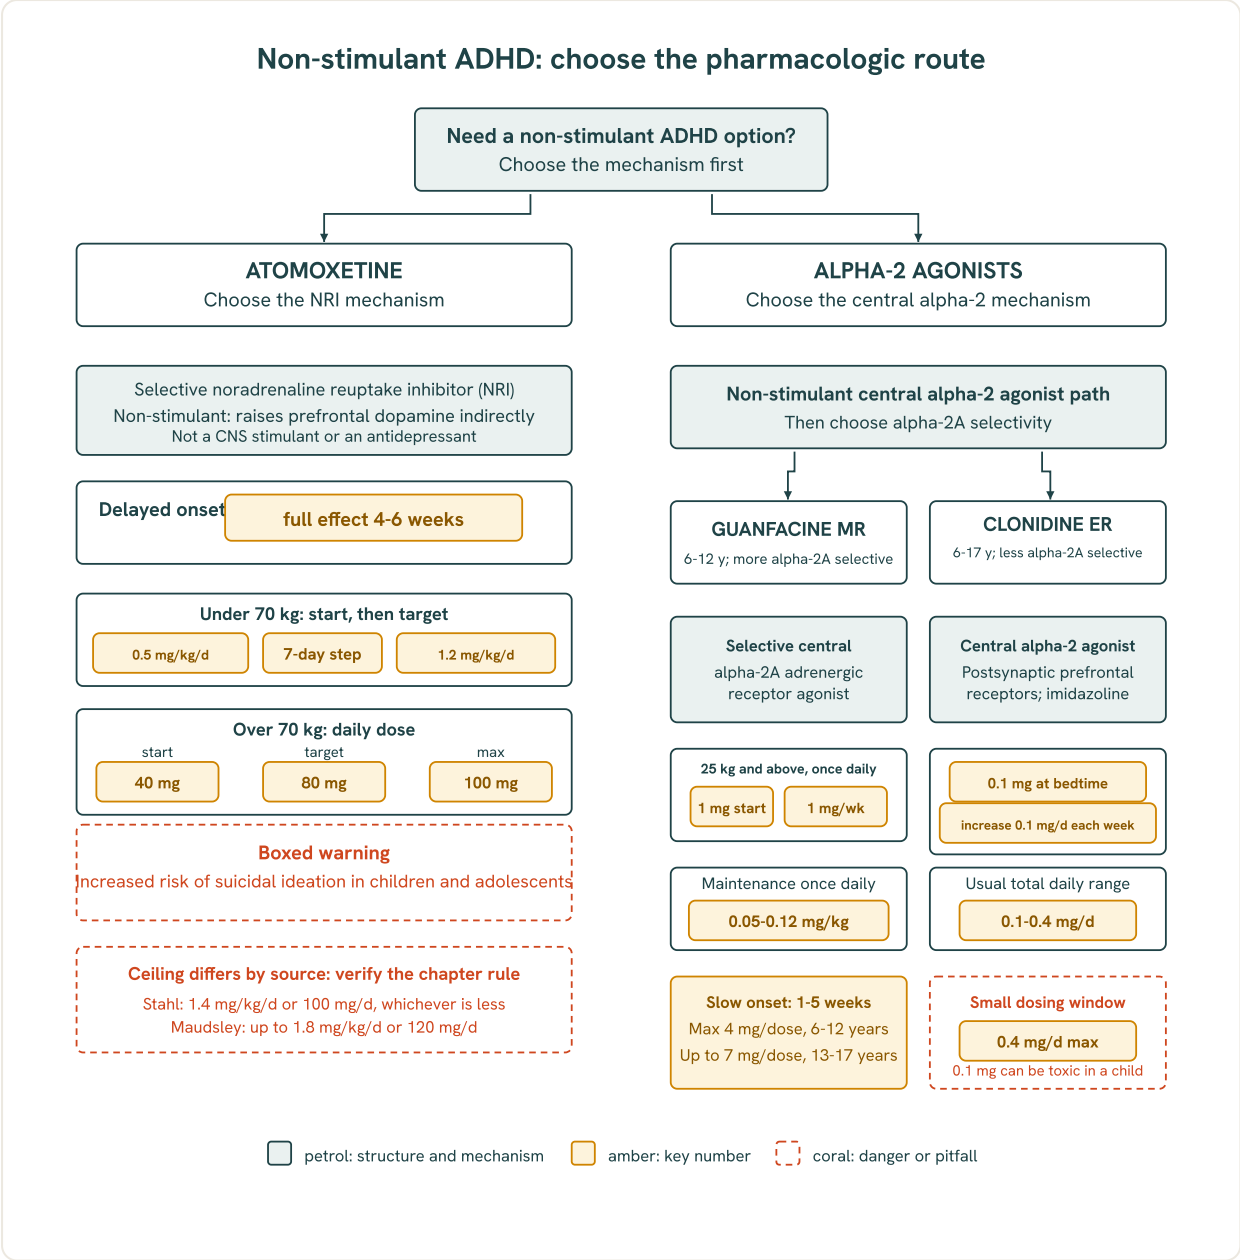

Fig 22.11. Non-stimulant ADHD choice: atomoxetine versus alpha-2 agonists.

11.1 The non-stimulant frame

Atomoxetine is a **selective noradrenaline reuptake inhibitor** and a non-stimulant. This matters because its clinical effect is understood through sustained noradrenergic modulation rather than an immediately perceptible stimulant effect. Its pharmacology also supports attention and behavioural control through prefrontal catecholamine regulation. The practical lesson is not to reduce mechanism to an examination label. Mechanism predicts the tempo of prescribing, the way a family interprets change, and the error made when an early partial response is called failure.

The adrenergic agonists work through a different regulatory pathway. **Guanfacine** is a **selective central alpha-2A adrenergic receptor agonist**. **Clonidine** has **central adrenergic agonist action in the prefrontal cortex**, including postsynaptic receptor activity relevant to ADHD. These descriptions are not interchangeable shorthand. Guanfacine has greater receptor selectivity, whereas clonidine has broader receptor action. That distinction is useful when one

explains why agents grouped together pharmacologically are not automatically interchangeable in formulation, schedule, or dose.

ATX	GUA	CLO
NON-STIMULANT OPTION	NON-STIMULANT OPTION	NON-STIMULANT OPTION

RULE **Choose and prescribe a non-stimulant as a complete treatment strategy, not as an afterthought.** Its mechanism, onset, formulation and review plan must be explained before a family can judge it fairly.

The distinction is also pedagogically useful. When asked to discuss non-stimulants, a high-quality answer starts with this pharmacological map and then moves to the individual agent. It does not collapse atomoxetine and adrenergic agonists into one undifferentiated list. Nor should it drift into the full assessment of ADHD, behavioural management, school intervention, or stimulant prescribing, each of which is addressed elsewhere in this chapter.

11.2 Atomoxetine: planning treatment around delayed benefit

Atomoxetine has a **delayed onset**; full therapeutic benefit may take **approximately 4-6 weeks**. This is the central counselling point. Families often judge medicines by what can be observed soon after a dose is started. With atomoxetine, early impressions should instead be organised around tolerability, adherence, and whether the intended course has had sufficient time to declare itself. A clinician who does not set that expectation creates an avoidable cycle of premature stopping, hurried switching, and loss of confidence in treatment.

The slower tempo also changes follow-up questions. Rather than asking only whether the child was “better” on a given morning, ask whether the medicine has been taken consistently, whether home and school can describe the same target difficulties, and whether observations are being compared with the pre-treatment baseline. The relevant outcome is functional improvement across the child’s everyday settings, not a dramatic subjective effect. This makes collateral information valuable, while detailed rating-scale selection and use remain the subject of the rating-scales section of this chapter.

MNEMONIC

SLOW

Scope the population, **L**ay out the titration, **O**wn the onset expectation, and **W**atch the agreed clinical targets. It is a prescribing spine rather than a claim that one drug suits every child.

When changing a plan, do not allow the phrase “non-response” to conceal several different possibilities. The treatment may not yet have been exposed adequately; the dose may not yet have reached its intended therapeutic range; adherence may be inconsistent; the outcome selected by adults may be too vague; or the underlying difficulty may demand parallel behavioural, educational, or family work. These are clinical questions, not reasons to multiply drugs reflexively. The wider multimodal plan is discussed in the multimodal treatment section of this chapter.

TRAP **Expecting atomoxetine to behave like an immediately acting medicine is a category error.** If delayed benefit was not explained at the outset, an early discontinuation may be recorded as drug failure when it actually reflects an inadequate therapeutic trial.

11.3 Atomoxetine dosing: state the whole tuple

For the lower-weight child, atomoxetine may be started at **about 0.5 mg/kg/day for the first 7 days** and then advanced towards **about 1.2 mg/kg/day**. The population qualification is essential: this is the regimen for a child **under 70 kg**, not an unlabelled paediatric formula to be transferred to every patient. The schedule may be given once daily or in divided doses. In teaching and in the case record, write the formulation and the population beside the number. A dose without its denominator and population is a trap awaiting a prescribing error.

There is a source divergence at the upper end of this regimen. Stahl gives a ceiling **below 1.4 mg/kg/day or 100 mg/day, whichever is less**, whereas Maudsley permits an increase **up to 1.8 mg/kg/day or 120 mg/day** when necessary. This is not a licence to blend two ceilings into an invented third schedule. It is a reason to use the local prescribing reference and product information that govern the individual prescription, document the rationale for any higher-dose plan, and seek senior review when the decision is not straightforward. The key examination point is to recognise the divergence rather than memorise an isolated maximum stripped of its source.

For an adult or a child over **70 kg**, begin at **40 mg/day** for the first week and then work towards **80 mg/day**, with benefit judged over the subsequent weeks; do not exceed **100 mg/day**. This separate schedule prevents a common error: carrying a weight-based paediatric instruction into a patient for whom the fixed-dose regimen is intended. The word “target” is clinically more useful than “destination”. It asks the clinician to assess response and tolerability at a planned dose, rather than treating dose escalation as an automatic ritual.

CLINICAL SCOPE	STARTING AND TARGET PLAN	UPPER LIMIT AND INTERPRETATION
Lower-weight child	Use the weight-based starting and target plan.	Use the ceiling from the prescribing authority being followed; Stahl and Maudsley differ at the upper end.
Adult or higher-weight child	Use the fixed-dose starting and target plan.	Use the maximum attached to that fixed-dose schedule.
Any atomoxetine plan	Record formulation, population and dosing schedule.	Interpret efficacy only after allowing for delayed onset.

PITFALL

Writing “atomoxetine at the usual dose” is clinically unsafe documentation. The correct prescription language makes the patient group, weight logic, formulation, schedule, target and source-specific ceiling visible to the next clinician.

11.4 Atomoxetine safety conversation

Atomoxetine carries a **boxed warning** for increased risk of **suicidal ideation in children and adolescents**. This requires a real conversation, not a hurried consent formula. Explain to the family what emerging concerning thoughts or behavioural change might look like in their child, who will be informed, and how they should obtain help if concern arises. A warning is not a prediction that the child will develop suicidality. It is an obligation to make risk visible and to ensure that the family does not feel abandoned between appointments.

Risk communication is best done in plain clinical language. Invite the young person, as developmentally appropriate, to describe distress directly rather than relying solely on adult report. Ask parents or caregivers to report abrupt changes rather than waiting for a routine review. The prescriber must distinguish a medicine-specific safety concern from the broader psychiatric assessment of mood, self-harm risk and family stress. Those domains should be evaluated clinically, but the full adverse-effect and monitoring framework for ADHD medicines belongs to the medication monitoring section of this chapter.

> **GOOD TO REMEMBER**
>
> Before atomoxetine is started, agree on a safety contact pathway. This transforms a boxed warning from an alarming sentence into a practical plan shared by clinician, young person and caregivers.

Documentation matters here. Record that the warning was discussed, the caregiver's understanding, the young person's account where available, and the plan for contact if risk emerges. Such notes improve continuity when care is shared and protect the therapeutic alliance by showing that safety was anticipated rather than raised only after a crisis. Do not make a family carry the burden of pharmacovigilance alone: the treatment plan must state how the clinical team will remain reachable and responsive.

11.5 Guanfacine modified-release

Guanfacine modified-release is a formulation-specific treatment. The words "modified-release" should remain attached to the dose whenever it is discussed, because pharmacological family membership does not make formulations interchangeable. For a child in the specified school-age and weight group, the starting dose is **about 1 mg** once daily. The row is scoped to children aged **6-12 years** who weigh at least **25 kg**. This is why copying a dose from a drug class summary without its heading is unsafe.

Titrate guanfacine modified-release in increments of **about 1 mg per week** when needed and tolerated. The usual maintenance range in the same child group is **0.05-0.12 mg/kg** once daily. Its onset is **approximately 1-5 weeks**, so it too requires an expectation of progressive rather than instantaneous benefit. A prescriber should decide before titration what observations will count as meaningful improvement, and should not confuse a calm consultation-room presentation with change in the child's ordinary functioning.

The maximum for children aged **6-12 years** is **below 4 mg per dose**. In those aged **13-17 years**, the maximum is determined by weight band and may rise **up to 7 mg per dose**. A good answer

does not simply quote the highest figure. It says that the adolescent ceiling is weight-band dependent, because that is the safeguard which prevents an age label from being mistaken for complete dosing guidance.

- Confirm that the intended product is guanfacine modified-release.
- State the age and weight scope before calculating or documenting a dose.
- Advance the dose only through the specified weekly steps and review the agreed clinical targets.
- Keep the delayed-onset expectation explicit for caregivers and school.

IN INDIA

Do not assume that a class name guarantees the same formulation, availability, or labelling across settings. Verify the product actually available to the family and prescribe from the locally applicable information rather than importing a regimen from an unfamiliar brand or market.

11.6 Clonidine extended-release

Clonidine should be approached with the same formulation discipline. The regimen here is for **clonidine extended-release** in children with ADHD aged **6-17**. Start at **about 0.1 mg** at bedtime. The small numerical scale is itself an important safety cue: it should make the prescriber pause before transferring an unrelated adrenergic agonist dose, a non-ADHD regimen, or a non-extended-release schedule into this context.

The extended-release regimen is advanced by **about 0.1 mg per week**. Doses are divided, with the larger portion at bedtime. The usual upper limit is **below 0.4 mg/day** in divided doses. Every element belongs together: drug, extended-release formulation, paediatric ADHD population, bedtime start, weekly advance, divided administration and ceiling. Separating the number from this tuple is the way correct-source information becomes incorrect prescribing.

Mechanistically, clonidine's prefrontal receptor action offers a coherent reason for its place among non-stimulants. Clinically, however, mechanism does not absolve the prescriber from precise instructions. Caregivers need a written plan that matches the product dispensed, uses plain wording for when doses are given, and tells them which member of the clinical team to contact when the plan cannot be followed. The medication monitoring section of this chapter addresses the wider safety checks required for ADHD pharmacotherapy.

11.7 Choosing, reviewing and integrating a non-stimulant plan

Choice between these agents begins with a clinical formulation, not a preference for a fashionable molecule. Consider the treatment goals, the symptom pattern that is impairing daily functioning, prior treatment experience, practical feasibility, family understanding, and the capacity for follow-up. The aim is to select a plan whose expected course can be observed honestly. If the family cannot state what change would matter at home and school, the next task is to define targets rather than to change the prescription.

Targets should be concrete enough to be recognisable but broad enough to matter. They may concern the child's capacity to remain with a task, to participate in class, to complete routine work with less conflict, or to recover a more manageable rhythm at home. The prescriber should ask each informant what would count as meaningful change and should note disagreement rather than forcing a false consensus. A medicine can be helping in one setting while a separate unmet need remains prominent in another. That pattern calls for formulation and coordination, not a simplistic verdict that the treatment either worked or failed.

At review, proceed in a sequence. Has the prescribed medicine actually been taken in the intended formulation and schedule? Has sufficient time passed for the agent's expected onset? Has the child's function changed in the domains that prompted treatment? This order protects against both therapeutic inertia and impulsive switching. It also makes room for the possibility that medication is a component of the plan rather than its entirety. Parent-focused work, behavioural intervention, educational support and school collaboration should proceed according to the child's needs, rather than being postponed until medication has solved every difficulty.

QUESTION AT REVIEW	REASONING TASK	USEFUL ACTION
Is the prescription being implemented as written?	Separate adherence or formulation problems from lack of efficacy.	Reconcile the medicine in hand with the documented regimen.
Has the expected onset been allowed for?	Prevent premature attribution of non-response.	Revisit the time course discussed at initiation.
What has changed in ordinary life?	Judge function rather than a vague global impression.	Obtain collateral from the settings where impairment occurs.
What remains unmet?	Identify needs that medication alone cannot address.	Integrate behavioural, family and school interventions.

For candidates, the mature answer is therefore structured and conditional. Name the mechanism, give a fully scoped regimen, state the onset expectation, identify atomoxetine's specific warning, and show how review is tied to function. For clinicians, that same structure prevents dangerous errors: prescribing a bare number without its population and abandoning a non-stimulant before its pharmacology has had a fair chance to work. It also makes handover safer, because another clinician can see the intended logic rather than having to reverse-engineer it from a number written in isolation.

> Non-stimulant prescribing is safe only when drug, formulation, patient group, dose, titration, onset expectation and review plan are documented as one clinical decision.

12 · Adverse effects and monitoring of ADHD medications (growth, cardiac)

Medication monitoring is active clinical care, not a formality after a prescription. In ADHD, the therapeutic question is never merely whether a medicine has been dispensed. The clinician must repeatedly ask whether the child is benefiting in the settings that matter, whether treatment is being tolerated, and whether an emerging problem represents a drug effect, the disorder itself,

an intercurrent difficulty, or a change in the child's circumstances. Monitoring makes the benefit-harm balance visible before it becomes a reason for avoidable discontinuation or avoidable persistence.

For the examination candidate, a strong answer links adverse effects to a method. It begins with a pre-treatment reference point, follows a small set of clinically meaningful domains, invites the child and caregiver to describe change in ordinary language, and records a reasoned response. The aim is not to create anxiety around ADHD medicines. It is to prescribe with enough attention that benefit can be sustained safely and that a concern is neither dismissed nor automatically attributed to the medicine.

Baseline	Growth	Vitals	Review
REFERENCE POINT	TRAJECTORY	CIRCULATORY SAFETY	BENEFIT AND BURDEN

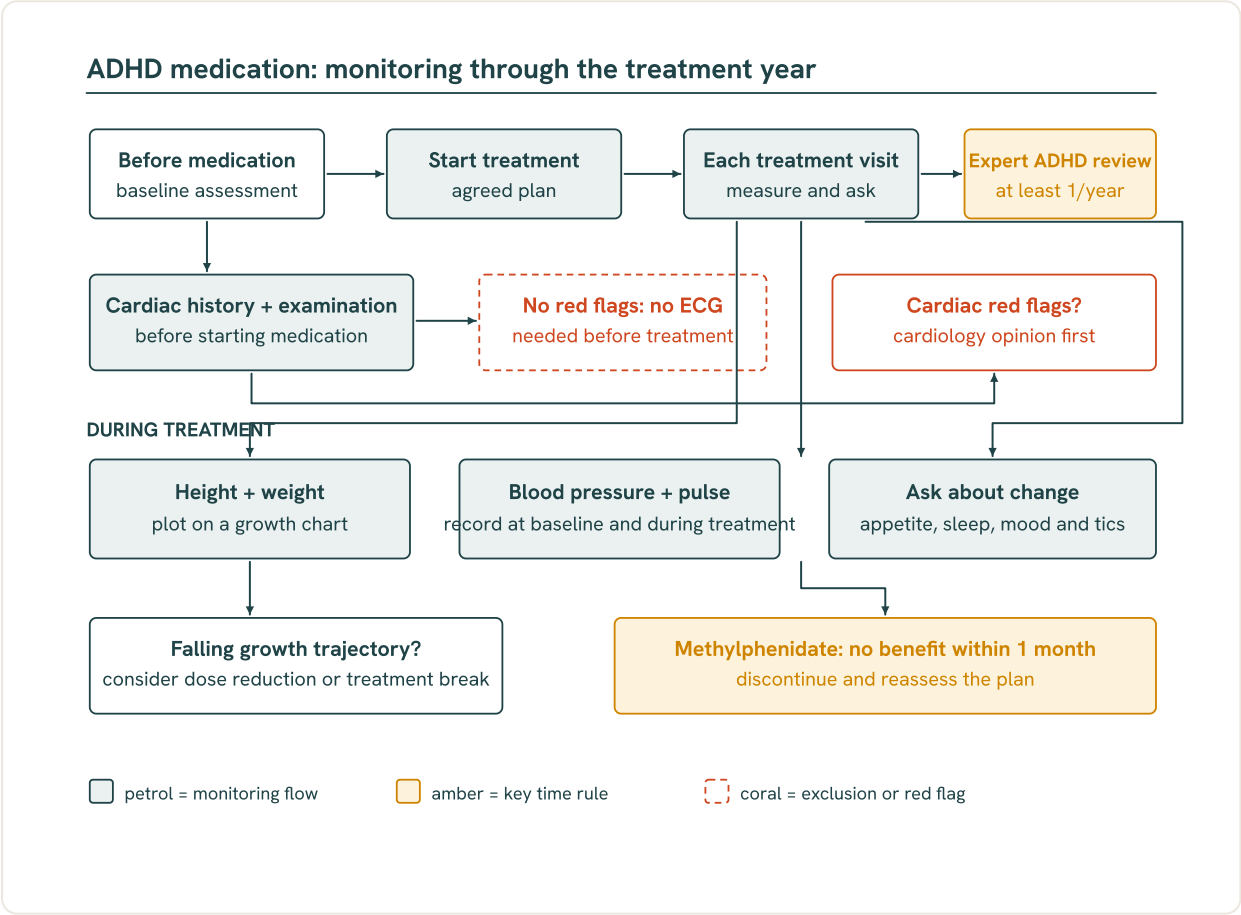

Fig 22.12. Growth, cardiovascular and adverse-effect monitoring during ADHD medication treatment.

12.1 The logic of surveillance

The useful monitoring consultation is longitudinal. An isolated observation has limited meaning unless it is interpreted against the child's prior state, current treatment exposure, reported functioning, and other plausible explanations. The task is therefore to make a clinical narrative from measurements, symptoms, school observations, family accounts, and examination.

Begin by agreeing what change would count as benefit and what change would prompt contact with the treating team. Ask the caregiver to notice the child's appetite, sleep, emotional tone, activity, and physical complaints without turning home into a surveillance ward. Ask the child

directly, in developmentally appropriate language, what feels different. A child may describe a bodily experience, a loss of spontaneity, or a change in evening functioning that an adult observer cannot infer from classroom behaviour. Conversely, a caregiver may notice a pattern across meals, mornings, or family routines that the child cannot place in context.

Monitoring is also an exercise in attribution. A symptom that appears after treatment begins may be related to the medicine, but timing alone does not settle causation. The clinician should reconstruct when it began, how it relates to medication exposure, whether it was present previously, whether it occurs when the medicine is not being taken, and whether illness, stress, sleep disruption, dietary change, or another medicine offers a more coherent explanation. This reasoning matters because the response may range from reassurance and observation to adjustment of treatment or assessment for an independent problem. The record should make that reasoning legible to the next clinician.

RULE **Monitor the child's trajectory, not an isolated complaint.** The reference state, the temporal pattern, the functional consequence, and the family's account together determine whether a finding calls for action.

Monitoring should be collaborative rather than punitive. Families sometimes conceal missed medication, appetite difficulties, or worries about mood because they fear criticism or fear that the only alternative is to stop treatment. A non-judgemental consultation makes clinically useful information more likely to emerge. It also permits a practical distinction between an inconvenience that can be managed and a burden that changes the overall acceptability of treatment. The prescriber retains responsibility for medical decisions, but the child and caregiver supply much of the information on which those decisions depend.

12.2 Growth and nutritional trajectory

Growth monitoring belongs at the centre of stimulant follow-up because treatment can interact with appetite, eating routines, and the child's developing physical trajectory. The core action is to **measure height and weight** and record them on a **growth chart**. The chart matters because it turns a sequence of measurements into a pattern. It helps the clinician distinguish an apparently concerning isolated value from a sustained change in trajectory and creates a shared object for discussion with caregivers.

Long-term stimulant treatment is associated with lower height and weight, described clinically as **growth deceleration**. This should be explained without fatalism. The association justifies systematic observation; it does not turn every child receiving a stimulant into a child with a growth disorder. The clinical question is whether the individual child's physical course remains acceptable in the context of treatment benefit, eating pattern, general health, and the family's concerns. A good note records the finding and the interpretation, rather than merely copying a measurement into a prescription sheet.

Appetite is the practical bridge between medication and growth. Ask about the child's usual pattern of meals, snacks, school-day eating, and what the family sees when the medication effect is most noticeable. Ask whether eating has become effortful, whether favourite foods have

changed, whether meals have become a site of conflict, and whether the concern is reduced intake, altered timing, or distress around food. These questions are not a substitute for measurement. They clarify the lived pathway by which a trend on the chart may matter, and they may reveal that a reported appetite problem has a different explanation.

When a concerning pattern is identified, the response should be individualized. Recheck the measurements and the history before declaring a causal conclusion. Review the treatment benefit and burden with the child and caregiver. The available claim supports considering **dose reduction or treatment breaks** as management options for growth-related concern; the decision must be integrated with functional need and clinical response rather than applied automatically. Nutritional or medical assessment may be appropriate when the history points beyond a medication effect. The fragment does not supply a numerical threshold for intervention, so it should not be invented in clinical practice or in an examination answer.

GOOD TO REMEMBER

A growth chart is a clinical conversation tool. Show the family the recorded trajectory, ask what has changed at home, and make the plan explicit. This converts a vague concern about "poor eating" into a monitored, revisitable decision.

TRAP **Do not equate appetite suppression with proof of clinically important growth harm.** Appetite, measured growth, general health, and treatment benefit must be considered together; either dismissing the complaint or stopping treatment reflexively is poor clinical reasoning.

Growth monitoring also prevents an important communication failure. Families may hear "we will monitor growth" as a warning that harm is expected, while clinicians may assume that a measurement has reassured the family. State the purpose plainly: the team is looking for a pattern early enough to respond thoughtfully. Invite the caregiver to bring observations from home and, where relevant, from school routines. The prescriber should avoid giving a false precision about the amount of change that is acceptable when the available evidence for this fragment does not provide such a threshold.

12.3 Appetite, sleep, mood, and tics

Physical monitoring is incomplete if it ignores the experiences that determine whether a child can live comfortably with treatment. Follow-up should actively enquire about **appetite change, insomnia, mood change, and the development of tics**. These domains deserve direct questions because families may not volunteer them, may regard them as unrelated to treatment, or may use broad labels that conceal an important distinction. "Sleep is worse," for example, needs a description of the child's actual pattern and its daytime consequences; "mood is different" needs clarification of affect, context, timing, and impact.

Sleep inquiry should be practical and neutral. Establish what bedtime and waking are like, whether the child is rested, whether there is distress around sleep, and whether the reported change is linked temporally to treatment. Do not assume that every sleep complaint is medication-related. ADHD, school pressures, family stress, medical illness, and pre-existing sleep

difficulty may all complicate the story. The monitoring task is to identify a clinically meaningful change and to decide whether it is best understood as a treatment burden, a co-occurring difficulty, or both.

Mood change warrants particular care because it can be described in many ways: irritability, tearfulness, emotional flattening, increased sensitivity, or a sense that the child is unlike themself. The clinician should ask the child as well as the caregiver, seek concrete examples, and assess whether the change is transient, context-bound, or functionally impairing. Avoid reducing all emotional change to non-adherence or all distress to a medication adverse effect. A careful history protects the child from both invalidation and inappropriate exposure to a medicine that is not being tolerated.

Tics require equally careful phenomenology. Clarify what is being observed, when it emerged, how it fluctuates, whether the child is distressed, and whether there is functional impact. The purpose of monitoring is not to make an unsupported causal declaration from temporal association. It is to identify change, assess its burden, and decide whether the treatment plan needs reconsideration or whether a broader clinical evaluation is needed. For fuller discussion of tic disorders, see the Child behavioural, emotional and other disorders notes.

- Ask what has changed from the child's own baseline.
- Ask when the change is most apparent and what makes it better or worse.
- Ask about distress, impairment, and the child's interpretation of the change.
- Record the family's observations alongside the clinician's assessment.

PITFALL

Do not ask only whether the medicine is "fine." That question invites reassurance rather than information. Domain-based enquiry about appetite, sleep, mood, and tics gives the family permission to report a concern before it becomes a crisis.

12.4 Cardiovascular assessment before treatment

Cardiovascular monitoring starts before medication is prescribed. Record **blood pressure and pulse** at baseline and continue to record them during treatment. Baseline values provide a reference against which later observations can be interpreted. Their value is not limited to detecting an abnormal result: they also discipline the clinician to ask whether a later change is new, sustained, symptomatic, or better explained by context.

An **ECG** is not a routine pre-treatment requirement for stimulants, atomoxetine, or guanfacine when **cardiac red flags** are absent. This is a useful corrective to indiscriminate testing. A test should answer a clinical question; ordering it automatically can delay care, create incidental findings, and obscure the importance of a careful cardiac history and examination. The absence of a routine ECG requirement is not permission to conduct a cursory screen.

Red flags call for a different route: seek cardiology opinion before starting treatment. The screen should identify known congenital heart disease, prior cardiac surgery, a **first-degree relative**

with sudden death before 40, breathlessness on exertion, syncope with exertion or fright, rapid regular episodic palpitations, chest pain suggestive of cardiac origin, features of heart failure, a murmur, blood pressure in an adult hypertensive range, and concurrent medication that increases cardiac risk. These are not a checklist to recite mechanically. Each finding changes the pre-treatment risk question and therefore requires an appropriately focused history and examination.

The interview must make room for ambiguity. Children and families may use the same words for anxiety-related sensations, ordinary exertional limitation, brief awareness of heartbeat, or a potentially important symptom. Ask for the setting, onset, duration, associated symptoms, recovery, and impact in a calm way. Do not reassure on the basis of a vague negative answer, but do not convert an imprecise symptom into a cardiac diagnosis. The clinical skill is to translate a narrative into a defensible decision about whether specialist input is required.

MONITORING DOMAIN	WHAT THE CLINICIAN ESTABLISHES	CLINICAL QUESTION ANSWERED	HOW THE FINDING IS USED
Cardiac history	Symptoms, prior cardiac care, family history, and concurrent medicines	Is there a cardiac red flag?	Decide whether cardiology opinion is needed before treatment
Examination	Relevant physical signs and cardiovascular observations	Is there a finding requiring further assessment?	Interpret alongside the history rather than in isolation
Blood pressure and pulse	Baseline values and subsequent observations	Has the circulatory state changed during treatment?	Compare with the child's documented course
ECG	A targeted investigation when red flags are present	Is testing clinically indicated?	Use as part of the specialist-directed assessment, not as a universal ritual

IN INDIA

Children may move between private clinics, public services, schools, and relatives who share care. A clear written baseline history, physical record, and explanation of which symptoms should prompt review make monitoring more reliable across these transitions. Ask caregivers to retain the record and bring it to follow-up rather than relying on memory alone.

12.5 Cardiovascular follow-up during treatment

Recording blood pressure and pulse during treatment is a continuing responsibility, not a pre-treatment box to tick. The purpose is to detect change while maintaining the broader perspective: a reading is interpreted in relation to the child's prior record, current symptoms, examination, treatment exposure, and clinical state. Stimulants may raise blood pressure and pulse, so these observations belong in the ordinary monitoring record rather than being reserved for a child who appears unwell.

When a finding is concerning, establish that it is a real clinical signal. Check the context of measurement, ask about symptoms, review the prior record, and examine the child as appropriate. Then decide whether the concern can be safely observed, whether treatment should be reconsidered, or whether medical or cardiology assessment is required. The correct response cannot be reduced to a universal number in this fragment, because no such threshold is supplied here. What matters is a documented clinical judgement that links the finding to the child's overall risk and treatment benefit.

Communicate the distinction between expected monitoring and alarm. Families should understand that blood pressure and pulse are recorded because treatment deserves competent follow-up, not because the clinician expects a cardiac event. At the same time, they should know to report new symptoms rather than waiting for a routine visit. This balanced explanation reduces both complacency and panic, and it preserves trust when the plan needs to change.

MNEMONIC

TRACE

Trend, **R**eported symptoms, **A**ttribution, **C**linical examination, **E**xplanation to the family. Use it to turn an observation into a reasoned cardiovascular follow-up note.

12.6 Review, response, and the decision to continue

A medication review brings efficacy and tolerability back together. The clinician should review treatment with ADHD expertise at least **once a year**. This is not an administrative renewal. It is an opportunity to reconsider whether the original target problems remain the right targets, whether benefit is present in the child's real environments, whether adverse effects are acceptable, and whether the child and caregiver still understand and agree with the plan.

Review is particularly important when the prescription has continued by habit. Function changes as school demands, family circumstances, developmental needs, and supports change. A medicine that was useful may require a different plan; a concern previously judged minor may become important; and an apparent loss of response may reflect a change in the setting rather than a pharmacological problem. The review should therefore integrate reports from the child, caregiver, and, when available and appropriate, school, rather than relying solely on the prescription history.

For methylphenidate, discontinue treatment if there is no benefit within **one month**. This statement is a safeguard against unexamined continuation, not an invitation to make a rushed judgement from a poorly observed trial. Before concluding that there is no benefit, establish whether the treatment was taken as intended, whether the target outcome was observable, whether the available reports were adequate, and whether adverse effects or contextual changes have distorted the picture. Dosing and titration belong to the stimulant pharmacotherapy discussion and should not be improvised here.

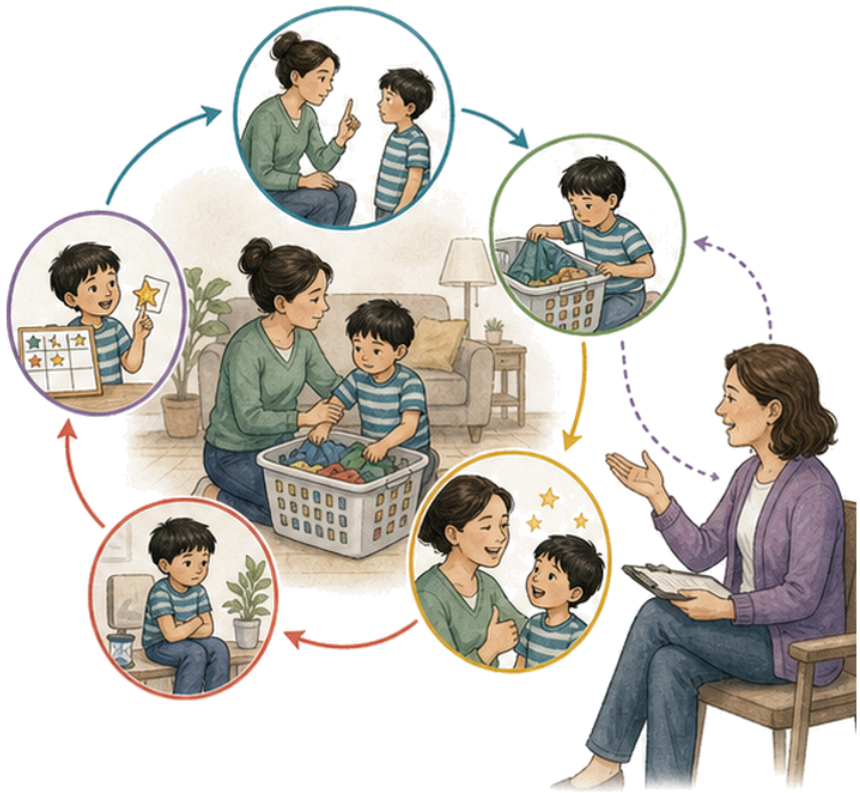
Document a concise clinical synthesis at each substantive review: the target symptoms and functioning, the child's account, caregiver observations, adverse-effect enquiry, growth and

cardiovascular observations, the attribution judgement, and the agreed plan. This documentation is not defensive bureaucracy. It preserves clinical continuity, allows later findings to be interpreted as a trajectory, and makes shared decision-making visible. It also prevents a later clinician from mistaking an old prescription for evidence that benefit was ever established.

- Revisit the treatment goal and observed benefit.
- Review growth, circulatory observations, appetite, sleep, mood, and tics.
- Ask the child what has improved and what has become harder.
- Decide explicitly whether to continue, modify, pause, discontinue, or seek further assessment.

12.7 A defensible monitoring plan

The best monitoring plan is simple enough to be followed and rich enough to detect a meaningful change. It starts with a baseline clinical record, including growth measures, blood pressure, pulse, and focused cardiac screening. It then turns routine follow-up into a repeated enquiry about benefit, physical trajectory, appetite, sleep, mood, tics, and cardiovascular symptoms. The plan names who will observe which domains, how concerns will reach the prescriber, and what information should be brought to the next visit.



When concerns arise, do not treat monitoring as a choice between reassurance and discontinuation. Return to the clinical sequence: describe the finding accurately, establish its timing and burden, look for alternative explanations, check the objective record where relevant, and weigh it against demonstrated benefit. Some concerns require a change in treatment; some require further assessment; some can be observed with a clear plan. What makes the plan safe is not a formula but disciplined follow-through and honest documentation.

This approach also keeps monitoring within its proper boundary. It does not replace comprehensive ADHD assessment, behavioural intervention, school support, or evaluation of comorbidity. Those elements are addressed elsewhere in this chapter. Medication surveillance contributes a distinct task: to ensure that a pharmacological intervention remains a justified, tolerable, and actively reviewed part of a broader treatment plan.

> Measure growth, record blood pressure and pulse, screen cardiac red flags, ask directly about appetite, sleep, mood and tics, and revisit whether benefit still justifies treatment.

13 · Behavioural and parent training interventions

Behavioural work changes the treatment environment, not merely the child. ADHD symptoms are expressed within ordinary routines: getting dressed, beginning homework, shifting away from a preferred activity, tolerating a limit, or completing a request. These moments can become repetitive coercive cycles in which the adult raises the intensity of instruction and the child either escalates or escapes the task. The purpose of treatment is to make expectations clearer, desirable behaviour more visible, and the adult response more predictable. This is why **behavioural parent training**, also termed parent management training, belongs in the core psychosocial management of childhood ADHD and disruptive behaviour.

- Clear request
- Immediate praise
- Planned reward
- Predictable consequence
- Review one target

Fig 22.13 Behavioural parent training changes the treatment environment through clear requests, immediate attention to desired behaviour, planned rewards and predictable consequences. The parent is coached, not blamed, and progress is reviewed against one observable target.

It is not a programme for blaming parents, nor is it a demand for flawless parenting. The clinical task is to convert understandable family frustration into observable, practicable responses that can be used repeatedly when the child is dysregulated, distracted, oppositional, or simply not yet able to organise behaviour independently. The therapist functions as a **teacher and coach**: explains a skill, models it, rehearses it with the caregiver, anticipates obstacles, and returns to what happened at home. The mark-scoring answer therefore names the intervention, explains its learning principle, and shows how a parent would apply it to a concrete target.

13.1 Therapeutic frame and treatment target

Manualised parent management training gives the clinician a disciplined way to work with behaviour that is impairing family life. The parent is the immediate agent of change because the daily environment supplies prompts, attention, access to preferred activities, and responses to rule-breaking. This does not mean that all difficulty is environmentally caused. Rather, it

recognises that a child with ADHD may need the environment to carry structure that cannot yet be carried consistently through self-direction.

The first move is to replace a global complaint such as “he never listens” with a target that can be seen and recognised by both parent and child. A useful target is described in positive, observable language: starting a task after a request, placing an item where it belongs, returning to an agreed activity, or using an acceptable way to seek attention. This reframing matters because caregivers cannot consistently reinforce an abstraction. They can, however, notice a particular behaviour when it occurs and respond to it in a planned manner.

The intervention also separates the child from the problem. Parents often arrive having tried more explanation, more warnings, louder instructions, or prolonged argument. Those reactions are understandable, but they may accidentally turn a small demand into a prolonged interaction. Parent training asks a different question: what happened immediately before the behaviour, what did the child do, and what followed? That formulation makes the family interaction available for change without reducing the child to “naughty” or the caregiver to “inconsistent”.

RULE **Teach the parent a response that can be delivered consistently at the moment the behaviour occurs.** Behavioural parent training works through coached practice in ordinary routines, not through advice that remains too general to implement.

13.2 The contingency principle

Contingency management is the organising principle of this treatment. It links the parent’s response to a behaviour rather than to the parent’s rising irritation or the child’s promise to improve later. Desired, prosocial behaviour receives **positive reinforcement**; problematic behaviour receives a brief, planned, and proportionate consequence when one is needed. The clinical logic is not that a reward purchases obedience. It is that a child learns more readily when the behaviour that adults want to see is noticed promptly and becomes predictably worthwhile.

For a child with ADHD, delayed benefits often compete poorly with the immediate pull of play, movement, conversation, or escape from an aversive task. Reinforcement makes the immediate pathway towards the desired behaviour clearer. It should be linked to a target the child can genuinely achieve. If the threshold is set beyond current capacity, the system becomes another experience of failure, the parent stops using it, and the child learns that the announced reward is unattainable. The treatment therefore begins with success and adjusts the demand gradually as the routine becomes established.

Consequences are not synonymous with punishment. A consequence may remove attention from a provocative behaviour, restore a missed expectation, or briefly restrict access to a positive activity. Its therapeutic value lies in predictability, calm delivery, and connection to a stated rule. A long moral lecture usually occurs after the learning moment has passed and may give more attention to disruptive behaviour than to the quieter behaviour the family wishes to increase. The clinician should help the parent distinguish an intended consequence from an emotional reaction.

Target	Response	Review
OBSERVABLE BEHAVIOUR	PLANNED CONTINGENCY	PARENTAL COACHING

GOOD TO REMEMBER

A reward system is a clinical experiment, not a test of parental authority. If it repeatedly fails, first review whether the target is clear, whether the reward is attainable, and whether the parent can deliver the response in the actual routine.

13.3 Giving instructions that can be followed

Effective instructions are an antecedent intervention: they alter what happens before the behaviour rather than waiting to react afterwards. The parent gains the child's attention, states one concrete action, uses language matched to the child's capacity, and avoids converting the instruction into a question if compliance is expected. The parent then allows enough space for the child to act before adding another demand. This is not harshness. It is a way of reducing ambiguity for a child whose attention and behavioural organisation fluctuate.

Vague or stacked instructions create avoidable failure. "Stop being difficult and get ready properly" contains several judgments but no clearly observable first action. In contrast, an instruction that identifies the next action gives the child a possible route to success. The parent is coached to notice even partial movement in the right direction. That notice is often more therapeutically useful than waiting until the entire routine has gone perfectly and then discovering that the opportunity for reinforcement has been lost.

Antecedent control also includes changing the routine so that the desired action is easier to initiate. The clinician may ask what prompts are present, whether competing attractions are active, whether the adult can prepare the situation before giving an instruction, and whether the task has been made needlessly broad. Such questions retain the behavioural focus without claiming that the intervention will remove the underlying neurodevelopmental vulnerability. The executive-dysfunction model that helps explain this vulnerability is addressed in the ADHD mechanism section.

- State the action rather than a criticism of the child.
- Give one manageable next step.
- Pause and allow the child to respond.
- Notice compliance promptly and specifically.

TRAP **Do not mistake repeated warnings for behavioural treatment.** Repeating an instruction without a planned follow-through teaches neither the requested behaviour nor the consequence of non-compliance, and it leaves both parent and child in a predictable argument.

13.4 Rewards, token systems, and success

A **token economy** makes reinforcement visible. The child earns a token, mark, or other agreed signal for a specified target and exchanges accumulated credit for an agreed privilege or reward. Its usefulness is practical: it helps a caregiver respond in the moment and gives the child a

concrete record of effort. The system should be explained as a route to practising a behaviour, not as a bargain that applies only when the adult is exhausted.

The clinician should spend time on the mechanics with the family. What exactly earns the token? When will the parent give it? What happens if the child protests? What rewards are meaningful but manageable? Who will remember the system when the household is rushed? These questions are more important than producing an attractive chart. A beautifully designed plan that cannot be used during a hectic morning is less therapeutic than a simple plan that survives the real household.

Rewards need not be material. Positive attention, choice, shared activity, access to a preferred routine, and acknowledgement of effort may all be useful when they are meaningful to that child. The key is that the child experiences the contingency as credible. When a parent makes an elaborate promise and cannot deliver it, the programme loses instructional value. When the parent chooses a small, available reinforcer and gives it reliably, the child encounters success and the adult sees a workable alternative to confrontation.

MNEMONIC

CLEAR

Choose one target, **L**ink it to an immediate response, **E**ncourage effort, **A**void unattainable rewards, and **R**eview what actually happened. This is a practical memory aid for running a reward plan, not a substitute for parent coaching.

Parent training succeeds when the child can repeatedly experience that a clear, achievable behaviour brings a dependable response.

13.5 Planned consequences and time away from reinforcement

Time-out is best understood as time away from positive reinforcement, not as isolation, humiliation, or a venue for prolonged reprimand. In a behavioural plan it is a structured response to a pre-specified behaviour, delivered with as little drama as possible. The parent explains the rule outside the conflict, applies the response when the rule is broken, and returns to ordinary interaction without reopening the argument. Its function is to interrupt the reinforcement that may be maintaining the behaviour and to preserve the adult's capacity to stay regulated.

A modified time-out may be one component of a broader consequence plan. It should never become the only intervention offered to a family. If the child receives most adult attention during disruption and little attention during cooperation, simply adding a consequence will not correct the imbalance. The parent must also practise recognising prosocial behaviour and building positive interaction into daily life. Otherwise the programme risks being experienced as a succession of sanctions rather than a structure for learning.

The clinician should explore feasibility and safety before recommending a consequence. A strategy that requires the parent to manage an intense struggle, cannot be applied in the available home environment, or leads to escalating physical confrontation is not a good plan merely

because it has a familiar name. Return to a smaller target, clearer antecedents, and a consequence the caregiver can deliver calmly. Behavioural treatment should lower the emotional temperature of the household.

> **PITFALL**
>
> Using time-out as an angry banishment reverses its purpose. If the adult lectures, negotiates, threatens, and repeatedly restarts the interaction, the child receives intense engagement rather than a clear, brief consequence.

13.6 Functional analysis beyond the home

The **A-B-C model** offers a compact method for thinking about behaviour in context: identify the antecedent, describe the behaviour without inference, and examine the consequence. It is particularly useful when parents report that the child behaves differently across settings. Rather than assuming that one observer is right and another is wrong, the clinician asks what is different about the demand, the available attention, the escape route, the waiting involved, or the response that follows the behaviour.

PART OF THE SEQUENCE	CLINICAL QUESTION	USE IN PARENT COACHING
Antecedent	What immediately set the episode in motion?	Make the prompt clearer or alter the situation before the demand.
Behaviour	What did the child actually do?	Define one observable target rather than a character judgment.
Consequence	What followed from the behaviour?	Plan reinforcement for the desired alternative and a calm response to the problem behaviour.

Why functional analysis matters. The same outward behaviour can serve different functions on different occasions. A child may be seeking attention in one situation and avoiding an overwhelming task in another. Parent training is therefore not a set of stock rewards pasted onto every complaint. It is a method for matching the adult response to the sequence that is actually occurring. This is also why the clinician reviews examples from the previous week rather than judging the programme solely by the parent's overall impression.

Public settings deserve the same analysis. The aim is not to create a display of parental control in front of others. It is to prepare a brief plan before entering a difficult situation, recognise early signs of dysregulation, reinforce the behaviour that permits the activity to continue, and leave or change the situation when a pre-agreed limit is reached. A parent who has a rehearsed plan is less likely to improvise from embarrassment or anger.

13.7 Collaboration with school and the Indian clinical setting

Home-school daily report cards connect the child's effort across the settings that matter most. The school identifies a limited, observable target and communicates whether it was met; the

caregiver then delivers the planned response at home. The report card is not a behaviour diary for public shaming, and it should not become a channel through which adults exchange frustration. Its purpose is to make the reinforcement pathway coherent for the child.

School-based adjustments, classroom strategy, and wider psychosocial management require their own plan and are considered in the school-based management section. In parent training, the relevant question is narrower: can home and school agree on language, targets, and feedback so that the child is not asked to decode incompatible expectations? When communication is difficult, a simple shared target is more useful than an elaborate form that neither setting completes.

IN INDIA

Parents may have to coordinate with teachers while managing crowded routines, shared caregiving, and uneven access to trained behavioural therapists. Teach a small set of skills that the family can practise without specialised materials, and adapt the home-school communication method to what the school can reliably sustain. The clinical standard is not a sophisticated chart; it is a plan that preserves dignity and can be used consistently.

Grandparents and other caregivers may be central to the child's day. Excluding them can create contradictory contingencies: one adult rewards a requested behaviour while another inadvertently reinforces refusal or argument. Invite key caregivers into the formulation where feasible, describe the target behaviour in plain language, and agree on the immediate response. The goal is not identical parenting styles. It is enough coherence that the child can anticipate what will happen after a behaviour.

13.8 Age, preference, and place in ADHD treatment

For children of preschool age, roughly **3 to 5 years**, behavioural and parent-training intervention is preferred as the initial treatment. This is clinically important because **psychostimulants** have lower short-term efficacy and lower tolerability in preschoolers than in school-aged children. Parent training offers a developmentally appropriate starting point: it increases structure around behaviour while the clinician continues to assess impairment, family capacity, and the need for additional intervention.

Age does not turn treatment into an automatic recipe. **AAP guidance** frames the balance of medication and behavioural treatment differently across development and gives family preference a meaningful role for younger children. For adolescents aged **12-18**, medication with or without behavioural therapy is described as first-line; behavioural therapy alone remains an option when the family declines medication. A candidate should state the age-sensitive principle without presenting behavioural work and medication as adversaries.

Behavioural parent training can be used alongside pharmacotherapy, but this fragment does not teach medication selection, dosing, adverse-effect monitoring, or the evidence for multimodal treatment. Those decisions belong to the pharmacotherapy, monitoring, and multimodal management sections. The parent-training contribution remains distinctive: it changes the

response pattern around behaviour, strengthens caregiver efficacy, and provides a way to work when symptoms continue to create friction despite other treatment.

14 · School-based and psychosocial management

School is a treatment setting, not merely a place where impairment is observed. For a child with ADHD, the classroom repeatedly asks for behaviour that is difficult to organise in the moment: beginning work, persisting through it, waiting, shifting attention appropriately, and responding to correction without disengaging. The clinical task is therefore not to ask a teacher to "manage ADHD" in the abstract. It is to help adults alter the immediate environment so that the desired behaviour is clear, observable, reinforced, and shared across the child's settings.

School-based management belongs within psychosocial treatment because it translates clinical formulation into the places where daily functioning is tested. It does not replace assessment, medication when indicated, parent work, or educational intervention for a coexisting learning difficulty. Its distinctive contribution is practical: the child meets the same understandable expectations at school and at home, and adults receive usable information rather than a succession of global reports that the child was "distracted" or "naughty". Good plans reduce blame on all sides. They make progress visible, preserve the teacher's authority, and give the child a credible route back to success after a difficult period.

School	Home	Plan
CLEAR TARGETS	LINKED INCENTIVES	SHARED REVIEW

14.1 The clinical logic of a school plan

ADHD-related difficulty is often interpreted morally because it is intermittent. A child may complete work under some conditions and fail under another; adults may then conclude that the difficulty reflects unwillingness. A psychosocial formulation asks a more useful question: what happens immediately before the behaviour, what does the adult do next, and what consequence makes the pattern more or less likely to recur? This shifts discussion from personality labels to modifiable contingencies. The target is neither compliance for its own sake nor a perfect classroom. It is participation in learning and relationships with less repeated failure.

The plan should start with a shared functional description. Vague objectives such as "be attentive" or "behave properly" leave each adult to apply a private standard. They are poor teaching targets because the child cannot tell, during a demanding moment, whether success has occurred. A useful target names an action that can be seen and recorded, describes the relevant context, and is phrased positively where possible. "Begins the allotted task when directed" gives adults a common observation point. "Does not create trouble" does not. The distinction matters because the latter invites a running catalogue of errors, whereas the former creates an opportunity to notice competence.

School intervention is most effective when it is formulated collaboratively rather than imposed as a clinical instruction. The teacher brings knowledge of classroom routines, peer dynamics, curricular demands, and what can actually be sustained. Parents bring knowledge of the child's

strengths, interests, pressure points, and how consequences work at home. The clinician protects the formulation from impossible standards and from treating a difficult school period as evidence that the child or adults have failed. The child should understand the plan in developmentally appropriate language and should experience it as help with a real problem, not as public surveillance.

RULE **Specify the behaviour before choosing the consequence.** A consequence cannot teach reliably when adults have not agreed on what counts as the target behaviour, when it occurs, and how it will be noticed.

Targets should be selected for functional importance, not because they are the most irritating behaviour in the room. Establish what blocks access to teaching or damages the child's place in the group, then ask whether the target is within the child's control under current conditions. A plan that begins with an unreachable demand creates repeated evidence of failure and will soon lose adult goodwill. A plan that begins with an achievable, meaningful behaviour gives the child an early experience of agency and gives adults a reason to continue using it.

14.2 Classroom contingencies and teacher partnership

The classroom side of treatment rests on **teacher consultation**, **contingency systems**, and teacher-led observation of the agreed behaviour. Consultation is not a lecture on diagnosis. It is a working conversation about where the target appears, what precedes it, which prompts are already available, how feedback will be delivered, and how information will reach home. The clinician should take the operational burden seriously. A beautifully designed plan that demands more attention than a teacher can spare will quietly disappear.

A contingency system makes the relation between a behaviour and its consequence more immediate and predictable. Recognition, access to a valued classroom privilege, or a token-like marker can all be used when they are tied to the agreed target. The therapeutic element is not the object itself. It is the clarity of the link: the child can see what action has earned the response. Equally important, feedback should not become a stream of criticism. A child who already expects correction may stop trying before the task begins; the plan must therefore create frequent opportunities for adults to catch and name the desired action.

Target-behaviour tracking allows the teacher to move from impressions to observations. It need not become an elaborate record. Its value lies in showing whether the chosen target is improving, whether the context needs modification, and whether home and school are describing the same problem. The record should be intelligible to the people using it. If a teacher cannot complete it within the normal rhythm of class, it is not a clinical instrument; it is an additional task waiting to be abandoned.

ELEMENT	CLINICAL PURPOSE	QUESTION FOR THE TEAM
Observable target	Turns a broad concern into a teachable action	Could each adult recognise it in the same way?
Teacher feedback	Links classroom behaviour to an immediate response	Can it be delivered without disrupting teaching?
Contingency	Makes success meaningful to the child	Does it follow the target consistently?
Brief record	Supports review instead of memory-based judgement	Does it show a pattern that can be acted on?
Home link	Extends the same message beyond school	Do caregivers understand what the record means?

Teacher partnership also requires protecting dignity. The child should not be singled out theatrically or made dependent on a public display of poor performance. Feedback can be clear without being humiliating. The clinician should ask how the plan will look to peers, whether it increases opportunities for repair after mistakes, and whether it preserves ordinary membership of the class. A child with ADHD often needs additional structure; that does not justify making the child the classroom's problem to solve in public.

> **GOOD TO REMEMBER**
>
> When a teacher says that a plan is impossible to carry out, treat this as clinical data rather than resistance. Simplify the target, move the feedback into an existing routine, or redesign the home link. Sustainability is part of treatment fidelity.

14.3 The daily report card as a home-school bridge

The **daily report card**, also described as a home-school report card, is a compact way of joining school performance to family support. It is not a report on the child's worth, and it should never read like a disciplinary diary. It is a brief communication tool focused on a small set of agreed behaviours. The teacher rates the target behaviour during the school routine, sends the information home, and the home response follows the information rather than a parent's guess about what happened in class.

Its strength is the direct bridge between settings. The card makes **parent-teacher collaboration** concrete: the teacher does not have to carry the whole intervention, and parents do not have to reconstruct the school routine from a distressed child's account. The child receives a consistent message that school effort matters at home and that adults are working from the same plan. This is why the report card is a psychosocial intervention rather than an administrative form.

The card should contain **one to four** specific school behaviours; in practice, **two to four** keeps the plan manageable. Keeping the list narrow prevents the card from becoming a score sheet of every difficulty. It also allows the child to know what to do next rather than facing a diffuse demand to improve. The language should describe the action that earns success, not merely prohibit an unwanted act. A meaningful target is tied to a setting where the child can

demonstrate it, such as work initiation, returning to a task after redirection, or following a classroom routine.

The teacher's rating should be simple enough to survive a busy classroom session and should be explained to the child before it is used. The home response should be planned in advance, not negotiated during a conflict at the end of the day. When the target is met, the child earns a home-based reward linked to the school behaviour. When it is not met, the card should signify that the goal was not reached, not that the child deserves shame or an escalating punishment. This distinction protects the learning function of the intervention. A negative card is information about the plan, the context, or the target, not an invitation for adults to intensify hostility.

MNEMONIC

CLEAR

Choose an observable target; **L**ink it to the classroom routine; **E**xplain the expectation; **A**cknowledge the result; **R**eview the record together. It is a practical spine for keeping a report card therapeutic rather than punitive.

Review is essential. If the same target is repeatedly not achieved, the question is not simply whether the child needs a harsher consequence. The team should revisit whether the target was clear, whether the classroom demand exceeded current capacity, whether the teacher had a workable prompt, and whether the home incentive still carries meaning. Conversely, when the child is doing well, adults should avoid silently raising expectations until success disappears. A plan has value when it teaches a skill and supports participation, not when it becomes a moving test of obedience.

TRAP **Do not turn the report card into a punishment ledger.** When every difficult moment is entered and the home response is mainly punitive, the card teaches avoidance and adult conflict rather than the school behaviour it was meant to strengthen.

14.4 Antecedent planning beyond the desk

School plans work better when they do not wait for disruption before acting. **Antecedent-based behaviour management** asks adults to prepare for predictable points of strain. The relevant questions are: what demand is approaching, what environmental feature increases the likelihood of difficulty, what expectation must be stated beforehand, and what response will follow success or non-success? This is a disciplined alternative to reacting only after behaviour has deteriorated.

The **A-B-C model** provides a usable sequence. Adults anticipate likely problems, restructure antecedents where possible, communicate the expectation, plan the consequence, and reward the positive behaviour. In a school context, this may mean thinking ahead about a transition, a demanding task, a period requiring waiting, or a situation in which peer stimulation is high. The point is not to remove all challenge. It is to make the path through a foreseeable challenge explicit enough that the child can practise a different response.

- Identify the situation in which the difficulty reliably emerges.

- State the expected behaviour before the demand begins.
- Arrange the adult response so that success is noticed and mistakes can be repaired.

Antecedent planning has a useful psychosocial effect on adults as well. It interrupts the familiar escalation in which adults interpret a child's difficulty as defiance, increase emotional intensity, and then receive more dysregulation in return. A pre-agreed response allows the teacher and parent to act with less improvisation. That does not make the child passive. On the contrary, it creates a repeated opportunity for the child to predict what is wanted and to experience that a different action leads to a different outcome.

Although it is especially visible in classrooms, the skill generalises to other structured settings. The same clinical logic can be used when a family anticipates a demanding routine outside home, when the child is entering a social situation, or when a planned activity has a known pressure point. The intervention remains psychosocial because it changes the interaction between demands, adult communication, and consequences. It should be coordinated with parent-training work rather than duplicated; the detailed parent-training framework is addressed in the behavioural and parent training interventions section.

PITFALL

Do not confuse anticipation with overprotection. The purpose is to prepare for a demand and teach participation within it, not to remove every situation that might be difficult. If the plan consistently shrinks the child's opportunities, it may reduce short-term conflict while preserving long-term impairment.

14.5 Coordination, review, and clinical boundaries

A school plan has to be embedded in a working relationship. The clinician should clarify who will explain the plan to the child, who will observe the target, how information will be communicated, and how disagreement will be handled. Parent and teacher may hold different views of the child's difficulties. That disagreement should be explored rather than solved by declaring one setting correct. Behaviour may genuinely vary with task demands, adult style, peer context, sleep, treatment effects, and emotional state. The goal is a shared intervention hypothesis, not a forced consensus about blame.

The school record can also improve clinical review. It gives the treating team a window into functional change that is closer to the learning environment than a retrospective global impression. It should not be treated as a diagnostic test, nor should it replace a comprehensive assessment of ADHD, comorbidity, learning needs, family context, or medication effects. Rating-scale selection and interpretation belong to the dedicated rating-scales section. Where a specific learning difficulty is suspected, assessment and remedial planning should be pursued through the relevant learning-disorder sections rather than attributing all academic struggle to ADHD.

Communication requires consent, clarity, and proportion. Families should know what information is being shared, why it is relevant, and who will receive it. Teachers need concise, practical guidance rather than confidential clinical detail that does not alter classroom

management. A note that says “use the agreed target and report-card routine” may be more useful and safer than a long diagnostic summary. The clinician should also resist treating the school as an extension of the clinic. Educational staff make their own professional judgements; psychiatric input is most helpful when it is collaborative, specific, and responsive to the school’s real constraints.

IN INDIA

School collaboration may involve a class teacher, a coordinator, and family members with different expectations about discipline, academic performance, and disclosure. Begin by identifying the adult who can reliably implement the agreed routine, use plain language for targets, and avoid assuming that a written communication channel is the only feasible home-school bridge. If educational accommodations or formal learning assessment are relevant, address them through the learning-disorder management and educational-provisions sections rather than adding unsupported promises to an ADHD behaviour plan.

There are clear limits to what school management can accomplish. It cannot compensate for an unrecognised learning disorder, an untreated emotional disorder, severe family stress, bullying, or a classroom environment that is unsafe for the child. Nor should it be used to postpone needed clinical treatment simply because a teacher has agreed to try harder. Conversely, the presence of medication does not make school intervention unnecessary. Pharmacological and psychosocial approaches address different parts of functioning; the evidence and logic of multimodal treatment are considered in the multimodal treatment of ADHD section.

When a plan is not working, revise the formulation before judging the child. Ask whether the target is meaningful and observable, whether adults are responding consistently enough for the child to understand the connection, whether the home incentive is still linked to the school behaviour, and whether the presumed problem is actually another unmet need. This stance keeps the intervention clinical. It also prevents a damaging drift from support toward surveillance.

14.6 What the candidate should be able to formulate

In an answer or case discussion, describe school management as a coordinated behavioural intervention rather than a list of generic classroom tips. Begin with functional impairment in the educational setting. Then state that the team will define an observable target, arrange teacher feedback and a classroom contingency, track the target behaviour, and link school information to a planned home response. Explain that this creates consistent incentives across settings and strengthens parent-teacher communication. The answer becomes more clinically persuasive when it shows why a target must be achievable, why a negative report should be treated as information, and why the plan must be reviewed rather than mechanically continued.

The most defensible formulation preserves several distinctions. Classroom contingencies are not public shaming. A daily report card is not a punishment sheet. Antecedent planning is not avoidance of all demands. Teacher consultation is not a transfer of medical responsibility to the school. Finally, school intervention is not a substitute for evaluating difficulties that lie outside its

scope. Holding these distinctions allows the clinician to be both practical and appropriately modest.

> A school plan for ADHD succeeds when adults agree on a small observable target, respond predictably to it, and connect school feedback with supportive consequences at home.

15 · Multimodal treatment of ADHD and MTA study evidence

Multimodal treatment is a clinical strategy, not a slogan. ADHD is expressed at home, in school and in relationships, so treatment has to be organised around the child's impairments, comorbidity, family capacity and school context. The important examination question is not whether medication or behavioural work is "better" in the abstract. It is what outcome is being pursued, which component can plausibly change it, and how the components are made to work together.

The **Multimodal Treatment Study of Children with ADHD** is the central comparative trial for this reasoning. Its enduring value is that it separates symptom control from broader functioning, compares an intensive treatment strategy with ordinary care, and forces a more mature conclusion than "combined treatment always wins."

579	7 to 9.9 years	four	14 months
RANDOMISED CHILDREN	ENTRY AGE	TREATMENT ARMS	PRIMARY PHASE

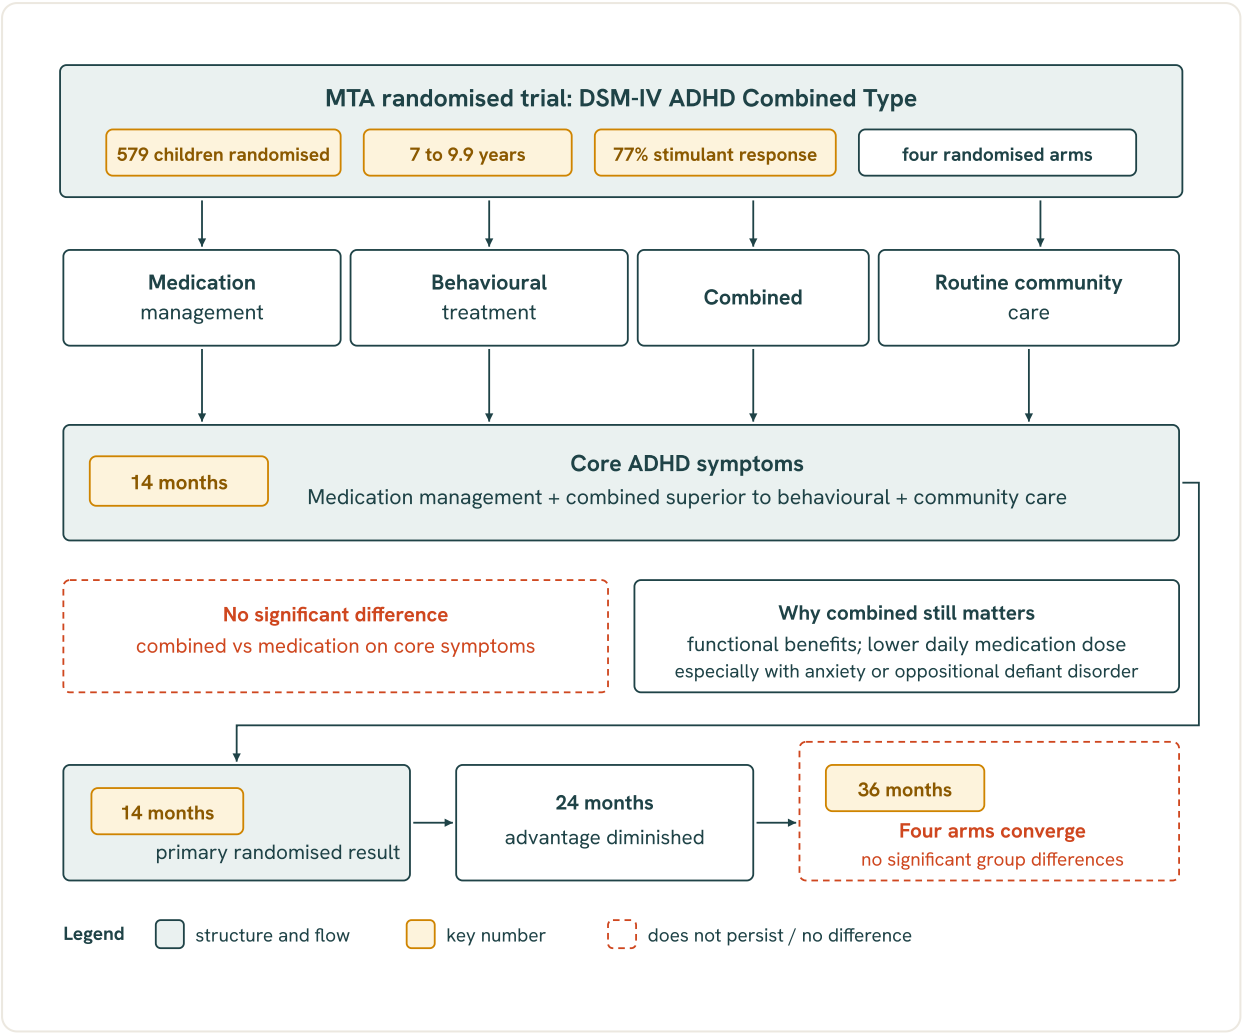


Fig 22.14. MTA four treatment arms: medication strategies led core ADHD symptoms at 14 months, but original-group differences converged by 36 months.

15.1 What multimodal treatment means in practice

Multimodal treatment means a coordinated plan in which biomedical, behavioural, educational and family-facing components have distinct jobs. It does not mean handing every family a standard bundle. A plan becomes genuinely multimodal when its parts are linked to a formulation: medication may be used to reduce core symptoms sufficiently for the child to participate in learning and skill practice; parent work may alter coercive interaction cycles and make routines more predictable; school measures may reduce the mismatch between demands and the child's current capacities. The aim is coherence across settings, not accumulation of referrals.

This distinction matters because a core symptom score and a meaningful improvement in daily life are related but not identical outcomes. A child may be less distractible yet continue to have conflict, academic underachievement, poor peer functioning or family strain. Conversely, a family may report smoother routines while impairing symptoms remain insufficiently controlled. The clinician should therefore specify the target outcome before declaring a treatment successful or unsuccessful. That discipline prevents both premature medication switching and the equally common error of continuing a psychosocial intervention without checking whether it is addressing the problem for which it was selected.

Multimodality is also a way of managing uncertainty. ADHD commonly appears with difficulties that change the treatment task, and the child's needs can differ between home and classroom. A formulation should identify the dominant impairment, available supports and barriers to implementation. The behavioural and school-based components are described in the relevant treatment sections; here, the key point is that they must be coordinated with medical care rather than treated as a competing ideology.

RULE **Match each treatment component to a defined impairment and a measurable outcome.** Medication, parent work and school support should be selected because each has a role in the formulation, not because "multimodal" sounds comprehensive.

15.2 Why the MTA study is clinically useful

The MTA enrolled children with **DSM-IV ADHD Combined Type**. This scope matters when interpreting the evidence. The study provides strong evidence about the population it studied, but it should not be converted automatically into a claim about every presentation, age group or clinical setting. Good evidence use starts with asking whether the child in front of us resembles the study population and whether the care system can deliver an intervention of similar intensity.

The randomised comparison had **medication management, behavioural treatment, combined treatment and routine community care**. These arms were not simply labels for a tablet, a few counselling sessions and "usual care." They represented treatment strategies. The medication arm involved systematic clinical management; the behavioural arm was a deliberately intensive package; the combined arm brought both strategies together. Community care was crucial because it asked whether a carefully delivered study strategy offered more than what families ordinarily received.

The primary comparison was made at **14 months**. This is the anchor for the initial result, not a licence to describe all later observations as though they were part of the same randomised treatment exposure. Once the intensive phase ended, treatment in the real world changed. Subsequent findings therefore illuminate the durability and transportability of early advantage, but they answer a different question from the primary randomised comparison.

For candidates, the study is useful because it tests propositions that are often blurred in clinical discussion:

- Whether a structured medication strategy improves core symptoms more than behavioural treatment alone or community care.
- Whether adding behavioural treatment improves core symptoms beyond well-managed medication.
- Whether a combined plan has advantages on outcomes that extend beyond the core symptom count.

MNEMONIC

Symptoms, Settings, Sustenance

Read the MTA by asking what happens to core symptoms, what changes across home and school settings, and whether the early advantage is sustained when care becomes naturalistic.

15.3 The initial result: symptom control is not the whole result

At the primary endpoint, **medication management and combined treatment** were superior to behavioural treatment alone and routine community care for core ADHD symptoms. This is the headline finding, and it supports a clear clinical conclusion: when core symptoms are the immediate source of impairment, a carefully managed medication strategy is an important part of evidence-based care. It does not imply that behavioural work is unimportant; it means that behavioural treatment alone did not match the symptom effect of the study medication strategies in this comparison.

Just as important, there was **no significant difference between combined treatment and medication management alone for core ADHD symptoms**. This is the sentence that protects against the simplistic claim that every child requires every component to obtain symptom control. Adding a component should be justified by the child's residual problems, comorbidity, family goals and functional setting, rather than by an assumption that a larger package must produce a larger symptom effect.

The combined arm nevertheless showed advantages on **non-core and functional outcomes**, including domains of behaviour, emotional symptoms, social competence, parent-child relations and reading achievement where medication management alone did not show the same advantage. This is not a contradiction. Core symptoms and functioning are related but separable targets. Behavioural and educational work can create opportunities for practice, reduce conflict and change environmental contingencies even when the additional effect on the core symptom outcome is not demonstrably greater.

QUESTION	MTA-INFORMED ANSWER	CLINICAL READING
Core ADHD symptoms	Medication management and combined treatment outperformed behavioural treatment and community care.	Do not mistake a broad plan for a substitute for adequate symptom treatment.
Combined versus medication alone	No significant core-symptom advantage was demonstrated for combined treatment.	Add components for a defined additional target.
Broader functioning	Combined treatment had advantages in selected functional and associated symptom domains.	Ask about relationships, school functioning and emotional burden, not symptoms alone.
Medication dose requirement	The combined arm required a lower average daily medication dose than medication management alone.	Do not translate this finding into an individual dose rule.

TRAP **"Combined treatment was not better, so behavioural work has no role."** This confuses a core-symptom comparison with the full treatment task. Functional outcomes and comorbidity can make a combined plan clinically preferable even when symptom scores do not separate the medication-containing arms.

15.4 What the comparison with community care actually shows

The community-care comparison is often misread as medication versus no medication. It was not. The study medication strategy was superior to **community care despite medication use within community care**. The clinically defensible interpretation is that treatment quality matters: diagnostic review, deliberate titration, follow-up, target monitoring and communication with the family are part of the intervention. A prescription without a management system is not equivalent to structured medication care.

This has a practical implication for follow-up visits. The clinician should not ask only whether the child is "better." Review should be tied to target symptoms, settings, adverse effects, adherence, practical obstacles and the family's account of benefit. When school feedback is available, it can test whether improvement seen in the consulting room transfers to the environment where sustained attention, organisation and inhibition are demanded. The precise medication regimen belongs with stimulant pharmacotherapy; the MTA lesson is about the quality and continuity of the strategy rather than a dose schedule.

It also explains why service context matters. Community care is heterogeneous. Some families receive fragmented reviews, limited school communication or an intervention that cannot be delivered consistently; others receive careful longitudinal care. The trial should therefore make the clinician more demanding about the process of treatment, not contemptuous of community clinicians or families. The question is whether the care plan has a feedback loop that can identify nonresponse, partial response, changing impairment and obstacles to adherence.

IN INDIA

A multimodal plan must be feasible for the family. Build the plan around realistic follow-up, a parent's capacity to carry out home strategies, and a school contact who can observe change. If intensive specialist behavioural input is not locally available, preserve the logic of coordination rather than offering a long, impracticable list of referrals.

15.5 Behavioural treatment in a combined plan

The MTA behavioural intervention was not a token add-on. It was an intensive package combining **parent training, a child-focused summer treatment programme and teacher consultation with classroom support**. This matters for interpretation: a trial finding about such a package should not be casually applied to a brief, poorly coordinated intervention that happens to be called behavioural treatment. Intensity, fidelity and cross-setting implementation influence what an intervention can plausibly achieve.

For the clinician, behavioural work is most useful when it addresses a problem medication alone cannot solve. Examples include conflict around routines, inconsistent reinforcement, difficulty

generalising gains across settings, a child's need for structured skill practice, or family distress that interferes with treatment implementation. Its role is not to prove that the child can manage without medication, nor is it to make parents responsible for a neurodevelopmental condition. It is a way of changing the contingencies and interactions through which impairment is maintained or expressed.

The MTA-derived clinical lesson is that **concomitant behavioural treatment may add benefit in comorbidity**, particularly when anxiety or oppositional defiant disorder is present. This is a formulation-based indication, not a universal rule. In such situations, the treatment plan needs targets that are wider than inattention and activity level: emotional distress, coercive family interactions, oppositional behaviour, avoidance, peer difficulties and school participation may require direct attention. The disorders themselves are addressed in the Child behavioural, emotional and other disorders notes.

GOOD TO REMEMBER

When a child has a satisfactory symptom response but remains impaired, ask what is still failing: the family routine, emotional symptoms, oppositional behaviour, peer functioning, reading, school accommodation or treatment implementation. The residual impairment, not a doctrine of "combination," selects the next component.

PITFALL

Do not call an intervention multimodal merely because several professionals have seen the child. Without shared targets, feedback and role clarity, parallel inputs can burden the family while leaving important impairments unaddressed.

15.6 Stimulant-response figures: define the denominator before quoting one

The MTA is also quoted for stimulant response, but the figure depends on the construct being described. The study reports a **77%** response rate in the medication titration context. This is a useful anchor when discussing response to the initial stimulant strategy, but it should not be made to answer a different question, such as cumulative response after an additional stimulant trial or maintenance of a particular regimen.

A separate framing describes cumulative response to the first or second stimulant trial as **about 90%**. It includes response to an initial methylphenidate trial and a subsequent dextroamphetamine trial. These figures are not interchangeable because the treatment exposure and denominator differ. In an examination answer, state what the number denotes. In a clinical conversation, avoid allowing a group response figure to become a promise about an individual child.

This distinction has broader value. "Response" can refer to symptom change, clinician judgement, parent report, school report, tolerability or continuing treatment. Before using response to guide a decision, define the target and obtain information from the setting in which impairment matters. A child may have a meaningful reduction in symptoms but an incomplete functional

recovery, or may stop a helpful medicine because the balance of benefit and burden is unacceptable. Neither situation is captured by a bare percentage.

15.7 Follow-up: early randomised advantage and later convergence

At **24 months**, the advantage of the medication strategy over behavioural and community care persisted, but was smaller than at the primary endpoint. This is a transition point in interpretation. It does not erase the early evidence for structured medication management; it indicates that effect sizes and between-group differences must be read in the context of changing treatment exposure and ordinary developmental and environmental change.

By **36 months**, the original treatment groups did not differ significantly on outcome measures, and the earlier medication-algorithm advantage was no longer apparent. This is not evidence that the initial result was false. Rather, it warns against treating the original randomisation as a permanent treatment state once families move into naturalistic care. Follow-up answers a different question: what happens to an initially randomised cohort after treatment pathways, adherence and circumstances have had time to diverge.

The follow-up samples remained substantial: 540 of 579 participants, or 93%, contributed at the earlier follow-up, and 485 of 579 participants, or 83.8%, participated at the later follow-up. Retention helps confidence in the observations, but it does not restore the original contrast once treatment is no longer controlled in the same way. Candidates should avoid claiming either that medication has no long-term value or that an early trial advantage proves an unchanging long-term between-group effect.

Across the cohort, **symptoms improved from baseline regardless of original assignment**. Initial severity, comorbidity, public assistance and parental ADHD predicted poorer later outcomes independently of the assigned treatment. This finding shifts the long-term clinical emphasis toward ongoing formulation and review. Treatment is not a single event at diagnosis. The clinician revisits impairment, context, comorbidity and supports as the child's developmental and educational demands change.

15.8 How to use MTA evidence in an individual formulation

The most useful MTA-informed formulation begins with a hierarchy of targets. If core symptoms are driving current impairment, make sure there is an adequately managed symptom treatment strategy. If the child also has family conflict, emotional symptoms, oppositional behaviour, social difficulty or academic impairment, decide which additional intervention has a credible mechanism for that particular target. Build review around observable change in the relevant setting. This is more rigorous than asking whether "multimodal treatment" has been given.

There are limits to what the trial can answer for an individual child. It does not replace assessment of learning, language, developmental history, safeguarding concerns, family stress or treatment preference. It does not tell the clinician which school accommodation will be feasible, nor does it replace a careful adverse-effect review. Those matters belong to the assessment, school management and medication-monitoring sections of this chapter. The MTA supplies a framework for integrating their findings, not a substitute for them.

Finally, communicate the evidence without polarising the family. Explain that medication can be important for core symptoms, that behavioural and school interventions can address meaningful functional problems, and that the plan will be revised according to the child's actual progress. This stance validates parental effort without implying that good parenting is a treatment for ADHD, and it avoids presenting medication as the whole of care. Coordinated, outcome-focused follow-up is the practical form of multimodal treatment.

> The MTA supports structured medication management for core ADHD symptoms, while combined care earns its place by targeting functional impairment, comorbidity and the child's real-world context.

ADHD beyond childhood and its outcome

16 · ADHD in adolescents and adults (persistence, transition)

Why this matters clinically. ADHD does not end at the clinic door when a young person leaves school. The developmental task is to recognise continuity without assuming that the childhood picture has remained unchanged. The adult consultation therefore asks a different question from the paediatric consultation: not merely whether symptoms are still present, but how their current form, context and functional consequences connect with a developmental history.

For the resident, this is a transition problem as much as a diagnostic one. A person may no longer look like the child described in an old school report, yet may still be impaired by a pattern that has changed in visibility rather than disappeared. Conversely, a current complaint of poor concentration should not be made to carry a childhood diagnosis without reconstructing its course. Good adult ADHD work holds both possibilities in mind, uses the patient's account respectfully, and actively tests it against available developmental evidence. That distinction affects engagement and planning as well as diagnostic accuracy.

16.1 Persistence is not an all-or-none outcome

The useful starting concept is **persistence**. It means that clinically meaningful ADHD may continue beyond childhood, but does not imply that every person retains the same symptom burden or the complete diagnostic syndrome. Follow-up findings differ according to how persistence is defined and how information is obtained. That methodological variation is not a reason to dismiss the finding; it is a reason to explain clearly what kind of persistence is being discussed.

One estimate suggests that ADHD persists in some form for **about 65%** of people with childhood ADHD. A separate estimate places persistence into early adulthood at **about 70%**. These figures should be read as convergent support for a substantial developmental continuity, rather than as competing verdicts about one fixed fate. The examiner is usually looking for the distinction between persistence of clinically relevant difficulties and persistence of the entire childhood syndrome.

Full diagnostic syndrome is the narrower outcome. It is retained by **about 15%** of childhood cases in adulthood. This is not a contradiction of the larger persistence estimate. It identifies the subgroup whose adult presentation continues to satisfy the full diagnostic threshold, while other people remain symptomatic or functionally affected without that full syndromal picture.

Partial remission is often the clinically more useful middle category. It refers to a developmental course in which difficulties remain important but no longer constitute the full syndrome. The proportion described in this range is **40% to 60%**. It prevents an unhelpful binary in which a patient is considered either wholly recovered or unchanged. In practice, partial remission may still matter greatly when the person's work, relationships or self-management demands have increased.

about 65%	about 15%	40% to 60%	about 2.5%
PERSIST IN SOME FORM	FULL SYNDROME	PARTIAL REMISSION	ADULT PREVALENCE

RULE **Persistence means continuity of clinically relevant ADHD, not automatic retention of the full childhood syndrome.** State this distinction before interpreting any adult symptom count or outcome label.

Adult ADHD is best understood as a developmental continuation whose expression may be full, partial, or no longer syndromal.

16.2 The adult presentation is a change in expression

Development alters the clinical surface of ADHD. The relevant shift is in the **symptom profile**: hyperactivity and impulsivity tend to decline across adolescence and early adulthood, whereas inattention often persists. The important word is "tend". A developmental tendency should guide enquiry, not become a stereotype that makes the clinician overlook an individual's current difficulties.

In adulthood, diminished overt motor activity may be experienced or described as inner restlessness, impatience, a sense of being driven, or difficulty slowing down. These descriptions need to be placed in the person's developmental narrative rather than treated as self-explanatory. They can be clinically relevant precisely because the visible childlike form has attenuated. The task is not to reproduce a classroom description in an adult consultation; it is to identify whether the present experience belongs to a persisting developmental pattern.

Inattention is often more durable and may be recognised through the person's account of organisation, task initiation, follow-through, distractibility and the effort required to maintain direction. Functional demands can expose these difficulties differently over time. An adult may have less externally imposed structure but more responsibility for creating structure. This can make an old vulnerability newly visible without proving that the disorder is newly acquired.

DEVELOPMENTAL FEATURE	ADULT EXPRESSION TO EXPLORE	CLINICAL IMPLICATION
Overt hyperactivity	Restlessness or difficulty settling	Ask about subjective experience, not appearance alone.
Impulsivity	Hasty responding or difficulty pausing	Place the report in the wider developmental pattern.
Inattention	Persistent difficulty directing and sustaining effort	Explore its functional expression in current roles.
External structure	Greater need to organise one's own tasks	Assess how context reveals or contains difficulty.

The table is a prompt for clinical translation, not a replacement for a developmental history. The core phenomenology of ADHD is addressed elsewhere in this chapter. Here, the key point is that the adult form is neither a miniature copy of the child form nor an unrelated concentration complaint. The meaning of the complaint emerges from its longitudinal pattern.

GOOD TO REMEMBER

When an adult says, "I was never hyperactive," clarify what they mean by hyperactive. A denial of visible childhood behaviour does not settle whether restlessness, impulsive action or attentional difficulty has followed a developmental course.

16.3 Predictors guide vigilance, not deterministic counselling

Persistence is associated with childhood symptom severity, childhood comorbidity and **parental mental health**. These are predictors of a course, not a checklist that can determine an individual outcome. Their clinical value lies in identifying who may need a more deliberate transition review and in prompting the clinician to look for persisting needs that may have been obscured by a change of setting.

Severity matters because a more prominent childhood burden may be more likely to remain clinically relevant. Childhood comorbidity matters because ADHD rarely appears in a vacuum, and the developmental story can become harder to interpret when another condition has affected functioning or reporting. Parental mental health belongs in the formulation as part of the developmental context and may also affect the quality and availability of collateral information. None of these factors should be used to convert a probability into a prognosis delivered as certainty.

An equally useful examination contrast is what should not be overread. **Individual IQ**, socioeconomic status and the quality of the parent-child relationship show no apparent impact on persistence. This does not make those matters irrelevant to care, opportunity or the patient's lived experience. It means that they should not be presented as established predictors of whether ADHD itself persists. The distinction protects against the common error of turning every contextual fact in a history into a causal explanation.

This distinction is also ethically important. A difficult family history, social disadvantage or an uneven educational opportunity may shape the consequences of ADHD and the help a person

can obtain. They should be addressed in care for that reason. They should not be casually recast as proof that the developmental condition will persist, nor should a favourable circumstance be treated as evidence that current impairment is implausible. Formulation is wider than prediction.

- Use recognised predictors to decide how carefully to review continuity.
- Separate a predictor of persistence from a factor that changes access to support.
- Keep comorbidity in the formulation without allowing it to erase the ADHD trajectory.
- Explain uncertainty honestly when discussing an individual course.

MNEMONIC

TRACE

Track the developmental course, **R**eview changing expression, **A**sk the adult, **C**heck collateral, and **E**xamine alternative explanations. It is a consultation spine, not a diagnostic shortcut.

16.4 Transition should preserve the developmental narrative

Transition is vulnerable when responsibility for care changes before the explanatory story has been carried forward. The young person may experience the move to adult services as a demand to begin again, while the receiving clinician may see only current complaints. A useful transition record therefore states the childhood pattern, the way the presentation has changed, the current areas of difficulty, the patient's own priorities, and the evidence that supports continuity. It is a clinical bridge, not an administrative summary.

Adolescent autonomy should be actively respected. The person's account becomes central, and it may differ from the family account without either account being discarded. The consultation should make room for privacy, consent and the patient's developing ownership of treatment decisions. At the same time, it should explain why a developmental condition may require carefully chosen collateral rather than relying on a single present-tense narrative.

Educational, occupational and domestic demands can change during this period. Do not assume that a change in achievement either proves remission or proves persistence. A person may be supported by a setting that compensates for difficulties, or may be struggling despite an outwardly acceptable record. The clinically relevant question is how attention, self-organisation, activity regulation and impulsivity affect the tasks the person is trying to perform, and whether that pattern is continuous with earlier life.

Transition is also a point at which the clinician should reconsider formulation rather than simply renew an inherited label. Current symptoms may have multiple meanings. The developmental history provides an anchor, but it does not excuse a failure to assess alternative explanations for present distress or impaired concentration. This preserves diagnostic rigour without making access to adult care depend on a perfect archive.

IN INDIA

When care moves across settings, create a concise handover that the patient can understand and retain. Agree with the patient whether family collateral may be sought, record what evidence is available, and do not allow missing paperwork to substitute for a developmental enquiry.

PITFALL

Equating an absent school record with an absent childhood history is unsafe reasoning. Records may be unavailable for many reasons; the correct response is to seek a careful developmental account and any feasible collateral, not to manufacture certainty in either direction.

16.5 The adult patient is the primary informant, but not the only source

Adult assessment begins from the patient's account. **Adult self-report** is ordinarily the primary source of information, unlike childhood assessment where parents and teachers are primary informants. This shift follows the patient's autonomy and direct knowledge of current inner experience. It also changes the clinician's stance: the patient is not a bystander to a history obtained from others.

Primary does not mean sufficient in every case. Adult ADHD requires a developmental account, and current self-report cannot independently recreate childhood. Collateral, past records and reports from people who know the person in relevant settings can help test continuity and clarify discrepancies. They should be sought with consent and used to add perspective, not to overrule the adult patient automatically. The quality of collateral depends on its proximity to the period and behaviour being described.

A good interview distinguishes present symptoms, remembered childhood experiences and the patient's interpretation of both. The adult may have learned explanatory language from prior contact, media, family discussion or their own reading. That does not make the account untrustworthy. It means the clinician should ask for concrete developmental examples and functional consequences rather than rewarding a fluent diagnostic narrative.

Collateral is especially valuable when the question is onset and course. It is less useful when it is treated as a vote on whether the person is "really" impaired. Informants observe different settings and may have their own blind spots. The clinician's role is to integrate accounts, identify the common developmental thread, and document remaining uncertainty rather than forcing consensus.

TRAP **Do not mistake "the patient is the primary informant" for "the patient's recall alone establishes childhood onset."** Adult autonomy and collateral history are complementary, not competing, principles.

16.6 Retrospective recall needs methodological humility

Self-report has a known limitation. **Young adults** are frequently poor reporters of ADHD symptoms, although reliability improves later in adulthood. In addition, both adults and parents may recall childhood ADHD poorly. This is not a moral failing and it is not peculiar to one family.

Retrospective memory reconstructs the past through current knowledge, current difficulties and the fragments that remain available.

Where prospective documentation exists, recalled onset may be reported **up to 4 years later** than the onset recorded at the time. The practical lesson is not that retrospective history is useless. It is that its time-line should be treated as an estimate requiring corroboration when the diagnostic question depends on it. A confident narrative can still be imprecise; an uncertain narrative can still contain a true developmental signal.

The consultation becomes stronger when it asks how a conclusion was reached. Explore what the patient personally remembers, what others observed, what documentary traces exist, and where the account remains inferential. This is a clinical reasoning exercise, not an interrogation. It enables the clinician to weigh evidence while preserving rapport and avoiding the false comfort of a single source.

- Separate current experience from remembered childhood experience.
- Ask what supports the proposed developmental time-line.
- Record discrepancy rather than editing it out of the history.
- Use uncertainty to guide further enquiry, not to prematurely close the case.

16.7 Adult-onset presentations remain a live controversy

Adult-onset ADHD is an emerging and unsettled idea. Emerging evidence has suggested that ADHD may arise in adulthood, challenging the assumption that it must always have a childhood neurodevelopmental origin. This should be presented as a controversy under examination, not as permission to abandon developmental assessment or as proof that every adult attention complaint represents a new disorder.

The controversy matters because it sharpens the clinician's reasoning. When symptoms appear to begin in adulthood, ask whether earlier symptoms were absent, unrecognised, compensated for, poorly recalled, or obscured by context. Then ask whether the current syndrome may be better explained by another process. The answer should come from a careful developmental reconstruction and a broad clinical formulation, not from allegiance to one side of a debate.

For examinations, the balanced formulation is strongest: adult presentations are clinically real and deserve assessment; continuity from childhood is often important; retrospective evidence has limitations; and the proposition of adult onset remains provisional. This avoids both extremes. One extreme dismisses adult suffering because childhood documentation is incomplete. The other accepts a current concentration complaint as ADHD without sufficient developmental or clinical scrutiny.

The accompanying prevalence figure reinforces that adult assessment is not a marginal afterthought to child psychiatry, even where the adult's account must still be weighed alongside developmental evidence. It is a distinct clinical task requiring developmental continuity, current functional understanding and disciplined handling of uncertainty.

17 · Prognosis and long-term outcome of ADHD

Prognosis in ADHD is a formulation, not a verdict. The diagnosis names a pattern of difficulty; it does not by itself describe how a particular person will function in later life. A useful account of outcome asks what difficulties have continued, what impairment has accumulated, which comorbid pathway is active, what supports are available, and whether treatment has been sustained. This matters because families often hear prognosis as a prediction of identity or worth, while the clinician needs to translate it into a plan for reducing avoidable harm and preserving participation in ordinary developmental roles.

For the postgraduate trainee, the central task is to move beyond the false choice between "will grow out of it" and "will always be disabled by it". Both statements collapse a heterogeneous course into a slogan. Prognosis should instead be written as a **developmental formulation**: current symptoms, functional demands, coexisting disorders, exposures that amplify risk, and interventions that may change the pathway. The companion discussion of adult presentation and transition belongs in the section on ADHD in adolescents and adults; the present focus is how to reason about long-term outcome without turning a population association into a prophecy about an individual.

Course	Function	Context	Risk
FOLLOW CHANGE OVER TIME	ASK WHAT PARTICIPATION COSTS	IDENTIFY SUPPORTS AND STRESSORS	LOOK FOR THE CONDUCT PATHWAY

17.1 What "outcome" should mean in ADHD

A long-term outcome is broader than whether a diagnostic label is still applied at a later assessment. It includes the person's ability to use attention and self-regulation in the settings that matter to them, to maintain relationships and work roles, to make safe choices, and to access care when needs change. This is a **functional outcome** perspective. It prevents the familiar error of judging success only by visible restlessness, while overlooking disorganisation, conflict, repeated underperformance, demoralisation, or dependence on others to keep daily life on track.

The same symptom pattern can carry different consequences in different environments. A person whose surroundings provide structure, reminders, predictable expectations, and a non-shaming response may have a very different experience from a person facing repeated criticism, unstable routines, academic exclusion, or unrecognised comorbidity. This is not a reason to make prognosis vague. It is a reason to describe the conditions under which difficulty becomes impairment. In clinical notes, it helps to distinguish the symptom burden from its consequences and from the supports that are currently compensating for it.

Outcome is also not restricted to a binary question of remission. A person may show fewer overt difficulties and yet continue to require considerable effort, environmental scaffolding, or treatment to function well. Conversely, an individual may retain symptoms but achieve stable participation when demands fit their strengths and support needs. The clinician should therefore ask about the quality and cost of functioning. This language is less deterministic, more useful for shared decisions, and kinder to the patient without minimising genuine risk.

- Describe the current pattern of impairment rather than assuming that symptom visibility captures the whole problem.
- Identify settings in which the person functions better, because these often reveal usable supports rather than a lack of disorder.
- Separate a present difficulty from an irreversible life conclusion.
- Revisit the formulation when developmental demands, living circumstances, or comorbid symptoms change.

RULE **In ADHD, prognosis is best expressed as an evolving risk-and-function formulation, not as a promise of recovery or decline.** The formulation makes explicit what is known now, what may change, and what can still be modified. It also protects against the clinical laziness of treating the diagnosis as the explanation for every later difficulty.

17.2 Course begins with the early clinical picture

When ADHD is identified in the preschool period, clinicians sometimes assume that the label is merely a transient description of high activity. The available follow-up evidence does not support casual reassurance of that kind. In children with **preschool ADHD**, the diagnostic picture was relatively stable across **6-year follow-up**; the reported course was generally chronic, with substantial symptom severity and impairment, particularly where the presentation was more severe, despite medication.

The correct teaching point is neither fatalism nor therapeutic nihilism. Early identification should prompt a careful longitudinal plan: clarify impairment, obtain collateral information, look repeatedly for changing needs, and support the adults who organise the child's environment. The persistence of difficulty in a follow-up cohort means that an early diagnosis deserves clinical seriousness. It does not mean that every child will have the same later experience, or that treatment has no value because symptoms remain.

Longitudinal thinking also corrects a common sequencing error. Prognosis should not be deferred until a crisis in schooling, family life, substance use, or the law has already developed. From the first assessment, the clinician can record what is impairing, what reduces impairment, and what risks would require a change in the care plan. This makes later review cumulative rather than reactive. It also allows the patient and family to understand that follow-up is not a sign of failure: it is the mechanism by which care responds to changing demands.

GOOD TO REMEMBER

At review, ask what has changed in the person's actual life, not only whether the original symptom description still sounds familiar. A functional account of outcome is more informative than a label carried forward without re-examination.

17.3 Heterogeneity is clinically important

ADHD is not a uniform pathway. The same diagnosis can coexist with very different temperaments, family resources, educational experiences, psychiatric comorbidities, and

opportunities for treatment. Prognostic work therefore begins by identifying **risk stratification** variables rather than searching for a single trajectory. The important question is not "what happens to ADHD?" but "what is happening to this person, through which pathway, and what can be changed?"

Such a formulation has practical consequences. It guides the intensity of follow-up, the urgency of collateral assessment, the need to involve family or other supports, and the threshold for addressing safety-related behaviour. It also disciplines communication. Patients should be told when an association is relevant, but should not be told that an associated outcome is inevitable. The clinician can be honest about risk while leaving room for agency, treatment, and the many contextual factors that influence a person's path.

PROGNOSTIC QUESTION	WHAT IT CLARIFIES	CLINICAL USE
What is the current impairment?	Which activities and roles are being affected	Sets a meaningful target for care
Which difficulties are persistent?	Whether support must be sustained across changing demands	Prevents premature discharge from follow-up
Is a comorbid pathway present?	Whether risk is being attributed too simply to ADHD	Directs assessment beyond core symptoms
What is helping already?	Which environmental or therapeutic supports are protective	Preserves effective supports during transition
What new exposure changes the risk?	Whether the formulation needs revision	Triggers timely intervention rather than retrospective explanation

This approach avoids two opposite mistakes. The first is diagnostic overshadowing: every academic, occupational, relational, or behavioural problem is automatically assigned to ADHD. The other is fragmentation: ADHD is treated as irrelevant once another problem appears. A sound formulation holds both possibilities in view. It asks whether ADHD is contributing to the burden, whether another condition better explains the change, and whether the interaction between them creates a new clinical priority.

MNEMONIC

COURSE

Current function, **O**utcomes already emerging, **U**nderlying comorbidity, **R**isks in the setting, **S**upports, and **E**ngagement with care. Use this as a structure for a prognostic review rather than as a substitute for clinical judgement.

17.4 The conduct-disorder pathway and severe adult outcome

The most consequential prognostic discriminator in the available evidence is not ADHD in isolation. **Comorbid juvenile conduct disorder** is the strongest predictor of severe adult outcomes. This changes the clinical formulation at once. It tells the trainee not to use ADHD as a

shorthand explanation for all externalising behaviour, and not to understate the significance of conduct problems when they are present.

The relevant severe outcomes include increased risk of **substance use disorders, criminality, and early mortality**. These are associations that demand careful assessment and preventive work; they are not labels to apply to a child. Their purpose in a textbook is to sharpen clinical attention to a higher-risk pathway, not to stigmatise young people or make families fear a predetermined future.

A candidate should be able to explain why this distinction matters. If the clinician describes the risk as "the outcome of ADHD", the patient may receive an incomplete assessment and the family may hear an inaccurate moral story. If the clinician identifies the **conduct-disorder pathway**, assessment can focus on behaviour, context, safety, substance exposure, peer influences, family stress, and engagement with care. The disorder itself is discussed in the Child behavioural, emotional and other disorders notes; here, it is the prognostic modifier that must be recognised.

Risk communication must be proportionate. State the association clearly, identify what needs closer review, and describe what the care team can do next. Avoid using severe outcomes as a threat to enforce adherence. Such communication invites shame and concealment, precisely when reliable collateral and continued contact are most needed. A better stance is firm, nonjudgmental, and behaviourally specific: name the concern, assess its current expression, and make a plan with the patient and caregivers.

TRAP **Do not attribute the worst adult outcomes to ADHD alone.** This erases the distinction between ADHD and the conduct-disorder pathway, and can lead to both stigma and an inadequate assessment of the actual risk pathway.

17.5 Substance use: risk, prevention, and causal humility

The substance-use question needs its own clinical discussion within a long-term prognostic review. It should be approached as a problem to detect early and manage collaboratively, not as evidence of personal failure. A useful review asks about use, consequences, attempts to reduce use, circumstances in which use becomes more likely, and the patient's own account of what the substance is doing for them. That conversation is often more informative than a moral warning.

The evidence also supports a potentially protective association: **early and sustained medication treatment** of childhood ADHD is associated with a reduced risk of substance use disorder in young adulthood. The wording matters. An association is not proof that medication alone caused the later difference, nor is it a guarantee for an individual. Treatment continuity may travel alongside many other influences, including engagement with care and the family's capacity to sustain a plan.

For clinical decision-making, causal humility does not mean inaction. The finding supports taking childhood ADHD treatment seriously and avoiding the simplistic claim that appropriate pharmacological treatment inevitably creates later substance misuse. It also reinforces the need to review treatment over time rather than treating a prescription as an isolated event. Medication is

part of a broader care plan that must address impairment, comorbidity, environment, adherence, adverse effects, and emerging risk. Detailed pharmacotherapy and monitoring are covered elsewhere in this chapter.

- Discuss substance use directly and without accusation when the clinical picture raises concern, and explain associations as risk information rather than certainty about the patient's future.
- Keep medication decisions linked to the wider formulation rather than fear-based assumptions, while escalating support when risk is active and maintaining a stance that invites disclosure.

PITFALL

Stopping at a generic statement about substance risk is clinically weak. It obscures the conduct-disorder pathway, ignores current context, and can turn a preventable problem into a stigmatising prediction.

17.6 Treatment changes prognosis, but does not abolish uncertainty

Prognosis is partly a statement about modifiable conditions. The aim of treatment is to improve the fit between a person's capacities and the demands placed upon them, support safer decision-making, and limit avoidable failure experiences. It should not be presented as a promise of a uniform future. The patient may need different forms of help as educational, occupational, relational, and health demands change, and the plan should be revised accordingly.

The preschool follow-up finding is especially useful here. Persistent symptoms or impairment despite medication should not be used to declare treatment futile. It should prompt a review of the formulation: whether the target is clear, whether the treatment is being taken and tolerated, whether environmental demands have changed, whether a comorbid disorder is contributing, and whether additional supports are required. In other words, lack of complete resolution calls for better clinical reasoning rather than either blame or resignation.

The phrase **protective factor** is often used too loosely. In prognosis, it should refer to something that can plausibly reduce exposure to risk or improve functioning, not merely something reassuring to mention. A supportive caregiver, reliable routines, treatment engagement, school accommodation, or a therapeutic alliance may each matter, but their relevance must be demonstrated in the person's own life. The clinician should preserve what works and investigate why it works before changing the plan.

Equally, treatment discussions must be transparent about uncertainty. It is reasonable to say that a treatment is intended to reduce impairment and potentially alter later risk, while also saying that outcome depends on more than a prescription. This protects informed consent and improves adherence because the patient understands the rationale for review. It also keeps the therapeutic relationship honest when progress is uneven.

17.7 Communicating prognosis in Indian clinical practice

Families may arrive with sharply polarised expectations: that ADHD reflects a temporary discipline problem, or that it forecloses education, employment, marriage, and independence. Both assumptions can distort care. The clinician's job is to replace them with a **shared prognostic formulation** that links current difficulty to concrete supports, identifies comorbid risk, and gives the family a reason to remain engaged even when improvement is gradual.

IN INDIA

Prognostic conversations need to account for the patient's family structure, school or workplace demands, access to follow-up, and the practical person who can help organise care. Do not assume that a recommendation is usable merely because it is clinically sound. Build a plan around the supports actually available and revisit it when circumstances change.

This is also where language matters. Avoid saying that a child is "bad", that an adult is "irresponsible", or that a family has failed. Such phrases confuse impairment, behaviour, and moral judgement. Instead, describe observed difficulties, their consequences, and the next workable intervention. When risk is present, be direct about it without presenting it as destiny. When progress occurs, name the supports that made it possible so they are not withdrawn prematurely.

Transition planning deserves the same clarity. The person should know which parts of the care plan need to travel with them, who can provide collateral when appropriate, and what changes should trigger renewed assessment. The detailed assessment battery and service pathways are addressed in the Child psychiatry: assessment, treatment, services and protection notes. The principle here is simpler: a good prognosis is made more useful by continuity of information, realistic expectations, and a plan that remains understandable to the patient.

17.8 Writing the prognostic formulation

A concise prognostic formulation can be organised around present function, course to date, comorbidity, active risks, protective supports, and engagement with treatment. It should identify the conduct-disorder pathway when present, describe substance-related concerns without moralising, and record what requires monitoring. It should also state what remains uncertain. **Clinical uncertainty** is not an omission when it is named and paired with a plan to reduce it through follow-up and collateral information.

This style of formulation is more clinically useful than an isolated phrase such as "guarded prognosis". A label of that kind does not tell another clinician what is driving the concern, what action is needed, or what improvement would look like. By contrast, a formulation connects risk to a next step. It can be updated when treatment engagement changes, when comorbidity emerges, or when a previously effective support is lost.

The prognosis of ADHD is shaped by functional course and modifiable context, but it must distinguish the higher-risk conduct-disorder pathway from ADHD alone.

Specific learning disorder

18 · Diagnostic criteria of SLD (DSM-5, ICD-11)

Why the criteria matter clinically. A learning complaint is not itself a diagnosis. Children, adolescents and adults may struggle because the teaching has been interrupted, the language of instruction is not yet secure, a sensory difficulty has not been corrected, or another developmental or mental disorder is shaping performance. The diagnostic task is therefore to show a persistent, functionally important and developmentally situated difficulty in a circumscribed academic skill, while actively considering better explanations. This prevents both the casual labelling of ordinary variation and the equally harmful dismissal of a person whose difficulty has been repeatedly explained away as poor effort.

DSM-5 specific learning disorder is diagnosed through a clinical synthesis rather than through a score, a school report, or a parental account in isolation. The framework has **four diagnostic criteria, A-D**. Its structure is useful because it forces the clinician to connect the presenting academic problem with its course, measured impact, developmental timing and exclusions. The diagnosis should read as a reasoned formulation of evidence, not as a label appended to a report.

18.1 The diagnostic architecture

The four criteria ask progressively different questions. Is there a persistent problem in an academic skill? Is the attainment meaningfully lower than expected and impairing? Did the difficulty begin in the developmental period relevant to learning? Is there a more adequate account of the presentation? Keeping these questions separate is an excellent safeguard against premature diagnosis. A learner can have an unmistakable complaint yet fail the diagnostic threshold if the complaint is transient, uncorroborated, not impairing, or better explained by circumstances outside a learning disorder.

A-D	1 of 6	6 months	mild to severe
DIAGNOSTIC ARCHITECTURE	ACADEMIC-SKILL SYMPTOMS	PERSISTENCE DESPITE SUPPORT	CURRENT-SEVERITY RANGE

RULE **Diagnose a disorder only when the whole pattern is coherent.** Criterion A establishes the academic difficulty, but the remaining criteria determine whether it is clinically significant, developmental and not better explained by another condition or context.

The wording also guards against a common false dichotomy: a child need not have difficulty in every academic area to have the disorder, and a person with broad educational disadvantage should not be presumed to have a neurodevelopmental disorder merely because attainment is low. The unit of reasoning is the individual learner in a particular educational and developmental context. That is why history, school information and psychometric evidence are interpreted together rather than treated as competing verdicts.

18.2 Criterion A: persistent difficulty in a taught skill

Criterion A academic-skill symptoms require **at least 1 of 6 listed symptoms**. The symptom domains cover inaccurate or slow effortful word reading, difficulty understanding what has been read, spelling difficulty, difficulty with written expression, difficulty mastering number facts or calculation, and difficulty with mathematical reasoning. These are not interchangeable labels for a generally weak student. They direct the interview toward the actual operation that is breaking down: decoding, extracting meaning, producing written language, retrieving or calculating number information, or reasoning with mathematical relationships.

The qualifier in Criterion A is as important as the symptom label. Difficulties must persist for **at least 6 months** despite targeted intervention. This does not mean that every learner must receive identical remedial input before diagnosis, nor does it turn diagnosis into a bureaucratic waiting exercise. It asks whether a relevant, intelligible attempt to help has led to adequate progress. Restricted progress or failure to catch up despite such help strengthens the inference that the problem is not simply a short-lived gap in exposure.

MNEMONIC

POSS

Persistent academic difficulty, **O**bjective low attainment, **S**chool-age onset and **S**creening for better explanations. This is a memory aid for the diagnostic spine, not a substitute for clinical judgement.

In practice, ask what was taught, what support was actually delivered, and what changed afterwards. A vague assurance that the learner “received tuition” is weaker evidence than a clear account of the target skill, the learner's engagement, the observed response and the continuing functional consequence. The diagnosis is not contingent on blaming the child, family or school. It depends on establishing that the academic problem persists even when a reasonable opportunity to learn and respond has been provided.

18.3 Criterion B: low attainment and functional interference

Criterion B achievement threshold requires the affected skill to be substantially and quantifiably below chronological-age expectation, confirmed by individually administered standardized achievement measures. The low attainment must also interfere significantly with academic work, occupational functioning or activities of daily living. This criterion prevents a diagnostic leap from a subjective complaint to a disorder. It asks both for corroboration of the skill deficit and for evidence that the deficit matters in the person's life.

Standardized assessment informs, rather than replaces, judgement. Scores need to be read with the referral question, educational history, language exposure, test behaviour and the particular skill measured in mind. For greatest diagnostic certainty, the diagnostic features describe performance at **1.5 SD below the population mean, a standard score <=78 and below the 7th percentile; clinical judgement may use a more lenient 1.0 SD threshold**. These boundaries are necessarily pragmatic because academic skills vary along a continuum. A clinician

should neither reify a single cut-off nor use the existence of a score just above it to disregard an otherwise compelling, impairing pattern.

Functional interference is the bridge between test performance and clinical relevance. It may be seen in the disproportionate effort required to complete ordinary academic tasks, inability to work independently in the affected area, persistent errors that compromise written communication, or difficulty using numerical skills in everyday demands. The precise manifestation changes with age and educational demands, but the diagnostic question remains the same: does the difficulty create a meaningful limitation in expected participation?

Criterion B is best understood as a convergence requirement. A low score that is inconsistent with the learner's observed work, language background or educational opportunity needs explanation before it is given diagnostic weight. Conversely, a highly coherent history of impairment should prompt careful review of whether the assessment sampled the relevant academic operation. The psychiatrist need not become a psychometric technician, but must be able to distinguish evidence of an affected skill from evidence that merely reflects an unfamiliar task, acute distress, poor attendance or an unsuitable testing context. The formulation becomes stronger when its different strands point in the same direction.

GOOD TO REMEMBER

A report is most clinically useful when it identifies the affected academic operation and links it to a real-world consequence. “Low score” alone is not the formulation; the formulation explains what the learner cannot do reliably and why that limitation matters.

18.4 Criterion C and Criterion D: developmental timing and exclusions

Criterion C onset places the learning difficulty during school-age years. It may not be fully apparent until academic demands exceed the learner's capacity, so a later presentation does not by itself contradict a developmental disorder. The useful question is whether credible history points back to difficulty during the school years, rather than simply when the family first sought help. Later demands can expose a longstanding vulnerability that earlier tasks did not reveal.

Criterion D exclusions require that the academic difficulty not be better accounted for by intellectual disability, uncorrected visual or auditory acuity problems, other mental or neurological disorders, psychosocial adversity, limited proficiency in the language of instruction, or inadequate educational instruction. The point is explanatory priority, not a simplistic rule that one diagnosis automatically cancels another. When a possible exclusion is present, determine whether it more convincingly accounts for the particular academic profile and its course.

- Consider intellectual functioning and adaptive functioning when the difficulty appears broad rather than circumscribed.
- Clarify whether sensory limitations have been recognized and corrected before attributing reading or writing difficulty to a learning disorder.
- Examine mental, neurological and psychosocial contributors in relation to onset, fluctuation and the affected skill.

- Establish the learner's opportunity to acquire the language and academic content in which difficulty is being judged.

The diagnosis generally presumes intellectual functioning above **about 70, allowing plus or minus 5 points**. This is a boundary aid, not permission to reduce assessment to an intelligence quotient. The clinical distinction from intellectual disability requires attention to the overall pattern of functioning, while the detailed differential is addressed in the Intellectual disability and autism spectrum disorder notes.

TRAP **Do not mistake an exclusion screen for a list of automatic exclusions.** The criterion asks whether another condition or circumstance better explains the learning difficulty. A coexisting problem may need treatment or accommodation without being the sole explanation for the academic pattern.

PITFALL

In multilingual settings, low performance in the language of instruction can be mislabelled as a learning disorder without documenting language exposure or teaching opportunity. This is precisely the contextual error Criterion D is designed to prevent.

18.5 Integrating evidence and diagnosing beyond school

The DSM formulation is made from history, school reports and psychoeducational assessment. Each source answers a different question. History establishes development, course and prior help; school information shows the learner's performance in the ordinary educational environment; formal assessment quantifies the relevant academic skill. Discordance is not a nuisance to be averaged away. It is a prompt to ask whether the tested construct, the teaching context, language demands or the time course explains the mismatch.

For people **17 years and older**, documented history of impairing learning difficulties may substitute for standardized assessment. This provision is clinically important when a person presents after leaving school or when an appropriate current assessment cannot be obtained. It does not lower the standard of reasoning. Documentation should still establish a credible history of impairment, developmental onset and absence of a better explanation.

IN INDIA

Educational histories may span changes of school, medium of instruction, curricula and access to remediation. The clinician should record these transitions explicitly before interpreting an academic complaint. The same score can carry very different meaning when opportunity to learn the tested language or skill has differed.

The full psychoeducational assessment process belongs in the assessment section of this chapter. At the diagnostic stage, the psychiatrist's responsibility is to ensure that the evidence has been put into a coherent clinical question: which skill is affected, how has it persisted, what is the functional consequence, when did it begin, and what competing explanation has been

considered? This is also the point at which a referral becomes a meaningful multidisciplinary collaboration rather than a request for a test to “confirm dyslexia”.

18.6 DSM recording and current severity

DSM recording specifies the affected domain or domains. The corresponding ICD-10-CM recording entries are **F81.0 impairment in reading; F81.81 impairment in written expression; F81.2 impairment in mathematics**. Each impaired domain is recorded separately. This matters because a single broad label can obscure the actual target for educational planning and follow-up. The descriptive terms commonly used for reading, written expression and mathematics should not be allowed to replace a clear account of the specific skill impairment.

Current severity runs across mild, moderate and severe levels, graded by the domains affected and the intensity of support needed. Severity is not a moral judgement about intelligence, effort or family engagement. It is a practical description of how much specialist teaching, accommodation and sustained support are required for adequate participation. A learner may show substantial difficulty in one domain and relative strength in another; severity should preserve that clinical texture rather than flatten it.

Severity should also be revisited when the educational context changes. The same underlying difficulty may become more or less disabling as demands alter, supports are introduced or a learner moves into work that depends differently on reading, writing or mathematics. The diagnosis names the disorder; the severity specifier communicates the present support burden.

18.7 ICD-11 developmental learning disorder

ICD-11 uses **6A03 developmental learning disorder**, replacing the older separation into scholastic-skill disorders. Its **essential features** are a significant and persistent limitation in reading, writing or arithmetic that is markedly below age expectation despite appropriate instruction, begins in early school years, is not attributable to external factors, and is not better explained by disorder of intellectual development or another neurodevelopmental, motor or sensory disorder. The overall clinical logic therefore closely resembles DSM reasoning: a persistent, developmentally arising academic limitation must be distinguished from contextual or broader developmental explanations.

The ICD-11 area-of-impairment options are **6A03.0 reading; 6A03.1 written expression; 6A03.2 mathematics; 6A03.3 other specified impairment of learning; 6A03.Z unspecified**. More than one area-of-impairment specifier may be applied. This is clinically useful when the learner's profile crosses domains, while retaining the discipline of describing each affected area rather than treating all academic difficulty as a single undifferentiated problem.

A key contrast is that ICD-11 has **no fixed persistence-despite-intervention duration**. It requires the limitation to be significant and persistent, whereas DSM makes the duration-and-response-to-targeted-intervention requirement explicit. This difference should not be turned into a superficial coding trick. In either system, the clinician still needs a defensible account of persistence, appropriate teaching and the absence of a better explanation.

18.8 Using the two systems without losing the patient

CLINICAL QUESTION	DSM APPROACH	ICD-11 APPROACH
Core academic problem	Symptom-based criterion linked to affected skills	Persistent limitation in reading, writing or arithmetic
Evidence of low attainment	Quantified low achievement and functional interference	Marked limitation below age expectation despite appropriate instruction
Developmental timing	School-age onset, even if demands reveal it later	Onset in early school years
Context and alternatives	Explicit exclusion criterion	External factors and developmental, motor or sensory explanations considered
Persistence wording	Explicitly linked to targeted intervention	Persistent limitation without a fixed numerical duration
Profile description	Affected domains and current support-related severity	Area-of-impairment specifiers, including multiple areas where relevant

The systems should be used to make documentation clearer, not to generate artificial disagreement. Both require an academic difficulty that is substantial, persistent, developmental and not better explained by another condition or by the learner's circumstances. The DSM framework is particularly explicit about the response to targeted help and the integration of standardized achievement evidence. ICD-11 foregrounds the developmental learning disorder category and allows the affected academic area to be specified. In either case, the diagnostic formulation should be intelligible to the family, school and clinician who will act on it.

When criteria are applied well, diagnosis does not end the enquiry. It creates a shared description from which educational intervention, accommodation and follow-up can be planned. When criteria are applied poorly, the same label can become an excuse for unexamined educational failure or for overlooking a remediable sensory, language or psychosocial contributor. The clinical discipline is to retain both truths: a genuine developmental learning disorder deserves recognition, and the learner's context must remain visible throughout the diagnostic process.

> Specific learning disorder is a diagnosis of a persistent, impairing and developmentally arising academic skill deficit after better explanations have been considered.

19 · Why specific learning disorder happens

Why mechanism matters clinically. A learning disorder is not explained by laziness, poor motivation, or a simple failure to try harder. Mechanistic models help the clinician translate an observed academic difficulty into a hypothesis about the mental operations that may be inefficient. That translation matters because children, families, and schools often describe the same problem in moral language: careless, inattentive, slow, or not interested. A mechanism-

based account replaces blame with a more useful question: which part of the journey from spoken language or visual symbols to fluent academic performance is breaking down?

Mechanism is not a diagnosis and does not substitute for a proper psychoeducational assessment. It is a framework for understanding patterns, anticipating associated difficulties, and explaining why two children with apparently similar reading complaints may need different forms of support. The discussion below concentrates on reading disability because its cognitive and neural models are especially well developed. The broader diagnostic framework, the types of specific learning disorder, formal assessment, remediation, and Indian educational provisions are addressed elsewhere in this chapter.

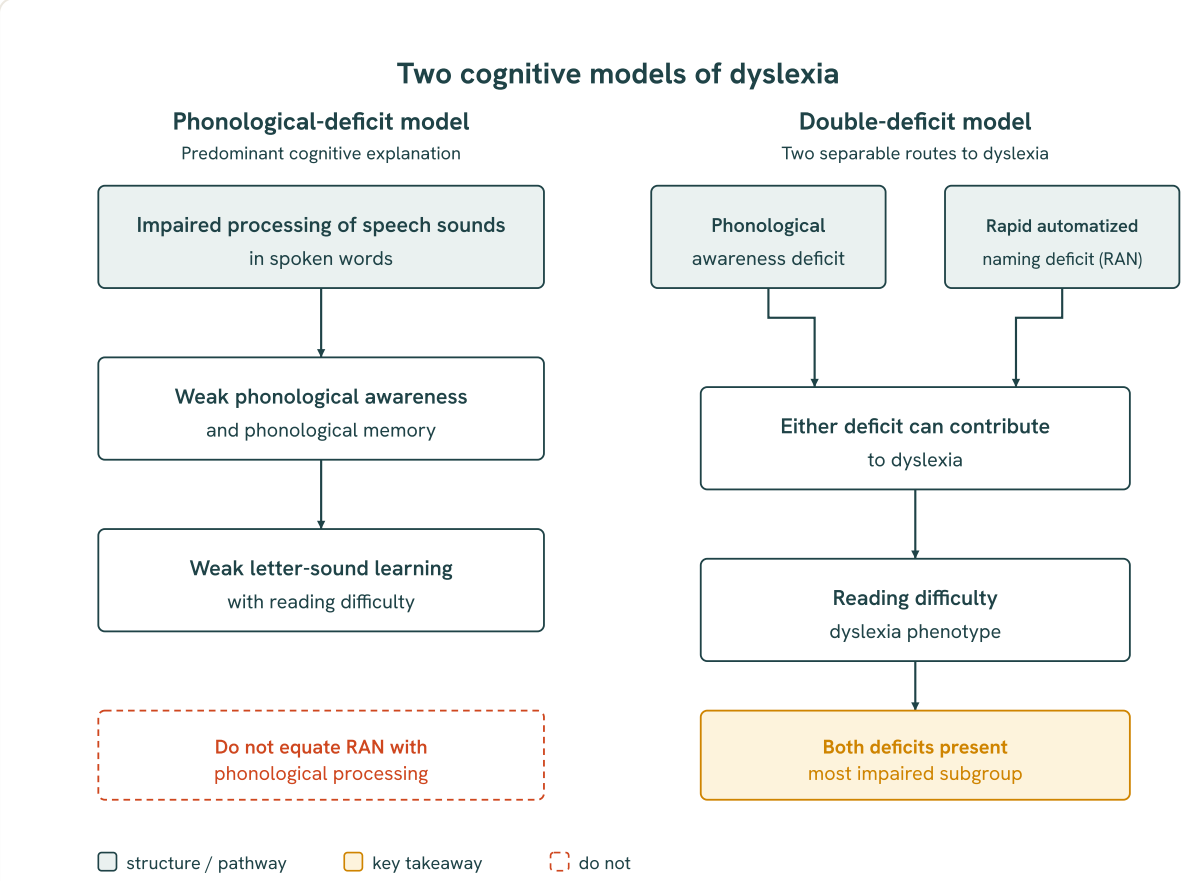

Fig 22.15. Phonological-deficit and double-deficit models of dyslexia.

19.1 From academic failure to component processes

Academic skills are complex achievements. Reading, writing, and mathematics each require a learner to coordinate several processes quickly enough that the task feels automatic. When one process remains effortful, the child may compensate for a time, but the cost is seen in slow output, errors, fatigue, avoidance, or a widening gap as classroom demands become more complex. It is therefore better to ask what operation is vulnerable than to assume that an observed error has a single cause.

The relevant operations are not confined to one sensory channel or one intelligence score. A clinical formulation may need to consider **phonological processing**, orthographic processing,

working memory, executive functions, symbol automatization, perceptual-motor integration, and processing speed. These are best understood as candidate pathways to difficulty, not as interchangeable labels. A weakness in one pathway can affect performance in another, and a child may have more than one weak pathway. The value of this language is that it gives the team a way to describe the pattern without reducing the child to the pattern.

In practice, the distinction between a skill and a process is important. A skill is the observable academic outcome: the child reads inaccurately, cannot spell reliably, or produces work too slowly. A process is a proposed operation contributing to that outcome: retaining speech sounds, linking a symbol to a sound, recognizing a familiar pattern rapidly, holding intermediate information in mind, or organizing a response. The process account should illuminate the observed difficulty. If it becomes a fashionable label with no explanatory link to the child's actual performance, it has ceased to be clinically useful.

- Ask whether the problem is most apparent when language must be analysed as sound, when familiar symbols must be named quickly, or when a written pattern must be recognized efficiently.
- Ask whether the child can demonstrate knowledge orally but loses accuracy or speed when that knowledge must be read, written, or calculated.
- Ask whether errors are stable and patterned rather than simply occurring when the child is distressed, distracted, or unfamiliar with the task.

RULE **Use a process model to explain a pattern of learning, never to replace demonstration of the learning difficulty itself.** The mechanism guides formulation and intervention planning; it does not permit diagnosis from a single cognitive weakness or from a scanner image.

IN INDIA

Language of instruction, home language, exposure to print, and opportunities to learn in a familiar script deserve deliberate attention before a cognitive explanation is fixed. In multilingual classrooms, apparent inconsistency may reflect a mismatch between the language in which a skill was acquired and the language in which it is being demanded. This is a formulation issue, not a reason to dismiss persistent learning difficulty.

19.2 The phonological account of dyslexia

The leading cognitive account of dyslexia is the **phonological-deficit model**. Its central proposal is that the child has difficulty processing the speech sounds that make up spoken words. This is not the same as a problem with hearing ordinary speech in a conversation. The issue is the ability to represent, notice, retain, compare, and deliberately manipulate the sound structure of language when the learning task requires it.

For a beginning reader, print must become connected to speech. The learner has to appreciate that a spoken word can be analysed into smaller sound units and that marks on the page consistently map onto them. If those sound representations are imprecise or difficult to access, letter-sound learning becomes laborious. The child may then rely on guessing from context,

memorizing whole word shapes, or waiting for someone else to read the text. These strategies can conceal the core difficulty briefly, but they do not make decoding automatic.

The model has explanatory reach because it links several commonly observed phenomena without claiming that every child has the same profile. It affects **phonological memory**, awareness of sound structure, and learning of letter-sound relations. Phonological memory matters when a child must hold a sequence of sounds long enough to blend or compare it. Awareness matters when the child must attend to sound as an object of thought rather than simply use language for meaning. Letter-sound learning matters because it provides the bridge by which a new written word can be decoded rather than guessed.

Clinically, this account also explains why comprehension can be misleading. A child may understand a story when it is read aloud and speak with age-appropriate vocabulary, yet struggle substantially when required to derive the same content independently from print. The discrepancy is not proof of a particular diagnosis. It is a cue to distinguish language comprehension from access to the written code. Conversely, weak reading comprehension may arise through several routes, so a phonological formulation should be made only when the pattern supports it.

The practical implication is not that every reading error should be interpreted as phonological. Rather, a clinician should look for convergence: difficulty with sound-based operations, insecure decoding, errors that recur across comparable words, and slow acquisition despite appropriate opportunity. The mechanism is strongest as a coherent account of a pattern, not as an explanation attached to one isolated mistake.

19.3 Naming speed and the double-deficit formulation

A second influential account distinguishes difficulty with sound structure from difficulty with rapid access to familiar verbal labels. **Rapid automatized naming** refers to the ability to name familiar alphanumeric stimuli, such as letters and numbers, and non-alphanumeric stimuli, such as colours and objects, rapidly. It is a marker of naming speed or processing speed and is conceptually distinct from phonological processing. A child may know an item perfectly well but retrieve and articulate its name with insufficient speed for fluent academic work.

This distinction matters because reading fluency is more than correct decoding. A reader who has to pause at each familiar item may eventually identify the word but will lose the rhythm needed to carry meaning across a sentence or passage. Slow naming can therefore make reading effortful even where sound-based work is relatively stronger. It can also help explain why a learner appears accurate in a calm individual setting but struggles to keep up with the pace of classroom reading and written work.

The **double-deficit model** proposes that dyslexia can arise from difficulty in phonological awareness, rapid naming, or both. The combined profile is associated with the greatest impairment. This is a useful corrective to the false choice between a sound-based explanation and a speed-based explanation. They are separable processes, but their effects can accumulate in the

same child: one difficulty makes initial decoding insecure, while the other makes familiar material slow to access.

FORMULATION FOCUS	WHAT IS INEFFICIENT	LIKELY CLINICAL EXPRESSION	REASON FOR DISTINCTION
Phonological pathway	Analysis and retention of speech-sound structure	Insecure decoding and sound-based errors	Explains difficulty linking print to spoken language
Naming-speed pathway	Rapid retrieval of familiar verbal labels	Slow, effortful performance despite recognition	Explains reduced automaticity and fluency
Combined pathway	Both sound processing and rapid access	More pervasive reading difficulty	Prevents an artificially single-cause formulation

The table is a conceptual map, not a substitute for testing. Naming tasks can be influenced by many immediate factors, including familiarity, anxiety, language proficiency, and the child's understanding of the task. Their contribution should be interpreted alongside the developmental and educational history, direct observation, and formal assessment described in the assessment section of this chapter.

TRAP **Do not equate slow naming with low ability or poor effort.** Speeded performance draws on access, coordination, and automaticity. A child may know the answer yet repeatedly fail to produce it fast enough for the task's demands.

19.4 Reading as a distributed neural system

Neural findings should be read as a systems account. Reading is not housed in a single centre; it depends on coordinated activity within a **left-hemisphere reading network** that includes occipito-temporal, inferior frontal, and inferior parietal regions. This network-level view fits the clinical fact that reading combines visual pattern recognition, speech-sound analysis, retrieval, and fluent integration. A disruption at any one point can alter the efficiency of the whole system, while different children may reach a similar behavioural endpoint through partly different routes.

Within this account, altered function of the left occipito-temporal region, often called the **visual word form area**, is relevant to rapid processing of letter and word patterns. This is sometimes described as a ventral route. Its importance is intuitive: fluent readers do not consciously labour over every familiar visual pattern. When recognition remains slow or unstable, reading consumes attention that would otherwise be available for meaning, monitoring, and written expression.

The phonological account has a neural correlate as well. Dysfunction or reduced activation in **left inferior frontal and temporo-parietal cortices** is associated with the phonological deficits of dyslexia. Descriptions of this pathway also include the **mid-temporal lobe**, alongside frontal, parietal, and occipito-temporal reading regions. These findings do not mean that a scan can establish the disorder in an individual child. They provide biological plausibility for a cognitive

model by showing that the processing difficulty corresponds to altered functioning in regions involved in the reading pathway.

It is tempting to turn network language into a neat map in which each area owns one task. That temptation should be resisted. Brain regions participate in interacting circuits; performance depends on connectivity, development, experience, and task demands. The educational consequence is more useful than anatomical reductionism: when a child is struggling, the clinician should describe the observable bottleneck and the support required, rather than claim that a named region has been damaged.

PITFALL

Do not present neuroimaging as an individual diagnostic test for a schoolchild with suspected learning disorder. Group-level evidence can clarify mechanism, but diagnosis remains a clinical and educational judgment based on the child's developmental history and demonstrated academic functioning.

19.5 Genes, families, and the meaning of heritability

Specific learning difficulties commonly aggregate in families. For reading ability and reading disability, heritability is **greater than 0.6**; this is observed across alphabetic and non-alphabetic languages. The clinical meaning is neither that a child's future is fixed nor that family experience is irrelevant. It means that genetic differences make an important contribution to variation in reading, and a careful family history is therefore informative.

Family history should be taken with care. Adults may not have received a formal label, particularly when their education occurred in settings with limited recognition of learning difficulties. Useful questions concern longstanding struggles with reading, spelling, copying, written examination performance, and the extra effort required to complete literacy tasks. A parent may describe having found a workaround rather than having had a disorder. That history can still sharpen the clinician's hypothesis and encourage earlier support for the child.

The observed familial pattern is substantial for both reading and mathematics. The figures below describe relative familial risk, not a prediction that an individual relative will necessarily have a disorder. They should never be used to stigmatize a parent or to imply that parenting caused the child's difficulty. Their value is in deciding who may benefit from attentive developmental surveillance and timely assessment.

4-8 times higher	5-10 times higher	about 20%	about 80%
READING SLD IN FIRST-DEGREE RELATIVES	MATHEMATICS SLD IN FIRST-DEGREE RELATIVES	READING-SKILL VARIANCE AT AGE 6	READING-SKILL VARIANCE AT AGE 12

Heritability is also not a fixed property of an individual child. Estimates of variance attributable to genes can change as educational experience becomes more uniform and environmental variation narrows. One account attributes roughly **50%** of variance in reading to genes overall, while the developmental estimates shown above rise as formal schooling progresses. The

important clinical inference is modest: high heritability does not make teaching or remediation futile. It explains why biological vulnerability and educational response must be considered together rather than placed in opposition.

GOOD TO REMEMBER

A positive family history should change the clinician's threshold for asking careful questions and seeking corroborating school information. It should not be used as a shortcut to label a child, and it should never be framed as parental fault.

19.6 Integrating mechanism into clinical formulation

A useful formulation moves in both directions. From the top down, it starts with the child's presenting difficulty: where academic performance is breaking down, how this affects participation, and what the family and school have already observed. From the bottom up, it asks which processes may account for that pattern. The two directions should meet. If a proposed mechanism does not explain the child's actual pattern of difficulty, it is an interesting theory rather than a clinical formulation.

Mechanistic thinking protects against several common errors. It makes it less likely that a child with slow reading will be dismissed as careless, and less likely that a child who understands spoken material will be assumed to have no genuine educational need. It also prevents the opposite error: attaching every academic problem to a reading mechanism. Poor school attendance, unfamiliar language of instruction, emotional distress, sensory difficulty, inadequate teaching opportunity, and attentional symptoms can all alter academic performance. Their assessment belongs in the broader child psychiatric and educational evaluation.

For psychiatry trainees, the most valuable use of these models is explanatory communication. Families benefit from a concrete account of why repeated practice alone may not produce automaticity. Teachers benefit from knowing that a child may need the task broken into the component that is failing rather than simply more of the same task. The child benefits when adults replace criticism with a coherent plan. That plan must remain individualized and should be linked to the formal assessment and remedial approaches discussed elsewhere in this chapter.

- State the academic skill that is impaired before naming a cognitive process.
- Describe the process as a hypothesis supported by a convergent pattern, not as a moral explanation.
- Explain to family and school that a biologically influenced difficulty still responds to appropriate teaching and support.

MNEMONIC

Sound - Speed - Script - System - Story

For a reading-mechanism formulation, consider the sound structure of language, the speed of access to familiar labels, the handling of written patterns, the distributed reading system, and the family story. The sequence is a prompt for formulation, not a diagnostic checklist.

Dyslexia is best understood as a heterogeneous learning difficulty in which phonological processing, naming speed, and the efficiency of a distributed reading network may each contribute to the child's observed pattern.

20 · Definition and types of specific learning disorder (dyslexia, dysgraphia, dyscalculia)

Why this distinction matters clinically. A child who is bright, articulate and curious can still repeatedly fail at a circumscribed school task. If that failure is dismissed as carelessness, poor motivation or a family problem, the child may acquire shame long before anyone identifies the learning need. If it is treated as evidence of globally limited ability, expectations may be lowered unnecessarily. **Specific learning disorder** provides a way of describing persistent, unexpected difficulty in acquiring particular academic skills while preserving the question that matters clinically: what, precisely, is hard for this learner?

The term is useful because it shifts attention from a vague report of "poor studies" to the architecture of the difficulty. Reading a paragraph, producing written work and doing mathematics all draw on several component skills. A learner may struggle in one domain, in more than one domain, or show a profile in which a weakness in one area makes another appear worse. The task of this section is to establish the language of the disorder and the boundaries of its common labels. Diagnostic criteria, formal assessment and intervention follow in their respective sections.

RULE **Specific learning disorder is a disorder of particular academic skills, not a synonym for low scholastic performance.** The clinical description must identify the affected skill and the way the child experiences failure in that skill.

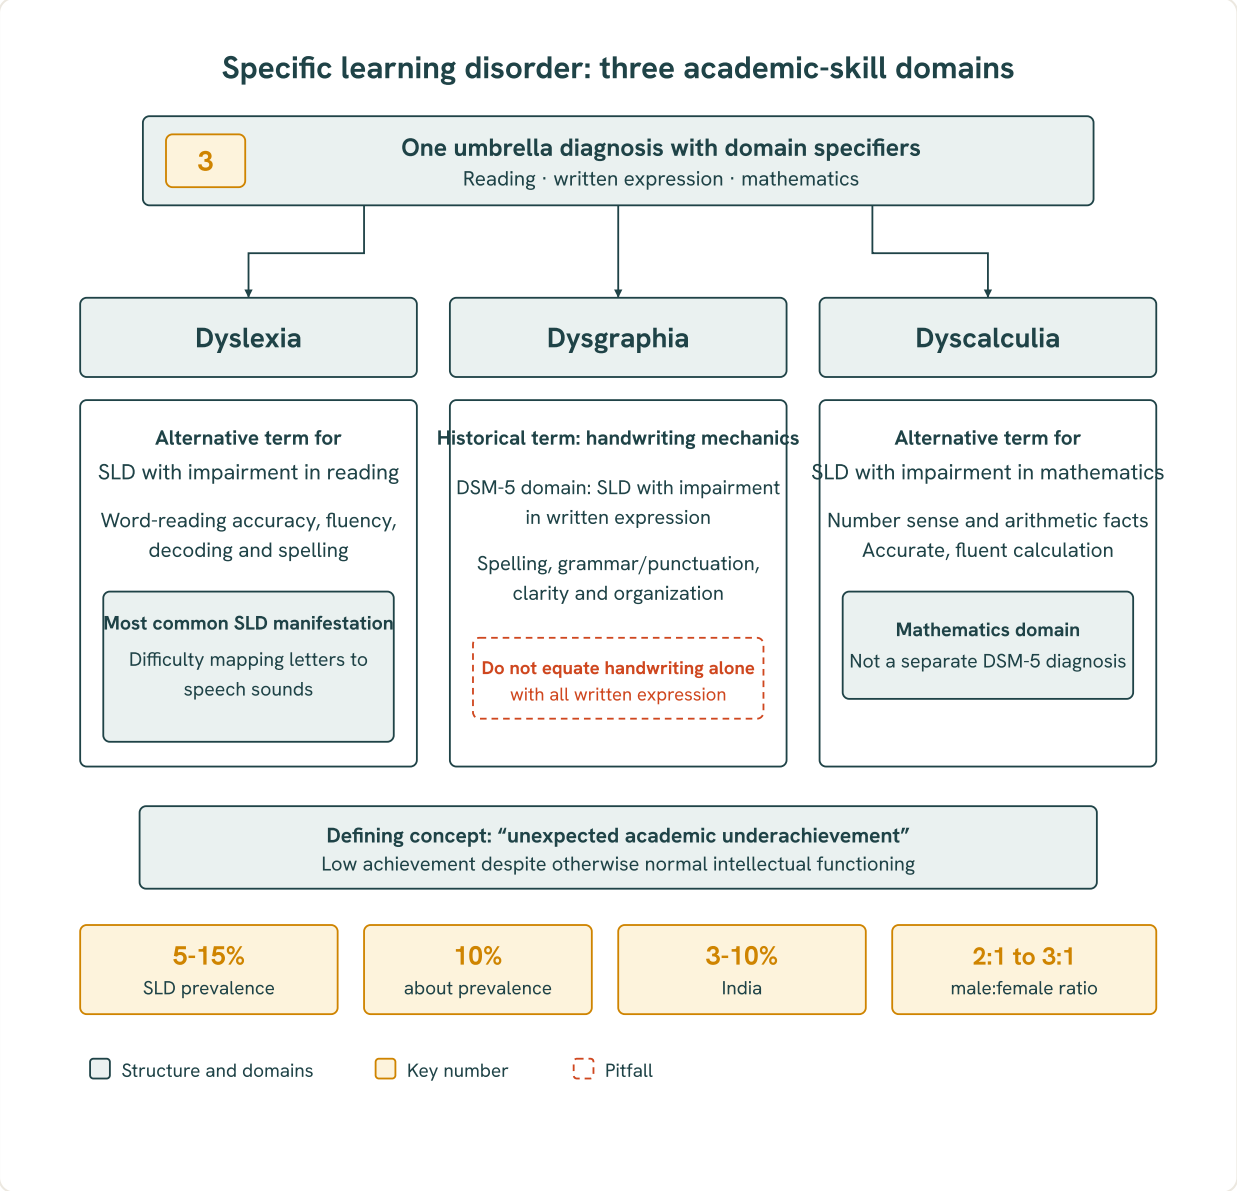

Fig 22.16. Specific learning disorder: dyslexia, dysgraphia and dyscalculia as domain-linked terms.

20.1 The defining clinical idea

The classic clinical idea is **unexpected academic underachievement**. The word "unexpected" is not a casual adjective. It asks the clinician to notice a discrepancy between an otherwise adequate capacity to learn and a sharply impaired route to learning in school. It also protects against a common conceptual error: a child whose schoolwork is poor for broad, pervasive reasons does not automatically have a specific learning disorder. The disorder concerns a selective failure in the acquisition or use of an academic skill.

"Specific" therefore refers to the academic function that is affected, rather than to a trivial or temporary complaint. A child may understand a lesson when it is explained aloud yet be unable to extract the same material from print. Another may answer fluently in class but produce a written answer that does not convey the knowledge they hold. A third may reason sensibly about everyday quantities but become lost when asked to manipulate symbols and procedures. These are not interchangeable presentations, and the label becomes clinically helpful only when it makes the profile clearer.

The phrase should never become a moral judgement about effort. Repeated failure can produce avoidance, irritability, reluctance to attend school, apparent inattention and conflict around homework. Those consequences may be prominent in the consultation, but they should not replace a description of the academic difficulty itself. Equally, a supportive home or a conscientious teacher cannot by itself remove a skill-specific learning disorder. The clinician's role is to translate the complaint into an observable learning problem, while allowing formal assessment to establish its nature and extent.

- Ask which academic activity breaks down first, rather than accepting “weak in studies” as a formulation.
- Ask how the child compensates: by guessing, avoiding, memorising, copying or relying on another person.
- Ask what the child can demonstrate orally that is not evident in written schoolwork.

GOOD TO REMEMBER

A good descriptive formulation names both the academic task and its functional consequence. “Cannot reliably decode unfamiliar written words and avoids reading aloud” is clinically more useful than “has poor scholastic performance.” The latter describes an outcome; the former identifies a learning route that needs examination.

20.2 One diagnosis, domain-based description

DSM-5 specific learning disorder is organised as a single umbrella diagnosis with specifiers for the affected academic domain. This is more than a change in labels. It prevents the clinician from treating reading, writing and mathematics as mutually exclusive illnesses when the same child can have a mixed profile. At the same time, the umbrella category does not erase the practical difference between a child who cannot read accurately and one whose main difficulty lies in constructing written language.

The academic-skill domains are **reading, written expression and mathematics**. The domain language gives a disciplined starting point for history-taking, communication with families and communication with schools. It also avoids treating older informal labels as if each were a complete diagnostic formulation. In clinical notes, the domain of impairment should be named clearly; the familiar term may then be used when it helps the family, teacher or multidisciplinary team understand the pattern.

Reading	Written expression	Mathematics
DOMAIN SPECIFIER	DOMAIN SPECIFIER	DOMAIN SPECIFIER

This approach has an important practical consequence. A child should not be placed in a single informal box merely because one difficulty is most conspicuous. Reading problems may obscure a written-expression problem because the child cannot access the material to be written about. Conversely, a child who reads adequately may still have very impaired spelling, grammar, punctuation, clarity or organisation in written work. Mathematics may be affected alongside

either profile, yet require its own description. The clinical formulation needs enough granularity to guide the next assessment step without converting a classroom observation into a diagnosis.

DOMAIN LANGUAGE	EVERYDAY LABEL OFTEN ENCOUNTERED	CLINICAL FOCUS
Impairment in reading	Dyslexia	Reading words and working with their written forms
Impairment in written expression	Dysgraphia, used loosely in some settings	Putting language into effective written form
Impairment in mathematics	Dyscalculia	Understanding and using numbers and calculations

TRAP **Do not use the umbrella diagnosis as if it made the affected domain unimportant.** "Specific learning disorder" without a domain description is incomplete clinical communication, especially when a school must understand which classroom task is failing.

20.3 Reading impairment and dyslexia

Dyslexia is the alternative term commonly used for specific learning disorder with impairment in reading. Its clinical core is difficulty with word reading, including accuracy, fluency, decoding and spelling. These components matter because the child's complaint is not always simply "I cannot read." Some children read slowly and laboriously, some misread familiar or unfamiliar words, some guess from context, and some avoid reading because the effort required is out of proportion to the task.

Decoding refers to working out the spoken form of a printed word. Accuracy concerns whether the word is read correctly. Fluency concerns the ease and pace with which reading proceeds once basic word recognition is attempted. Spelling is included in this reading-related profile because it requires stable knowledge of written word forms. In the consultation, these distinctions help convert a parent's broad concern into a useful question: is the principal difficulty recognising words, working them out, reading them efficiently, or retaining their conventional written forms?

Reading impairment is the **most common manifestation of specific learning disorder**. This does not permit the clinician to assume that every struggling reader has the same problem, nor does it justify overlooking writing and mathematics. It does explain why dyslexia is often the first label a family hears. A careful clinician should use the familiar term as an entry point, then clarify what the child can and cannot do with print.

The emotional meaning of dyslexia is often shaped by the classroom. Reading aloud may expose errors in front of peers; homework can become prolonged negotiation; a child who has learned to avoid print may appear oppositional or disengaged. Such secondary behaviours are understandable adaptations to repeated difficulty. They should be explored respectfully, but they do not define the reading disorder. The central description remains the impairment in the reading skill itself.

- Word-reading accuracy: the child reads a word incorrectly or substitutes another word.

- Reading fluency: the child can read but does so with marked effort, slowness or loss of continuity.
- Decoding and spelling: the child has difficulty moving reliably between written letters and spoken word forms.

20.4 Written expression and the careful use of dysgraphia

Dysgraphia is a historical term that strictly refers to the mechanics of handwriting. It is often used more broadly in schools and in informal discussion, which is why clinicians must be precise rather than dismissive. The contemporary diagnostic domain is specific learning disorder with impairment in written expression. That domain concerns the written product as language and communication, including spelling, grammar, punctuation, clarity and organisation of writing.

The distinction is clinically useful. Handwriting may be difficult to read, slow or effortful, yet the child may be able to formulate a coherent answer when allowed another means of expression. Conversely, handwriting may be adequate while the child cannot translate an idea into a logically ordered written answer. A child may also have both forms of difficulty. Calling every weak written output "dysgraphia" collapses these different questions and can send assessment in the wrong direction.

Written expression makes demands that oral conversation does not. The learner has to select words, hold a plan in mind, build sentences, apply conventions and monitor whether the reader can follow the argument. In an examination answer, the problem may appear as scant content, disconnected statements, repeated spelling errors or an answer whose organisation obscures what the child knows. The clinician should avoid inferring laziness from an untidy or sparse notebook. The notebook is evidence of difficulty, but it must be interpreted as part of a wider learning profile.

> **PITFALL**
>
> Do not use "dysgraphia" to mean every problem in written work. A handwriting-mechanics complaint and a written-expression complaint overlap in everyday language but focus the clinical enquiry differently. Document the observed difficulty in plain terms, then use the domain terminology accurately.

For families, this distinction can be reassuring without being falsely simplifying. It explains why a child may be able to tell a detailed story yet produce only a few disorganised lines when asked to write it. It also explains why improving handwriting alone may not resolve the difficulty in composition. The purpose of the label is not to create a hierarchy of deficits, but to make the source of the educational barrier visible.

20.5 Mathematics impairment and dyscalculia

Dyscalculia is the alternative term for specific learning disorder with impairment in mathematics. The mathematics profile includes difficulty with number sense, arithmetic facts and accurate or fluent calculation. Number sense refers to an intuitive grasp of quantity and numerical relationships. Arithmetic facts are the basic numerical combinations that should

become available for use. Calculation concerns carrying out procedures correctly and with sufficient ease to support more complex work.

The presentation can be missed when adults focus only on whether answers are right or wrong. A child may arrive at an answer through an unusually effortful route, be unable to judge whether an answer is plausible, lose track of a procedure, or rely heavily on counting strategies when peers have moved to more efficient methods. These observations are clinically more informative than a blanket statement that the child is "weak in maths." They point towards the particular numerical function that needs formal exploration.

Mathematics also places language, attention and working habits under pressure, so a poor score alone cannot settle the nature of the difficulty. The clinician should describe the numerical difficulty before attributing it to a learning disorder. This discipline matters particularly when there are coexisting concerns in reading or written expression: a child may misunderstand the language of a problem, fail to record steps clearly, or have a separate difficulty in numerical understanding. The domain formulation permits these possibilities to remain visible rather than forcing an early, simplistic explanation.

In everyday life, families may notice difficulty with quantities, money-related tasks, time-related calculations or following a numerical sequence. Such reports can guide questioning, but they should not be treated as a substitute for an academic profile. The diagnosis concerns academic skills, and the assessment section addresses how that profile is established. At this stage, the teaching point is narrower: dyscalculia names a mathematics-specific learning difficulty, not a general lack of intelligence or interest.

20.6 Mixed profiles and clinical communication

The **three** domains are analytically separate, but children do not experience schoolwork in separate compartments. Reading supports access to instructions and textbooks. Written expression is required to display knowledge in many examinations. Mathematics problems are often presented in language and require written working. A child with difficulties in more than one domain may therefore present with a broad academic crisis even when the underlying weaknesses can be described separately.

This is why clinical communication benefits from both the umbrella diagnosis and the domain description. The umbrella term acknowledges that the child's learning needs may be interconnected. The domain wording prevents the formulation from becoming vague. It also keeps the conversation with teachers practical: which activity should be observed, what form of schoolwork best demonstrates the problem, and which accommodations or remediation questions should be taken forward? The answers belong to assessment and management, but the quality of those later steps depends on the precision of the initial language.

MNEMONIC

Read - Write - Calculate

Use this simple clinical sweep when a family reports poor scholastic performance. Ask separately about reading printed words, expressing ideas in writing and handling numbers. It is a history-taking prompt, not a diagnostic shortcut.

Do not infer causation from a mixed presentation. It is tempting to explain all failure by the most obvious domain, especially reading, but that can conceal an independent difficulty in written expression or mathematics. Similarly, do not convert secondary distress into the primary disorder. School refusal, low self-confidence and anger around study are important consequences that may need attention, yet they do not tell the clinician which academic skill is impaired.

Name the affected academic domain before using the familiar label: dyslexia for reading, dysgraphia carefully for handwriting mechanics or written expression, and dyscalculia for mathematics.

20.7 Frequency, sex pattern and Indian relevance

Specific learning disorder is common enough that psychiatrists working with children should expect to encounter it. In school-age children, reported prevalence across the academic domains is **5-15%**. A lifetime estimate in the population is **about 10%**. These figures are best read as a reminder of clinical visibility rather than as a substitute for careful local assessment. Prevalence varies with the population studied, the educational context, the method used to identify difficulty and the threshold applied.

IN INDIA

Indian studies of schoolchildren have reported a prevalence range of **3-10%**. For clinical work, the immediate implication is not to apply a prevalence figure to an individual child. It is to recognise that a persistent, specific academic difficulty is a familiar developmental and educational problem in Indian classrooms, including in children whose distress is initially presented as a behavioural or emotional concern.

Specific learning disorder is more common in males, with a reported male-to-female ratio of **2:1 to 3:1**. The practical safeguard is to let the learner's profile, rather than a stereotype about who is likely to have a learning difficulty, determine the enquiry. Avoidance, compensatory effort, internalised distress and disruptive responses to failure may each bring a child to attention, but none is itself the definition of the disorder.

A psychiatrist's contribution is often to make the hidden learning problem discussable without reducing the child to it. Explain that the diagnosis describes a particular route through which academic learning is difficult; it does not describe the whole child, their intelligence, their character or their potential. When questions arise about global developmental functioning or related neurodevelopmental conditions, use the broader framework in the Intellectual disability

and autism spectrum disorder notes. When the concern is whether apparent inattention reflects ADHD, the careful comparison belongs in the chapter section on differentiating SLD from ADHD and slow learner.

21 · Assessment of learning disorder (psychoeducational testing, NIMHANS battery)

Assessment is the point at which a complaint about poor school performance becomes a defensible clinical formulation. The task is not to locate a single low score, nor to decide that a child is unmotivated, inattentive, or simply struggling. It is to establish the pattern of difficulty, its educational consequences, the conditions under which the child performs better or worse, and the alternative explanations that remain plausible. A careful assessment gives the family and school a shared description of the problem. It also prevents the psychiatrist from attaching a diagnostic label to a difficulty that has not been properly characterised.

For the postgraduate candidate, the marks lie in describing a reasoned process rather than naming a test. The assessment must connect the referral concern to the child's developmental and educational history, direct clinical observation, cognitive data, and evidence of actual academic performance. This fragment addresses that psychoeducational work. Diagnostic criteria, remedial planning, educational provisions, and the discrimination from other neurodevelopmental conditions are dealt with in their respective sections of this chapter and in the Child psychiatry: assessment, treatment, services and protection notes.

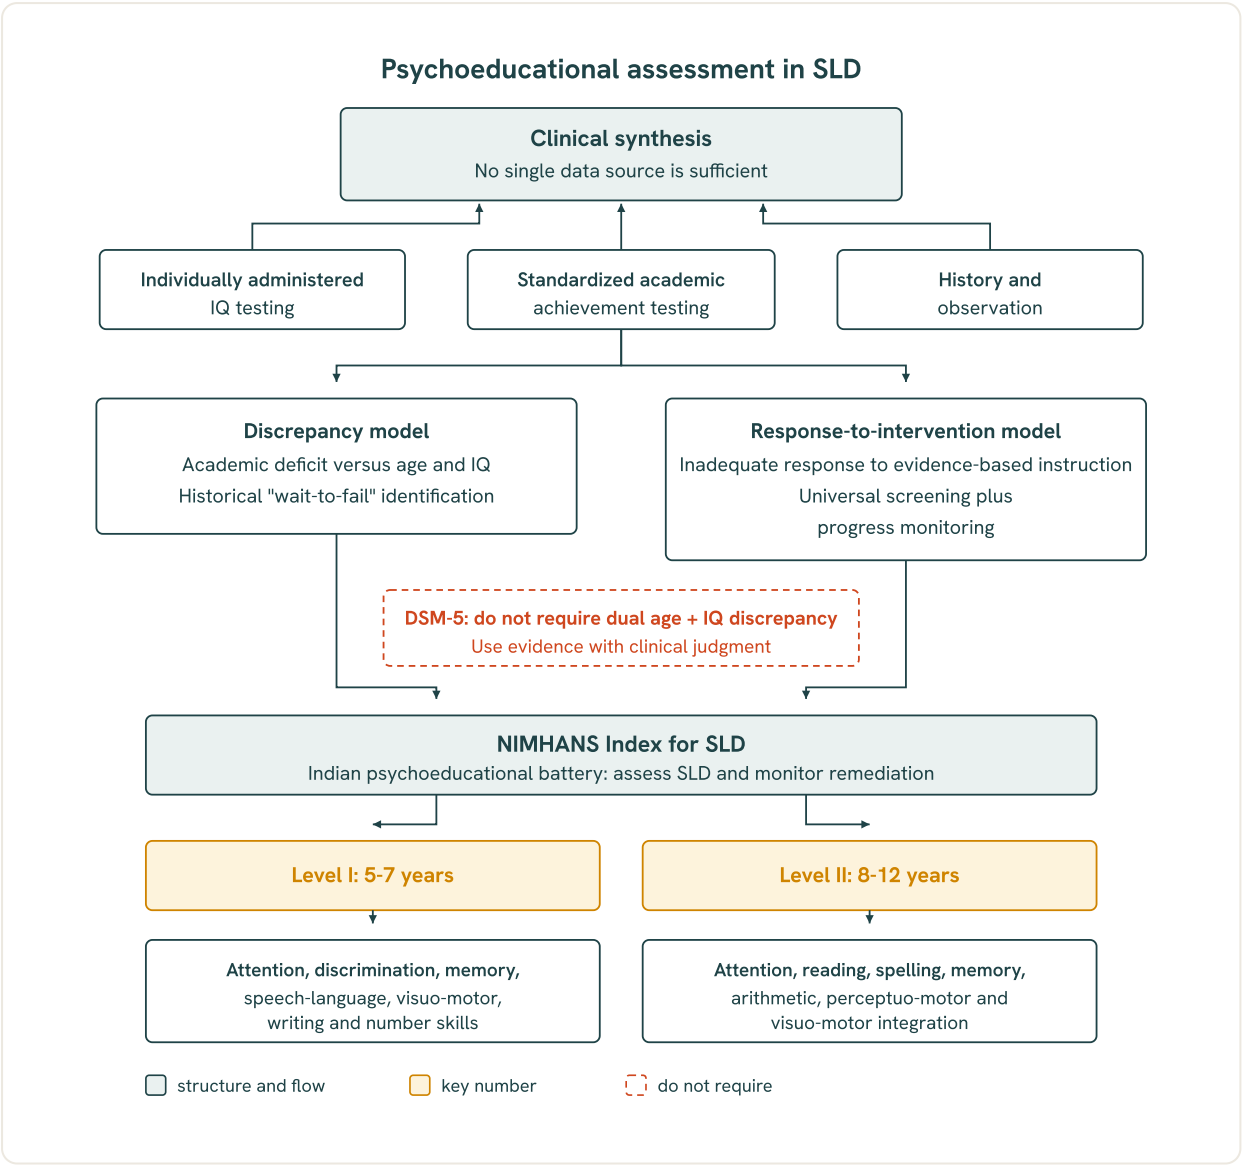

Fig 22.17. Psychoeducational assessment combines testing with clinical synthesis; the NIMHANS Index structures Indian SLD assessment across two age levels.

21.1 The purpose and architecture of psychoeducational assessment

A **psychoeducational assessment** asks a clinical question: does the child's attainment show a circumscribed and meaningful difficulty in learning, and what information is needed to explain it responsibly? It combines individually administered IQ testing, standardised academic-achievement testing, and history with observation. None of these sources can carry the diagnosis alone. A score only acquires meaning when it is interpreted alongside the child's opportunity to learn, language of instruction, behaviour during testing, and the family and school account of how the difficulty has unfolded.

RULE **Interpret the child, not an isolated score.** Cognitive testing, attainment testing, history, and observation must converge before the assessment can support a learning-disorder formulation.

The referral question should be made explicit before testing begins. “Poor studies” is a presenting complaint, not a useful assessment question. Clarify whether the concern is decoding written material, reading fluency, spelling, written expression, number work, classroom pace, or an

uneven profile across these areas. Ask what work is manageable without help, what elicits avoidance, which tasks require disproportionate time or adult scaffolding, and whether the pattern remains similar across settings. This turns a broad complaint into observations that can later be compared with formal findings.

Why the history remains indispensable. Testing samples performance in a bounded setting. The history supplies its ecological validity. It establishes the educational trajectory, changes in demands, attendance and interruptions, teaching language, access to teaching, previous support, and the child's response to such support. It also identifies emotional distress, behavioural resistance, sensory or neurological concerns, sleep problems, medication effects, and family stressors that may alter performance. These possibilities do not invalidate testing; they determine how cautiously a result should be interpreted.

ASSESSMENT STREAM	QUESTION IT ANSWERS	CONTRIBUTION TO FORMULATION
Referral clarification	What is actually failing in daily schoolwork?	Defines the target for assessment.
Developmental and educational history	How has the difficulty evolved in context?	Tests whether the narrative coheres with the measured pattern.
Clinical observation	How does the child approach, sustain, and recover from tasks?	Qualifies the validity and interpretation of performance.
Cognitive assessment	What is the profile of cognitive strengths and vulnerabilities?	Helps interpret the nature of difficulty, not merely its presence.
Academic-achievement assessment	What can the child demonstrate in school-relevant skills?	Documents the functional academic problem.
Clinical integration	Do the strands point to the same explanation?	Produces a usable formulation and report.

The psychiatrist's contribution is often synthesis rather than test administration. The report should be read as a description of performance under stated conditions, not as a verdict on ability or effort. When data conflict, the discrepancy is clinically informative. A child who appears competent in conversation but fails written tasks may need achievement assessment to make the hidden demand visible. Conversely, a weak test performance obtained amid marked distress, refusal, fatigue, or poor comprehension may require corroboration rather than premature certainty.

21.2 From referral complaint to testable clinical questions

Begin by listening to the words used by the child, caregiver, and teacher, but translate them into observable learning behaviours. "He does not study" may describe task avoidance after repeated failure. "She is careless" may refer to omissions in written work, loss of place while reading, inconsistent spelling, or errors under time pressure. The clinician should ask for concrete samples of classwork, homework, notebooks, and examination scripts when available. These reveal whether errors are stable, whether the presentation is uneven across subjects, and whether the school complaint matches the child's own experience.

Observation during the interview and assessment adds a different kind of evidence. Notice how instructions are understood, whether the child asks for clarification, how errors are handled, whether the child can explain a strategy, and whether performance changes with encouragement or structure. Observe the emotional meaning of schoolwork. Shame, anticipatory defeat, irritability, and disengagement may be consequences of chronic academic struggle; treating them as proof of laziness is both clinically crude and practically harmful.

- Clarify the principal academic complaint in the language of actual tasks.
- Map the child's learning history, including changes in curriculum, school, language, and support.
- Obtain collateral that describes classroom functioning rather than only examination results.
- Review representative written work for recurrent rather than incidental errors.
- Record factors during the session that could strengthen or limit confidence in the findings.

TRAP **Do not convert a complaint of inattention into a learning-disorder assessment, or a learning complaint into an attention diagnosis.** The complaint directs the enquiry; the pattern across history, observation, and formal assessment determines the formulation.

It is tempting to use familiar labels to shorten this work. That shortcut obscures the clinical task. The psychiatrist should hold competing explanations in mind without turning the assessment into a catalogue of diagnoses. If broader developmental concerns become evident, follow the relevant assessment pathway and use the Intellectual disability and autism spectrum disorder notes and the Normal child development and milestones notes for the appropriate conceptual framework. The purpose here is to determine what the psychoeducational evidence can and cannot establish.

GOOD TO REMEMBER

Parents often bring a global account of decline, whereas the child's work shows a stable and specific bottleneck. Asking for examples makes the assessment more respectful as well as more accurate: it shows the family that the clinician is interested in the child's actual effort and experience, not merely in a label.

21.3 Cognitive and attainment evidence: complementary, not interchangeable

Individually administered cognitive assessment is useful because it provides a structured account of how the child performs on tasks that draw on different cognitive processes. It should not be treated as a measure of school achievement. An academic-attainment measure is needed because the clinical problem concerns learned skills in educational tasks. The important interpretive question is how the cognitive profile, attainment profile, history, and observed approach to tasks fit together.

The older **IQ-achievement discrepancy model** treated a learning disorder as an academic deficit significantly discrepant from expectations for both age and IQ. Under **DSM-IV**, this dual discrepancy was required. The subsequent approach abandoned that requirement in **DSM-5**.

This historical shift matters because a candidate may still encounter discrepancy language in reports, schools, or older examination answers. It should be recognised as a framework that influenced identification, not used mechanically as the sole gatekeeper for a clinically meaningful learning problem.

Discrepancy thinking had an intuitive appeal: it seemed to identify a child performing below an apparent potential. Its weakness is that it can turn assessment into a search for a sufficiently dramatic gap and postpone help until the gap is conspicuous. It can also make the IQ score appear more decisive than the child's demonstrated difficulties. In clinical practice, the central question is not whether a calculated contrast is impressive. It is whether reliable evidence shows persistent academic difficulty that requires explanation and support.

A cognitive profile may nevertheless deepen the formulation. In the **WISC profile, performance IQ is usually higher than verbal IQ, with an ACID pattern of weaker Arithmetic, Coding, Information, and Digit-span**. Weaknesses in verbal comprehension, working memory, and processing speed may also be relevant. These observations are profile findings, not diagnostic signatures. A profile can prompt more focused enquiry, but it cannot replace evidence from academic achievement or the child's educational history.

> **PITFALL**
>
> Do not tell a family that an IQ result proves or excludes a learning disorder. Such a statement confuses cognitive assessment with attainment assessment, and it can falsely reassure or unnecessarily stigmatise a child whose school difficulties have not yet been directly measured.

Standardised attainment measures make the academic domain visible in a way that a general interview cannot. The available batteries include the **WRAT, WIAT, Woodcock-Johnson III/IV, and KTEA**, among others. Their names are less important than their function: they sample specific academic skills in a standardised manner and permit the clinician to compare the reported problem with observed performance. Selection should be guided by the referral question, the child's language and educational context, and the competence of the assessor.

21.4 Response to instruction as assessment evidence

The **response-to-intervention model** approaches identification differently. Rather than waiting for an IQ-attainment discrepancy, it considers whether the child shows an inadequate response to evidence-based instruction. Universal screening and progress monitoring are central to this approach. The clinical attraction is obvious: it focuses attention on the child's learning trajectory and on what happens when teaching is deliberately matched to the problem.

This approach does not mean that every child who needs extra help has a learning disorder. Nor does it make the school's provision irrelevant. A poor response must be interpreted in context. The clinician needs to know what was offered, whether it was delivered consistently, whether the child could access it, and what changed in observable learning behaviour. The same phrase, "did not improve," can mean very different things when the instruction, attendance, language demands, or emotional state are different.

For psychiatry, response evidence is valuable because it links assessment to ordinary functioning. It shifts the conversation from an abstract contrast between test scores to a practical question: after appropriate teaching has been tried, what still remains difficult, and in what form? It also reduces the tendency to wait for repeated failure before taking a child's difficulties seriously. Yet it must be integrated with individual assessment rather than substituted for it. Inadequate response is evidence to be understood, not a standalone diagnosis.

MNEMONIC

Ask, Observe, Measure, Integrate

Ask what the learning problem is in daily work; observe how the child tackles it; measure cognition and attainment where indicated; integrate every source before writing the conclusion.

A useful report states both findings and limits. It should distinguish direct observations from informant accounts, identify where the data converge, and say when a conclusion is provisional. This is not defensive writing. It protects the child from categorical interpretations based on incomplete evidence and gives the referrer a clear account of what further information would resolve uncertainty.

21.5 The NIMHANS Index in Indian psychoeducational assessment

Why this matters in Indian practice. The **NIMHANS Index of Specific Learning Disabilities** is the most commonly used SLD assessment battery in the Indian context, with established reliability and validity. It is an Indian psychoeducational battery and is administered by clinical psychologists or special educators. For the psychiatrist, its value is not simply local familiarity. It offers a structured way to document the child's pattern of learning-related skills while retaining the clinical obligation to interpret that pattern in educational and developmental context.

IN INDIA

When a referral asks for assessment of specific learning difficulty, know the NIMHANS Index well enough to explain what it examines and what its findings mean. The report is strongest when the clinician links its findings to the child's lived classroom difficulties and to school-based evidence, rather than presenting the battery name as the conclusion.

The Index has distinct levels aligned to the child's age. **Level I is for ages 5-7 years**, while **Level II is for ages 8-12 years**. This structure encourages the assessor to ask developmentally appropriate questions rather than assuming that the same demonstration of skill is expected across childhood. The age band should guide test selection; it does not relieve the assessor of judging whether the child understood the task and whether the results reflect the referral concern.

5-7 years	8-12 years	Assessment + monitoring
LEVEL I	LEVEL II	INDEX FUNCTION

INDEX LEVEL	AGE GROUP	SKILLS SAMPLED	CLINICAL USE
Level I	5-7 years	Pre-academic skills: attention, visual and auditory discrimination, visual and auditory memory, speech and language, visuo-motor, writing, and number skills	Characterises early learning-related vulnerabilities.
Level II	8-12 years	Attention, reading, spelling, perceptuo-motor, visuo-motor integration, memory, and arithmetic skills	Characterises the profile of academic and associated skills.

At the earlier level, the emphasis is on **pre-academic skills**. This is clinically useful because a concern about later academic failure may have a history of difficulty in the foundational processes sampled by the assessment. At the later level, the child's profile includes **reading, spelling, perceptuo-motor functioning, visuo-motor integration, memory, and arithmetic skills**. The value of this organisation is that it preserves the distinction between a broad learning profile and the specific school complaint that led to referral.

The Index is used both to assess SLD and to **monitor progress after remediation**. This is a major practical advantage. A baseline assessment should not be filed away after a diagnostic discussion. It can organise subsequent review around the skills that were difficult at baseline and clarify whether a change in functioning is visible after targeted educational work. Monitoring is most meaningful when the same questions are asked each time: what has changed in daily academic work, what has the school observed, and how do updated findings relate to the original formulation?

21.6 Interpretation, reporting, and the limits of test findings

Interpretation is an act of clinical reasoning. The assessor should ask whether the measured pattern is coherent with the referral complaint, whether it is consistent with available school evidence, and whether the testing conditions permit confidence in the result. A report that merely lists subtests gives the referrer data without a formulation. A report that announces a conclusion without explaining the evidence gives the family no basis for understanding it. The useful middle path is a concise narrative of the problem, the sources of evidence, the observed pattern, and the implications for further assessment or educational planning.

Language deserves particular care. The language spoken at home, the language of instruction, and the language used in assessment can each shape apparent performance. The same applies to familiarity with test materials and prior opportunity to learn. These are not excuses to abandon assessment. They are reasons to record context explicitly and avoid interpreting a language-mediated difficulty as a fixed deficit without adequate corroboration.

The clinician should also avoid turning test labels into explanations. A child may have a recognisable profile and still need a careful account of emotional response, classroom demands, family understanding, and practical obstacles to attendance or study. Conversely, distress around schoolwork should never be used to dismiss the possibility of a genuine learning difficulty. Assessment is strongest when it respects both: the measurable pattern and the child's subjective experience of repeatedly encountering it.

> Psychoeducational assessment is a clinical synthesis of cognitive evidence, academic performance, history, and observation - never a single score or battery name.

21.7 Communicating the formulation and using assessment over time

Feedback is part of assessment, not an administrative afterthought. Families need a clear explanation of what was assessed, what the findings support, what remains uncertain, and what the findings do not mean. Use plain language without collapsing the clinical formulation into blame. Children should hear a description that protects dignity: the assessment has identified areas in which learning is harder, not evidence that they are unintelligent, lazy, or beyond help.

For the school, translate the report into observable needs. A teacher can act on a description of the tasks that become difficult, the conditions that support performance, and the evidence required for later review. The psychiatrist should avoid prescribing a generic educational programme from a test score alone. Detailed remedial planning belongs with professionals and settings able to implement and review it; management and remedial education are addressed elsewhere in this chapter.

Reassessment should be purposeful. It is indicated when the clinical question has changed, when progress is being reviewed, when the original testing conditions limited confidence, or when a major educational transition requires an updated account of functioning. Repeating a battery merely because time has passed produces information only if the result will change understanding or action. The clinician should state the question that the follow-up assessment is expected to answer.

Finally, preserve diagnostic humility. A robust assessment can make a strong formulation, but the child continues to develop and the educational environment continues to change. Keep the report open to new evidence, document the basis for conclusions, and coordinate with the relevant child mental-health and educational professionals. That is how psychoeducational testing becomes clinically useful rather than a bureaucratic endpoint.

22 · Management and remedial education for SLD

Management is an educational treatment, not an afterthought. Specific learning disorder is managed by converting a carefully described pattern of difficulty into teaching that the child can actually use. The psychiatrist does not substitute for the educator. The clinical task is to define the functional problem, explain it without blame, coordinate the adults around the child, and protect participation while the missing academic skill is being taught. A useful plan is therefore neither a

generic tuition referral nor a collection of concessions. It is a linked programme of skill teaching, access support, monitoring, and family-school collaboration.

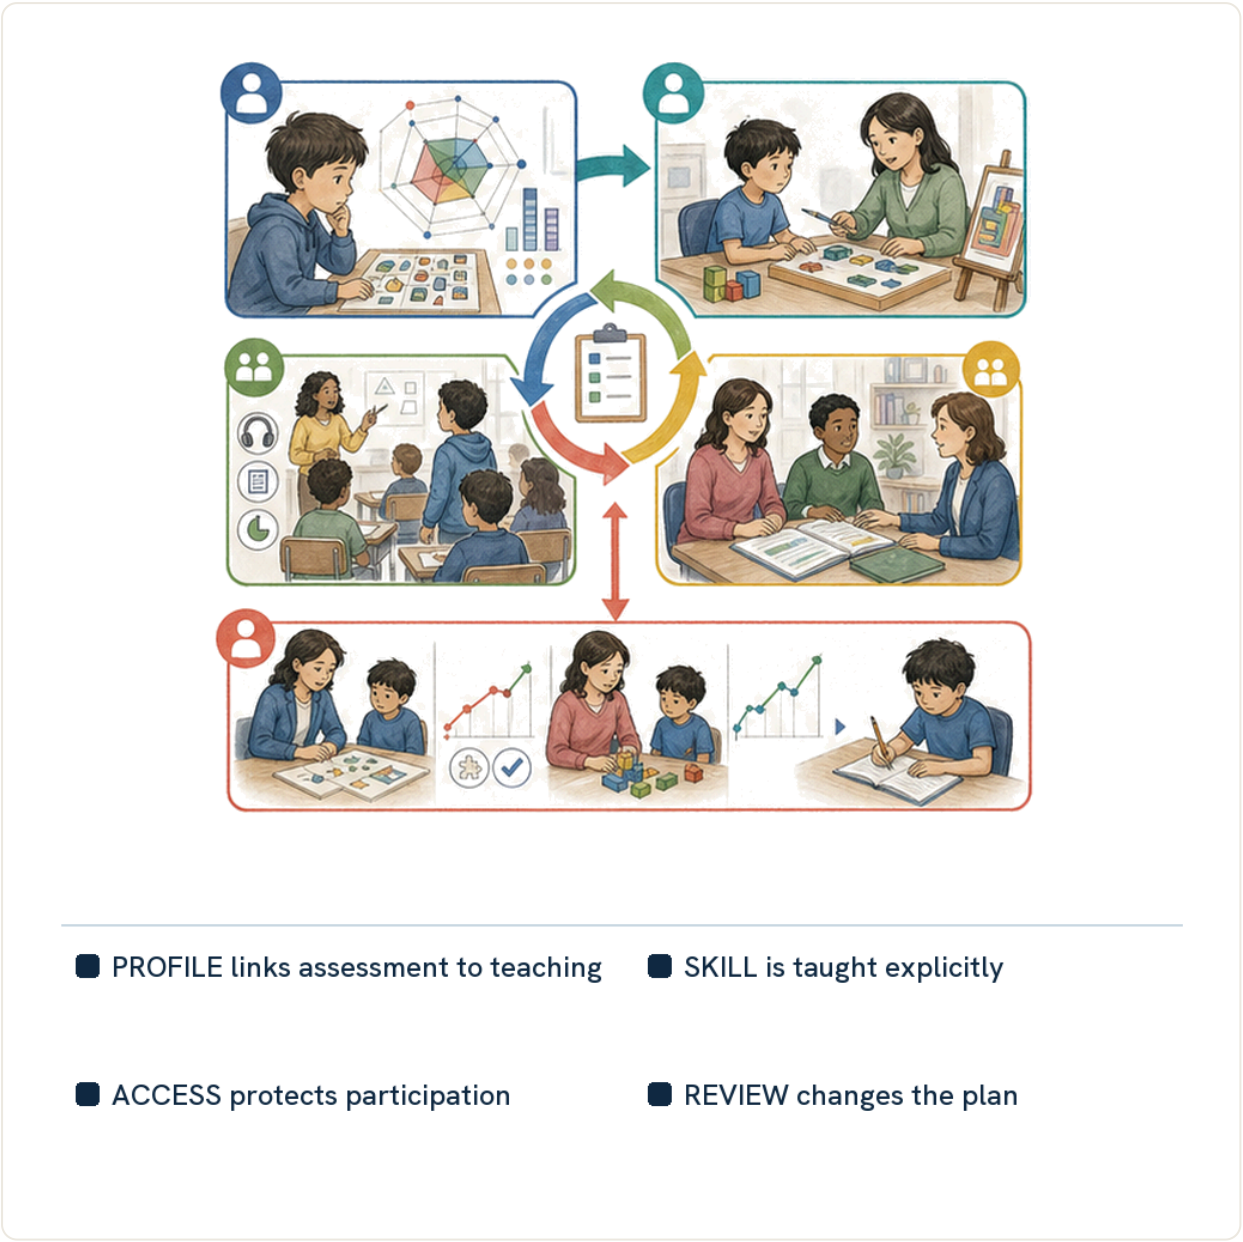

Fig 22.18 Management of specific learning disorder links the assessed learning profile to explicit skill teaching, protects participation through access support, and changes the plan through repeated review. It is an educational treatment, not generic tuition.

The marks in this area are usually earned by making a distinction that is easy to say but often poorly applied: treatment should both change what can be changed and reduce the immediate cost of a continuing difficulty. The child needs an explicit learning plan, rather than repeated exhortations to work harder. When this is done well, schoolwork becomes a source of graded mastery rather than a daily confirmation of failure.

PROFILE	SKILL	ACCESS	REVIEW
LINKS ASSESSMENT TO TEACHING	IS TAUGHT EXPLICITLY	PROTECTS PARTICIPATION	CHANGES THE PLAN WHEN NEEDED

22.1 Therapeutic frame and goals

Remedial education means planned teaching directed at the academic skill that is not developing adequately. It is not merely extra time spent on the same worksheet, and it should never be presented as punishment for poor effort. Its purpose is to build **age-appropriate foundational academic skills** through teaching that matches the child's pattern of strengths and difficulty. The practical implication is that the learning profile must shape the intervention. A child whose difficulty lies in decoding needs a different teaching emphasis from a child whose main barrier is written output or calculation, even when both are described by adults as "weak in studies".

The initial conversation has therapeutic value in its own right. Families and teachers may have accumulated explanations based on laziness, carelessness, oppositionality, or low intelligence. The clinician should reframe the difficulty as a specific problem in learning a particular academic skill. This is not an excuse for abandoning expectations. It is a reason to make expectations teachable, observable, and fair. The child should hear that difficulty is being taken seriously, that improvement requires practice, and that adults will alter the route to learning rather than simply demand a result.

RULE **Teach the impaired skill explicitly, then judge progress against that skill.** A remedial plan begins with the academic task that breaks down, identifies the component skill to be learned, and gives practice at a level where correction can be used. Repeating an activity that the child cannot decode, spell, write, or calculate independently rehearses failure rather than competence.

Goals should be functional and intelligible to the people implementing them. They may concern more accurate reading of instructional material, greater independence with written work, or reliable use of an agreed support. The point is not to promise a global transformation of school performance. A good goal defines what the child will be able to do more effectively and how adults will know whether the teaching approach is working. It also preserves the child's dignity by separating a learning problem from personal worth.

22.2 Designing the remedial programme

The intervention must be **individualized education program** work: systematic, structured skill-building tailored to the child's cognitive profile and the severity of the academic difficulty. Individualized does not mean improvised. It means that teaching content, pace, practice, correction, and review are selected after considering the child's actual performance. Structured does not mean rigid. It means that the teaching sequence is visible, cumulative, and capable of being adjusted when evidence from the child shows that a prerequisite has not been mastered.

- Translate assessment findings into a small set of observable learning targets.
- Identify the prerequisite skill that is preventing success with the current classroom demand.
- Arrange direct teaching, guided practice, and independent application in a predictable sequence.

For the psychiatrist, the formulation protects against a common systems error: referral without communication. A report that merely labels the disorder leaves the educator to guess what to teach. The useful clinical document describes the functional bottleneck, the child's relative strengths, the anticipated emotional consequences of repeated academic failure, and the need for a structured plan. It should support collaboration while respecting the educator's expertise in instruction. The psychiatrist remains responsible for the wider clinical picture, including distress, avoidance, family strain, co-occurring conditions, and whether a mismatch between school demand and support is amplifying impairment.

CLINICAL QUESTION	EDUCATIONAL RESPONSE	WHAT TO REVIEW
Which academic activity repeatedly fails?	Specify the component skill to be taught.	Whether the target matches the observed difficulty.
What can the child already do?	Begin from an accessible level and build from relative strengths.	Whether teaching is sufficiently challenging without becoming overwhelming.
Where does participation break down?	Provide an access support while remediation proceeds.	Whether support is enabling work rather than replacing teaching.
What is maintaining demoralisation?	Give feedback that identifies effort, strategy, and progress.	Whether avoidance, shame, or conflict is reducing engagement.

A programme should be documented so that it survives changes in personnel and can be discussed at review. Recording the target, method, response to correction, practice completed, and barriers to implementation makes the plan clinical rather than aspirational. It also lets the team distinguish a teaching approach that requires adjustment from a plan that was never delivered consistently. The aim is not bureaucratic perfection. The aim is continuity for a child who is often asked to begin again with every new adult.

GOOD TO REMEMBER

Ask the school to describe the task at which the child stops being independent, not simply the subject in which marks are low. That description is often the most useful bridge between a psychiatric formulation and a teachable target.

22.3 Reading remediation: the instructional core

Where reading difficulty is central, remediation should teach the relationship between spoken language and print directly. The core content is **phoneme awareness**: learning to hear and work with the sound units in words, including taking them apart and joining them. This is paired with **phonics**, in which the learner is taught the correspondence between letters and sounds. Contextual reading practice then gives the child an opportunity to use these skills in connected material rather than leaving them as isolated exercises.

The educational logic matters. Reading is not improved by asking a child to memorise larger and larger sets of words when the child does not have a dependable way of mapping print to sound. Nor is it enough to practise isolated sound exercises without helping the child apply them to text.

Direct work on sound structure supports decoding; explicit letter-sound teaching gives a route from print to speech; reading in context tests whether that route is becoming useful. Instruction should make errors visible and correctable. A child who guesses a word needs feedback that returns attention to the print and the sound pattern, not praise for a plausible guess that bypasses the skill being learned.

Multisensory structured language instruction is a helpful organising principle for this work. The teaching remains phonics-based and structured, but it deliberately gives the learner more than a purely passive encounter with print. The point is not novelty for its own sake. It is to make the sound-symbol relationship explicit, actively practised, and repeatedly retrieved in a coherent sequence. Such teaching should remain clear enough for the educator to observe whether the child is learning the intended correspondence.

MNEMONIC

Hear - Map - Read

Use this as a teaching spine: hear the sound structure in spoken words, map sounds to letters, then read the pattern in connected text. It keeps remediation directed at a usable reading skill rather than at nonspecific classroom activity.

TRAP **Do not mistake more reading exposure for reading remediation.** Exposure is valuable only when the child has a supported way to process the print. Unstructured repetition of material beyond the child's current decoding capacity can deepen avoidance and may persuade adults that the child lacks motivation when the actual problem is an unaddressed skill.

22.4 From accuracy to fluent, meaningful reading

Accuracy is necessary, but it is not the whole endpoint. **Repeated oral reading** can be used to improve fluency. It allows the child to revisit the same passage with feedback until word recognition becomes less effortful. This should be understood as supported practice, not as public performance. A child who has experienced correction as humiliation may avoid reading aloud altogether; the remedial setting must make error correction routine, private, and useful.

Fluency work should not be treated as proof of comprehension. A learner may become more rapid while still failing to derive meaning from what is read. The clinician should therefore keep comprehension in view as part of the wider language task. When a child understands spoken material better than independently read material, the barrier may lie principally in access to print. When understanding remains limited even after print has been supported, broader language comprehension becomes important to the educational formulation. This distinction prevents a narrow fluency goal from being mistaken for the child's full learning need.

At review, ask what changed in the child's everyday academic functioning. Has the child begun to approach text with less avoidance? Can the learner use the taught strategy in unfamiliar material? Is reading still so effortful that content learning is blocked? These questions keep teaching linked to participation rather than allowing a practice task to become an end in itself. They also help the

psychiatrist identify the point at which emotional support, classroom access, and remediation need to be intensified together.

22.5 Remediation and accommodation serve different jobs

The distinction is clinically decisive. **Remediation** builds a deficient skill. **Accommodations** enable access to educational material without changing that skill. These approaches work best as partners rather than competitors. The child may need access support now because a current curriculum cannot be put on hold while skill development proceeds. At the same time, access without teaching leaves the underlying academic difficulty untouched.

QUESTION	REMEDIATION	ACCOMMODATION
Primary purpose	Build the impaired academic skill.	Enable participation despite the current barrier.
Immediate focus	Direct, structured instruction and practice.	How the learner receives, produces, or demonstrates educational work.
Clinical error if used alone	Ignoring the child's present access needs.	Assuming that access has taught the missing skill.
Examples	Teaching directed at the identified learning target.	**Audiobooks, spell-checkers, and assistive technology** when these enable access.

An accommodation should be chosen by asking what unwanted barrier it removes. If a support lets a child obtain the meaning of material despite a reading barrier, or express knowledge despite difficulty with mechanics, it may protect access to the curriculum. It should not be framed as an unfair advantage. Equity means that the child is given a route to show learning that is not needlessly dominated by the disability being treated. The detailed statutory, certification, and examination route is outside the scope of this clinical management discussion.

PITFALL

Do not use an access support as a reason to stop remediation. A tool can reduce the immediate penalty of a learning difficulty, but it does not by itself establish the academic skill that the child is still being helped to acquire.

22.6 Working with family, school, and the child

Management fails when adults hold incompatible explanations. Parents may be asked to supervise exhausting homework that does not teach the relevant skill; teachers may interpret slow output as defiance; the child may conceal difficulty to avoid embarrassment. The psychiatrist should bring the discussion back to a shared formulation: which task is difficult, what skill is being taught, what support allows participation, and how progress will be recognised. This gives each adult a role without turning the family home into a remedial classroom.

- Explain the learning difficulty in language that separates it from intelligence, effort, and character.

- Agree on a consistent channel for communication between home, school, and the treating team.
- Notice avoidance, anxiety, irritability, and loss of confidence as signals that the educational burden needs review.

The child's view is indispensable. Ask which classroom moments feel impossible, which supports feel exposing, and what kind of feedback encourages continued effort. This is not merely rapport-building. A plan that is technically sound but experienced as shaming will be poorly used. Conversely, a child who can identify a successful strategy is more likely to apply it outside the remedial setting. Where co-occurring attentional, emotional, behavioural, communication, or developmental concerns affect learning, they should be assessed and managed in their own right rather than being used to explain away the specific learning problem.

IN INDIA

Access to trained remedial educators and assistive tools may differ sharply across schools and localities. The clinical plan should therefore state the instructional principle clearly enough that it can guide whatever educational resource is available, while avoiding a vague recommendation for "special help" that no adult can operationalise. The statutory and examination pathway belongs to the educational provisions section of this chapter.

22.7 Starting early, monitoring honestly, and sustaining hope

Remedial action should begin when the pattern of difficulty is clear enough to justify help; it should not be postponed while adults wait for a formal dyslexia label or for another episode of academic failure. Delay has consequences beyond marks. Repeated failure can reshape the child's expectations, reduce willingness to attempt difficult work, and make school refusal or behavioural conflict appear to be the primary problem. Early, specific teaching is therefore also preventive mental-health care.

The plan should be reviewed using direct information from the learning setting: whether the child is receiving the intended teaching, whether the selected task has become more manageable, whether supports are being used, and whether emotional strain is reducing. Lack of progress is not a cue to intensify blame. It is a cue to reconsider the match between the child's profile, the teaching target, the instructional method, and the environmental demands. Sometimes a target was too broad; sometimes a prerequisite was missed; sometimes implementation was inconsistent; sometimes a co-occurring problem requires parallel attention.

Progress review is also an opportunity to preserve coherence. The family may report a small but important change that is invisible in a broad school result, such as willingness to attempt a previously avoided task or use of a taught strategy without prompting. The school may identify a barrier that was not apparent in the clinic. Bringing these observations together prevents premature abandonment of a useful approach and prevents persistence with an approach that has lost its fit. The question is always practical: what should the child, educator, and family continue, modify, or stop doing?

Prognosis should be communicated with realism and confidence. With appropriate remedial education and relevant provisions, **most children** can achieve academic competence. This statement should not be converted into a promise of effortless parity in every academic task. Its clinical value is that it replaces fatalism with a process: identify the barrier, teach the skill, maintain access, and revise the plan from observed response. It gives the child and family a credible reason to remain engaged.

> Remediation teaches the skill; accommodation protects access while that teaching is taking effect.

23 · Certification and educational provisions for SLD in India

Why certification matters. In specific learning disorder, a clinical formulation does not by itself unlock educational support. Certification is the bridge between a child's demonstrable academic difficulty and enforceable participation measures in school and examinations. The psychiatrist therefore needs to understand the route well enough to guide families, interpret what a certificate does and does not establish, and avoid converting a school complaint into either a global cognitive label or an administrative shortcut.

The legal bridge is deliberately narrow here. **Specific learning disability is a specified disability under the Rights of Persons with Disabilities Act, 2016**. That status places the child within a disability-rights framework, but it does not replace careful clinical assessment, psychoeducational evaluation, or a school plan. The Act's general machinery is dealt with in the Intellectual disability and autism spectrum disorder notes; the present discussion concerns the SLD-specific statutory and educational route.

LAW	SCHOOL	TEAM	BOARD
RIGHTS ROUTE	SCREENING ROUTE	ASSESSMENT ROUTE	ACCESS ROUTE

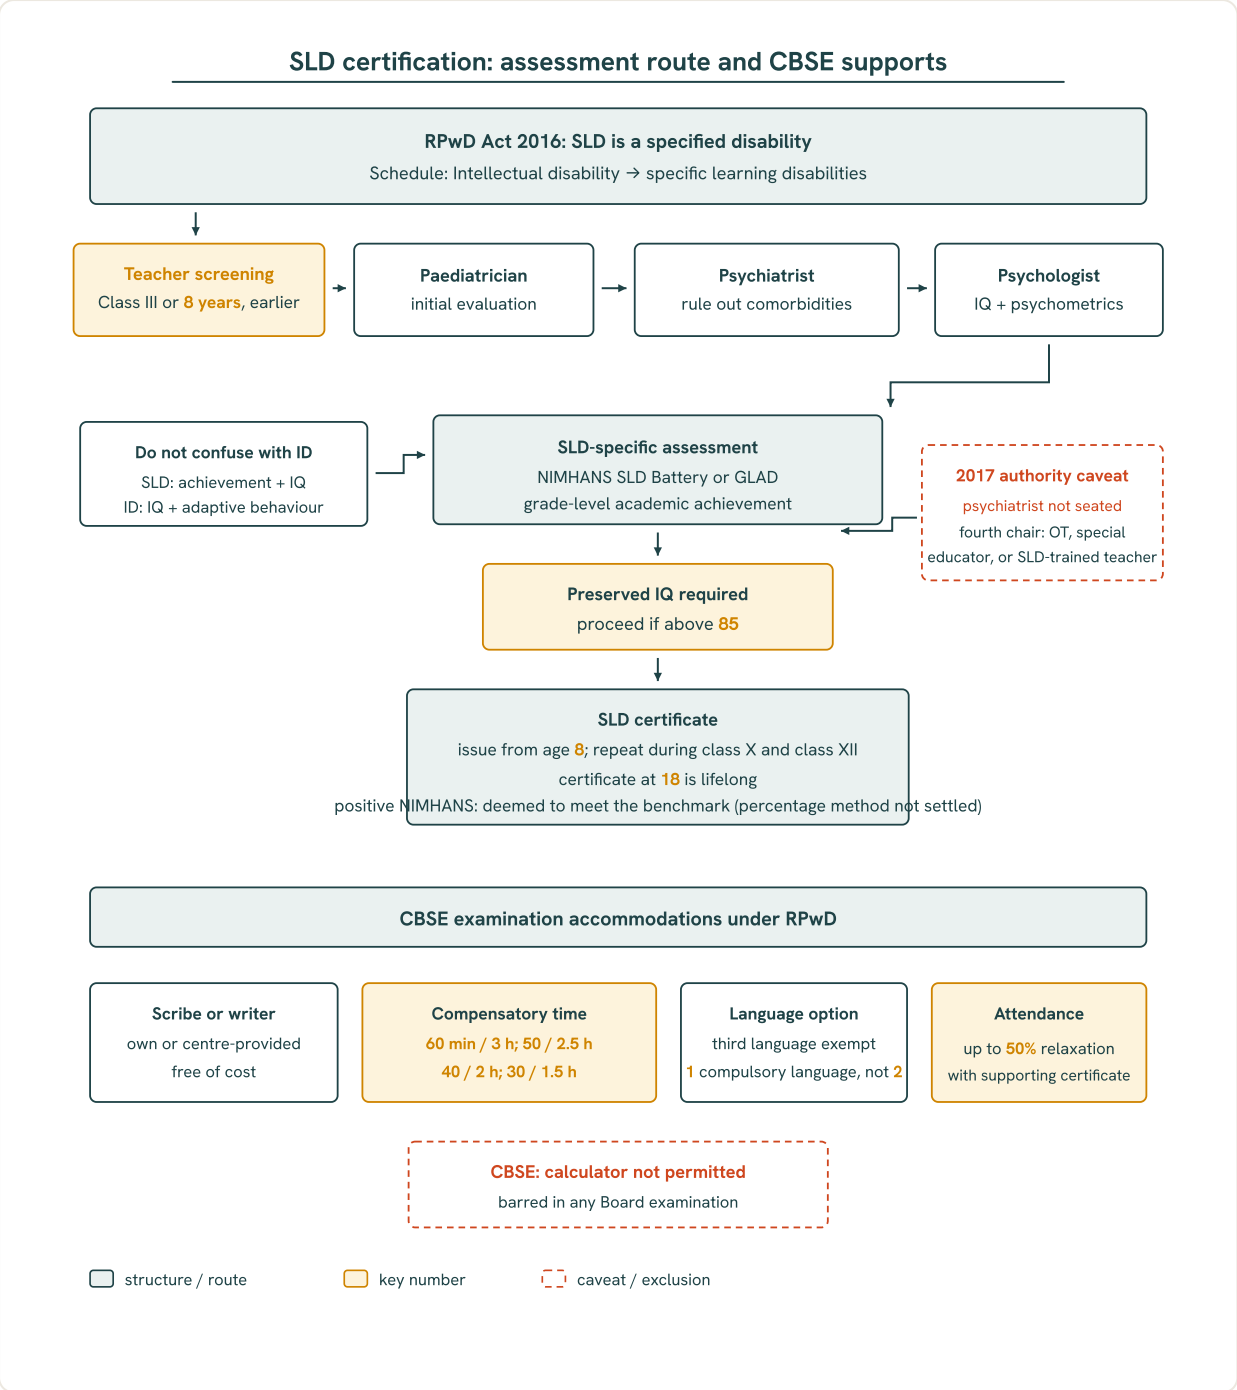

Fig 22.19. Indian SLD certification pathway and CBSE examination accommodations.

23.1 Statutory location and its clinical meaning

The first distinction is between a statutory description and a psychiatric taxonomy. The Act places SLD under the Schedule head concerned with intellectual disability: its **Schedule placement** is as "specific learning disabilities" under that head, alongside autism spectrum disorder. This grouping should not be read as equating SLD with intellectual disability. It is a legislative arrangement for specified disabilities, whereas clinical differentiation rests on the pattern of functioning and the assessment route.

The **statutory definition** describes a heterogeneous group in which difficulty in processing spoken or written language becomes evident in comprehension, expression, reading, writing, spelling, or mathematical work. Its wording includes perceptual disabilities, dyslexia, dysgraphia,

dyscalculia, dyspraxia and developmental aphasia. This is wider than a neat examination list of academic skill deficits. A candidate should neither force all of these labels into a psychiatric diagnosis nor discard a child's functional difficulty because it sits awkwardly beside a clinical classification. In certification work, the relevant question is whether the child's documented pattern fits the notified route.

IN INDIA

Use the statutory language when explaining eligibility and the clinical language when formulating the disorder. They overlap but serve different purposes. Confusing them produces opposite errors: treating every poor scholastic performance as a disability, or assuming that a clinically meaningful learning difficulty cannot attract support because its label is not a familiar diagnostic heading.

RULE **Certification follows the SLD-specific educational assessment route, not a global-intelligence label.** The legal category creates access to support; it does not collapse SLD into intellectual disability.

23.2 From school concern to formal evaluation

School recognition is not a casual referral note. It is a structured initial filter intended to identify children whose persistent academic difficulty warrants a fuller pathway. Under the certification guidance, school-based teacher screening begins at **Class III or 8 years of age, whichever is earlier**. The screening committee is led by the principal, and teachers administer the questionnaire in public as well as private schools. This is useful because teachers see the curriculum demand, the child's response to repeated instruction, and the practical consequences of the difficulty.

Screening is an entry point, not a diagnosis. A teacher can appropriately identify a child who repeatedly fails to acquire expected academic skills despite classroom opportunity, but the teacher cannot determine the cognitive basis, psychiatric comorbidity, sensory contribution, or validity of a disability certificate. Conversely, a normal-looking classroom behaviour profile does not settle the matter if a child is using avoidance, copying, memorisation, or family support to conceal a marked skill deficit.

After a positive screen, the **multidisciplinary pathway** moves through an initial paediatric evaluation, psychiatric assessment for comorbidity, and psychometric and IQ testing by a psychologist. It protects against premature attribution. The paediatric assessment addresses medical and developmental context; psychiatric review asks whether comorbidity is altering performance or participation; and the psychologist documents the psychometric profile. Each professional answers a different question. A referral letter that merely says "rule out SLD" is less useful than a concise account of the scholastic complaint, prior support, course, school observations and relevant emotional or behavioural symptoms.

- Clarify the academic task that is failing, rather than accepting "poor studies" as a formulation.
- Ask what teaching and remedial opportunity the child has actually received, because achievement cannot be interpreted without opportunity.

- Seek school work and collateral that show the pattern over time, not only the family's account of a recent examination result.
- Screen clinically for comorbidity that may coexist with, amplify, or mimic academic underperformance.

GOOD TO REMEMBER

The psychiatrist's most useful contribution is often not administration of an academic battery. It is protecting the formulation from diagnostic overshadowing: anxiety, mood symptoms, attentional symptoms, developmental language difficulty, sleep disturbance, adversity, or a neurological history may change how the child performs and what support is needed.

23.3 Assessment logic and the boundary with intellectual disability

The assessment route differs in kind from the route used for intellectual disability. SLD certification rests on psychoeducational, grade-level academic-achievement assessment with preserved intellectual functioning, whereas intellectual disability certification uses an IQ-plus-adaptive-behaviour route. This distinction is clinically important. A child can be severely disabled in a particular academic domain while showing no global pattern of limitation that would justify intellectual-disability certification.

In the notified SLD pathway, SLD-specific assessment proceeds when IQ is **above 85**. This is not a reason to use an IQ score as the explanation for a child's scholastic struggle. It is a gate within this certification route, intended to separate the educational-achievement assessment from the intellectual-disability pathway. Clinically, the clinician must still consider the quality of the testing, language and schooling context, effort, emotional state, and the consistency of the profile with the child's real-world work.

QUESTION	SLD CERTIFICATION ROUTE	INTELLECTUAL DISABILITY ROUTE
Central concern	Specific academic achievement	Global intellectual and adaptive functioning
Assessment emphasis	Psychoeducational and grade-level work	IQ together with adaptive behaviour
Clinical implication	Plan targeted access and learning support	Plan support around broader functioning
Common error	Calling all low marks SLD	Calling a focal academic deficit global disability

That table is deliberately an assessment distinction, not a substitute for diagnostic criteria. The clinical definition and diagnostic criteria of SLD are addressed elsewhere in this chapter, while the broader differential including slow learner is addressed in the chapter's discrimination section. In practice, the safe sequence is to establish the child's functional academic pattern, examine the testing context, integrate psychiatric and developmental information, and only then determine whether the notified certification threshold and pathway apply.

TRAP **Do not treat the IQ gate as the diagnosis.** A score used for eligibility cannot explain a child's reading, writing, spelling, or mathematical difficulty, and it cannot replace a grade-level achievement assessment.

23.4 Approved batteries and what a result means

The notified academic tools are the **NIMHANS SLD Battery** and the **Grade Level Assessment Device (GLAD)**. Their value is not that they provide a mechanical label. They make the academic judgement auditable by linking the child's performance to expected grade-level work. The report should preserve the profile of strengths and weaknesses, the language and educational context, the source of collateral, and the implications for accommodations and remediation.

The choice of battery must be appropriate to the child's schooling context and the skills being examined. It is tempting to treat any cognitive test, informal dictation exercise, or school mark sheet as interchangeable with a notified achievement battery. They are not interchangeable. Informal material can sharpen the clinical question and can be valuable evidence of functional impairment, but certification needs the designated psychoeducational route. The task for the psychiatrist is to ensure that the evaluation answers the practical question being asked, not simply to accumulate test names.

Current guidance describes a positive result on the NIMHANS Battery as meeting the **benchmark-disability determination**, while not providing a graded percentage method for SLD. Thus, SLD certification is best understood as a positive-or-negative determination based on the notified battery, rather than as a ladder of progressively assigned disability percentages. The cited guidance itself identifies a need for clarification about the continuing application of this position. In a certificate-related consultation, it is prudent to document the source report precisely and avoid inventing a severity percentage that the SLD framework does not supply.

PITFALL

Do not translate a psychoeducational result into a generic "percentage disability" in clinic correspondence. That may sound administratively helpful, but it can misstate the SLD-specific framework and obscure the assessment on which eligibility rests.

23.5 Certificate timing, review and professional roles

Certification is reserved for children **aged 8 and above; the current notified guidelines schedule repeat certification during class X and class XII, and a certificate issued at 18 is valid lifelong**. This schedule recognizes that educational demands and the documented profile need review as the child progresses through schooling. Families should be told early that certification is part of a continuing educational record, not a one-time diagnostic performance. Delayed referral can therefore have practical consequences when schools and examining bodies need documentation within their own processes.

There is an important nuance about the psychiatrist's place in the process. The certifying medical authority described in the earlier rules does not seat a psychiatrist; its additional position may be held by an occupational therapist, special educator, or teacher trained in SLD. This **board-**

composition limitation must not be distorted into "psychiatrists have no role." The amended diagnostic pathway separately describes psychiatric assessment to rule out comorbidity. The sensible reading is functional rather than territorial: the psychiatrist contributes clinical formulation and comorbidity assessment, while certification is completed through the designated authority and educational assessment process.

This distinction also helps with interprofessional communication. The psychiatrist should not demand to control an academic determination, and the school or assessment team should not dismiss mental-health symptoms as irrelevant to performance. A good report states what the psychiatric assessment establishes, what it does not establish, and which part of the certification record must come from the appropriate educational and certifying process.

MNEMONIC

Screen - Sort - Study - Support

Screen at school, **sort** medical and psychiatric contributors, **study** the psychoeducational profile, then arrange certified **support**. The phrase is a workflow memory aid, not a diagnostic criterion.

23.6 Examination accommodations: access, not advantage

Educational accommodations aim to reduce the disability-related barrier to showing knowledge. They should not be presented as rewards for a diagnosis or as a promise that marks will improve. The key question is whether the examination format places a disproportionate barrier on the student's ability to demonstrate the intended competence. The **CBSE scribe or writer facility** permits an eligible candidate to use either a personal writer or a writer provided without charge by the examination centre. A personal writer must have a lower qualification than the candidate. A reader may be used when the candidate does not opt for a writer.

Compensatory time is a distinct accommodation. It may be taken instead of, or in addition to, a writer where the rules permit. In the relevant board schedule, the **compensatory-time allocation is 60 minutes for a 3-hour paper, 50 minutes for 2.5 hours, 40 minutes for 2 hours, and 30 minutes for 1.5 hours**. The clinical point is that extra time addresses speed and written-output burden; a writer addresses a different barrier. A certificate alone does not tell the school which arrangement will preserve the examination's purpose. That decision should be grounded in the documented functional difficulty.

PROVISION	WHAT BARRIER IT ADDRESSES	CLINICAL CLARIFICATION
Writer or scribe	Written output	Do not assume it is needed for every student with SLD
Compensatory time	Slower processing or output	It can be relevant even when a writer is not used
Language option	Additional language demand	It changes subject requirements, not the underlying learning need
Attendance relaxation	Difficulty meeting attendance requirement	Requires the stipulated supporting recommendation

For the language provision, eligible candidates are exempt from the third language and may take a reduced compulsory-language requirement. The **CBSE language exemption** is therefore a defined curricular concession, not a broad waiver from language learning. Counselling should be careful and non-stigmatising: the relevant choice may reduce an avoidable barrier, but it should be considered alongside the child's educational goals, strengths, and confidence rather than imposed as a default.

Attendance relaxation is similarly conditional rather than automatic. The **CBSE attendance relaxation** can extend up to **50%** when the prescribed attendance requirement cannot be met, on the school principal's recommendation and supporting certification from a registered medical practitioner or authorised psychologist. In clinical letters, describe the actual disability-related functional issue and avoid certifying a benefit whose educational criteria have not been met.

23.7 The calculator question and board-specific advice

One of the most persistent sources of misinformation is the assumption that dyscalculia automatically permits a calculator. For examinations conducted by CBSE, use of a calculator is barred. The **CBSE calculator provision** is therefore a prohibition, despite the fact that calculator access is often repeated in generic lists of concessions and may be available in other board settings. This is a useful example of why clinicians should never promise an accommodation from memory.

Advice to families must be board-specific and document-specific. The psychiatrist can explain the functional rationale for an accommodation and can provide an accurate clinical report. The school and examination authority determine what their current rules allow. Where a family is considering subject choices, a writer, extra time, or language exemption, encourage early verification with the relevant authority rather than a late appeal after examination arrangements have closed.

TRAP **Do not promise a calculator for dyscalculia.** A commonly repeated concession is not a universal entitlement, and for CBSE examinations the rule is explicitly restrictive.

23.8 A practical psychiatrist's approach

For the resident, the high-yield approach is to hold the clinical and administrative tasks together without confusing them. Begin with the child's functional academic complaint and the evidence from school. Establish whether the concern has been adequately assessed through the designated psychoeducational pathway. Review psychiatric comorbidity and contextual factors that could alter performance. Explain the certificate as an access document rather than a total account of the child. Then help the family translate the documented functional profile into a realistic school and examination plan.

Communication is often the intervention that prevents harm. A child who has repeatedly been called careless or lazy may hear certification as proof of incapacity; a family may hear it as a guaranteed route to concession. Both interpretations are damaging. The better formulation is that a specific barrier has been identified and documented, and that targeted supports are meant to

allow fair demonstration of learning. Remedial education remains central; accommodations do not teach the skill, and teaching alone may not remove an examination barrier.

- Use school evidence to define the functional problem before discussing a certificate.
- Refer through the notified educational assessment route rather than relying on an informal impression.
- Record psychiatric comorbidity clearly, while avoiding the claim that it establishes SLD.
- Match accommodation discussion to the documented barrier and the applicable board rule.

Treat SLD certification as a psychoeducational access pathway: document the academic profile, assess comorbidity, use the designated authority, and verify each accommodation against the relevant board rule.

Communication and motor disorders

24 · Communication disorders (language, speech sound, childhood-onset fluency, social communication)

Communication is a clinical function, not merely a school subject. A child may have difficulty understanding language, formulating it, producing intelligible speech, maintaining fluent speech, or using communication appropriately with other people. The diagnostic task is to locate the impaired function, establish its developmental pattern and functional consequence, and then ask whether another condition explains the presentation more parsimoniously. These distinctions matter because a child who cannot make an intelligible request, follow a classroom instruction, or understand the implied meaning of a peer's remark will be impaired in a different way, even when the family describes all of them as “speech delay”.

The **communication disorders** are developmental disorders of communication. They sit beside, rather than inside, the broader assessment of neurodevelopmental functioning. A careful formulation therefore separates the child's linguistic or speech difficulty from hearing, oral-motor, neurological, structural, intellectual, emotional, and environmental contributions. It also avoids treating a language difference in a multilingual family as proof of disorder. The relevant developmental context is addressed in the Normal child development and milestones notes, and a full service-based child assessment is addressed in the Child psychiatry: assessment, treatment, services and protection notes.

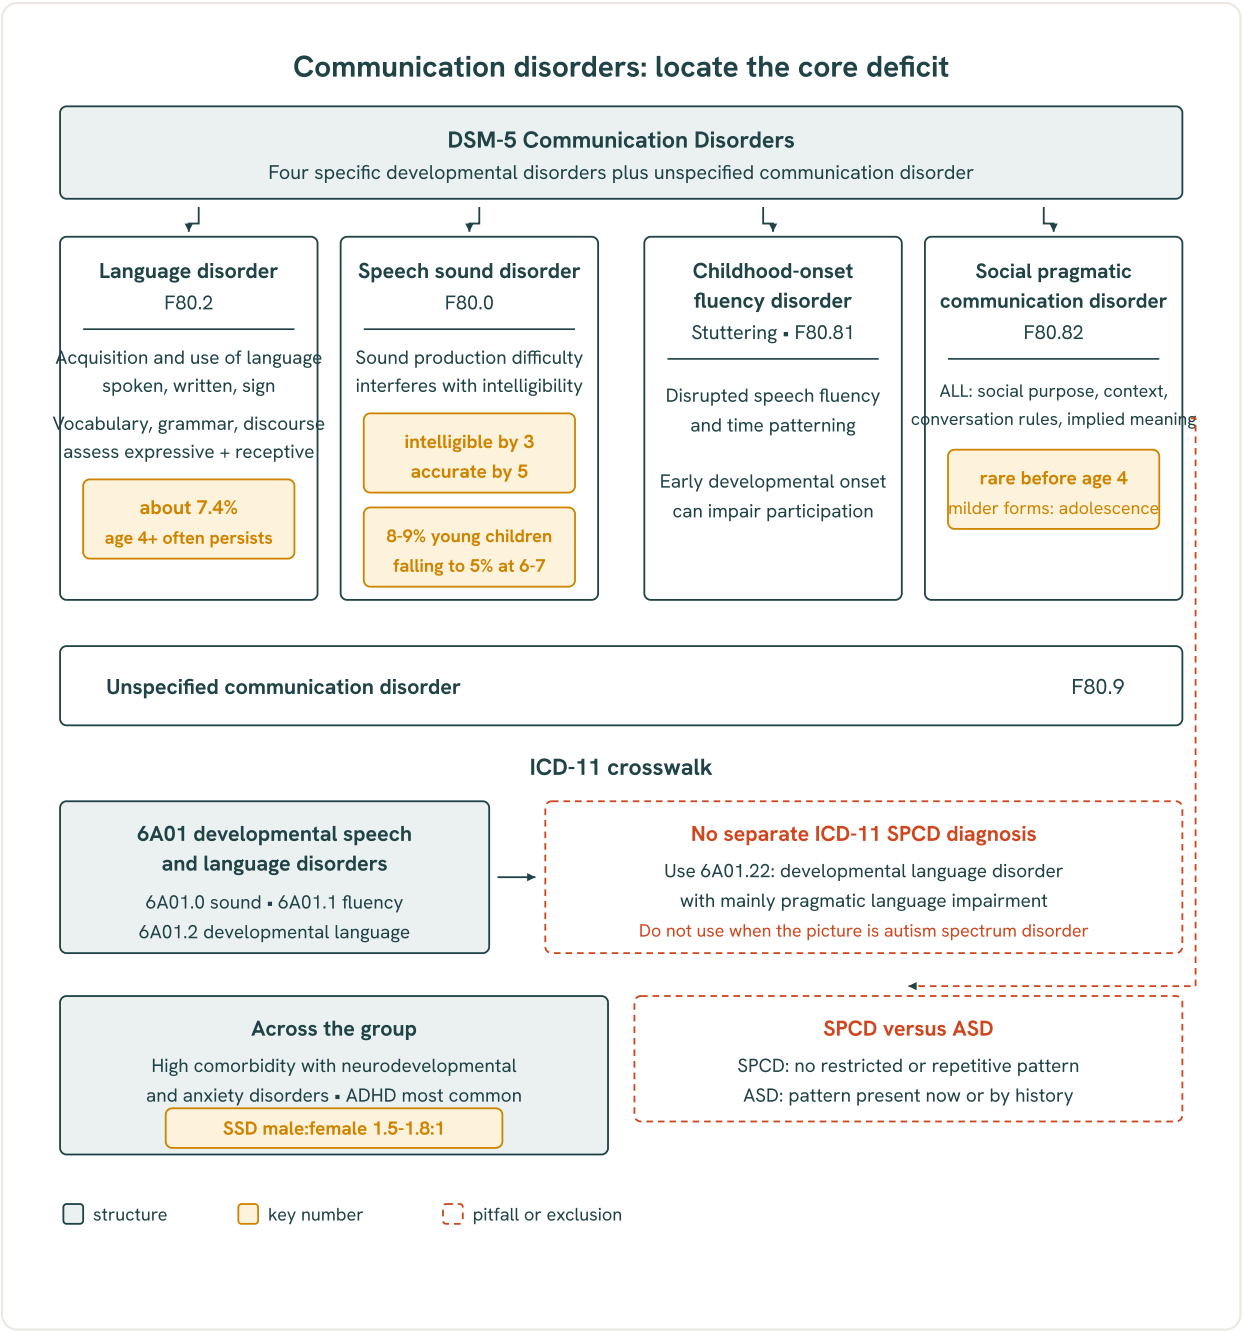

Fig 22.20. Communication disorders map: core deficit, ICD-11 crosswalk and the SPCD exclusion.

24.1 Diagnostic map and the unit of impairment

The DSM communication-disorder group includes **language disorder**, **speech sound disorder**, **childhood-onset fluency disorder**, **social (pragmatic) communication disorder**, and an unspecified category. The names identify the principal clinical bottleneck. Language concerns understanding and expression of meaning through an organised symbolic system. Speech sound concerns the production of sounds that make spoken output intelligible. Fluency concerns the temporal flow of speech. Social communication concerns whether verbal and nonverbal communication is used effectively with another person in a context.

For documentation and examination answers, the corresponding DSM coding labels are language disorder **F80.2**, speech sound disorder **F80.0**, childhood-onset fluency disorder **F80.81**, social (pragmatic) communication disorder **F80.82**, and unspecified communication disorder **F80.9**.

Coding is not a substitute for formulation. A code tells the reader where the principal problem has been placed; the formulation must still say how it affects participation, learning, relationships and family life.

The ICD approach groups developmental speech and language conditions together, including language, speech sound and fluency presentations. This is useful to remember when records use different classificatory languages. The important clinical question remains unchanged: which communicative operation is persistently compromised, and is that compromise the primary explanation for the observed impairment?

RULE **Name the impaired communication function before naming the diagnosis.** "Speech problem" is an initial complaint, not a formulation. Decide whether the child cannot understand, formulate, articulate, speak fluently, or use communication socially.

- Ask what the child understands when contextual cues are removed.
- Ask how the child conveys a novel idea, need, or narrative.
- Listen for intelligibility, sound-pattern errors, effort and fluency.
- Observe reciprocity, turn-taking, repair after misunderstanding and sensitivity to context.

These observations should be gathered from more than the consulting room. A child may speak freely with a parent yet fail when required to comprehend decontextualised classroom language, explain an event, negotiate with peers, or respond to an unfamiliar adult. Conversely, silence in a strange clinic can be an anxious state rather than evidence that language has not developed. The clinician should use the child's strongest available means of communication and seek examples that show both capacity and performance.

24.2 Language disorder: a disorder of learning and using language

Language disorder is characterised by persistent difficulty acquiring and using language across spoken, written, or signed modalities. The deficit may involve comprehension, production, vocabulary, grammar, sentence organisation, or discourse. In assessment, **receptive and expressive language** must both be examined. A child with apparently fluent output can still have poor comprehension, while a child who says little may understand considerably more than they can express. The distinction changes both formulation and prognosis.

Clinically, the difficulty is not simply an absence of a few words. It is a problem in building a usable language system: attaching stable meanings to words, combining them according to rules, understanding relationships within a sentence, and using connected language to explain, recount, infer and learn. The impairment must be persistent and consequential. A quiet child, a child who chooses brief answers, or a child who is still adapting to the language used at school should not be relabelled on the basis of a single brief encounter.

The disorder begins in the developmental period. Before 4 years, ordinary variation can be difficult to distinguish from an enduring disorder; by that age, individual differences become more stable and informative, and a disorder diagnosed then commonly continues into adult life.

This does not mean that a clinician should wait passively when a child is struggling. It means that the assessment should record the developmental trajectory, repeated functional observations and response to appropriate support rather than claiming false precision early on.

The profile may be predominantly expressive, predominantly receptive, or mixed. **Receptive impairment** carries a less favourable outlook and is more resistant to intervention than a largely expressive presentation. This is clinically intuitive: when comprehension is compromised, the child has less reliable access to the language input from which learning, conversation and teaching are built. It should prompt a careful search for the child's actual understanding, not an assumption that fluent repetition or a few familiar routines demonstrate comprehension.

GOOD TO REMEMBER

When a parent says, "He knows everything but does not speak," test that proposition gently. Ask the child to show understanding of unfamiliar instructions, relationships, sequence and implied meaning, using familiar language and low-pressure interaction. The answer often determines whether the formulation is expressive alone or includes comprehension.

Language disorder can affect academic work without being reducible to an academic diagnosis. Classroom tasks place heavy demands on understanding instruction, learning vocabulary, constructing explanations and following discourse. Socially, a child may appear inattentive, oppositional or immature because the conversational load has exceeded their comprehension. These are hypotheses to test, not labels to attach automatically. The evaluation of specific learning disorder is covered elsewhere in this chapter, while the wider assessment of attention and behaviour must preserve the possibility that communication difficulty is contributing to the observed behaviour.

24.3 Speech sound disorder: intelligibility is the functional anchor

Speech sound disorder is a persistent difficulty in producing speech sounds that reduces intelligibility or prevents effective verbal communication. It may reflect difficulty with phonological knowledge, articulatory coordination, or both. The diagnosis requires that the presentation is not better explained by a hearing, structural or neurological cause. This is why "mispronunciation" alone is an inadequate conclusion: one must decide whether the pattern is developmental variation, a primary speech sound difficulty, or a manifestation of another condition.

The clinical anchor is **speech intelligibility**. The question is not whether an adult can identify an occasional imperfect sound after listening carefully. The question is whether the child's usual speech can be understood sufficiently for ordinary communication with familiar and unfamiliar listeners. The functional impact may become conspicuous when the child is expected to answer in class, make needs known outside the family, participate in group play, or be understood over a telephone or audio-only interaction.

Speech development must be interpreted against developmental expectations. Overall speech is ordinarily intelligible by 3 years, whereas at 2 years only about 50% may be understandable; most

words are accurate by 5 years. These anchors prevent two opposite errors: pathologising expected immaturity and reassuring a child whose intelligibility has remained functionally limiting beyond the point at which ordinary maturation is a sufficient explanation.

about 7.4%	about 8-9%	about 5%	about 1.5-1.8:1
LANGUAGE DISORDER AT KINDERGARTEN ENTRY	SPEECH SOUND DISORDER IN YOUNG CHILDREN	SPEECH SOUND DISORDER, SCHOOL AGE	BOYS:GIRLS IN SPEECH SOUND DISORDER

Speech sound disorder is common in young children and becomes less frequent later in childhood. Boys are more likely than girls to be affected. The useful examination point is not to overinterpret the epidemiological figure, but to connect it to the clinical interview: a common presentation still requires a structured differential, and male predominance never makes the diagnosis automatic in a boy or implausible in a girl.

PITFALL

Do not equate a regional accent, home-language transfer, or an isolated unfamiliar sound with disorder. Evaluate the child's speech pattern in the languages and settings in which the child actually communicates, and focus on persistent functional intelligibility rather than an adult's preference for a particular pronunciation.

24.4 Childhood-onset fluency disorder: identify it, then keep the boundary

Childhood-onset fluency disorder is the fluency member of the communication-disorder group. It should be considered when the central difficulty is the flow and temporal organisation of speech rather than language formulation or sound production. Families may use the word "stammering" for many forms of hesitant speech, including a child searching for words, anxiety-linked inhibition, or a normal transient disfluency. The clinician must first establish what is actually occurring during speech and how the child responds to it.

The initial interview should attend to the child's own experience, avoidance, anticipation of speaking, and the contexts in which fluency changes. It should also ask whether the apparent disruption is better accounted for by a primary language difficulty, a motor or neurological condition, medication or substance exposure, a hearing problem, or a situational emotional state. These questions prevent a descriptive label from obscuring the relevant formulation.

This section deliberately does not reproduce the syndrome's features or management. Those belong to the dedicated discussion of stuttering elsewhere in this chapter. Here, the practical point is diagnostic placement: do not call a child's speech "language delay" when the language system is intact and the principal difficulty is fluent delivery; do not call it speech sound disorder when intelligibility is reduced by interruptions in flow rather than sound-pattern production.

TRAP **Do not use "speech delay" as a catch-all.** It collapses language, articulation and fluency into one label, conceals the actual impairment, and leads to an unhelpful referral question.

24.5 Social (pragmatic) communication disorder: language in relation to another mind

Social (pragmatic) communication disorder concerns persistent difficulty in the social use of verbal and nonverbal communication. The problem is not merely shyness, politeness, vocabulary size or grammatical correctness. It is the failure to deploy communication effectively for social purposes: to greet and share information, adjust expression to context, follow conversational and narrative conventions, and understand nonliteral or implied meaning. In this diagnostic construct, all of these pragmatic deficits are required.

Pragmatics are most visible in interaction. The child may give an answer without recognising what the listener needs to know, continue speaking without detecting that the partner is disengaged, take an idiom literally, or fail to repair a misunderstanding. A structured history should seek examples from home, school and peers. Clinic conversation is informative but can be falsely reassuring when the adult carries the conversational burden, supplies the topic, overlooks missed cues, or accepts answers that a peer would not understand.

The disorder begins in the developmental period, but a diagnosis is unusual before 4 years because sufficient speech and language must first be available to judge social use. Milder difficulties may become apparent only in early adolescence, when conversation becomes less scripted and social demands depend more heavily on inference, narrative, tact and flexible adaptation. This later recognition does not make the difficulty newly acquired; it can reveal a longstanding vulnerability exposed by a more complex social environment.

Classification systems describe this area differently. DSM retains a standalone diagnosis. ICD does not use a separate social-pragmatic disorder; it places a predominantly pragmatic profile within developmental language disorder. The distinction is administrative as well as conceptual, so the clinical formulation should describe the observed social-communication pattern rather than rely on the diagnostic label alone.

24.6 Differential diagnosis: use the discriminator, not a superficial resemblance

The essential differential for social-pragmatic communication difficulty is autism spectrum disorder. The discriminator is the presence or absence of **restricted and repetitive patterns** of behaviour, interests or activities. Social (pragmatic) communication disorder requires their absence; autism spectrum disorder requires their presence currently or by history. Similar social-communication symptoms do not settle the question. The history must actively look for the restricted or repetitive dimension rather than infer its absence because it was not volunteered in a brief interview. The wider assessment of autism is covered in the Intellectual disability and autism spectrum disorder notes.

Social anxiety disorder can also resemble social-pragmatic difficulty, but the developmental sequence is decisive. In social anxiety, effective social communication was present and is not used because anxiety inhibits its use. In social (pragmatic) communication disorder, effective social communication has not been established. The observed silence, avoidance or awkwardness may look similar; asking what the child could do before the anxiety emerged often clarifies whether the underlying skill was available.

CLINICAL QUESTION	LANGUAGE DISORDER	SPEECH SOUND DISORDER	SOCIAL-PRAGMATIC DISORDER
Primary difficulty	Learning or using language	Producing intelligible speech sounds	Using communication effectively with others
Useful observation	Understanding and formulation	Intelligibility in ordinary speech	Reciprocity, context and implied meaning
Misleading shortcut	"Quiet means expressive delay"	"Any mispronunciation is pathology"	"Awkward social communication equals autism"
Key corrective step	Assess receptive as well as expressive ability	Exclude hearing, structural and neurological explanations	Ask specifically about restricted and repetitive patterns

Hearing impairment, intellectual developmental disorder, neurological and structural conditions, and selective performance problems should be considered whenever they plausibly account for the communication profile. This does not imply that a communication disorder cannot coexist with another neurodevelopmental condition. It means the psychiatrist should state whether the communication difficulty is expected from the other condition, disproportionate to it, or independently impairing. Intellectual disability and autism require their own full assessment in the Intellectual disability and autism spectrum disorder notes.

24.7 Assessment, comorbidity and care planning

Assessment begins with the referral language, then moves from labels to observable functions. Elicit the developmental history of communication, languages used at home and school, hearing and medical history, family observations, school examples, peer functioning, and the child's own account of difficulty. Observe spontaneous communication and structured demands separately. Clarify what is understood, what is produced, what is intelligible, what happens to fluency, and whether the child can adapt communication to the listener and setting.

Communication disorders show male predominance and commonly coexist with other neurodevelopmental disorders and anxiety disorders. The associated neurodevelopmental conditions include autism spectrum disorder, ADHD, specific learning disorder and intellectual developmental disorder; ADHD is the most common psychiatric comorbidity. Comorbidity should broaden assessment, not erase the communication formulation. For example, inattention may make a child miss an instruction, but poor language comprehension may itself produce behaviour that resembles inattention. The clinician must establish which mechanism is operating in each setting.

IN INDIA

In multilingual practice, document the languages the child hears, understands and uses, and obtain school examples in the language of instruction. An apparent deficit may reflect a mismatch between the language sampled in clinic and the language in which the child is most competent. A communication disorder is identified by persistent functional difficulty, not by departure from the clinician's preferred language or accent.

Care planning should translate the formulation into a functional question. What communication barrier currently blocks participation: understanding instructions, being understood, entering peer interaction, or speaking without avoidance? The psychiatrist coordinates assessment of associated developmental, sensory, neurological and emotional concerns, explains the profile to caregivers and school, and ensures that communication goals are concrete and observable. The intervention plan belongs to the relevant communication and educational professionals, while psychiatric follow-up monitors participation, comorbidity, family burden and barriers to sustained engagement.

MNEMONIC

MAPS the communication problem

Meaning and comprehension, **A**rticulation and intelligibility, **P**ace and fluency, **S**ocial use. It is a bedside organising aid, not a diagnostic instrument.

Classify communication disorders by the function that is persistently impaired, then use development, functional impact and the differential to decide whether that impairment is primary.

25 · Stuttering (childhood-onset fluency disorder) features and management

Why it matters clinically. A child who stutters is often heard through the discomfort of listeners rather than through the child's own communicative experience. The task is not to reward a fluent performance or to make the child speak faster. It is to recognise a disturbance in fluency, establish its developmental course, identify the patterns that create struggle or avoidance, and arrange help that protects participation as well as speech.

- Repetition or prolongation
- Block or visible effort
- Avoidance
- Developmental course
- Protect participation

Fig 22.21 Childhood-onset fluency disorder is assessed through the form and developmental course of dysfluency, visible struggle, avoidance and its effect on participation. Management does not demand faster or perfect speech; it protects communication while arranging proportionate speech-language help.

Childhood-onset fluency disorder, commonly called stuttering, is a developmental disorder of speech fluency. It is coded **F80.81** in a diagnostic classification and **6A01.1** in the international classification. The marks are usually won by describing the speech phenomena accurately, distinguishing a transient developmental pattern from a persistent disorder or an acquired change, and offering a proportionate management plan rather than a reflex prescription.

25.1 What the clinician is hearing

Fluency is the ease and temporal flow with which speech is produced. In stuttering, the disruption is not merely an occasional hesitation. The child may repeat a sound or syllable, prolong a sound, break a word, stop in the middle of an intended utterance, substitute a less difficult route around a word, or force a word out with visible effort. A **block** may be audible, or it may be a silent arrest in which the child appears unable to initiate the intended sound. Whole-

word repetition can also occur, especially when it is brief and effortless, so its meaning depends on the pattern around it rather than on its presence alone.

The useful clinical distinction is between a speaker who is searching for language and a speaker who knows what is to be said but cannot release speech in the expected flow. The latter may show tightening of the face or body, a sudden change of word, reduced eye contact, or an attempt to finish the interaction before the feared word arrives. These are not theatrical additions to a speech problem. They are part of the child's adaptation to an experience of loss of control in communication.

SPEECH OBSERVATION	WHAT TO LISTEN OR LOOK FOR	CLINICAL INTERPRETATION
Repetition	Recurring sound or syllable repetition, especially when effortful	Supports a fluency disturbance when embedded in a broader pattern of dysfluency
Prolongation	A sound carried beyond its usual duration	Suggests difficulty maintaining forward movement of speech
Block	Audible or silent interruption before the intended word emerges	May be missed if the interview attends only to what is spoken
Circumlocution	A word is avoided and the sentence is rerouted	May reveal anticipation and avoidance rather than a vocabulary deficit
Physical effort	Excess tension during word production	Signals struggle and a risk that the speech difficulty is shaping behaviour

The interview should therefore allow enough time for an utterance to emerge. Interrupting, supplying the word, or converting the encounter into a test of speed changes the very phenomenon being assessed. Observe spontaneous conversation and, where feasible, speech with a familiar adult and during a lower-pressure activity. The aim is a description of form, effort, anticipation and effect on communication, not a verdict based on a brief difficult sentence.

25.2 Clinical pattern and situational variation

Stuttering is characteristically variable. Dysfluency may worsen when there is **pressure to communicate** and may be absent while the child reads aloud, sings, or speaks to a pet or an inanimate object. This variation is diagnostically useful because it demonstrates that fluent speech is possible in some conditions. It must not be used to accuse the child of choosing the symptom. The speaking demand has changed: urgency, audience, self-monitoring and fear of interruption may all change at once.

Associated **motor movements**, such as blinking, facial tremor or a head movement, can occur when the child struggles to speak. They should be described in their temporal relation to the dysfluency. A movement that arrives as the child attempts to push through a block has a different clinical meaning from a recurrent vocal or motor tic occurring independently of speech. Stress and anxiety may exacerbate stuttering, but the clinician should avoid the lazy causal narrative

that makes emotional distress the origin of the fluency disorder. Distress can be a consequence of difficult speaking situations and can then maintain avoidance.

RULE **Situational improvement is a clue to speaking demand, not evidence of conscious control.** Ask what the setting changes for the child: time pressure, listener attention, anticipation, fear of interruption, or the need to perform.

In practice, parents may report that the child is fluent at home yet becomes markedly dysfluent when required to answer in class, speak to an unfamiliar adult, or respond before others. Conversely, a parent may notice a change only when the household becomes alert to it. Both reports deserve respect, but neither substitutes for a careful chronology and direct observation. The clinician's language matters here: calling the child "nervous" risks moving attention from communication demands to character.

GOOD TO REMEMBER

Ask the child, in developmentally appropriate language, what happens just before a difficult word and what they do when it happens. This often reveals avoidance, anticipation and the social cost of dysfluency more clearly than an adult observer can.

25.3 Course, frequency and family context

Onset is usually in the preschool period, typically at **2 to 7 years**; by age **6**, onset has occurred in **80 to 90%** of affected people. This developmental timing is why a chronological history is indispensable. Ask when dysfluency was first noticed, whether the onset was gradual or abrupt, whether it has waxed and waned, and how the child and family responded. A late change in fluency requires a different diagnostic frame from a childhood developmental presentation.

about 1%	4 to 5%	about 3 : 1	65 to 85%
CURRENT PREVALENCE IN YOUNGER CHILDREN	EVER AFFECTED IN THE POPULATION	MALE PREDOMINANCE MAY REACH	CHILDREN WHO RECOVER

Current prevalence and the proportion ever affected should not be treated as competing answers. A higher cumulative figure alongside a lower current figure is compatible with substantial natural recovery. For prognosis, severity at age 8 helps distinguish a course that is more likely to recover from one that is more likely to persist. That does not justify either fatalism or reassurance without follow-up. It tells the clinician to observe severity and functional adaptation over time rather than to rely on the first presentation alone.

Stuttering is more frequent in males, with male predominance reported as high as the ratio shown above. Family history is relevant: risk among first-degree biological relatives is more than 3 times that of the general population. A family history should be elicited without implying parental fault. It helps with formulation and vigilance, while the child's current speech pattern and experience remain the basis for clinical action.

Prognostic discussion must be honest and humane. Recovery is common, yet a child who is currently struggling does not experience the problem as a population statistic. The immediate

question is whether dysfluency is narrowing participation, provoking effort, or teaching the child to avoid being heard. This is where apparently reassuring epidemiology can be clinically unhelpful if it is used to minimise a child's present impairment.

25.4 Assessment and differential diagnosis

Assessment begins with a narrative rather than a checklist alone. Establish the onset and trajectory, the observable forms of dysfluency, situations of relative fluency, visible effort, avoidance, the child's own appraisal, and effects at home and school. Invite a parent to describe what they do when the child becomes stuck. The answer often identifies an interactional loop: hurried prompting, sentence completion, repeated correction, or a well-meant demand to begin again. These are modifiable features of the environment, not evidence that the family caused the disorder.

- Clarify whether dysfluency is effortless or accompanied by struggle and physical tension.
- Ask whether the child changes words, remains silent, or withdraws from speaking situations.
- Compare familiar, low-pressure and performance-like situations without treating any setting as a test of sincerity.
- Obtain the school account of participation, oral answering and peer responses.
- Ask about a family history of fluency difficulties in a neutral, non-blaming manner.

Normal childhood dysfluency may include whole-word or phrase repetitions and interjections. The contrast is not made by counting every hesitation. Persistent sound or syllable repetitions, prolongations, silent blocks and visible struggle are more concerning than a relaxed, transient disruption of speech flow. The examination answer should show this distinction clearly: normal dysfluency is a possibility to consider, not a label with which to dismiss a child who is working hard to speak.

Vocal tics can be confused with speech dysfluency when they interrupt communication, but their phenomenology and temporal relationship to intended speech differ. Tourette's disorder and other tic disorders are addressed in the Child behavioural, emotional and other disorders notes. The present assessment should simply determine whether the sound is a disruption of intended verbal output or a recurrent vocal phenomenon with its own pattern.

Adult-onset dysfluency is another important distinction. A new fluency disturbance later in life, particularly in the setting of a neurological insult or medical cause, is not a childhood neurodevelopmental disorder and needs an acquired-disorder evaluation. Do not force a developmental label onto a history that does not fit its course.

TRAP **Do not diagnose from a repetition alone.** A fluent-speech disorder is recognised from the form of dysfluency, effort, persistence, context and effect on communication. Counting a single conversational habit without this frame creates false certainty.

PITFALL

A silent block may be mistaken for refusal, shyness or lack of knowledge because the clinician hears no repeated sound. Watching the attempt to speak, and asking what happened in that pause, prevents a punitive or dismissive response.

25.5 Formulation and the decision to observe or intervene

A useful formulation integrates the speech pattern with its consequences. Describe the predominant dysfluencies, the degree of struggle, triggers that increase speaking demand, avoidance, the child's emotional meaning of the problem, family responses and school impact. This formulation is more useful than a yes-or-no statement that the child either has or does not have stuttering. It tells the treating team what must change: speech motor pattern, anticipatory fear, social participation, listener behaviour, or some combination of these.

Not every preschool dysfluency requires immediate formal treatment. In a preschool child without struggle or self-consciousness, **watchful waiting** with review in about 6 months can be appropriate before speech therapy begins. The point of observation is active surveillance, not abandonment. Parents need a return plan and a clear explanation of what changes should prompt earlier reassessment: increasing visible effort, avoidance, distress, or reduced participation.

Conversely, the presence of struggle or self-consciousness changes the clinical priority. When a child begins to fear a word, to reroute sentences, or to retreat from conversation, waiting can allow the secondary problem to become more entrenched. The decision to refer is therefore based on the child's trajectory and adaptation, not on the clinician's wish to eliminate every imperfect utterance. The child should not be turned into a project for adults who are more uncomfortable with pauses than the child is.

IN INDIA

Explain the referral in functional terms: the aim is to improve ease of communication and participation, not to test intelligence or assign blame. Where specialist speech services are not immediately accessible, the psychiatrist can still prevent harm by coaching the family and school to slow the interaction, allow the child to finish, and avoid public correction while arranging appropriate assessment.

25.6 Speech intervention and psychological support

Speech therapy is the mainstay of management. Its value lies in skilled assessment and in making the work fit the child's actual pattern rather than applying a generic instruction to "speak slowly". Broad therapeutic orientations are useful to understand. **Fluency-shaping** approaches work towards producing more fluent speech. **Stuttering-modification** approaches work towards speaking with less tension, avoidance and interruption even when stuttering occurs. In practice, the clinical aim is not perfection; it is a more manageable, less feared way of communicating.

The psychiatrist's role is collaborative. Ensure that the speech intervention is linked to the child's lived goals, not merely to a listener's judgement of smoothness. Explore embarrassment, anger, anticipatory anxiety, bullying or withdrawal when these are present, and offer counselling for

self-concept effects. Psychological work can reduce the secondary burden of a communication difficulty and help the child re-enter avoided situations. It should not be presented as a substitute cure for the speech disturbance itself.

Psychotherapy alone is not effective for stuttering itself, and anxiolytic or tranquilising medication is not effective for stuttering itself. This is an important corrective to a common psychiatric reflex: anxiety around speech does not make the primary disorder an anxiety disorder. Treat clinically significant emotional consequences in their own right, while maintaining speech-focused intervention as the central treatment for fluency.

Goals should be concrete but person-centred. They may concern initiating a conversation, completing an answer without being rushed, tolerating a moment of dysfluency without abandoning the message, or participating in school despite anticipated difficulty. A good plan makes room for communication agency. It does not tell a child that being an acceptable speaker depends on sounding like everyone else.

25.7 Working with family and school

Families often arrive with a repertoire of intuitive but unhelpful instructions: "take a breath", "think before you speak", "start again", "slow down", or "say it properly". Some children may find a particular cue useful in a therapeutic context, but repetitive correction from every listener can increase self-monitoring and turn speech into a public examination. The more reliable family stance is calm attention to the message, time to finish, and permission not to repair every dysfluency.

School is a treatment setting because it is where speaking is repeatedly evaluated in front of others. The clinician can ask that staff do not complete the child's words, do not demand a restart after dysfluency, and do not use oral performance as a moral test of effort. The child should be offered a predictable, respectful way to participate. This is not an exemption from learning; it is removal of a communication barrier that may otherwise obscure what the child knows.

Parents may need help separating their worry from the child's needs. Persistent watching, recording every disruption, or discussing speech in front of the child can turn an intermittent difficulty into a family preoccupation. Conversely, pretending not to notice when the child is distressed can feel invalidating. The balanced response is simple: notice the effort, listen to the content, make time available, and invite the child to say what kind of help is welcome.

25.8 Review, communication and examination synthesis

Review should return to the same domains used in the initial formulation: speech pattern, effort, avoidance, participation, self-appraisal, listener responses and school experience. Apparent fluency in a brief clinic conversation is not enough to declare success if the child is still avoiding a classroom answer or avoiding particular words. Equally, occasional dysfluency after treatment is not treatment failure if struggle, interruption and fear have diminished and participation has expanded.

For the written answer, lead with the developmental fluency disorder and its characteristic dysfluencies. Then show that age of onset, course, familial risk and situational variation inform formulation. Distinguish normal childhood dysfluency, vocal tics and acquired later-onset dysfluency. Finish with proportionate management: observe selected preschool presentations, refer for speech therapy when indicated, address secondary psychological and social effects, and change the family and school interaction around speech.

> Stuttering management is speech-focused, participation-focused and shame-reducing: assess struggle and avoidance, use speech therapy as the mainstay, and treat the child's communication world as carefully as the dysfluency.

26 · Developmental coordination disorder

Why it matters clinically. A child who is slow with dressing, avoids ball games, produces laborious written work, or repeatedly drops objects can be misunderstood as careless, oppositional, inattentive, or simply insufficiently practised. Developmental coordination disorder is the diagnostic framework for a developmental difficulty in motor coordination when the difficulty is demonstrable, functionally important, early in origin, and not better accounted for by another condition. The task for the psychiatrist is therefore not to label clumsiness. It is to decide whether a recognisable developmental motor difficulty is impairing the child's ordinary participation, while protecting the child from an inappropriate psychiatric explanation for a neurological or sensory disorder.

The diagnostic work is often deceptively demanding because the referral language is usually an activity complaint rather than a motor formulation. A parent may describe untidiness, avoidance, slow self-care, or an inability to keep up with peers. A teacher may describe poor written output, difficulty using classroom materials, or reluctance during play. These observations become clinically useful only when translated into the motor task, the context in which it occurs, the opportunity the child has had to learn it, and the consequence for participation. That sequence is also a good answer structure: establish the motor deficit, establish impairment, establish developmental onset, and exclude better explanations.

26.1 Core clinical construct

The centre of the disorder is **coordinated motor-skill acquisition and execution** that is substantially below what would be expected for the child's chronological age and **opportunity to learn**. Both parts of this formulation matter. A child may know what is wanted, be motivated to do it, and still have trouble converting the intention into a smooth, efficient movement. Conversely, a child who has not had a reasonable chance to acquire a particular skill should not be judged against an assumed competence in that skill.

The clinical picture can involve **fine and gross motor skills**. Fine-motor difficulty may be evident in use of scissors, cutlery, or handwriting, or other tasks requiring control and sequencing. Gross-motor difficulty may be evident while catching, cycling, or participating in sports. Dropping objects and bumping into things convey the everyday meaning of clumsiness,

whereas slowness and inaccuracy show why a child may complete a task only with disproportionate effort. These are examples that make the construct visible; none is diagnostic in isolation.

It is useful to ask what happens when the child repeats the task. The relevant concern is not a single awkward performance in a strange clinic room. It is a consistent pattern across familiar activities, described by people who see the child in ordinary settings. A careful account also distinguishes quality from speed. Some children can eventually complete a task but do so so slowly that its practical use is compromised; others work quickly but inaccurately; still others have both difficulties. The history should preserve this distinction, because it explains the real burden on the child better than the global word "clumsy".

RULE **Diagnose a developmental motor disorder from a pattern of impaired coordination and its consequences, not from an isolated complaint about handwriting or play.** The clinician has to show that the motor difficulty is developmental, materially below expectation after opportunity to learn is considered, and meaningful in the child's life.

26.2 Functional impairment gives the diagnosis clinical weight

Criterion B is not an administrative add-on. It requires **persistent functional interference**: the motor deficit must significantly interfere with age-appropriate activities of daily living and affect participation in school productivity, prevocational or vocational activity, leisure, play, or all of these. The key word is participation. The psychiatrist should ask what the child cannot do independently, efficiently, or reliably enough to take part on the same terms as expected in that setting.

Functional questions convert a vague complaint into an observable formulation. In self-care, ask about tasks that require manipulating clothing or utensils, and whether assistance, extra time, or avoidance is needed. In school, clarify whether the difficulty lies in producing written work, handling materials, copying, or sustaining output over the routine demands of the class. In leisure and play, ask whether the child chooses not to join, falls behind because of motor inefficiency, or is excluded by peers. This approach separates impairment from a parent's understandable worry about performance and also identifies the situations in which support should be designed.

"Persistent" means that the difficulty is not inferred from a transient fluctuation in confidence, a recent injury, or a task that has only just been introduced. Obtain examples over time and across settings, then look for convergence between the child's account, caregiver observations, and school information. A child may minimise embarrassment, while adults may normalise it as a personality trait. The clinician's job is to make the functional cost explicit without converting every difference in skill into pathology.

- Identify the specific motor task that breaks down.
- Ask what the child does instead: avoids it, accepts help, takes excessive time, or persists inaccurately.
- Establish the effect on self-care, school work, play, or leisure.

- Ask whether the difficulty is present in more than one ordinary context.
- Record the child's own experience of frustration, shame, or exclusion without assuming that these feelings constitute the disorder.

GOOD TO REMEMBER

The most useful formulation names an activity rather than merely writing "poor coordination". It links the motor problem to a concrete participation cost, which then gives the family, school, and rehabilitation professionals a shared target.

26.3 Developmental timing and diagnostic caution in young children

The required **early developmental onset** prevents an acquired movement problem from being folded into this diagnosis. The history should seek the earliest recognisable pattern, not merely the age at which a teacher or family first became worried. Delayed motor milestones may be the first sign when intellectual disability is absent, but their presence should lead to a developmental history and examination rather than a reflex diagnosis. Apparent onset is often shaped by the changing demands placed on the child: a difficulty may become obvious only when the child is expected to manage more complex self-care, classroom work, or play.

There is particular value in diagnostic humility in early childhood. Normal variation in motor development is broad at that stage, and performance may be highly dependent on familiarity, attention, confidence, and the demands of the setting. A formal diagnosis **under age 5** is initiated only when impairment is severe; it is usually confirmed with a second motor assessment at least 3 months apart. This is not a reason to dismiss concern. It is a reason to document the observed difficulty carefully, address present functional needs, and revisit the formulation as the developmental picture becomes clearer.

In practice, chronological detail strengthens the history. Ask whether the child has always needed more help with motor tasks, whether there has been loss of a previously acquired ability, and whether the pattern is stable or progressive. Loss or progression changes the clinical question and should prompt reconsideration of the exclusionary assessment. The aim is neither premature certainty nor passive waiting. It is a defensible account of what is known now and what needs reassessment.

IN INDIA

School concerns may reach the clinic through a complaint of slow written work, poor neatness, or avoidance of games rather than through a motor-development referral. Ask the family and school to describe the actual task, the assistance already provided, and the child's opportunity to practise it. This avoids mistaking limited access or unfamiliarity for a developmental motor disorder.

26.4 Exclusion is active clinical work

Criterion D requires that the coordination deficits are not better explained by intellectual developmental disorder or visual impairment, and are not attributable to a neurological condition affecting movement. The relevant **neurological and sensory exclusion** is therefore not a

sentence added after the history. It is the part of the assessment that establishes whether the observed motor difficulty belongs within a developmental coordination formulation at all.

Take a focused account of vision, neurological symptoms, developmental pattern, and change over time, then examine the child sufficiently to decide whether a neurological assessment is needed. Significant ataxia, hypotonia, or asymmetry warrant neurological assessment. A child with such signs should not be reassured by the convenience of a behavioural label. Similarly, when visual impairment or intellectual developmental disorder is present, the question is whether these better explain the motor difficulty, not whether the child also appears awkward. The diagnosis asks for a judgement about explanation, not a checklist of coexisting labels.

Use the examination to test the coherence of the history, not to stage a performance test in front of an anxious child. Observe how the child approaches a task, responds to instruction, corrects an error, and manages the motor demands of the consultation. Then compare that observation with the caregiver's and teacher's accounts of familiar activities. An unexpectedly poor clinic performance may reflect unfamiliarity or distress; an apparently fluent clinic performance does not erase a well-described functional difficulty at home or school. What matters is a reasoned synthesis of longitudinal evidence, direct observation, and the exclusionary examination.

The wording of the final assessment should show this reasoning. State the activity-level evidence, the functional effect, the developmental history, and the findings that make a competing explanation less likely. If an exclusion remains unresolved, record the diagnostic uncertainty and arrange the appropriate assessment rather than treating the provisional label as settled. This is especially important when the presenting complaint is narrow but the examination suggests a wider movement problem.

DIAGNOSTIC QUESTION	WHAT THE CLINICIAN ESTABLISHES	WHY IT CHANGES THE FORMULATION
Motor skill	Motor coordination is materially below expectation after opportunity to learn is considered.	Moves the history beyond a non-specific complaint.
Daily participation	Functional interference is persistent and affects age-appropriate everyday activity or productivity.	Distinguishes a clinically important disorder from an isolated weak skill.
Developmental history	The developmental pattern begins early.	Guards against misclassifying an acquired problem.
Alternative explanation	Alternative explanations have been actively considered.	Protects against diagnostic overshadowing.

TRAP **Do not call every child with poor handwriting "developmental coordination disorder".** Handwriting may be the presenting activity, but the diagnosis requires the full motor, functional, developmental, and exclusionary formulation. A narrow school complaint is a starting point for assessment, not a conclusion.

PITFALL

Do not allow an ADHD label to terminate the motor assessment. Inattention can make performance look disorganised, yet a history of persistent coordination difficulty with functional consequences still needs its own formulation and exclusions.

26.5 Epidemiology and clinically relevant co-occurrence

Among school-age children, the reported prevalence is about **5 to 6%**. This anchors the disorder as a familiar clinical possibility rather than a rare explanation for school difficulty. The estimate is documented across diverse regions, but prevalence should not be used as a shortcut to diagnosis in an individual child. The child still needs the functional and exclusionary work described above. A severe presentation has been reported in about **1.8%** of children at age 7, reminding the clinician that severity is expressed in the extent of everyday burden rather than in the vividness of a single symptom.

Recent population studies report a male:female ratio of about **2 : 1**. This is useful background, not a diagnostic rule. Sex ratio cannot establish or exclude the disorder in a particular child and should never displace the direct account of motor function. Older clinical samples reported higher ratios, which further cautions against making broad inferences from a child's sex.

DCD and ADHD frequently meet in clinical practice. DCD co-occurs with ADHD in about **30 to 50%** of cases. Communication disorders and specific learning disorders may also be comorbid, and inattentive symptoms are most associated with motor problems. The practical implication is not that all difficulties belong to one diagnosis. It is that each domain should be assessed for its independent functional contribution. ADHD is addressed elsewhere in this chapter; communication and learning difficulties should be named and evaluated on their own merits rather than being treated as proof of DCD.

A	B	C	D
MOTOR SKILL	FUNCTIONAL IMPACT	DEVELOPMENTAL ONSET	ALTERNATIVE EXPLANATIONS

26.6 Classification and coding

Cross-system language should be handled precisely. In ICD-11, developmental motor coordination disorder is coded 6A04. The older ICD-10 formulation required an IQ of at least 70 and motor performance at least 2 SD below the mean on a standardised test. DSM-5-TR does not set those ICD-10 numerical thresholds. A candidate who quotes a threshold without naming the classification system creates a false impression of equivalence.

This distinction is more than a coding footnote. Classification language directs the clinician towards different forms of documentation. A descriptive formulation should still state the observed motor difficulty, its functional consequences, developmental timing, and the basis on which alternatives were considered. Coding follows that reasoning; it does not replace it. When reports from different settings use different terminology, make the clinical formulation readable before resolving the administrative label.

RULE **Never transfer a numerical threshold from one classification system into another.** State the system first, then the criterion it actually uses. This preserves diagnostic accuracy and prevents a coding convention from being mistaken for a universal clinical rule.

26.7 From diagnosis to a useful care formulation

A diagnosis is clinically useful only when it clarifies what must change in the child's environment and support plan. Start with the activity that is actually impaired, the setting in which the impairment is most costly, the help already available, and the child's experience of repeated failure. The resulting plan should be coordinated with caregivers, school, and relevant rehabilitation professionals, with goals framed around participation rather than around an abstract wish to make the child less clumsy. Documentation should make it possible to review whether the assistance is reducing the real functional burden.

Psychiatric care also includes protecting the child's self-understanding. Recurrent failure in visible tasks can invite criticism from adults and peers, while the child may respond with avoidance, irritability, or apparent disinterest. These responses require empathic enquiry, but they should not be used to explain away the motor difficulty. Conversely, emotional distress should be assessed on its own terms and not assumed to follow automatically from DCD. A formulation that preserves both the motor problem and the child's psychological experience is more likely to be accurate and humane.

When the diagnostic picture is complex, the broader assessment and service framework is set out in the Child psychiatry: assessment, treatment, services and protection notes. Developmental expectations and milestone interpretation are addressed in the Normal child development and milestones notes. Intellectual disability, autism, and the relevant diagnostic discriminations are addressed in the Intellectual disability and autism spectrum disorder notes. These cross-references prevent a motor formulation from becoming a substitute for a comprehensive developmental assessment.

MNEMONIC

SKILL

Skill deficit, **K**nown functional consequence, **I**nitial developmental onset, **L**ook for better explanations, **L**ink supports to participation. Use it as a sequence for organising the history and examination, not as a replacement for them.

Developmental coordination disorder requires a developmental motor coordination deficit, persistent functional impact, early onset, and exclusion of better explanations.

27 · Stereotypic movement disorder

Why it matters clinically. Repetitive movements are common reasons for referral, but the psychiatric task is not to label every unusual movement as a disorder. The useful distinction is between a pattern that is transient or contained and a pattern whose form, impact, associated

injury, and developmental context demand a diagnostic formulation. **Stereotypic movement disorder** is the diagnosis used when repetitive motor behaviour is apparently driven, non-functional, and often rhythmic. It sits at the junction of developmental psychiatry, behavioural observation, neurological differential diagnosis, and safeguarding. A good answer therefore describes the movement before naming the diagnosis.

The examination value of the topic lies in discrimination. A candidate should be able to recognise a fixed rhythmic movement, determine whether it is impairing or injurious, and distinguish it from tics and compulsions without turning a movement description into a diagnosis by reflex. The same approach matters in practice: the movement may be the most visible part of a broader developmental or medical presentation, while the immediate clinical priority may be the harm it causes or the distress it signals.

27.1 The clinical phenomenon

A stereotypy is best approached as a movement pattern with a recognisable form. It is repetitive, seemingly driven and **non-functional motor behaviour**, often with a rhythmic quality. The term "purposeless" can be useful descriptively, but it should not be mistaken for an accusation that the child is choosing to misbehave. A movement can look non-functional to the observer and still have a subjective regulatory role for the child, for example by easing an aversive internal state. Apparent lack of ordinary purpose does not establish volition, and apparent relief does not turn the movement into a preventive ritual.

The visible repertoire is broad. It may include hand shaking, waving or flapping; body rocking; **head banging**; mouthing objects; self-biting; skin picking; or hitting the body. Describing the exact topography in the history is more informative than recording only "abnormal movements." Ask what body part moves, whether the sequence is recognisably the same on different occasions, whether it is rhythmic, what precedes it, what interrupts it, and what follows it. This preserves the phenomenology that later permits a defensible differential diagnosis.

There is an important conceptual boundary here. Stereotypic movements are defined by their patterned repetition and relative simplicity, not by their dramatic appearance. A striking movement can be benign in context, while a small repetitive act can deserve urgent attention if it causes injury or derails ordinary activity. The assessment should therefore move from description to consequence rather than allowing the observer's discomfort with the movement to determine severity.

RULE **Name the movement before naming the disorder.** A precise account of rhythm, form, context, interruption and consequence is the clinical evidence from which the diagnosis follows.

27.2 When the behaviour becomes a disorder

The diagnosis requires more than a movement that is repetitive. The behaviour must produce **interference with social, academic or other activities**, or it may result in self-injury. This threshold redirects attention from oddness to burden. Interference may arise because the movement repeatedly interrupts participation, draws the child out of a task, limits access to

ordinary settings, or creates conflict around the behaviour. It should be documented in concrete functional terms rather than inferred merely because an adult regards the movement as inappropriate.

The safety question comes early. Self-injury changes the urgency and content of the assessment. Clarify the tissue damage or other harm, the circumstances in which it occurs, the ability of caregivers to interrupt it safely, and the immediate environmental risks. The movement itself may be the target of clinical attention, but the formulation must also ask what makes the child vulnerable at the time it occurs: demand, frustration, arousal, sensory context, separation, boredom, discomfort, or an unrecognised medical problem. These are hypotheses to explore, not assumptions to impose.

Onset belongs in the **early developmental period**. This makes developmental history central, not ornamental. Establish when caregivers first noticed the pattern, whether the movement has retained a similar form, and how it sits alongside the child's broader developmental trajectory. Current diagnostic framing does not require the clinician to prove that the movement is intentional. It also does not impose a fixed minimum duration before the movement can be considered diagnostically. These changes matter because an insistence on demonstrated intent or arbitrary waiting can delay attention to a child whose movements are already harmful or disabling.

- Record the movement in plain observable language before using diagnostic terminology.
- Establish functional impact and injury directly rather than treating either as incidental.
- Place the onset and course within developmental history.

> **GOOD TO REMEMBER**
>
> Caregivers may report that the child "does it when upset" or "does it when excited." Treat this as useful context, not as a substitute for describing the movement itself. The same trigger can accompany different movement phenomena, whereas the form and purpose of the behaviour drive the differential.

27.3 Classification and formulation

Classification should support, rather than replace, clinical description. In DSM terminology, stereotypic movement disorder is coded **F98.4**. The diagnosis is specified as with or without self-injurious behaviour. In ICD terminology, the parent code is **6A06**, with further coding that records the self-injury status. The coding distinction is clinically meaningful because self-injury signals a different risk burden and makes the immediate consequences of the behaviour explicit in the record.

The formulation should also state whether the stereotypy is associated with a known genetic or medical condition, a neurodevelopmental disorder, or an environmental factor. This does not reduce the movement to an automatic by-product of an associated condition. Instead, it forces the clinician to decide whether the repetitive behaviour is clinically important in its own right and what context changes its interpretation. In a child with developmental difficulties, for

example, the question is not simply whether stereotypies are "expected," but whether this particular behaviour is causing injury, functional restriction, or caregiver strain.

The specifier is especially relevant where repetitive self-injury becomes a focus of treatment in the context of intellectual disability. It permits the clinical record to represent the behaviour without assuming that intellectual disability alone explains the current problem. Intellectual disability and autism spectrum disorder should be understood through *the Intellectual disability and autism spectrum disorder notes*; those conditions are named here only because they can shape the setting in which stereotypies are seen.

Rhythmic pattern	Early development	Functional impact	Self-injury
CORE DESCRIPTION	EXPECTED ONSET FRAME	DIAGNOSTIC THRESHOLD	ESSENTIAL SPECIFIER

27.4 Developmental context and frequency

Developmental context prevents overdiagnosis. Rhythmic activity may occur in children without disabilities and recede as more complex functional behaviours are mastered. Available data indicate that **about 80%** of children show rhythmic activities that disappear by age 4. Repetitive body rocking is reported in about 20% of this group. These observations do not make all rhythmic movement reassuring; rather, they explain why diagnosis depends on impairment, injury, persistence in a clinically concerning form, and context rather than simple presence of a movement.

Head banging illustrates the same point. Among children without disabilities, the reported frequency is **3 to 15%**; it is reported in about three times as many boys as girls. It commonly emerges between 5 and 11 months, and only about 5% persist beyond age 3. The lesson is not to reassure indiscriminately. A movement that is developmentally familiar may still warrant a full assessment when it causes harm or interferes with ordinary life.

Conversely, stereotypies are particularly salient in people with intellectual disability. They occur in about two-thirds of institutionalised individuals with intellectual disability and in about 20% of those with severe intellectual disability. Self-injurious behaviour is reported from **about 2 to 3%** among community children and adolescents to about 10 to 15% among adults with severe or profound intellectual disability in residential care. These figures cannot predict risk for an individual child. Their clinical value is to make self-injury an active enquiry, especially where communication limitations make pain, distress, or environmental mismatch hard to express directly.

IN INDIA

Children may reach assessment through paediatrics, a school concern, a disability service, or a child mental-health clinic. Whichever route brings the family, the record should preserve the observable movement, injury, functional consequences, developmental context, and family account. This makes later communication across services clearer and avoids a vague label following the child without the phenomenology that justifies it.

27.5 Associations that change the clinical question

Stereotypies and self-injury can feature in **Lesch-Nyhan, Rett, Fragile X, Cornelia de Lange, Smith-Magenis and Cri-du-Chat syndromes**. Stereotypies are also common in blindness and autism spectrum disorder. These associations should prompt a broader formulation, not a shortcut to genetic attribution. The movement alone neither establishes an associated condition nor explains it. Ask whether there are features in the history or examination that make a developmental, genetic, sensory, medical, or neurological context plausible, and pursue that context through appropriate multidisciplinary assessment.

The distinction between association and explanation is clinically protective. Attributing every self-injurious act to a known developmental diagnosis can obscure pain, environmental stress, or another cause requiring attention. The reverse error is to investigate endlessly while failing to address the injury and daily interference already evident. The best formulation keeps the current behaviour and its possible contributors visible together.

Caregivers often need language that avoids blame. Explain that the assessment is trying to understand the pattern and its consequences, not to decide whether the child is "naughty" or whether the family has caused it. This improves the quality of observation supplied by families and helps clinicians obtain reports that separate a repetitive movement from the emotions surrounding it.

MNEMONIC

RIF: Rhythm, Impact, Framework

Use this brief spine when observing a repetitive movement: define its **R**hythm and form, establish its functional **I**mpact and injury, then place it in its developmental and clinical **F**ramework.

27.6 Assessment: from observation to formulation

Assessment begins with a movement description and expands only as the formulation requires. Obtain an account from the people who have seen the child in ordinary settings, then clarify the setting, antecedents, consequences, and attempts to interrupt the behaviour. The clinician should distinguish an observed fact from an interpretation: "repeatedly struck the side of the head in a similar rhythm during waiting" is a useful observation; "attention-seeking" is a hypothesis that requires evidence.

Direct observation is valuable, but absence of the movement during a brief consultation does not invalidate a carefully elicited history. Ask what the movement looks like at its worst, whether it occurs in more than one setting, what adults do when it appears, and whether those responses alter the sequence. Enquire separately about injury, pain, sleep, feeding, sensory difficulties, medication and substance exposure, and neurological or medical symptoms, because the diagnosis must not be made when another explanation better accounts for the movement.

- Describe form, rhythm, complexity, and fixedness of the movement.
- Map the setting, the child's state, functional interference, and self-injury.

- Review developmental, medical, neurological, medication, substance, and collateral context.

This assessment style is deliberately cautious. It avoids treating a family's account as either unquestionable fact or irrelevant anecdote. It also avoids a false choice between "behavioural" and "medical" explanations. A good formulation can identify a stereotyped pattern, retain uncertainty about its drivers, and still make a clear decision about current risk and functional need.

PITFALL

Do not record "self-injury" as if it explains itself. It is a consequence that demands a description of the act, its severity, the context in which it occurs, and possible contributors. Collapsing these questions into a single label makes risk assessment and later review less reliable.

27.7 Differential diagnosis: tics and compulsions

The most tested discrimination is from tics. **Stereotypies** are more likely to be rhythmic, repetitive, simple, fixed, and present from earlier in development. **Tics** are not rhythmic, carry an involuntary quality, and can be suppressed only for limited periods. This is a comparison of movement phenomenology, not a request for the child to provide a sophisticated account of inner experience. Observe what the movement does over time and ask caregivers whether its form shifts, whether it has a recognisable rhythm, and what happens when it is interrupted. Tics and Tourette syndrome are addressed in the Child behavioural, emotional and other disorders notes.

The other essential differential is from obsessive-compulsive behaviour. **Compulsions** are more complex and ritualised, usually non-rhythmic, and are performed to prevent a feared event or relieve a sense of incompletion. Stereotypies are simpler and rhythmic, and they are not preventive acts. The distinction is especially important when a repetitive action is described using words such as "has to." That phrase can reflect an adult's impression of persistence rather than the child's experience of a feared consequence or incompleteness.

FEATURE	STEREOTYPY	TIC	COMPULSION
Pattern	Rhythmic and fixed	Not rhythmic	Usually not rhythmic
Complexity	Relatively simple	Involuntary quality	Complex and ritualised
Function	Not a preventive measure	Suppression is limited	Preventive act or in-completeness-driven

TRAP **Do not call every repetitive act a compulsion.** A compulsion has a ritualised, preventive or incompleteness-driven quality; persistence alone does not supply that meaning.

27.8 Exclusions, synthesis, and the examination answer

The diagnosis should not be made when the movement is better explained by a substance or medication, a medical or neurological condition, tic disorder, obsessive-compulsive disorder, or trichotillomania. These **exclusions** are not a checklist to recite after the diagnosis. They direct

the history and examination: medication and substance exposure may point to a movement effect; medical or neurological findings may redirect the formulation; the structure and subjective meaning of the act may indicate tic, compulsion, or hair-pulling rather than stereotypy.

In an examination answer, begin with the core phenomenon, then state the requirement for impairment or self-injury and early developmental onset. Follow with the self-injury and association specifiers, then contrast the movement with tics and compulsions using rhythm, fixedness, complexity, and preventive function. Conclude by stating that alternative substance-related, medical, neurological, tic, obsessive-compulsive, and trichotillomania explanations must be excluded. This sequence demonstrates clinical reasoning rather than memorised labels.

For the clinician, the same sequence produces a usable record. It identifies what the child does, why it is currently important, what risk is present, where it sits developmentally, and which alternatives need active consideration. The aim is not to eradicate every repetitive movement from childhood. It is to recognise the pattern that has become impairing or harmful, avoid misclassification, and make the formulation clear enough for the family and treating team to act on it together.

> Stereotypic movement disorder is a non-functional, often rhythmic repetitive movement pattern that is fixed, arises in early development, and becomes clinically significant through impairment or self-injury, after relevant alternatives have been excluded.

Discriminate, apply and consolidate

28 · Differentiating SLD from intellectual disability, ADHD and slow learner

Why it matters clinically. A child who is not progressing at school may look inattentive, unmotivated, immature, anxious, or simply "weak in studies". Those descriptions are observations, not formulations. The diagnostic task is to decide whether the difficulty is confined to a particular learned skill, reflects a broad limitation in intellectual functioning, follows from difficulty regulating attention and behaviour, or represents globally lower but non-diagnostic ability. The labels carry different implications for explanation, documentation, educational planning and the conversation with family and school.

The useful organising question is not "How poorly is the child performing?" but **"Is the problem specific or global?"** A second question follows immediately: is there meaningful difficulty managing the ordinary demands of daily life, or is the concern principally academic? This prevents the common error of treating all low achievement as a learning disorder, and the equally damaging error of treating a circumscribed reading, writing or mathematics difficulty as evidence of global intellectual limitation. These distinctions are especially important when the presenting complaint has been compressed into the school's shorthand.

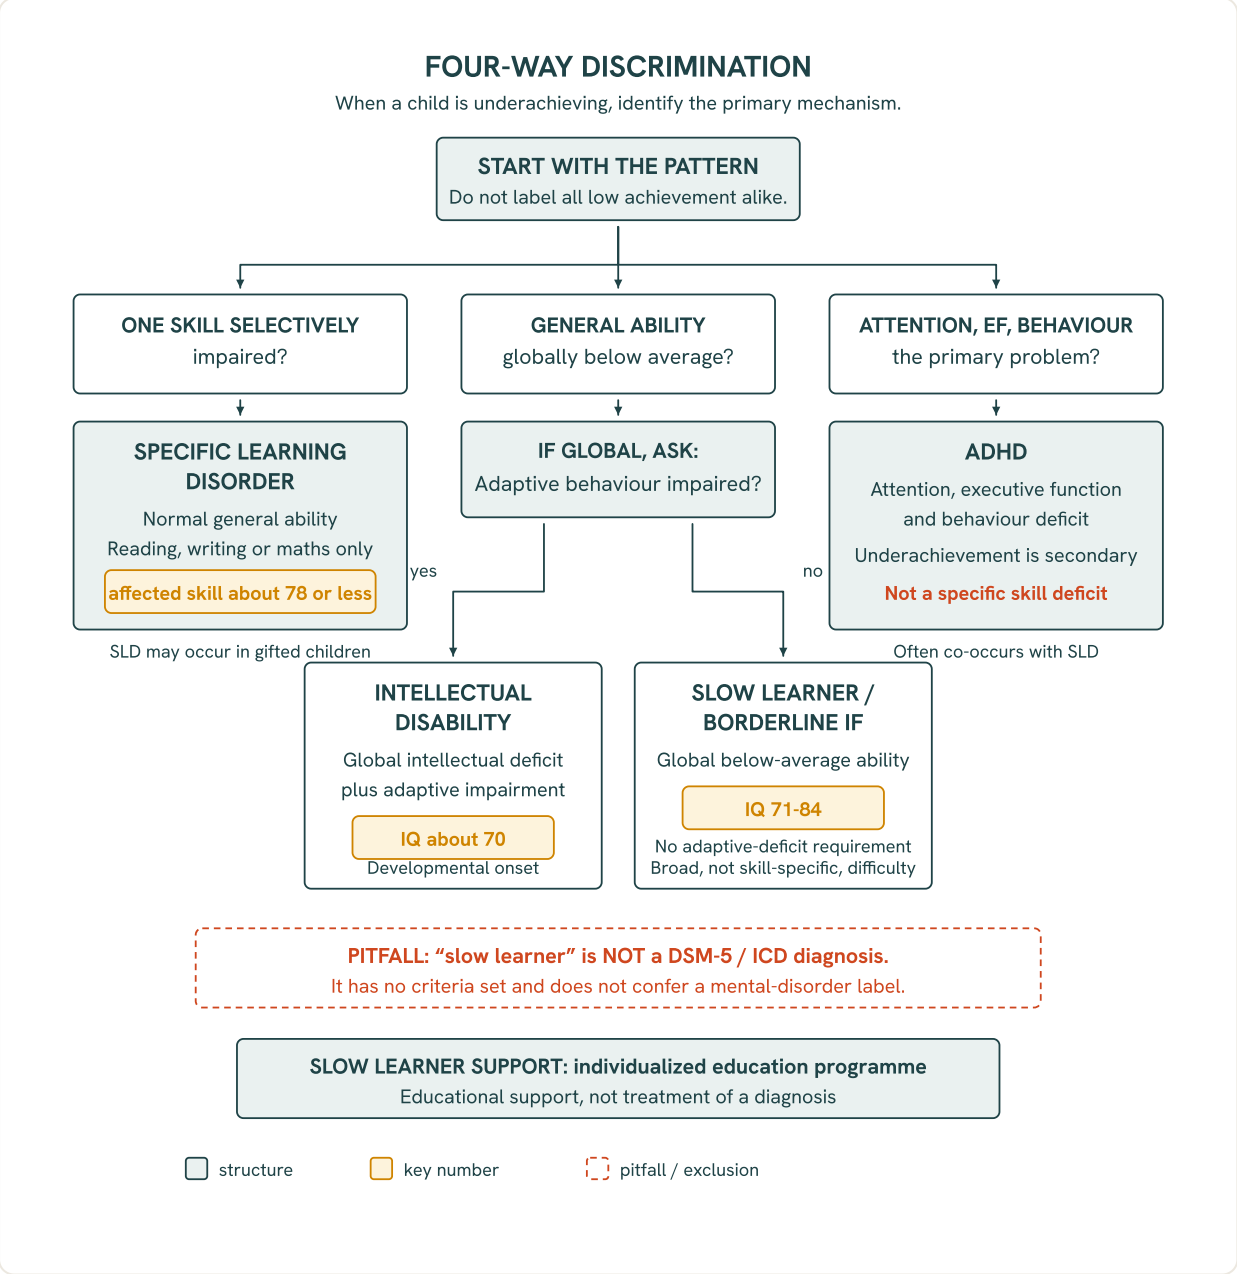

Fig 22.22. Four-way discrimination of specific learning disorder, intellectual disability, ADHD and slow learner / borderline intellectual functioning.

28.1 Start with the pattern, not the school mark

School performance is an outcome produced by several interacting capacities. It is influenced by the match between the child's skills and the curriculum, sustained attention during teaching and independent work, the opportunity to learn, emotional state, language of instruction, attendance, family expectations and the school's response to difficulty. A low mark therefore establishes educational need, but it does not by itself reveal the nature of that need. The clinician should resist premature labels based on a single report such as "poor in everything" or "cannot concentrate".

For differential diagnosis, map the difficulty across tasks rather than accepting a global adjective. Ask whether the child can reason, converse, learn practical routines and understand material when it is presented without the affected academic demand. Then ask whether the failure is sharply concentrated in reading, written expression or mathematics, whether it extends across

school learning, or whether output varies chiefly with the demands on attention and self-regulation. This is pattern recognition, not an exercise in finding a single test score that can settle the case.

Specific	Global	Secondary	Broad
ACADEMIC SKILL	ABILITY PATTERN	ATTENTION EFFECT	EDUCATIONAL NEED

A **specific learning disorder** is suggested when general intellectual ability is in the normal range but achievement in an academic skill is distinctly weak. The weakness is not merely a lower preference for a subject or a temporary fall in performance. It is an isolated deficit in a skill domain against a background of otherwise adequate general ability. A child may show intact oral explanation, practical problem solving and curiosity, yet struggle persistently when required to decode text, produce written work or manipulate numerical material. The discrepancy between what the child can understand and what the child can demonstrate through the affected skill is the clinical clue.

The comparison is not a contest between intelligence and effort. A child with an isolated academic-skill deficit can work very hard and still produce poor output in that skill. Conversely, a child with lower broad ability may be diligent and improve with teaching, while continuing to find the general pace and abstraction of the curriculum difficult. The interview should make room for both truths. Blaming the child obscures the pattern; idealising effort as proof that no disorder is present does the same.

RULE **Classify the shape of the difficulty before naming it.** A skill-bound failure, a broad limitation, and variable work caused by inattention can all produce underachievement, but they are not interchangeable explanations.

28.2 Specific learning disorder and intellectual disability: the central separation

The distinction between specific learning disorder and **intellectual disability** rests on the distribution of impairment. In specific learning disorder, the defining clinical picture is a disproportionate academic-skill deficit with otherwise normal-range general ability. Achievement in the affected skill may be **at least 1.5 SD below** the population mean for age, corresponding to a score of **about 78 or less** on that skill. These figures support the identification of a clinically significant skill deficit; they do not replace the need to understand the child's developmental and educational context.

Intellectual disability is different in kind, not simply in degree. It involves a global deficit across intellectual domains together with significant impairment in **adaptive functioning**, with onset during the developmental period. The relevant intellectual level is approximately **2 SD below** the mean, or an IQ of **about 70**. The decisive clinical addition is adaptive impairment. A child's ability to manage conceptual demands, social judgement and practical everyday tasks gives the score its meaning. Low academic attainment without this broader pattern should not be converted automatically into intellectual disability.

AXIS	SPECIFIC LEARNING DISORDER	INTELLECTUAL DISABILITY
General ability	Normal range overall	Globally impaired
Academic pattern	Deficit concentrated in an academic skill	Difficulty extends across intellectual learning demands
Adaptive functioning	Does not require adaptive impairment	Significant impairment is part of the clinical picture
Clinical inference	Ask what makes the affected skill uniquely difficult	Ask how broad intellectual and daily-life limitations affect support needs

Do not reduce adaptive functioning to academic independence. A pupil may need support with homework because reading is difficult and still manage age-appropriate routines, relationships and practical demands. That presentation fits a skill-specific formulation more readily than a global one. In contrast, when information must repeatedly be simplified across contexts, practical learning is also limited and everyday independence is compromised, the clinician should think beyond a school-skill disorder. Full assessment of intellectual disability belongs with the Intellectual disability and autism spectrum disorder notes; here the point is to preserve the boundary while evaluating the presenting educational complaint.

TRAP **Do not diagnose intellectual disability from school failure alone.** Academic work is only one expression of functioning. The diagnosis requires a global intellectual pattern and adaptive-behaviour impairment, not a disappointing report card or a low score in a single skill.

28.3 Specific learning disorder and ADHD: primary mechanism versus co-occurrence

ADHD is principally a difficulty of attention, executive function and behaviour, rather than a specific academic-skill deficit. Academic underachievement may follow because the child misses instruction, abandons work, makes careless errors, loses materials, rushes through tasks or cannot sustain the sequence needed to complete them. The key clinical question is whether attention-related difficulty explains the underachievement across tasks, or whether a particular skill remains disproportionately impaired even when attention is supported and the child is engaged.

A child with ADHD may perform inconsistently. The same task can be managed better when novelty, structure, supervision or immediate feedback reduces the attentional load, and worse when work is prolonged, repetitive or unstructured. This variability should prompt close examination of the conditions under which work succeeds and fails. It should not be used as a shortcut to conclude that a child with persistent, selective difficulty in reading, writing or mathematics merely has ADHD.

Equally, the presence of a learning disorder does not exclude ADHD. The conditions **frequently co-occur**. In such a child, **secondary academic underachievement** from inattention can coexist with a genuine skill-specific deficit. The formulation must then describe both contributions. If the clinician labels every error as inattentive, the learning need is missed. If the clinician labels every incomplete worksheet as a learning disorder, the behavioural and executive contribution is missed. The task is additive rather than competitive.

- When difficulty is widespread but fluctuates with attention demands, consider whether attention and behavioural regulation are driving the academic outcome.
- When a particular academic skill remains persistently and disproportionately weak, look for a skill-specific deficit even if ADHD is present.
- When both patterns are evident, record both rather than making one diagnosis explain every classroom problem.

The assessment should therefore compare observations from activities with different attentional and academic demands. Review work samples for the nature of errors, not only their quantity. Explore whether the child can explain an answer orally but cannot read or write it, whether calculation fails despite adequate persistence, and whether difficulties are present even in brief, highly supported work. Such questions do not replace formal psychoeducational assessment. They help the clinician decide what hypothesis must be tested and prevent a referral question from becoming the answer.

GOOD TO REMEMBER

When ADHD and a learning disorder coexist, treatment and educational planning must address both. Improvement in attention may make the child more available for teaching, but it does not by itself establish that the academic-skill deficit has resolved.

28.4 Slow learner: an educational descriptor, not a disorder

The term **slow learner** is prominent in Indian educational practice and corresponds to borderline intellectual functioning. It describes globally below-average ability that does not reach the threshold for intellectual disability. The IQ range is approximately **71 to 84**. The term can be clinically useful when it accurately communicates a broad educational vulnerability, but it becomes harmful when treated as a diagnosis, a fixed prognosis or an explanation that ends further enquiry.

Slow learner is **not a diagnosis**. It has no diagnostic criteria set and should not be promoted into a mental disorder merely because a school needs a label. The clinician's responsibility is to describe the observed pattern, identify practical educational needs and avoid granting the phrase a diagnostic authority it does not possess. The distinction matters both ethically and administratively: a non-diagnostic educational descriptor is not a substitute for a careful diagnostic formulation.

Compared with specific learning disorder, the academic difficulty of a slow learner is broad. General ability is lower across domains, and school underachievement tends to reflect that broad pattern rather than a single isolated skill failure. A child may find acquisition slower in several subjects and need more repetition, concrete teaching and a pace matched to capacity. In specific learning disorder, by contrast, general ability is normal range and the prominent weakness is concentrated in an academic skill. The useful contrast is **broad underachievement** versus a circumscribed skill deficit, not "mild learning disorder" versus "severe learning disorder".

Compared with intellectual disability, a slow learner is **above the intellectual-disability threshold** and does not meet the adaptive-deficit requirement. The border can be clinically imprecise, particularly when school reports are sparse or social and practical expectations have been heavily scaffolded by family. That imprecision is an argument for careful assessment, not for casually assigning intellectual disability or for pretending that slow learner has diagnostic status. Where the broader question of intellectual disability remains live, the clinician should assess it explicitly rather than allowing an educational term to conceal uncertainty.

IN INDIA

"Slow learner" is often the phrase brought by parents and teachers. Translate it into a description of broad learning pace and support needs before accepting or rejecting it. An **individualized education programme** can support academic functioning; this is educational intervention, not treatment of a diagnosis.

PITFALL

Writing "slow learner" as the final psychiatric diagnosis can close the assessment prematurely. It may conceal an unrecognised specific learning disorder, ADHD, intellectual disability or an educational mismatch, while also giving a non-diagnostic descriptor an authority it does not have.

28.5 A disciplined route from complaint to formulation

Begin with the exact educational concern. "Cannot read", "does not finish work", "fails in all subjects" and "takes longer than peers" are different referral statements and should not collapse into the same pathway. Establish the temporal course, the settings in which the problem appears, the academic activities that expose it and the activities in which the child is competent. The aim is to define the pattern in the child's actual work, rather than in adult frustration around that work.

Next, examine the breadth of difficulty. A narrow problem in a particular academic skill raises the possibility of specific learning disorder. Difficulty across intellectual learning coupled with limitations in everyday adaptive functioning raises the possibility of intellectual disability. Broad but non-diagnostic lower ability points toward the slow-learner descriptor. Widespread variable underperformance, especially when linked to attention and behavioural regulation, raises the possibility that ADHD is contributing. These are working hypotheses, not labels to be assigned at the first interview.

Then test the hypothesis against disconfirming evidence. A proposed learning disorder formulation should be questioned if difficulties are genuinely global. A proposed ADHD formulation should be questioned if a specific skill remains markedly impaired regardless of structure and effort. A proposed slow-learner formulation should be questioned if performance reveals an unexpectedly sharp, isolated skill deficit or if adaptive limitations are more significant than the school label suggests. This habit of actively looking for what does not fit is what turns a differential list into clinical reasoning.

Finally, state the formulation in layers. Describe the academic symptom pattern, the broad intellectual and adaptive context, the contribution of attention and behaviour, and the resulting educational needs. If evidence supports more than one condition, say so plainly. If the available information supports only a descriptor and educational planning, do not inflate it into a diagnosis. If uncertainty remains, document what needs clarification rather than concealing it beneath a familiar label. Detailed psychoeducational methods are covered in the assessment section on learning disorder, and the broader child psychiatric assessment framework is in the Child psychiatry: assessment, treatment, services and protection notes.

MNEMONIC

Skill - Scope - Supports - State

Ask which **skill** is weak, how far the difficulty extends in **scope**, whether daily-life **supports** are needed because of adaptive impairment, and whether attention and behavioural **state** are altering the child's available performance.

28.6 How the distinction changes clinical communication

The language used with families and schools should explain the pattern without turning it into blame. For specific learning disorder, the central message is that the difficulty is real and confined to an academic skill despite adequate general ability. For intellectual disability, the message concerns broad intellectual and adaptive support needs. For ADHD, explain that attention and behavioural regulation can interfere with learning and may coexist with a skill deficit. For a slow learner, clarify that the term describes a broad educational vulnerability and does not confer a psychiatric diagnosis.

These formulations lead to different practical questions. A skill-specific formulation directs attention to targeted educational support and the school demands that reveal the weakness. A global intellectual and adaptive formulation directs attention to support across daily life as well as learning. An ADHD formulation directs attention to the conditions that help the child engage, organise and complete work. A slow-learner formulation directs attention to expectations, pacing and an individualized education programme. None of these plans should be used as proof of a diagnosis; intervention can begin while assessment is being clarified.

Communication also matters because schools often want a simple binary answer: "learning disorder or not?" The clinician should avoid solving the school's administrative discomfort by erasing complexity. A concise formulation can remain precise: describe whether the evidence is skill-specific, global with adaptive impairment, attention-mediated, broadly lower ability, or mixed. That clarity allows the school to act without asking the child to carry an inaccurate label.

28.7 The synthesis to retain

The most reliable discriminator is the relationship between general ability, academic skill and adaptive functioning. Specific learning disorder has normal general ability with an isolated academic-skill deficit. Intellectual disability has a global intellectual deficit together with adaptive impairment. ADHD affects attention, executive function and behaviour, so academic

underachievement is secondary to those difficulties and may coexist with a learning disorder. Slow learner refers to broadly borderline ability and remains a non-diagnostic educational label. Once that structure is clear, the differential becomes clinically manageable rather than a list of competing school labels.

For the resident, the important discipline is to keep diagnosis, description and support separate. A diagnosis should explain a coherent pattern and meet its defining requirements. A description should be honest about what is observed without claiming more certainty than the evidence permits. Support should be offered because the child needs it, not withheld until every boundary is perfectly resolved. This approach protects against both overdiagnosis and neglect.

> First decide whether the difficulty is skill-specific or global, then determine whether adaptive impairment and attention-related mechanisms change the formulation.

29 · Worked cases

Why vignettes matter. Neurodevelopmental presentations are rarely delivered in the tidy form of a short-answer question. A parent may report that a child is careless, a teacher may report that the child cannot keep up, and the child may describe school as exhausting or humiliating. The task is not to attach the first plausible label to that account. It is to decide what the observed difficulty represents, where it occurs, what demands expose it, and what additional information would change the formulation. The vignettes below rehearse that disciplined sequence.

Use each case as an exercise in clinical reasoning. Begin with the **presenting problem**, but do not stop there. Separate the behaviour that is visible to adults from the function that may be failing for the child. Then seek a **cross-setting pattern**, examine the developmental and educational context, and ask whether the impairment is broad, task-bound, or secondary to another difficulty. A good answer explains both the leading formulation and the reason its nearest rival is less convincing.

Pattern	Context	Demand	Function
WHAT RECURS	WHERE IT EMERGES	WHAT MAKES IT FAIL	WHAT SUPPORT CHANGES

29.1 A method for reading a developmental vignette

A vignette is not a compressed case sheet. It is a deliberately incomplete account designed to test whether the reader knows what is diagnostic, what is contextual, and what remains uncertain. The first move is to translate an adult conclusion such as “lazy,” “naughty,” “weak in studies,” or “not listening” back into observations. What does the child actually do? What happens immediately before the difficulty? What changes when the material is presented differently, when the task is shorter, when the setting is quieter, or when a familiar adult provides structure?

The second move is to identify the **task-specific failure**. A child who loses the thread only when reading is required is presenting a different problem from a child who loses the thread during play, meals, conversation, and written work. Likewise, a child who avoids copying because the

hand is slow or inaccurate may look inattentive to an observer who sees only an unfinished page. The behaviour is real, but its meaning is not yet settled.

- State the difficulty in observable language before naming a syndrome.
- Ask what the child can do when the suspected demand is removed or reduced.
- Compare home, school, and other routine settings without assuming that reports must be identical.
- Look for the emotional consequences of repeated failure, including avoidance, anger, shame, and withdrawal.

RULE **Behaviour is a clue, not a formulation.** A developmental label becomes useful only after the pattern, context, functional impact, and competing explanations have been examined.

Clinical reasoning should remain provisional. In a real assessment, one would return to the child, family, school information, developmental history, physical and sensory considerations, and relevant assessment findings. In a written answer, say what must be clarified rather than pretending that the vignette contains it. This is not evasiveness. It demonstrates that diagnosis rests on converging evidence rather than on a dramatic phrase in the history.

Absence of a reported feature should also be handled with care. A brief school report may be silent about home functioning because no one asked, and a parent may not have observed a classroom difficulty because the setting never places the same demand on the child. Silence in a vignette therefore has different meanings from a clearly stated absence. A defensible answer distinguishes what is present, what is explicitly absent, and what is unknown. This habit protects against premature exclusion as much as it protects against premature diagnosis.

29.2 The child described as careless and disruptive

Vignette. A school-going child is repeatedly sent out of class for calling out, leaving the seat, and abandoning written work. At home, homework becomes a prolonged conflict. The parent says that the child can remain absorbed in a preferred activity but becomes restless when asked to read, copy, or complete a worksheet. The teacher reports that verbal participation is lively, yet work requiring independent reading is often incomplete. The family asks whether this is simply poor discipline.

The tempting answer is to treat every visible behaviour as evidence of **attention regulation difficulty**. That may be part of the formulation, but the vignette has placed a warning sign in plain view: the difficulty intensifies around literacy-heavy demands. The clinician should ask whether inattention and impulsive behaviour are evident across activities that do not rely on reading, writing, or sustained academic decoding. If they are, an ADHD formulation may remain compelling. If the apparent inattention is concentrated around a particular academic demand, a learning disorder may be contributing to the picture or may be the more immediate explanation for the classroom behaviour.

Do not treat focused engagement in a preferred activity as proof against ADHD. The clinically useful question is not whether the child can ever concentrate. It is how attention is allocated when novelty, reward, structure, effort, comprehension, and frustration change. Equally, do not treat classroom disruption as proof of ADHD. A child who expects failure may escape the task, provoke removal from it, or use movement and talking to mask confusion. This is a functional account of behaviour, not an excuse for overlooking impairment.

QUESTION RAISED BY THE VIGNETTE	FINDING THAT WOULD SUPPORT AN ADHD FORMULATION	FINDING THAT WOULD MAKE A LEARNING DIFFICULTY MORE CENTRAL
Where is the behaviour seen?	It recurs across ordinary demands and settings.	It is chiefly linked to a particular kind of school task.
What happens when the task changes?	Organisation and self-regulation remain difficult even when content is accessible.	Behaviour improves when the academic load is presented in an accessible way.
What is the child avoiding?	The pattern is not confined to one academic skill.	A consistent skill demand evokes frustration, delay, or escape.
What should happen next?	Assess the full attentional and behavioural pattern, including impairment.	Clarify the learning profile while also assessing attention where indicated.

The best formulation may include both pathways. Co-occurrence should not be used as an intellectual shortcut, but neither should a search for a single explanation erase a second genuine difficulty. The practical consequence is that management needs to address the mechanism of the unfinished work. Increasing behavioural pressure on a child who cannot access the task is unlikely to restore learning. Providing academic support without addressing pervasive dysregulation may be equally insufficient.

> **GOOD TO REMEMBER**
>
> When a teacher reports inattention, ask for the exact classroom demand that preceded it. The answer often distinguishes a broad self-regulation problem from distress around a specific learning task.

29.3 Uneven attainment, broad difficulty, and the misleading label of slow learner

Vignette. A child is described as quiet, cooperative, and slow to finish schoolwork. The family has accepted the school's description of "slow learner." The child appears comfortable in conversation and is effective in everyday routines, but falls far behind peers in selected academic tasks. Another child in the same clinic struggles more generally with classroom learning, practical problem solving, and independent adaptation to everyday expectations. The referral question is whether both children have the same condition.

They should not be treated as interchangeable. The phrase **slow learner** may express a school's concern about pace or level of performance, but it does not itself explain the pattern. It can conceal a specific learning disorder, broader cognitive difficulty, inadequate opportunity to learn,

emotional distress, sensory problems, language mismatch, or a poorly described classroom environment. It should therefore trigger clarification, not end the assessment.

In the child with uneven attainment, the crucial observation is the contrast between areas of clear difficulty and areas of relative competence. The clinician asks whether the child has had an adequate chance to learn, whether the difficulty persists despite ordinary support, and whether it has functional consequences beyond disappointing marks. In the child with broad difficulty, the question shifts towards a **global learning difficulty** and its relationship to everyday adaptive functioning. The distinction matters because a profile of circumscribed academic difficulty calls for a different educational response from a broadly limited developmental profile.

Intellectual disability must be considered carefully when functioning is broadly affected, but it must not be used as a catch-all explanation for poor school performance. The fuller account of that diagnostic framework is in *the Intellectual disability and autism spectrum disorder notes*. In this chapter, the applied point is simpler: an isolated academic weakness cannot be interpreted without considering the child's broader functioning, and broad difficulties cannot be inferred from marks alone.

IN INDIA

School labels can become part of a family's explanatory model before a clinical assessment occurs. Ask what the school means by "slow," which tasks are difficult, what teaching language is being used, and what support has already been attempted. This protects the child from both inappropriate reassurance and premature diagnostic labelling.

PITFALL

Do not write "slow learner" as though it were a formal diagnosis. It is a prompt to map a learning profile and context, not a conclusion that substitutes for assessment.

29.4 When apparent inattention is a communication problem

Vignette. A young child appears not to follow classroom instructions, gives answers that do not match the question, and often watches peers before beginning an activity. The child is described as distractible and socially aloof. At home, caregivers report that the child becomes frustrated when asked to narrate events, struggles to find words, and uses short or poorly organised responses. In familiar routines, the child participates more readily.

Here, the clinician should not begin by counting inattentive acts. First ask whether the child understood the linguistic demand. A child who cannot reliably process the instruction, formulate a response, or follow a rapid exchange can appear disengaged, oppositional, anxious, or inattentive. Waiting for peers may be a compensatory strategy rather than a sign of indifference. The relevant formulation concerns **communication demands** and the child's ability to meet them.

Observe how the child manages when language is simplified, when visual demonstration accompanies speech, and when the clinician allows time for a response. These observations do

not replace formal evaluation, but they help distinguish a failure to attend from a failure to understand or express. Also examine the social consequences. Repeated misunderstanding can lead a child to withdraw, interrupt, joke, or avoid group activity. Such behaviour may resemble a primary behavioural or attentional disorder while being sustained by communication frustration.

The communication disorders chapter provides the diagnostic framework and management approach. For the vignette, the key lesson is that a child's outward silence or apparent non-compliance must be interpreted in relation to language comprehension, expressive capacity, speech clarity, fluency, and social use of communication. Asking the child to repeat an instruction is less informative than checking whether the instruction was understood and can be acted upon.

TRAP **Do not call a child inattentive before checking whether the child could understand the demand.** An observer can see a delayed response; the observer cannot infer its cause without examining communication.

29.5 The child who avoids writing and games

Vignette. A child avoids handwriting, takes an unusually long time to dress, is reluctant to join games requiring coordinated movement, and becomes tearful before practical classroom activities. The teacher describes poor effort and incomplete work. The family notices that the child knows what to say but struggles to translate an idea into a written page. Behaviour becomes worse when adults insist that the child "try harder."

This vignette calls for attention to **motor coordination** and its daily consequences. The unfinished page may arise from a planning or execution difficulty rather than inattention, defiance, or lack of understanding. Avoidance is often intelligible when a task repeatedly exposes the child to failure in front of peers. The clinician should ask what exactly is hard: initiating the movement, sequencing it, maintaining speed, coordinating both hands, using tools, organising the page, or tolerating the effort involved. The answer helps identify the next assessment question without reducing the child to a handwriting complaint.

It is also important to distinguish a motor-based difficulty from a specific learning problem and from ADHD. These may coexist, and each can amplify the visible impairment. A child with motor difficulty may need much of the available attentional capacity simply to control the task, leaving little capacity for content. Conversely, a child with ADHD may show disorganised output without a primary coordination disorder. The formulation should describe the contribution of each suspected pathway and avoid assuming that one label explains every failure.

Observe the emotional and relational loop. Criticism may increase anticipatory anxiety, which worsens performance and reinforces the adult's impression of poor effort. A useful intervention begins by making the demand achievable, protecting dignity, and coordinating with school rather than escalating punishment. The diagnostic and management details for developmental coordination disorder belong in its dedicated section; the applied lesson is to notice when movement is the hidden bottleneck.

29.6 Turning a vignette into a defensible formulation

A strong answer does not end with a label. It explains the working formulation, names the uncertainty, identifies the information needed next, and links the formulation to a practical response. This prevents the common error of treating diagnostic reasoning and management planning as separate tasks. If the difficulty is most visible under a particular demand, the immediate support should make that demand more accessible while assessment continues. If impairment is broad and persistent, the plan should involve the environments in which it occurs rather than placing responsibility only on the child.

For every vignette, complete the following formulation in prose: the child's main difficulty is seen in a defined context; the leading explanation is supported by a recognisable pattern; the nearest alternative remains possible or less likely for stated reasons; further collateral and assessment are required; and support should reduce barriers while preserving participation. This structure is deliberately portable. It can be used for ADHD, learning disorders, communication disorders, and motor disorders without pretending that these conditions are interchangeable.

MNEMONIC

MAPS the vignette

Map the observed behaviour, **A**sk what demand exposes it, identify the **P**attern across settings, and choose the next **S**tep that tests the formulation or reduces the barrier. The mnemonic is a reasoning sequence, not a diagnostic checklist.

Describe the pattern before naming the disorder, and make the support fit the function that is failing.

What earns marks in an applied answer. The examiner is looking for discrimination, not diagnostic bravado. Show that a behaviour can have more than one pathway, that context can reveal the pathway, and that comorbidity may require more than one response. Where the vignette is incomplete, say what you would seek from the child, family, and school. The detailed child psychiatric assessment approach is available in *the Child psychiatry: assessment, treatment, services and protection notes*; the present task is to use its logic to prevent premature closure.

30 · Consolidate: the master mnemonic, the retrieval prompts and the synthesis map

Consolidation is where recognition becomes usable clinical reasoning. A candidate can know isolated labels, criteria, instruments and interventions yet still produce an unsafe or unconvincing answer when the task changes from recall to a child in front of them. The purpose of this closing section is to make the chapter retrievable as a sequence of decisions: clarify the presenting difficulty, test the leading explanation against alternatives, identify what must be assessed, and state what follows from the formulation. It is deliberately answer-free. Use it to expose an omission before the examination, the case conference, or the clinic rather than to create the comforting illusion of familiarity.

The chapter is best retained as a **clinical map**, not as a pile of headings. The map has room for ADHD, learning difficulty, communication difficulty and motor phenomena, while also forcing the clinician to ask what the child can do, where the difficulty occurs, what collateral evidence supports it, and what functional consequence matters. The same map prevents a false choice between diagnosis and context. A sound answer neither reduces a child to a label nor loses diagnostic discipline in a long narrative of school and family stress.

30.1 Start with the question, not the label

Before retrieving any diagnostic material, restate the clinical problem in ordinary professional language. Is the referral primarily about attention and activity, acquisition of an academic skill, speech or language, fluency, social use of communication, coordination, repetitive movement, or a mixture? That opening move matters because the referral label is often an interpretation offered by someone else. It may be useful, but it is not yet the formulation. A child described as inattentive may be struggling to access teaching; a child described as weak in studies may have a broader pattern of difficulty; a child described as disruptive may be communicating frustration. The consolidation task is to preserve uncertainty long enough to ask discriminating questions.

Build the opening sentence around **functional impairment**. Name the setting in which the concern is visible, the task that becomes difficult, the consequence for participation, and the source of the report. This keeps the answer clinically anchored. It also makes it much harder to mistake an isolated complaint for a pervasive disorder or to dismiss a serious difficulty because the child is doing well in another area. Functional description is not a decorative introduction. It is the bridge between observed behaviour, developmental history, school information and any later diagnostic conclusion.

- What exactly is the referrer asking for help with?
- What does the child, caregiver and teacher each identify as the main difficulty?
- What activity, relationship or educational participation is being affected?

RULE **Formulate the problem before you retrieve the diagnosis.** A label may organise inquiry, but the presenting difficulty determines which evidence is relevant and which alternative explanations deserve active consideration.

In a written answer, this approach also gives the examiner a visible reasoning trail. Rather than launching into a memorised list, state the clinical question and show how history, informants and observation will answer it. The result is more concise as well as more defensible: every later detail has a job. If a detail does not alter the formulation, the differential, the assessment plan or the management plan, it does not need to dominate the answer.

30.2 Retrieve the assessment as a chain of evidence

Assessment should be recalled as **triangulation**. No account, behaviour sample or score can carry the whole clinical judgement alone. The candidate should be able to explain how information from the child, family, school and direct clinical encounter is brought into conversation. Agreement across sources may strengthen confidence, while disagreement is not an

inconvenience to be erased. It can reveal variation by task demand, setting, relationship, structure or support. The question is not which informant is "right" in the abstract. The question is what each account is measuring.

Use a **developmental formulation** to hold the evidence together. Retrieve the history that clarifies the course of the concern, the child's strengths, the educational context, communication and motor development, emotional state, behaviour, sleep, sensory or physical contributors, family experience and previous support. The aim is not a maximal checklist. It is a coherent account of why the problem now looks the way it does. A formulation should leave room for coexisting conditions without assuming that every difficulty has a separate diagnosis.

EVIDENCE SOURCE	QUESTION TO RETRIEVE	HOW IT CHANGES REASONING
Child and caregiver account	What is noticed across ordinary routines and tasks?	Clarifies lived difficulty, expectations and priorities.
School information	What happens when learning, language, behaviour or coordination is observed in context?	Tests whether the reported concern fits educational demands and supports.
Clinical observation	What can be directly described without overinterpreting it?	Connects reported behaviour with the examination encounter.
Focused testing or specialist input	What question requires structured measurement or another discipline?	Refines the formulation rather than replacing it.

When recalling rating scales, psychoeducational assessment or other structured tools, retrieve their purpose before their names. Ask what construct is being sampled, whose perspective is represented, what the result can support, and what it cannot decide on its own. This protects against score-driven diagnosis. A measurement can sharpen a question; it cannot repair a vague referral, a missing school history, or an unexamined alternative explanation.

> **GOOD TO REMEMBER**
>
> If reports conflict, do not average them into a meaningless middle. Describe the contexts in which the difficulty is and is not visible, then ask what those contexts demand from the child. The discrepancy may be the most clinically useful finding.

30.3 Make discrimination explicit

The difficult marks lie in **diagnostic discrimination**, not in repeating a definition. A strong response tells the reader what observation or history finding would make a rival explanation less likely, what evidence remains necessary, and why an apparently similar presentation has a different clinical meaning. This is particularly important when attentional symptoms coexist with academic underachievement, when a broad developmental difficulty is mistaken for a circumscribed learning problem, or when a communication difficulty changes how behaviour is interpreted.

Keep the contrast at the level of the clinical question. Is the problem broad or circumscribed? Is it stable across tasks or most visible when a particular skill is demanded? Does it follow lack of access to instruction or persist despite appropriate opportunity? Are attention and activity the central difficulty, or are they secondary to repeated failure, anxiety, boredom, misunderstanding or environmental mismatch? Does the account suggest a communication barrier, a motor barrier, an emotional difficulty, a sensory or physical issue, or a different neurodevelopmental profile? These prompts organise a differential without pretending that any isolated sign settles it.

- State the leading formulation in a neutral sentence.
- Name the alternative explanation that would cause the greatest error if missed.
- Specify the history, observation or collateral information that separates them.

TRAP **Do not convert poor performance into a diagnosis by relabelling it.** Poor academic output, restlessness, slow completion, unclear speech or clumsiness are clinical starting points. They require a formulation that accounts for pattern, context, development and impairment.

The comparison between ADHD, specific learning disorder, intellectual disability and the educational term “slow learner” should be retrieved from the dedicated discrimination section rather than reconstructed from shorthand. The same restraint applies to the relationship between ADHD and its comorbidities. A consolidated answer should show that coexistence is possible while still asking which condition explains which part of the presentation. For the wider developmental differentials, use the Intellectual disability and autism spectrum disorder notes and the Normal child development and milestones notes.

PITFALL

Once a referral label has become familiar, clinicians may read every subsequent report through it. Counter this by writing down what finding would genuinely change the formulation. If no imaginable finding could do so, the assessment has become confirmatory rather than diagnostic.

30.4 Link diagnosis to action without collapsing the formulation

A diagnosis is clinically useful only when it changes what the team does. Retrieve the **multimodal plan** as a linked response to the child’s needs, not as a menu of unrelated treatments. The plan may include psychoeducation, family work, behavioural support, school collaboration, remediation, communication or motor intervention, treatment of coexisting emotional or behavioural difficulty, and medication where indicated. In an answer, make the connection visible: identify the target difficulty, the intervention directed at it, the person or setting involved, and the outcome that will show whether the plan is helping.

This is also where candidates should distinguish management of a condition from management of its consequences. A child can need help with participation, confidence, behaviour in class, family conflict or access to learning even while diagnostic clarification is continuing. Conversely, an intervention should not be presented as proof that a diagnosis was correct. Support can be appropriate in the presence of uncertainty, provided its purpose is clear and progress is reviewed.

- Which difficulty is the immediate target for change?
- Which adult, service or setting must be involved for the plan to work?
- What observable improvement would justify continuing, adapting or escalating support?

Why the feedback loop matters. The initial plan is a clinical hypothesis in action. Follow-up asks whether the target has moved, whether the child can use the support in ordinary life, whether an unrecognised comorbidity or barrier is now clearer, and whether the balance of burden and benefit remains acceptable. This safeguards against therapeutic inertia. It also prevents the opposite error of changing several things at once and then being unable to explain what helped.

IN INDIA

When an answer has an educational or administrative component, retrieve the relevant local documentation and institutional pathway alongside the clinical formulation. Do not assume that a generic label automatically answers the practical question. The dedicated section on specific learning disorder certification and educational provisions is the place to retrieve the statutory route and accommodations.

30.5 Use active recall to test the whole chapter

Active recall should be demanding enough to reveal where the map breaks. Reading a highlighted page gives rapid recognition, but recognition does not test whether the relevant distinction can be produced under pressure. Close the text, choose a prompt, and speak or write a brief answer from memory. Then reopen the relevant section and compare the structure of the answer with the text. Correct missing reasoning, not just missing nouns. The useful question is not "Did I remember a fact?" but "Could another clinician see how I got from complaint to plan?"

Use **retrieval practice** in mixed order. Do not always move from diagnosis to assessment to treatment, because real cases rarely arrive in that order. Begin at different points: a school complaint, a parent's concern, a finding on observation, a treatment question, or a differential dilemma. Mixing prompts forces the learner to rebuild the clinical pathway rather than recite a fixed sequence. It also reveals whether knowledge of ADHD has become disconnected from knowledge of learning, communication and motor disorders.

MAP	TEST	ACT	REVIEW
PRESENTING PROBLEM	ALTERNATIVE EXPLANATION	TARGETED SUPPORT	RESPONSE AND REVISION

Use the following prompts without looking up the answer until you have committed to a structure:

- Frame an assessment for a child referred for inattention when the school report emphasises academic underachievement.
- Explain how you would distinguish a circumscribed learning difficulty from a broader developmental concern without prematurely naming either.

- Describe how communication, motor, emotional, behavioural, sensory, physical and educational factors alter the meaning of a presenting complaint.
- Set out a management plan that joins family, school and child-focused work to a clear review question.
- Explain why a structured scale or test can strengthen, but not substitute for, clinical formulation.
- Write a concise differential paragraph that names uncertainty and states how it will be resolved.

After each attempt, identify the type of failure. A missing definition calls for focused revision. A confused differential calls for a comparison table. An unlinked management list calls for reformulation around targets and settings. An inability to explain what a result means calls for return to the assessment section. This is more efficient than rereading the entire chapter after every weak answer, and it turns errors into precise revision tasks rather than evidence of global incompetence.

30.6 Write answers that show reasoning

In a long answer, use a **clinical argument**. Begin with the problem and the relevant frame, then move through assessment, differential diagnosis, formulation and management. Within each part, prefer explanation to disconnected lists. A list of scales, treatments or accommodations gains little unless the reader can see when it is used, what it contributes and what limitation is being respected. Conversely, a polished narrative without structured headings makes it difficult to find the core answer. The best balance is explanatory prose supported by short, purposeful lists and comparisons.

For a short note, choose the few ideas that demonstrate command rather than trying to compress the whole chapter into a paragraph. State what is being distinguished, the evidence that matters, the broad management direction and the principle of review. If a prompt asks for an instrument, a medication, a criterion set or a statutory provision, retrieve that detail from its dedicated section rather than guessing from the consolidation. This closing section is a map to knowledge, not a substitute for the precise content held elsewhere in the chapter.

WEAK ANSWER PATTERN	WHAT IS MISSING	REPAIR
A label followed by a long list	The path from presentation to conclusion	State the discriminating evidence and its clinical meaning.
A detailed history with no conclusion	A formulation that orders the information	Summarise the leading explanation and the remaining uncertainty.
A treatment catalogue	A target and a setting for each intervention	Link each action to the difficulty it is intended to change.
A test result treated as a verdict	Context, collateral evidence and limitation	Explain what the result contributes to the broader assessment.

The same discipline matters in clinical documentation. A later clinician should be able to tell what was reported, what was observed, what remains uncertain, what was agreed and what will be reviewed. That record supports continuity without turning uncertainty into indecision. For broader service and protection questions, return to the Child psychiatry: assessment, treatment, services and protection notes.

30.7 Protect against the recurring errors

The recurring error across this area is **premature closure**. It appears in several forms: accepting the referral label without testing it, treating academic struggle as synonymous with a learning disorder, treating a score as synonymous with a diagnosis, attributing every difficulty to the most visible condition, or presenting a plan without deciding how its effect will be judged. These are not merely examination faults. They weaken communication with families and schools because they obscure what is known, what is inferred and what still needs attention.

Counter premature closure with a brief final pause before committing to a conclusion. Ask whether the formulation accounts for the child's strengths as well as difficulties, whether the school context has been understood, whether an alternative explanation has been actively considered, whether coexisting problems have been separated rather than merged, and whether the management plan is proportionate to the evidence. This pause does not require indecision. It creates disciplined confidence: act on what is clear, state what is uncertain, and arrange review around the uncertainty that matters.

Retrieve the pathway: problem, pattern, proof, plan, and progress.

30.8 The master recall spine

MNEMONIC

MAPS: Map the problem, Ask across settings, Probe alternatives, Support and review

MAPS is a recall spine, not a diagnostic shortcut. Map the concern in functional language. Ask across informants and contexts. Probe alternatives and coexisting difficulties. Support the child and systems around the child, then review whether the plan has changed the target difficulty.

Use this spine to close any answer in the chapter. It keeps the candidate from mistaking memorised detail for clinical judgement, while leaving each detail in the section that owns it. If the prompt concerns ADHD, retrieve its criteria, assessment, treatment and outcome from the relevant sections. If it concerns learning, communication or motor disorders, return to the relevant definition, assessment and management sections. If the question crosses categories, use MAPS to decide which material belongs in the answer and in what order.

Previously asked

Genuine past questions from this chapter's territory, with their board of origin. No catalogued theory question falls inside attention-deficit/hyperactivity disorder, specific learning disorder or the communication and motor disorders in the examined window, so none is printed here. No question is reconstructed, paraphrased into a new one, or invented to pad the list. That a topic has not been asked as a set-piece essay does not lower its yield: ADHD pharmacotherapy, the rating-scale discrimination, the specific-learning-disorder criteria and the Indian certification route are all live short-note and viva territory, and the chapter is built to answer them.

TRAP **An unasked topic is not a low-yield topic.** The absence of a past essay is a fact about one board's recent papers, not about what an examiner may ask this year. Prepare the discriminations, not the past paper.

The quick review

One table, read down the left column, cover the right. Every line is taught in full somewhere above; nothing here is new. Where the sources disagree, the disagreement is the answer.

ASK	HOLD
WHAT DSM-5 REQUIRES FOR ADHD	At least 6 of 9 symptoms in a domain (5 if aged 17 or older), several present before age 12, in at least 2 settings, for at least 6 months, with impairment. The count and the age are the marks.
DSM PRESENTATIONS AGAINST ICD-11	Three DSM-5 presentations: predominantly inattentive, predominantly hyperactive-impulsive, combined. ICD-11 codes it 6A05 and asks for 'several' symptoms with no fixed count or onset age. Naming ICD-10 hyperkinetic disorder as identical to DSM ADHD is the error.
WHAT EXECUTIVE DYSFUNCTION IS FOR	It is the mechanism that links the fronto-striatal dopamine and noradrenaline circuit to the symptoms. It explains the domains; it is not a fourth symptom.
THE THREE RATING SCALES ARE NOT INTERCHANGEABLE	Conners 3 is norm-referenced, a T-score instrument (mean 50, SD 10), bought under an MHS licence. Vanderbilt (ages 6 to 12) and SNAP-IV are raw-score cut-off screens, free to obtain and use but not free to republish. Different raters, ages, constructs and cut-off logic. Listing three that measure differently is the exam trap.
FIRST-LINE ADHD MEDICATION AND THE DOSE RULE	Methylphenidate. Every dose carries its population: the typically-developing child starts around 5 to 10 mg immediate-release and titrates weekly, whereas a child with autism starts lower. A dose without its population is not an answer.

ASK	HOLD
THE CLONIDINE AND AMPHETAMINE CAUTIONS	Clonidine and guanfacine doses are small (clonidine about 0.1 mg at night up to about 0.4 mg per day); a mg/kg clonidine figure that looks large is wrong. Amphetamines and lisdexamfetamine are not marketed in India; methylphenidate and atomoxetine are.
WHAT THE MTA SHOWED	At 14 months, medication management and combined care beat behavioural care and community care for core symptoms; by 36 months the groups converged. Cite the stimulant response as about 77 percent; do not print a divergent figure across chapters.
ADULT ADHD	It persists into adulthood in a substantial proportion; overt hyperactivity fades while inattention and inner restlessness remain. This chapter owns adult ADHD in full.
WHAT DSM-5 REQUIRES FOR SPECIFIC LEARNING DISORDER	Difficulty in an academic skill persisting at least 6 months despite targeted intervention, achievement substantially below age expectation, onset in the school-age years, and not better explained by intellectual disability, sensory deficit, adversity or inadequate instruction. General ability is preserved.
THE MECHANISM OF DYSLEXIA	A core phonological-processing deficit; the double-deficit model adds slow rapid automatised naming. The neurobiology is left-hemisphere temporo-parietal and occipito-temporal underactivation.
HOW SLD CERTIFICATION DIFFERS FROM ID CERTIFICATION IN INDIA	SLD rests on psychoeducational, achievement-discrepancy assessment (the NIMHANS battery) with a preserved IQ; intellectual disability rests on an IQ-plus-adaptive-behaviour route. The current guidelines schedule repeat certification during class X and class XII.
SLOW LEARNER	Borderline intellectual functioning, an Indian educational-practice term for an IQ of roughly 70 to 85. It is not a DSM or ICD diagnosis and has no criteria set. Promoting it to a diagnosis is the error item 79 exists to prevent.
SOCIAL COMMUNICATION DISORDER AGAINST AUTISM	Social communication disorder shows the social-pragmatic difficulty without the restricted and repetitive behaviours; their presence, now or historically, points to autism.
STEREOTYPY AGAINST TIC	Stereotypies are rhythmic, fixed, simpler and present from earlier; tics are not rhythmic, involuntary and only briefly suppressible.
WHAT THE SOURCES REFUSE TO TELL YOU	Several Indian prevalence figures, the exact statutory SLD percentage method, and a firm growth-suppression magnitude are simply not in the literature consulted. The chapter says so where it happens rather than inventing them.

References

Every specific in this chapter is bound to one of the sources below, and the count is the number of claims each carried. Books and guidelines are cited author, title and year in the house convention; no PMID is asserted for a book. For the statutory material the primary document is the authority: the Rights of Persons with Disabilities Act 2016 and the CBSE examination-concession circular were read directly, and where a textbook paraphrase diverged from the primary text the primary text was followed and the divergence named where it falls. The must-have-papers cross-check was NOT performed for this Paper III chapter, because the paper lists do not yet exist in the intel index; for Paper III the topic bank plus the syllabus scaffolding is the completeness authority.

Child Behavioural, Emotional and Other Disorders

The behavioural and emotional disorders of childhood, from conduct and oppositionality through anxiety, tics and elimination.

01 Conduct disorder

02 Oppositional defiant disorder and the impulse-control disorders

03 Childhood anxiety, OCD and trauma disorders

04 Childhood mood disorders, disruptive mood dysregulation, early-onset psychosis and paediatric suicidality

05 Attachment disorders of childhood

06 Tic disorders and Tourette syndrome

07 Elimination and feeding disorders

08 Discriminate, apply and consolidate

PAPER III

Child behavioural, emotional & other disorders

Seven bands . one complete notes document

Conduct disorder

1 · The five groups and the shape of the chapter

A chapter reads more easily once you can see its skeleton. The disorders gathered under this heading are the ways children and adolescents come to behave, feel and function outside the expected range, and set out as a bare list they can look like a loose and only distantly related collection: conduct problems next to bedwetting, tics next to school refusal, a withdrawn deprived toddler next to a defiant teenager. That impression is misleading, and it is worth dissolving at the outset, because the candidate who carries a shape into the exam answers a mixed vignette far better than one who has memorised each entity as an island. The chapter's own title supplies the shape. It names three things in order: the behavioural disorders, the emotional disorders, and the other disorders, and those are not three arbitrary drawers but a genuine organizing logic that the rest of this material fills in.

The aim of this opening is to hand you that logic before any single disorder is taught. Three moves do the work. The first is an axis that links the two largest groups, distinguishing distress that a child turns outward from distress a child turns inward. The second is the recognition that not every childhood disorder belongs on that axis: three further families keep their own logic and are misread if forced onto it. The third is a principle that runs underneath the whole chapter, that these are disorders of degree and of context, judged against a developmental baseline that is itself moving. Hold those three and the individual diagnoses that follow slot into place rather than accumulating as a list.

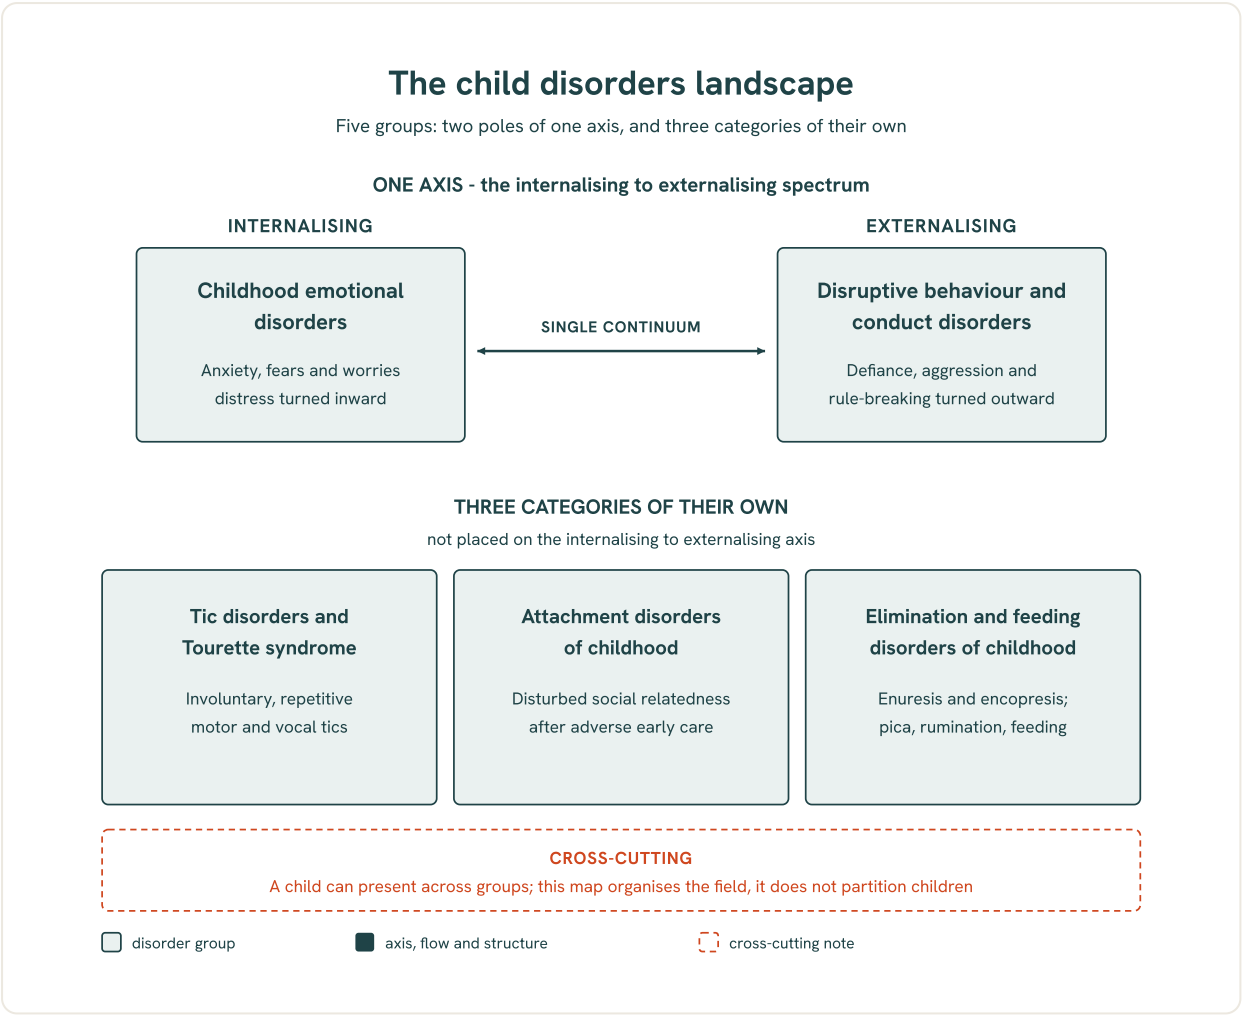

Fig 23.1. The child disorders landscape: emotional (internalising) and disruptive or conduct (externalising) disorders sit at the two poles of one axis, while tic, attachment, and elimination or feeding disorders form three categories of their own.

1.1 The organizing axis: distress turned outward and distress turned inward

The two largest groups are two directions of the same problem. The most useful single distinction in child psychiatry is between the disorders in which difficulty is expressed **externally**, as behaviour that impinges on other people and on the surrounding world, and those in which it is experienced **internally**, as suffering the child largely carries within. The externalising, or behavioural, group is the disruptive one: conduct disorder, oppositional defiant disorder and the impulse-control disorders, where the presenting problem is what the child does to others and the first complaint usually comes from an adult. The internalising, or emotional, group is the group of anxiety, obsessive-compulsive and trauma-related disorders and the childhood mood disorders, where the presenting problem is what the child feels and the first complaint, if it comes at all, often comes late and quietly. The value of the axis is not taxonomic tidiness but clinical direction: it tells you who is likely to be referred and who is likely to be missed, whose distress announces itself and whose has to be sought.

RULE **Externalising and internalising is one organizing dimension, not a complete classification.** It is a lens laid across the disorders to show a pattern, chiefly that outward-directed problems are referred and inward-directed ones are overlooked. Read it as a filing system into which every childhood disorder must drop and it stops helping, because several of the disorders in this chapter do not sit on it at all.

1.2 The three families that keep their own logic

The "other disorders" of the title are three groups with their own organizing principle. A frequent error is to treat the outward-inward axis as exhaustive and then to squeeze the remaining disorders onto it. They do not belong there, and each is better understood on its own terms. The **tic disorders**, including Tourette syndrome, are neurodevelopmental and motor in nature; their defining feature is an involuntary movement or vocalisation, not an emotional state turned in or a behaviour turned out. The **attachment disorders** are relational disorders that arise specifically from grossly deficient early care, so their organizing principle is the child's history of caregiving rather than any internalising or externalising temperament. The **elimination and feeding disorders** are disorders of bodily function and its regulation, from enuresis and encopresis to the feeding and eating problems of early childhood. Naming these three as their own categories, rather than as odd members of the behavioural or emotional groups, is itself a piece of examinable understanding, and it is why the chapter is built as five families and not two.

FAMILY	ORGANIZING LOGIC	REPRESENTATIVE MEMBERS (TAUGHT IN FULL IN THEIR OWN PLACE)
Behavioural (externalising)	Distress turned outward onto others and the world	Conduct disorder, oppositional defiant disorder, the impulse-control disorders
Emotional (internalising)	Distress carried within, often referred late	The childhood anxiety, obsessive-compulsive and trauma-related disorders, the childhood mood disorders
Tic disorders	Neurodevelopmental and motor; involuntary movement or vocalisation	Transient and chronic tic disorders, Tourette syndrome
Attachment disorders	Relational; rooted in grossly deficient early care	Reactive attachment disorder, disinhibited social engagement disorder
Elimination and feeding	Disorders of bodily function and its regulation	Enuresis, encopresis, and the feeding and eating disorders of childhood

The five families of the chapter set against the principle that organizes each. The axis of the first section explains only the top two rows; the lower three are named here as their own categories and are developed, each in full, later in this chapter.

1.3 Why the axis is a lens and not a wall: comorbidity across it

Outward and inward disorders live together far more often than the neat split suggests. The axis earns its keep by directing attention, but a candidate who treats it as a partition will be

caught by the commonest examination presentation of all, the child who sits on both sides at once. The disruptive, acting-out child very frequently carries an internalising disorder underneath the behaviour, and the anxious or depressed child not uncommonly presents through irritability and rule-breaking that look, at first glance, purely behavioural. That the two directions co-occur is not an untidy exception to the scheme; it is the clinical rule, and it is precisely why the outward-inward distinction has to be held as a way of looking rather than as a boundary between separable populations.

TRAP **Treating externalising and internalising as mutually exclusive.** The vignette that describes a defiant, aggressive boy invites the label of a pure behavioural disorder and tempts the candidate to stop there. The stronger answer notices that the behaviour may be the visible surface of an anxiety, trauma or mood disorder beneath it, and that the two so-called opposite groups are the disorders most likely to be found in the same child.

GOOD TO REMEMBER

When a child is referred for what one side of the axis makes obvious, look deliberately for the other. Screen the acting-out child for the anxiety, trauma and mood that hide behind conduct, and ask the withdrawn or anxious child about the irritability and defiance that a caregiver may not have thought worth mentioning. The referral tells you which door the family came through, not the whole of what is inside.

1.4 Disorder against a moving baseline: the developmental continuum

Almost every symptom in this chapter also exists as a normal part of growing up. Tantrums, fears, defiance, bedwetting, repetitive movements, clinginess at separation and the odd untruth are ordinary features of childhood, present in well children and expected at particular ages. This is the principle that sits under the whole chapter and separates its disorders from the developmental noise around them: a childhood disorder is rarely a behaviour that healthy children never show, and is far more often the same behaviour grown persistent, pervasive, developmentally out of step, and impairing. The **developmental continuum** is therefore not a soft caveat but the working definition of pathology here, because what is normal at one age is a red flag at another, and the baseline against which any symptom is read keeps shifting as the child grows. What counts as expected at a given age is set out in the Normal child development and milestones notes; the specific thresholds that separate each disorder from its normal counterpart, and the map that sets the whole set of them side by side, are drawn together toward the end of this chapter, where the comparisons can be made once and properly.

PITFALL

The characteristic error at this level is to diagnose from the behaviour alone, without asking where the child sits on the developmental continuum. A defiant three-year-old, a frightened five-year-old and an occasionally wet seven-year-old are, far more often than not, well children doing age-appropriate things. Reaching for a disorder because the behaviour is present, rather than because it is persistent, pervasive and impairing for that age, over-pathologises ordinary development and is the mirror image of the more familiar failure to recognise a genuine disorder.

1.5 Reading the chapter, and a word on classification in Indian practice

The map is worth carrying into every question this chapter can ask. With the five families and the two principles in hand, the chapter equips you to do a small number of things reliably, and it is worth naming them before the detail begins:

- place any child presentation into its family, and recognise when a presentation straddles two of them;
- read the outward-inward axis as a lens on referral and detection, not as a partition;
- separate a disorder from its normal developmental counterpart by persistence, pervasiveness and impairment rather than by the behaviour alone;
- and know which of these childhood presentations point outward, to the adult disorders and to the wider systems of assessment, services and protection that lie beyond this chapter.

Where the child's presentation reaches into the domains this chapter deliberately leaves to others, the pointers are fixed: attention-deficit/hyperactivity disorder and its treatment belong to the ADHD and specific learning/communication disorders notes, and the full assessment battery, the child mental health services and the machinery of child protection to the Child psychiatry: assessment, treatment, services and protection notes.

IN INDIA

Two realities colour how this chapter is used in Indian practice. The operative classification is ICD-11, so the labels that appear in most case files and referrals are its labels rather than the DSM equivalents, and the family-based, service-scarce setting means these children very often reach a paediatrician, a general physician or a school long before they reach a child psychiatrist. The organizing consequence is practical: the outward-inward axis predicts which of them arrive at all. Disruptive, externalising problems are brought in because they trouble the adults around the child, while the internalising disorders, which cause the child the greater private suffering, are the ones most likely to go unrecognised in a system with few dedicated child mental health services. The frame is not only a way to revise the chapter; it is a reminder of where to look hardest.

MNEMONIC

Out, In, and three apart

Two families share a single axis, the child who turns distress **Out**, the behavioural or externalising disorders, and the child who turns it **In**, the emotional or internalising disorders. **Three** further families keep their own logic **apart** from that axis: the tic disorders (neurodevelopmental and motor), the attachment disorders (relational, rooted in early care), and the elimination and feeding disorders (of bodily function). The whole chapter hangs on those five, and every one of them is read against the moving developmental baseline.

The spine of the chapter: two families on one axis, distress turned Out (behavioural, externalising) against distress turned In (emotional, internalising), and three families apart from it - tic, attachment, and elimination and feeding disorders - with every disorder defined against the developmental baseline rather than by the behaviour alone.

Out	In	Apart
THE BEHAVIOURAL, EXTERNALISING DISORDERS	THE EMOTIONAL, INTERNALISING DISORDERS	TIC, ATTACHMENT, ELIMINATION AND FEEDING

2 · Conduct disorder diagnostic criteria and subtypes (childhood-onset, adolescent-onset)

The diagnosis turns on a pattern, not on a single act. **Conduct disorder** is the syndrome of childhood and adolescence in which a young person repeatedly and persistently behaves in ways that violate the basic rights of others or the major age-appropriate rules of society. It is one of the commoner reasons a child reaches psychiatric attention: one-year population prevalence in high-income settings has been estimated at a median of about **4%**, with estimates ranging from 2% to more than 10% across studies, and it falls more heavily on boys and men, whose lifetime prevalence has been put at about **12.0% in men and 7.1% in women**. Marks accrue here because the diagnosis is deceptively easy to reach for and genuinely hard to make well. The behaviours are dramatic, the temptation to label a difficult adolescent is strong, and the criteria exist precisely to separate a disorder from ordinary misbehaviour, from isolated delinquency, and from the friction of a hard upbringing.

This topic owns the diagnostic architecture: the essential feature, the count and timeframe of Criterion A, the behavioural groupings the criteria fall into, the impairment and adult-exclusion criteria, the developmental onset subtypes that are the item's real teaching point, and the severity grading. The callous-unemotional presentation captured in the limited prosocial emotions specifier, the causes and risk factors, the full assessment and its instruments, the treatments, and the long-term trajectory into adult antisocial outcomes are each developed in their own right elsewhere in this chapter. Here they are named where the criteria demand it, not reopened.

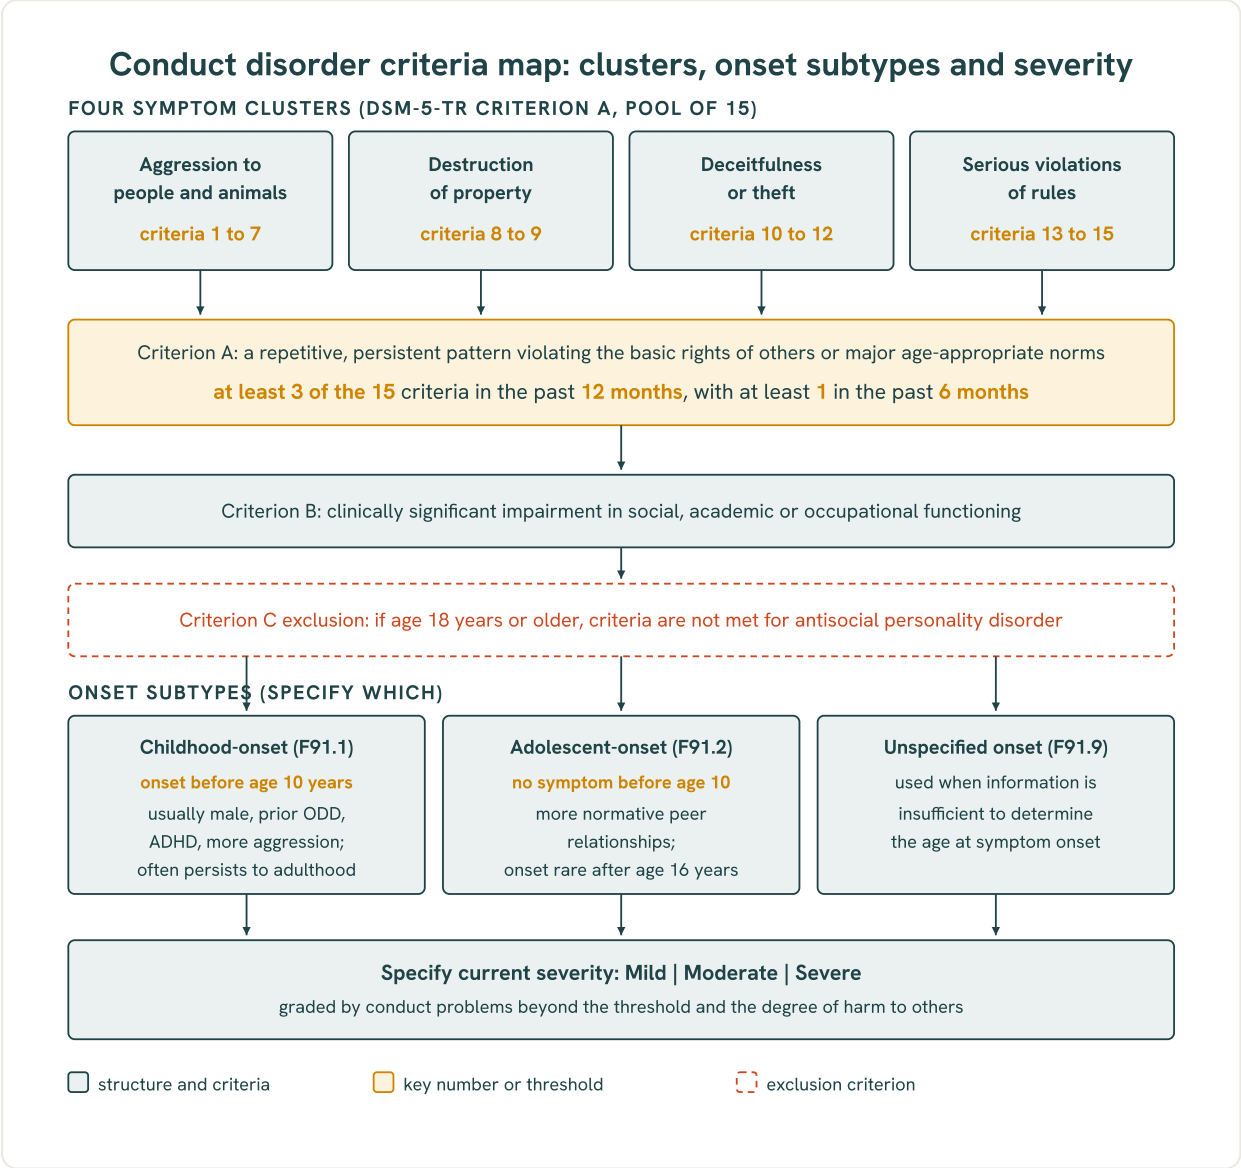

Fig 23.2. Conduct disorder criteria map: the four DSM-5-TR symptom clusters feeding the three-of-fifteen Criterion A threshold, the impairment and antisocial-personality-disorder gates, the childhood-onset and adolescent-onset subtypes, and the mild to moderate to severe severity grading.

2.1 The essential feature: a pattern, not an incident

The unit of diagnosis is a pattern of conduct over time. The essential feature is a repetitive and persistent pattern of behaviour in which the young person violates either the basic rights of others or the major age-appropriate norms and rules of society. Each part of that definition matters. Violating the rights of others captures aggression, cruelty, intimidation, and the taking of what belongs to someone else; violating major societal norms captures the serious rule-breaking, from chronic truancy to running away, that need not have a direct victim at all. What unifies the picture is not any single behaviour but its repetition and its persistence, and this is exactly why a solitary serious act, however shocking, does not by itself constitute the disorder. A first arrest, a single fight, or one episode of theft is an event to be understood, not a diagnosis to be made. The clinician's task is to establish whether a durable pattern sits behind the presenting incident, because it is the pattern, and not the incident, that predicts the course and justifies the label.

RULE **Conduct disorder is a pattern, never a single act.** The diagnosis rests on a repetitive and persistent course of rights-violating or norm-violating behaviour, so the assessor's first question is never what did the child do but what pattern does this belong to. An isolated offence read as a disorder is the error the criteria are built to prevent.

2.2 Criterion A: the count and the clock

The threshold and the timeframe are the examinable core. Criterion A operationalises the pattern into a rule that can be applied and defended. It requires that at least **three** of the **15** defined behaviours have been present within the past 12 months, with at least one of them present within the past 6 months. Each number earns its place. The count separates a genuine syndrome from a handful of troubling behaviours, and the recency window forces the clinician to show that the problem is current rather than historical, so that a child who has genuinely settled is not carried indefinitely under an old label. The number of symptoms present beyond the minimum is not wasted information either, because it feeds directly into the severity rating. Applied honestly, Criterion A is what stops the diagnosis drifting into a catch-all for any troublesome adolescent.

The core rule to carry into the exam: at least three of the 15 behaviours within 12 months, at least one within the past 6 months, forming a pattern and not a single act.

2.3 The four behavioural groupings

Fifteen behaviours, grouped into coherent families. The criteria are not a random list; they sort into four groupings that together describe the reach of the disorder from covert acts to overt ones. The first is **aggression to people and animals**, the behaviours that threaten or inflict physical harm, including bullying, fighting, cruelty, and the use of a weapon. The second is destruction of property, such as deliberate firesetting and other damage done on purpose. The third is deceitfulness or theft, the covert dimension of lying, conning others, and stealing with or without confrontation. The fourth is serious violations of rules, such as staying out at night against parental prohibition, persistent truancy, and running away from home. Reading a young person's symptoms as a profile across these families, rather than as a scatter of unrelated incidents, is what turns a list of complaints into a clinical picture.

MNEMONIC

Hurt, Wreck, Lie, Break

The groupings in order of how overtly they present: **Hurt** (aggression to people and animals), **Wreck** (destruction of property), **Lie** (deceitfulness or theft), and **Break** (serious violations of rules). Holding the families in mind stops the assessor cataloguing behaviours singly and missing the pattern that the diagnosis actually requires.

2.4 Impairment and the adult boundary: Criteria B and C

The behaviour must cost something, and the label must not outlive its usefulness. Criterion B keeps the diagnosis clinical rather than merely descriptive: the disturbance of conduct must

cause clinically significant impairment in social, academic, or occupational functioning. Behaviour that breaks rules but carries no cost to the young person's functioning does not qualify, which guards against pathologising nonconformity. Criterion C then draws the upper boundary. Conduct disorder can still be diagnosed in an adult, but only where the person, if aged 18 years or older, does not meet the criteria for **antisocial personality disorder**. Once that adult syndrome is established it takes precedence, and conduct disorder is reserved for those who have not crossed into it. The adult disorder itself, and the pathway a proportion of children take toward it, belong respectively to the Personality disorders notes and to a later discussion in this chapter; here the point is only the diagnostic hierarchy that Criterion C encodes.

TRAP **Conduct disorder does not automatically stop at adulthood.** Candidates assume the diagnosis is purely paediatric and expires the moment the patient turns adult, or conversely that every antisocial adult once carried it formally. Criterion C is subtler: in a person aged 18 or older the diagnosis still stands, provided the full criteria for antisocial personality disorder are not met. The exclusion is conditional, not automatic.

2.5 The developmental onset subtypes

When the trouble began matters more than what form it takes. DSM-5-TR requires the clinician to specify the developmental course, because the age of onset is the specifier with the greatest prognostic weight. In the **childhood-onset type**, at least one characteristic symptom of conduct disorder is present before age **10**; it is coded F91.1. In the **adolescent-onset type**, no characteristic symptom is present before age 10, the first appearing only in the teenage years; it is coded F91.2. Where the history is too incomplete to establish which course applies, for instance when the early childhood years cannot be reliably reconstructed, the diagnosis is left as unspecified onset, coded F91.9. The division looks administrative, but it is anything but: it sorts children who can look broadly similar at presentation into groups whose correlates and outlook differ sharply, which the next section takes up.

2.6 Why onset age matters: the clinical correlates

Early onset marks the more severe and more persistent illness. The reason the subtypes are worth specifying is that they carry different clinical company and different trajectories. The childhood-onset form is the more ominous. Such children are usually male, their peer relationships are frequently disturbed, and their conduct problems are often preceded in the earlier years by **oppositional defiant disorder**. They tend to show more aggression, and they frequently carry a concurrent attention-deficit/hyperactivity disorder, the assessment and treatment of which belong to the ADHD and specific learning/communication disorders notes. Crucially, the childhood-onset form is the one more likely to persist into adult life, which is why it, and not the adolescent-onset form, is the subtype that carries the recognised risk of an antisocial adult outcome. The adolescent-onset form, by contrast, tends to arise against a background of more normative peer relationships and is more often a reaction to the pressures and affiliations of adolescence than the expression of a long-standing trait. That contrast is the clinical heart of the distinction: conduct that is present from early childhood tends to reflect a more pervasive and enduring vulnerability, whereas conduct that emerges only in adolescence is

more often tied to a particular developmental phase and its social affiliations, and is correspondingly more likely to remit as that phase passes. Onset of the disorder is rare after age 16. A further high-risk subgroup, marked by the callous-unemotional presentation captured in the limited prosocial emotions specifier, is developed in its own right elsewhere in this chapter.

FEATURE	CHILDHOOD-ONSET	ADOLESCENT-ONSET
First symptom	Before age 10	Not before age 10
Peer relationships	Often disturbed	More often normative
Aggression	More prominent	Comparatively less
Course into adulthood	More likely to persist	More likely to remit

The onset subtypes set against the correlates that give the childhood-onset form its worse outlook; the adolescent-onset column is defined chiefly by the absence of early symptoms and by more normative peer relationships.

2.7 Grading the disorder: the severity specifier

The diagnosis is incomplete until it is graded. DSM-5-TR asks for a rating of **current severity** as mild, moderate, or severe. The grade reflects the number of conduct problems present beyond the minimum needed to make the diagnosis, together with how much harm those problems do to others. A young person who just clears the threshold, with problems that are minor and cause limited harm, sits at the mild end; one with many problems, or with conduct that inflicts considerable harm, sits at the severe end. Severity is rated independently of onset, so either developmental subtype can present in mild, moderate, or severe form. The grade is not cosmetic. It summarises the current burden and travels with the young person into every service and record that follows, shaping the urgency and intensity of the response.

> **GOOD TO REMEMBER**
>
> Always assign the severity, and treat it as clinical information rather than a formality. A mild adolescent-onset case and a severe childhood-onset case share a diagnostic label but are different clinical problems with different outlooks, and the grade you record is often the single most useful line in the entry for whoever reads it next.

2.8 The nearest neighbours: oppositional defiant disorder and normal limits

Most diagnostic errors cluster at the borders of the diagnosis. The first border is with oppositional defiant disorder. The two share defiance, anger, and a tendency to blame others, and childhood-onset conduct disorder is frequently preceded by it, but they part on a single decisive line: oppositional defiant disorder does not involve the violation of the basic rights of others or of major societal norms that defines conduct disorder. Argumentative, spiteful, and rule-refusing behaviour that stops short of aggression, destruction, deceit, and serious rule-breaking is the lesser diagnosis, which is developed in its own right elsewhere in this chapter. The second border is with ordinary development. Rule-testing, occasional lying, the odd fight, and adolescent risk-taking are common and usually self-limiting, and what counts as expected at a given age belongs to the Normal child development and milestones notes. The diagnosis is reserved for the persistent, impairing, rights-violating pattern, and not for any one behaviour taken alone.

- a single serious act, however grave, does not meet the pattern requirement;
- defiance and argumentativeness without violation of others' rights point toward oppositional defiant disorder, not conduct disorder;
- transient, situational rule-testing that fits the child's developmental stage is not a disorder;
- the behaviour must cause clinically significant impairment before it counts at all.

PITFALL

The commonest clinical error is over-reach: attaching the label to a defiant, delinquent, or simply hard-to-manage adolescent because the behaviour alarms the adults around them, rather than because a persistent pattern of rights-violating conduct has actually been established over time. A chaotic or depriving environment can generate rule-breaking that is adaptive to its setting; the diagnosis asks for a pattern in the young person's conduct, not a verdict on their circumstances.

2.9 The ICD-11 counterpart and how it differs

The manual that governs most Indian practice draws the same disorder with a different rule.

In ICD-11 the entity is **conduct-dissocial disorder**, coded 6C91. Its required feature is the same repetitive and persistent pattern of behaviour violating the basic rights of others or major age-appropriate social or cultural norms, sustained and recurrent over an extended period, for example 1 year or more, and it states explicitly that the mere commission of isolated delinquent acts is not sufficient. The behaviours fall into the same four groupings. The material difference is at the threshold: ICD-11 sets no fixed symptom count of the kind DSM-5-TR uses, treating the diagnosis as a clinical judgement about the pattern rather than a tally against a list. The same developmental split is preserved, as childhood onset (6C91.0, with one or more features before age 10) against adolescent onset (6C91.1, with none before that age).

AXIS	DSM-5-TR	ICD-11 (CONDUCT-DISSOCIAL DISORDER)
Symptom threshold	At least three of 15 criteria, with a recency rule	No fixed count; a persistent pattern over an extended period
Behaviour groupings	The same four	The same four
Onset subtypes	Childhood (F91.1) and adolescent (F91.2)	Childhood (6C91.0) and adolescent (6C91.1)
Diagnostic logic	Operationalised count and timeframe	Clinical judgement of the pattern

The same disorder under the two classifications; the load-bearing difference is that ICD-11 requires a persistent pattern but not a fixed count, which places the weight on documented clinical judgement.

IN INDIA

Because Indian services classify under ICD, the operative label in most case files, referrals, and official reports is conduct-dissocial disorder rather than the DSM term. The absence of a fixed symptom count is not a licence for looseness: it puts a premium on documenting the pattern, its persistence, and its impact carefully, since the diagnosis rests on the clinician's recorded reasoning rather than on a number that can be checked off. Where a young person's conduct intersects with the law, the juvenile-justice framework is taken up separately in this chapter, and the wider machinery of child protection and services in the Child psychiatry: assessment, treatment, services and protection notes.

3 · Limited prosocial emotions specifier (callous-unemotional traits)

The specifier answers a different question from the diagnosis itself. The diagnosis of conduct disorder tells you that a young person repeatedly violates the rights of others or the major rules of society; it says nothing about the emotional machinery driving that behaviour. The **limited prosocial emotions** specifier, the formal home of what the developmental literature calls **callous-unemotional traits**, is the manual's attempt to mark out the subgroup whose conduct problems are accompanied by a genuine deficit in the affective and interpersonal capacities that normally restrain antisocial behaviour. Marks accrue here because this is a high-yield discrimination that examiners love: the same headline behaviour, delinquency and aggression, can sit on top of two very different internal pictures, and the presence of this specifier changes what the clinician expects of severity, of persistence, and of response to the usual behavioural treatments.

This topic owns the specifier: its defining logic, its threshold, its four constituent features, the assessment demands it imposes, and the way it maps onto the international classification differently from the American one. The conduct disorder criteria and the onset subtypes, the wider etiology in which callous-unemotional traits sit as one developmental pathway, and the trajectory into adult antisocial outcomes for which these traits are a recognised predictor are each developed in their own right elsewhere in this chapter. Here they are named where the argument needs them, not reopened.

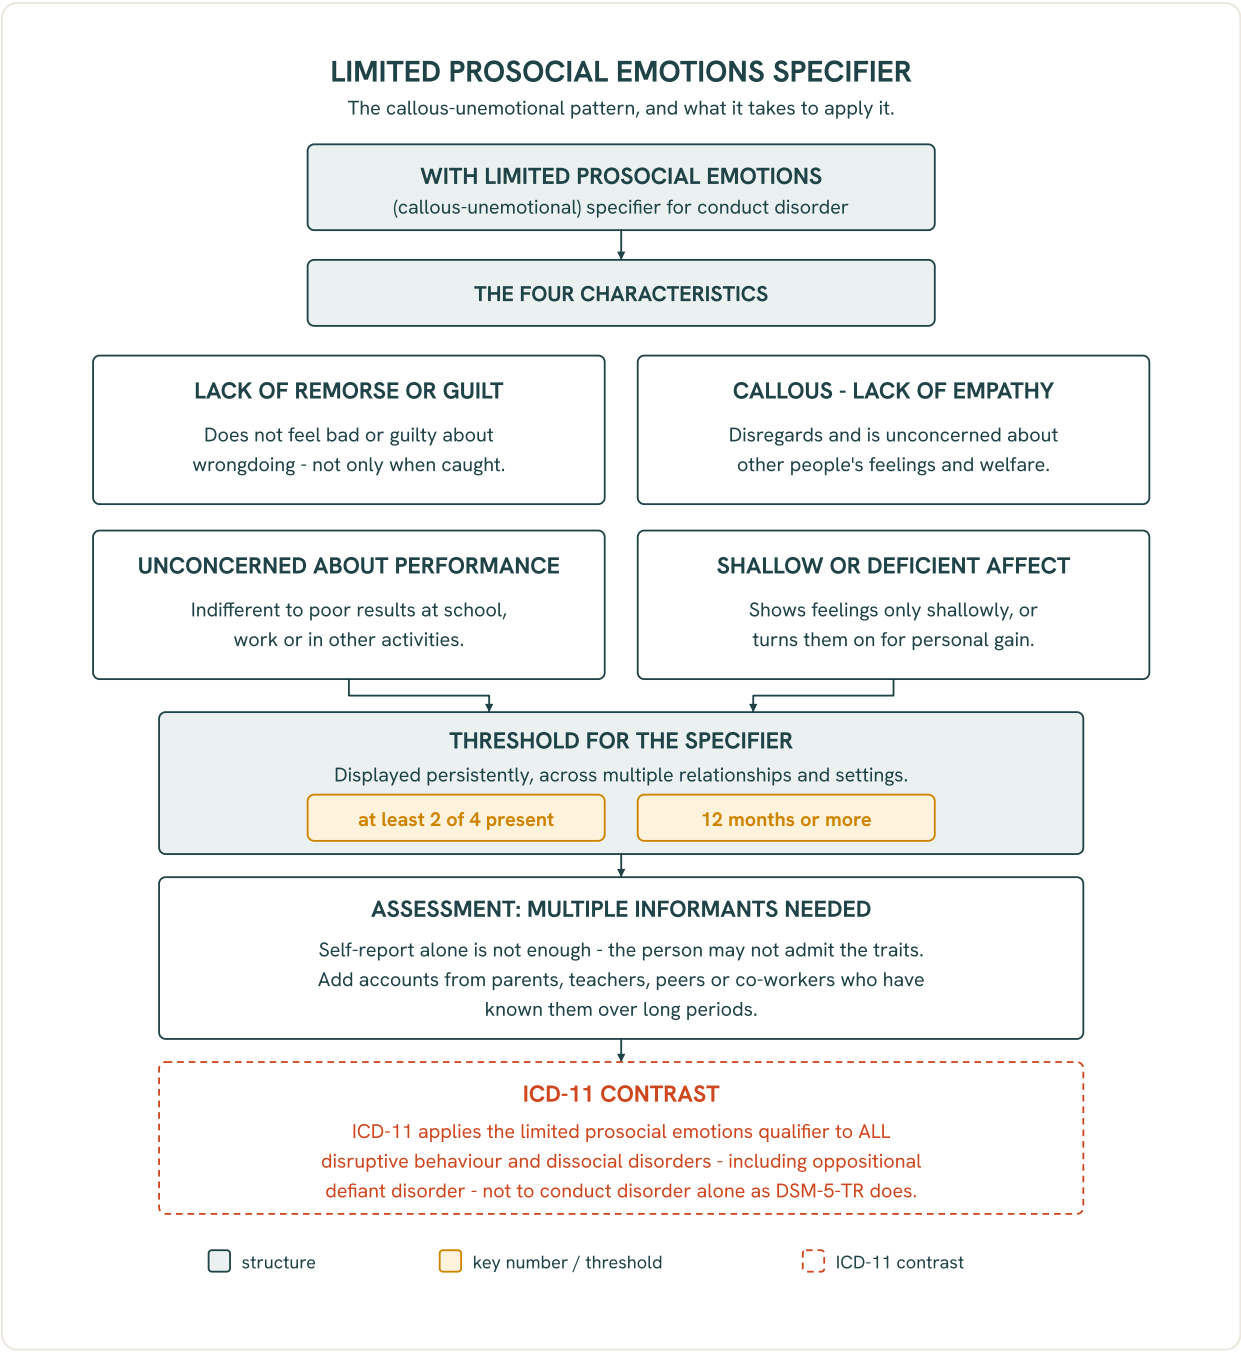

Fig 23.3. Limited prosocial emotions specifier: the callous-unemotional pattern for conduct disorder, its four characteristics, the threshold to apply it, and the ICD-11 contrast.

3.1 What the specifier marks, and why it is not the same as severe conduct disorder

It grades the emotional style of the behaviour, not its quantity. The commonest conceptual error is to treat this specifier as simply the top end of a severity scale, so that the most violent or most prolific offender automatically earns it. That is wrong, and understanding why is the whole point of the topic. Severity in conduct disorder counts how many behaviours are present and how much harm they do; the specifier instead asks about the affective-interpersonal quality that underlies the behaviour, the presence or absence of guilt, empathy, concern and genuine feeling. A frightened, reactive adolescent whose aggression is impulsive and who feels real remorse afterwards may carry a severe rating and still fall well short of the specifier. Conversely, a young person whose offending is more calculated and less florid may show exactly the cold, unemotional style the specifier captures. The two axes are orthogonal: one measures how much, the other

measures of what kind. Reading the specifier as a synonym for "worst" collapses that distinction and loses the clinical information the manual was trying to preserve.

RULE **The specifier describes the affective style of the conduct problem, not its magnitude.** It is applied on the presence of a callous, guilt-poor, empathy-poor interpersonal pattern, independently of how many symptoms or how much harm the severity rating records. A severe case need not qualify; a qualifying case need not be the most severe.

3.2 The threshold: a stable pattern, not an occasional coldness

Two of four features, sustained over time and across relationships. To apply the specifier the clinician must establish that the young person has displayed **at least two** of the **four** defining characteristics, and the qualifying words do more work than the count. The features must have been present persistently, over a period of **12 months** or more, and they must show themselves in multiple relationships and settings rather than in one strained situation. This is a deliberate guard against over-diagnosis. Every adolescent is capable of a cold, dismissive moment, particularly toward an adult they are in conflict with; what the specifier is reaching for is a typical way of relating and feeling, a trait rather than a state. Requiring the pattern across settings and informants means the clinician is describing how this young person characteristically operates in the world, and not simply how they presented in a single tense encounter. The threshold is low in number and high in stringency of pattern, and that combination is exactly what the examiner wants you to be able to state.

> The must-memorise threshold: at least two of the four features, present persistently for at least 12 months and shown across multiple relationships and settings, so that a typical pattern and not an occasional occurrence is being described.

3.3 The four features

Each feature names a specific missing capacity. The four characteristics are not interchangeable synonyms for coldness; each points at a distinct deficit, and being able to name and illustrate all four is standard examination fare. The first is a **lack of remorse or guilt**, an absence of feeling bad about wrongdoing that is genuine and not merely the sullen regret of having been caught. The second is being **callous, with a lack of empathy**, a disregard for and unconcern about the feelings of others that shows in how the young person treats the people they harm. The third is being **unconcerned about performance** at school, at work or in other activities, where the ordinary drive to do well and the discomfort of doing badly appear muted. The fourth is a **shallow or deficient affect**, an emotional life that seems thin, or feelings that are expressed only superficially or turned on and off in a way that looks instrumental. Read together they sketch the affective core of what, in the adult, becomes the interpersonal-affective dimension of antisocial pathology.

FEATURE	WHAT IT NAMES	THE DISCRIMINATING MARKER
Lack of remorse or guilt	No genuine bad feeling after wrongdoing	Regret only when caught does NOT count
Callous, lack of empathy	Disregard for others' feelings	Cold toward those they have harmed, not just detached generally
Unconcerned about performance	Muted drive to do well	Poor results provoke little discomfort or effort
Shallow or deficient affect	Thin or instrumental emotional expression	Feelings shown superficially or switched on for gain

The four features set against the marker that separates each from an ordinary adolescent equivalent; the "only when caught" qualifier on remorse is the one most often tested.

MNEMONIC

No Regret, No Feeling-for-others, No Drive, No Depth

The four features as four absences: **No Regret** (lack of remorse or guilt), **No Feeling-for-others** (callous, lack of empathy), **No Drive** (unconcerned about performance), and **No Depth** (shallow or deficient affect). Holding them as a quartet of deficits, rather than one vague idea of coldness, is what lets you demonstrate that at least two are present.

3.4 Assessment: why a single interview cannot make the call

The specifier is the one place where self-report is least trustworthy. There is a structural problem in assessing these traits, and the manual is explicit about it: the very features being sought, low guilt and a willingness to present a self-serving surface, make the young person an unreliable narrator of their own callousness. Some will minimise, some will manage the clinician's impression, and few will volunteer that they do not care about the people they hurt. For this reason the assessment cannot rest on the clinical interview or on self-report alone. It requires information from others who have known the individual over extended periods, and their observations are weighed alongside, and often above, what the young person says of themselves.

- parents and other caregivers, who see the child across the domestic and emotional life a clinic never observes;
- teachers, who see performance, peer conduct and response to correction over months;
- the extended family, peers and, in older adolescents, co-workers, who see the pattern in relationships the clinician has no access to;
- direct observation and history, set against self-report rather than replaced by it.

GOOD TO REMEMBER

Treat a bare clinic interview as insufficient to apply or exclude this specifier. If you cannot corroborate the affective pattern with someone who has watched the young person over time and in more than one setting, the honest position is that the specifier is not yet established, not that it is absent. Building the multi-informant picture into the assessment from the start saves you from a judgement the data cannot support.

3.5 Who qualifies, and why it matters for the outlook

The specifier identifies a smaller, harder subgroup. Only a minority of young people with conduct disorder meet the threshold for limited prosocial emotions, and those who do are not a random slice of the diagnosis. The specifier is more likely to be present in the childhood-onset presentation and in cases carrying a severe severity rating, which is to say it concentrates in exactly the group whose conduct problems are already the most entrenched. This is why it earns its place clinically rather than merely descriptively. Callous-unemotional traits function as one developmental pathway into persistent antisocial behaviour, and as a recognised predictor of the poorer long-term trajectory, both of which are developed where this chapter takes up etiology and prognosis. The traits also colour treatment expectations: interventions that lean on the child's attunement to others' distress and on a wish to please have less to work with when empathy and the drive to perform are precisely what is thinned, which is one reason the management of these cases is harder and the response often more limited. None of that lowers the therapeutic obligation; it sharpens what the clinician must plan for.

3.6 Where the two classifications part: scope of the qualifier

A material difference the Indian candidate must hold. The American manual attaches the limited prosocial emotions specifier to conduct disorder alone. The international classification takes a wider view: its equivalent **with limited prosocial emotions** qualifier may be applied across the whole grouping of disruptive behaviour and dissocial disorders, and in particular it may be applied to oppositional defiant disorder (**6C90**) as well as to conduct-dissocial disorder. This is not a cosmetic wording change. It reflects a genuine difference of view about where the callous-unemotional dimension belongs: as a modifier reserved for the full conduct syndrome, or as a cross-cutting affective specifier that can qualify the milder oppositional presentation too. For an examination governed by the international system, being able to state that the qualifier reaches oppositional defiant disorder in that scheme, and does not in the American one, is the discrimination that is actually asked.

AXIS	DSM-5-TR	ICD-11
Name of the marker	Specifier: with limited prosocial emotions	Qualifier: with limited prosocial emotions
Where it may be applied	Conduct disorder only	All disruptive behaviour and dissocial disorders
Reaches oppositional defiance?	No	Yes, including oppositional defiant disorder (6C90)

The same affective construct, differently scoped; the load-bearing contrast is that the international scheme lets the qualifier modify oppositional defiant disorder while the American one confines it to conduct disorder.

IN INDIA

Because Indian services classify under the international system, the operative form in case files and reports is the qualifier that may sit on any disorder in the disruptive-behaviour grouping, not the conduct-disorder-only specifier of the American manual. In practice this means the callous-unemotional pattern should be actively considered, and documented, even in a young person carrying only an oppositional defiant diagnosis, and not held back until the full conduct syndrome is reached. The wider scope is a prompt to look for the affective deficit earlier, which fits the pathway on which these traits are known to precede the more entrenched picture.

3.7 The traps and the near misses

Most errors here are errors of over-attribution or of mistaken equivalence. Three confusions recur. The first is reading regret-on-being-caught as remorse; the specifier explicitly requires that the absence of guilt be genuine, so contrition that appears only once consequences arrive counts toward the feature, not against it. The second is equating the specifier with a formal adult diagnosis: callous-unemotional traits in a child foreshadow, but are not the same as, the interpersonal-affective dimension of the adult antisocial personality, which is taken up in the Personality disorders notes, and applying an adult label to a child on the strength of these traits is a category error. The third is confining the assessment to the consulting room, where the young person controls the impression and the traits are least likely to declare themselves.

TRAP **Remorse only when caught is not remorse.** Candidates count a display of regret after discovery as evidence against the lack-of-guilt feature, and mark the specifier absent. The criterion is the opposite way round: guilt that surfaces only once the young person is caught does not rescue them from the feature, because the feature is about the absence of genuine, unprompted bad feeling about the wrongdoing itself.

PITFALL

A quieter clinical error is diagnosing the callous-unemotional pattern from a single hostile interview, in which a frightened or defended adolescent presents as flat and indifferent because that is how they cope with the encounter, not because it is how they characteristically feel. Detachment produced by the assessment situation is not the trait the specifier names, and treating one guarded meeting as sufficient evidence is how the label gets over-applied to children who do not warrant it.

4 · Etiology and risk factors of conduct disorder

There is no single cause, and the examinable skill is holding several at once. The causes of conduct disorder are asked about precisely because a candidate who reaches for one explanation -

bad parenting, bad genes, bad company - has already failed. The disorder is the end-point of a developmental system in which an inherited liability, a temperament, a family, a peer group and a neighbourhood act on one another over years, and no term in that chain is sufficient on its own. What earns the marks is the ability to name the contributors at each level, to say how they combine rather than merely coexist, and to keep the honest uncertainty that the evidence itself carries: much of what is measured is a correlate of the disorder, not a proven cause of it.

This topic owns the etiology and the risk factors: the heritable liability and what is actually transmitted, the gene-environment interplay, the temperamental and neurocognitive substrate, the family and social adversities, the self-amplifying family process, the two developmental trajectories, the callous-unemotional route, and the neurobiological correlates. The diagnostic criteria and the onset subtypes belong to the definition of the disorder and are developed in their own right elsewhere in this chapter; the callous-unemotional specifier and its features have their own section; the trajectory into adult antisocial personality disorder, and the treatments that follow from these causes, are each taken up separately. Here those are named where the causal story demands them, not reopened.

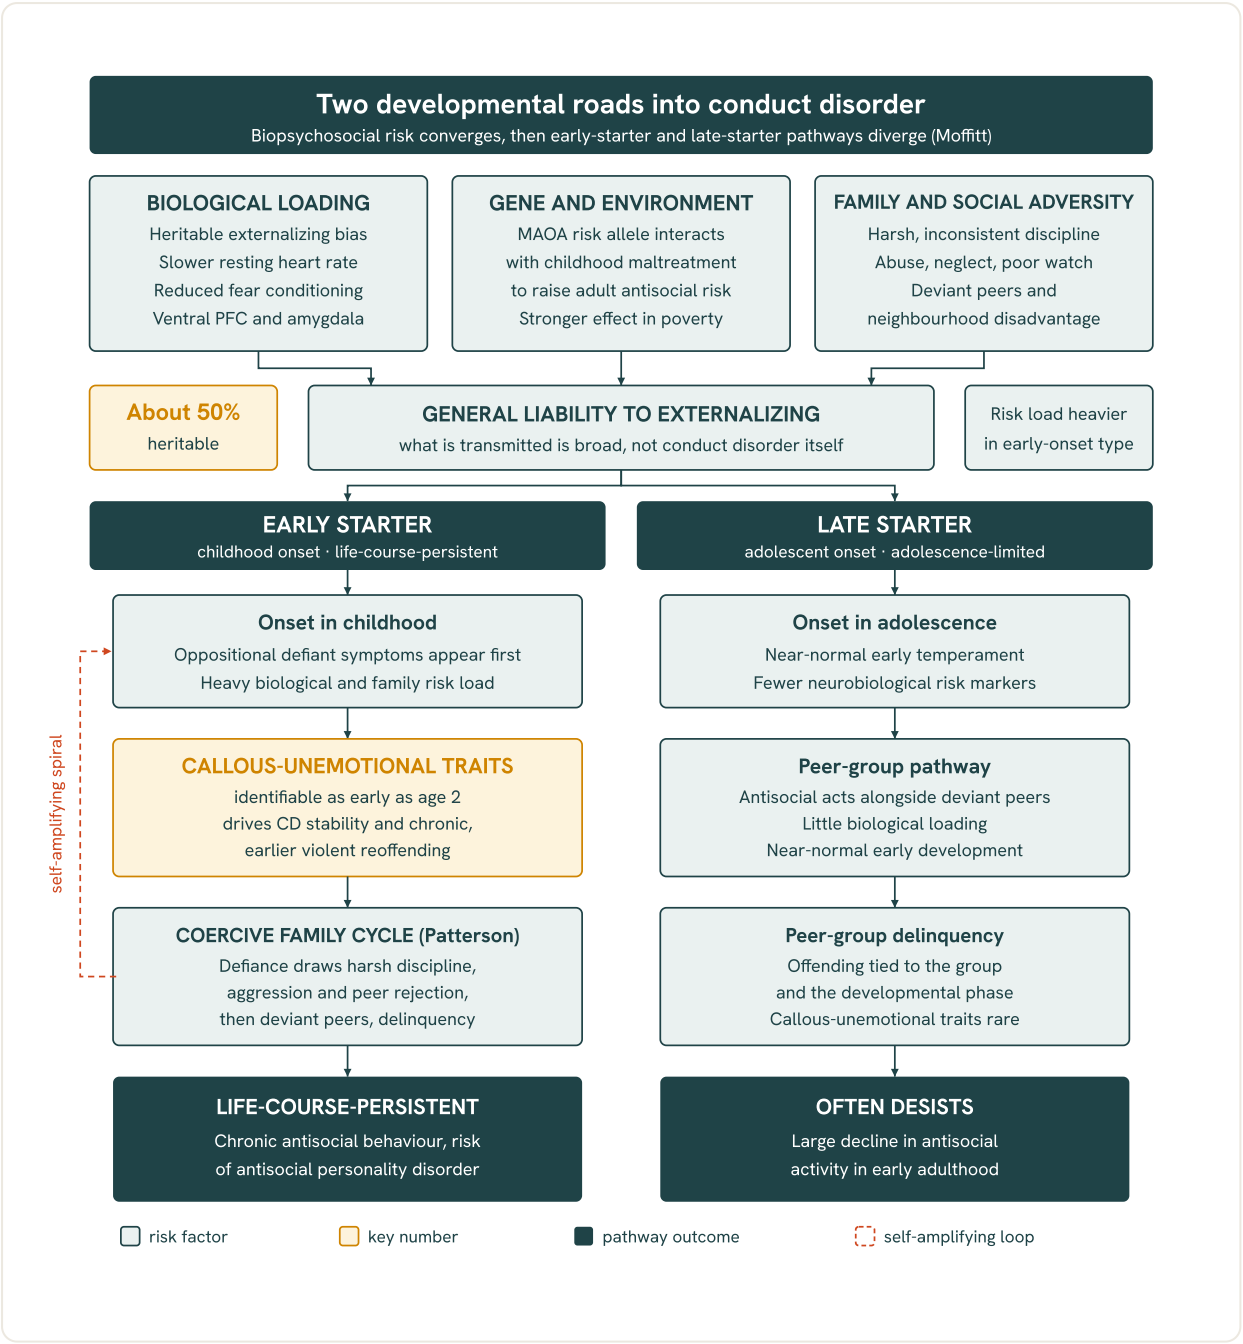

Fig 23.4. Developmental pathway to conduct disorder: biopsychosocial risk converges on a general externalizing liability, then diverges into an early-starter, life-course-persistent road and a late-starter, adolescence-limited road.

4.1 Etiology as a system, not a cause

The right frame is a developmental cascade, not a checklist of causes. Conduct disorder is best understood as the visible result of risk accumulating and compounding across development. A vulnerability present early, whether constitutional or temperamental, shapes how the child acts on the world; those actions shape how caregivers, teachers and peers respond; and those responses feed back to entrench or to soften the original vulnerability. The same starting liability can therefore end in very different places depending on what the environment does with it, which is why identical twins are discordant and why prevention is possible at all. This is not a soft statement that everything matters. It is the specific claim that the causes are probabilistic and interactive, so that any single factor raises risk without determining outcome, and the clinician's job is to read where in the cascade a given child sits and which links are still movable.

RULE **Conduct disorder has no single cause; it is the outcome of interacting risks across development.** Genetic liability, temperament, family process, peers and community each raise probability without any one being sufficient or necessary, so an etiological formulation names contributors at every level and, more importantly, says how they combine. A candidate who offers one cause has answered a different question.

4.2 The heritable liability, and what is actually inherited

Antisocial behaviour is substantially heritable, but heritability is not diagnosis-specific. Twin and adoption studies put the **heritability** of the antisocial behaviour underlying conduct disorder at **about 50%**, which sounds like a strong genetic case until the second half of the finding is added. What appears to be transmitted is not conduct disorder as a discrete entity but a broad, general liability to the externalizing disorders as a family, the shared disposition that also surfaces as oppositional behaviour, attention-deficit/hyperactivity disorder and, later, substance use and antisocial personality. The specifically conduct-disordered shape of that liability is contributed largely by the shared environment rather than by genes. This is why the same familial loading can express as several different externalizing outcomes in different children, and why a family history is a risk marker for the class of problems rather than a prediction of this one diagnosis. Reading heritability as if a gene for conduct disorder were being passed down is the commonest way to misuse the number.

> Carry this as the spine of the genetics: heritability of the underlying antisocial behaviour is about 50%, but what is inherited is a general liability to externalizing disorders, with the shared environment shaping it specifically into conduct disorder.

4.3 Genes and environment interact, they do not merely add

The genome sets a reactivity to experience, not a fixed destiny. The most instructive genetic findings in this field are not main effects of any gene but interactions in which a genotype changes how strongly an environmental adversity bites. The classic example concerns an allele of the **monoamine oxidase A (MAOA)** gene, which was found to raise the risk of adult antisocial behaviour specifically among individuals who had experienced childhood adversity, while carrying little consequence for those who had not. The gene did not code for antisociality; it conditioned the impact of maltreatment. The same logic appears at the population level, where genetic influences on problem behaviour are stronger in children growing up in poor families than in affluent ones - adversity does not swamp the genes, it unmasks them. For the exam this reframes the whole nature-nurture question: the two are not competing percentages to be apportioned but partners whose product is what matters, and an intervention that changes the environment can blunt a genetic risk that would otherwise have been expressed.

IN INDIA

The environmental half of that interaction is not evenly distributed. Overcrowding, large family size, harsh corporal discipline as an accepted norm, parental alcohol use, disrupted or absent caregiving and periods of institutional living are all more prevalent in the settings many Indian children grow up in, and the gene-environment finding implies that an identical inherited liability will be expressed more readily where such adversity is dense. The practical reading is optimistic rather than fatalistic: because so much of the operative risk is environmental and modifiable, the leverage sits in the family and the neighbourhood, and the wider machinery of child protection and welfare services relevant to these children is taken up in the Child psychiatry: assessment, treatment, services and protection notes.

4.4 Temperament and the neurocognitive substrate

The child brings something to the interaction from the start. Long before any conduct problem is diagnosable, some children show a temperament that raises risk: a **difficult, undercontrolled** infant style, marked by high negative emotionality, poor regulation of arousal and low behavioural inhibition, is one of the earliest measurable contributors. Alongside it sits a neurocognitive profile in which lower verbal IQ is characteristic - a relative weakness in language and verbal reasoning that impairs the capacity to talk problems down, to represent consequences in words, and to profit from purely verbal correction. What separates such a temperament from ordinary difficultness, and what counts as within the normal range of infant reactivity, belongs to the Normal child development and milestones notes; the point here is that these constitutional features are not the disorder but a soil in which it grows more easily. A hard-to-soothe, verbally weaker child evokes harsher and less consistent handling, does worse at school, and is more readily pushed toward the aggressive and rule-breaking solutions that the later diagnosis is built from. Temperament is thus both a direct risk and, more importantly, the child's opening move in the cascade that follows.

PITFALL

The clinical error here is to collapse into one side of the causal story. A family in crisis invites the verdict that the conduct is simply a product of bad parenting, which erases the child's heritable and temperamental contribution and the way a difficult child shapes the adults around them; the opposite error reads a slow-to-soothe, verbally weak child as constitutionally destined and quietly abandons the family work that is the most modifiable link in the chain. Both are reductions. The formulation has to hold the child's disposition and the family's response as reciprocal, because that is where the intervention actually acts.

4.5 Family and social adversity

The environmental risk factors are the densest and, mercifully, the most modifiable. The evidence identifies a consistent cluster of family-level adversities that raise the risk of conduct disorder and, importantly, are more common and more severe in the earlier-onset presentation. They are worth knowing as a family rather than as isolated items, because they tend to travel together and to reinforce one another.

- parental rejection and neglect, and inconsistent, unpredictable child-rearing;
- harsh or erratic discipline, and physical or sexual abuse;
- lack of supervision and monitoring of the child's whereabouts and company;
- early institutional living and frequent changes of caregiver, disrupting stable attachment;
- large family size and parental criminality in the home.

Beyond the household sit the community-level factors, which take over as the child moves outward into the social world: peer rejection in the early school years, subsequent affiliation with a delinquent peer group, neighbourhood disadvantage, and exposure to violence in the surrounding environment. The developmental sequence matters as much as the list: family adversity dominates the early years and peer and neighbourhood factors gather force through middle childhood and adolescence, which is why the same risk factors carry different weight at different ages.

DOMAIN	REPRESENTATIVE FACTORS	CLINICAL LEVERAGE
Temperamental / neurocognitive	Difficult undercontrolled temperament; lower verbal IQ	Largely fixed; guides how, not whether, to intervene
Family	Rejection, neglect, harsh or inconsistent discipline, abuse, poor supervision, caregiver instability, parental criminality	The most modifiable link; target of parenting work
Community	Peer rejection, delinquent peer group, neighbourhood disadvantage, exposure to violence	Partly modifiable; the focus of wider system work

The risk factors sorted by level and by how much the clinician can move them; the family row carries the most leverage, which is why the treatments that follow are built around it.

4.6 The coercive family process

Risk is not only a set of factors but a self-amplifying process between child and parent. The single most useful mechanistic model of how disruptive behaviour is built and maintained is the **coercive** family process described by Patterson. Its power is that it is dynamic rather than static: early defiance in the child provokes harsh and inconsistent discipline from the parent, which breeds further aggressiveness and, at school, peer rejection; the rejected, aggressive child then drifts toward association with deviant peers, and from there into antisocial acts, substance use and conflict with the law. Each step is both a consequence of the last and a cause of the next, so the chain tightens on itself over time. This model is not academic. It explains the observed dose-response relationship, in which the higher the number and variety of disruptive behaviours a child shows, the worse the adult outcome, because a busier, broader early pattern feeds a faster-turning coercive loop. It is also the explicit rationale for parent management training, the intervention that tries to interrupt the cycle at the parent-child step, whose detail belongs to the treatment section of this chapter.

MNEMONIC

Defiance draws discipline, discipline drives deviance

The coercive loop in three beats: a child's early **defiance** pulls harsh, inconsistent **discipline** from an overwhelmed parent, which breeds aggression and peer rejection and pushes the child toward **deviant** peers, antisocial acts and trouble with the law. Holding the loop as a cycle rather than a list is what makes the point that it can be interrupted.

GOOD TO REMEMBER

The etiology is not just background - it prescribes the treatment. Because so much of the operative risk lives in a modifiable family process rather than in fixed constitution, the first-line response to a young child with conduct problems works on the parent-child interaction, not on the child in isolation. When a formulation names the coercive cycle, it has already named where the intervention must act.

4.7 Two developmental trajectories

The same behaviour can sit on two very different developmental paths. One of the most robust organizing ideas in the field is Moffitt's distinction between a **life-course-persistent** path and a desisting, **adolescence-limited** one. The life-course-persistent group carries the heavier causal load: it is predicted by early onset, with oppositional defiant symptoms typically appearing first, by greater severity of the conduct problems, and by dense exposure to the risk factors already described. Its antisocial behaviour begins early, runs on across development, and is the pattern that carries forward. The adolescence-limited group looks similar at the peak but has a different origin and a different fate - it arises against a more normative background, is more a phenomenon of the adolescent phase and its affiliations, and desists. Consistent with this, a large decline in delinquent and antisocial activity is commonly seen as young people move into early adulthood, which reflects the adolescence-limited majority ageing out rather than everyone improving. Distinguishing the two prospectively is imperfect, but the predictors of persistence - early onset, severity, and the weight of accumulated risk - are exactly what the etiological assessment is trying to read.

AXIS	LIFE-COURSE-PERSISTENT	ADOLESCENCE-LIMITED
Onset	Early, oppositional symptoms first	In adolescence
Predicted by	Early onset, severity, dense risk exposure	Adolescent phase and peer affiliation
Background	Heavy constitutional and family risk	More normative
Course	Persists across the life course	Desists, with a large decline in early adulthood

The two pathways set side by side; the load-bearing difference is that early onset, severity and accumulated risk mark the persistent path, while the adolescence-limited majority accounts for the marked decline in antisocial activity in early adulthood.

4.8 The callous-unemotional pathway

A distinct early route runs through low affective empathy rather than through adversity. Not every child on the persistent path arrives there by the coercive, adversity-driven route. A separable developmental pathway runs through **callous-unemotional traits** - a style of low empathy, shallow affect and limited guilt that can be identified as early as **2 years of age** and appears to be largely responsible for the stability of conduct disorder in the children who show it. This pathway is more heritable and less obviously a product of harsh parenting than the coercive route, which is part of why it is worth separating out: adolescents with these traits are at higher risk of earlier and more chronic violent reoffending, so the pathway carries real prognostic weight. The trait cluster is formalised as a diagnostic specifier with defined features, which are taught in their own section of this chapter; the etiological point here is only that it names a second, affect-based road into persistent conduct disorder that sits alongside, and can combine with, the adversity-and-process road of the earlier subtopics.

4.9 Neurobiological and psychophysiological correlates

There are reproducible biological markers, and the trap is to over-read them. Several biological findings recur reliably in conduct disorder. The most striking is autonomic: a **slower resting heart rate** has been found consistently and is notable for not being characteristic of any other mental disorder, which makes it the field's most specific psychophysiological signature. Alongside it, reduced autonomic fear conditioning - indexed by low skin conductance responses - is well documented, fitting a picture of blunted responsiveness to cues of threat and punishment that would ordinarily restrain rule-breaking. Structural and functional neuroimaging points to differences in the ventral prefrontal cortex and the amygdala, regions central to the appraisal of emotion, threat and reward and to the inhibition of prepotent responses. These findings cohere into a plausible account of a nervous system that is under-aroused and under-deterred, and they matter for understanding mechanism. What they are not is diagnostic: none of them is sensitive or specific enough to identify the disorder in an individual, and they belong to the explanation of conduct disorder, not to its detection.

TRAP **The biological markers explain, they do not diagnose.** Candidates recite the slow resting heart rate, the low skin conductance and the ventral-prefrontal and amygdala findings as though they confirmed the disorder. They are group-level correlates, robust in the aggregate but neither sensitive nor specific in the individual; the diagnosis remains clinical, and presenting any of these as a diagnostic test is the error the examiner is watching for.

5 · Assessment and clinical evaluation of conduct disorder

A conduct disorder assessment is won or lost on where the information comes from, not on how the child behaves in the room. Assessing **conduct disorder** is a distinct clinical skill, separate from knowing the criteria, because the young person in front of you is the one

informant with the least incentive to describe the problem accurately. Children and adolescents with conduct disorder characteristically minimise their conduct problems, so a clinician who takes the interview with the child as the primary evidence base will systematically underestimate the disorder. The whole method is built to correct for that: it draws on several informants who each see the young person in a different setting, it treats disagreement between them as informative rather than as noise, and it anticipates that the young person, and sometimes the family, will not cooperate freely.

The marks here reward candidates who can describe a defensible process rather than recite a checklist. This topic owns the evaluation method: how a reliable diagnosis is assembled from multiple sources, how the purpose of the referral changes the way the assessment is conducted, what history domains and functional understanding must be covered, and the standardised instruments that quantify and track the picture. The diagnostic criteria and subtypes, the callous-unemotional specifier, the causes and risk factors, the treatments, and the long-term trajectory are each developed in their own right elsewhere in this chapter and are named here only where the assessment reaches for them.

5.1 The purpose of the referral shapes the whole assessment

Ask first who wants this assessment and why. Conduct disorder is unusual among child psychiatric presentations in how often the request originates outside the family. An evaluation may be requested by **parents, schools, courts, children's lawyers or social services**, and each of those origins carries a different question, a different standard of proof, and a different limit on confidentiality. A parent asking why their child is unmanageable wants a clinical formulation and a plan. A court or a child's lawyer wants an opinion that may be tested adversarially and disclosed, which changes what you can promise the young person about privacy before you begin. Establishing the purpose at the outset is therefore not a courtesy but a structural decision: it determines who you will speak to, what you will document, what you can keep confidential, and how you frame the evaluation to the child and family. A clinician who begins gathering history without settling this can find that the confidentiality they implied cannot be honoured, or that the assessment they conducted does not answer the question that was actually asked.

IN INDIA

A large share of conduct disorder assessments reach services through schools and through the statutory child-welfare and juvenile-justice route rather than through parents seeking help, which means the confidentiality and consent frame is frequently set by an institution before the child arrives. The psychiatric perspective on juvenile delinquency is taken up separately in this chapter, and the wider machinery of child protection, welfare committees and services sits in the Child psychiatry: assessment, treatment, services and protection notes. The practical lesson for the assessment itself is that the referral source is often a third party with its own agenda, so clarifying whose question you are answering, and what will be shared with whom, is the first task in the room.

5.2 The multi-informant, collateral method

No single informant is sufficient, and the child least of all. The reliable diagnosis of conduct disorder rests on **an evaluation by an experienced clinician drawing on several sources**, typically the child, the parents and the teachers, supplemented by questionnaire data. The reason this is doctrine rather than preference is the informant problem set out at the start: because the young person minimises, the clinician must actively seek out additional informants, and because behaviour is situation-specific, an informant who sees the child in only one setting gives only part of the picture. Parents see the home; teachers see the classroom and the playground; the child alone can report internal states, fears and motives that no observer can access. The skill lies in holding these accounts together. Reports from different informants frequently disagree, and the beginner reads that disagreement as one source being wrong. It is better understood as each source being right about a different context: a child who is compliant at school and defiant at home, or the reverse, is telling you something real about where the behaviour is triggered and maintained. The accounts complement each other precisely because they diverge.

RULE **Diagnose conduct disorder from collateral sources, never from the child's self-report alone.** The young person minimises the very behaviour under evaluation, so an experienced clinician assembles the picture from parents, teachers and the child together, supplemented by questionnaires. Discrepant reports are not a problem to resolve down to one true version; they map where the behaviour is and is not expressed, and that map is itself diagnostic and treatment-relevant.

Expect resistance and plan for it. Because the referral is often involuntary and the behaviour often brings the young person into conflict with authority, noncooperation and resistance are to be expected rather than treated as a complication that derails the assessment. A refusal to engage, a flatly minimising account, or open hostility is part of the presentation, not a failure of the interview, and the collateral method exists so that the evaluation does not collapse when the child will not talk. The experienced assessor builds the diagnosis from what the informants and instruments provide and reads the young person's reluctance as data about the therapeutic task ahead.

5.3 History domains and the functional understanding

Map the behaviour onto its context and its function. A conduct disorder history has to reach well beyond the catalogue of behaviours into the environment that shapes them. The domains that must be explored include **parenting style, the quality of parent-child interactions, inconsistent parenting, maternal depression, parental drug use, and the possibility of sexual abuse**. These are asked about here not to settle causation, which belongs to the discussion of etiology and risk factors elsewhere in this chapter, but because they are the modifiable context in which the behaviour is embedded and because some of them, notably abuse and a depressed or substance-using parent, are urgent findings in their own right. Alongside the content of the history sits its logic. A good assessment builds a **functional understanding** of the behaviour: what antecedents reliably precede it and what consequences follow and maintain it. Reading each problem behaviour as a link in an antecedent-behaviour-consequence chain turns a list of

complaints into an account of why the behaviour persists, and it is this functional account, not the diagnostic label, that points toward what an intervention should target.

PITFALL

The recurring clinical error is to assess the child and skip the context, producing a diagnosis that names the behaviour but explains nothing and guides no treatment. A behaviour that looks like pure defiance often turns out, once the antecedents and consequences are traced, to be maintained by an inconsistent contingency at home or by escape from an intolerable classroom demand. Stopping at the label, without the functional analysis and without probing parenting, parental mental illness and possible maltreatment, both misses treatable maintaining factors and risks leaving a safeguarding concern unaddressed.

5.4 Assessing across all symptom domains: comorbidity

Conduct disorder rarely travels alone, and the comorbidity is often the more treatable half. A competent evaluation deliberately covers all symptom domains so that comorbid disorders are not overlooked, because the conditions that accompany conduct disorder are frequently what respond best to treatment. The three that must be actively screened for are attention-deficit/hyperactivity disorder, mood disorders and substance misuse. The overlap with ADHD is close enough that the two are easily conflated, and its assessment and treatment belong to the ADHD and specific learning/communication disorders notes; the point for the conduct disorder evaluation is simply that it must be looked for rather than assumed absent. A depressive disorder can drive irritability and acting-out that mimics or amplifies conduct problems, and substance misuse both worsens and is worsened by the behaviour. An assessment that stops at conduct disorder because the disruptive behaviour is the loudest presenting feature will miss the disorder that is quietly doing much of the damage and is often more amenable to intervention.

- attention-deficit/hyperactivity disorder, closely overlapping and easily conflated, screened for and cross-referred rather than assumed;
- mood disorders, where irritability and acting-out may be depressive in origin;
- substance misuse, which both aggravates and is aggravated by the conduct problems.

5.5 Standardised rating instruments

Questionnaires quantify and track what the clinical interview establishes. The clinical evaluation is supplemented by structured questionnaires, chief among them the broad-band **Child Behavior Checklist**, together with narrower disruptive-behaviour scales such as the **Eyberg Child Behavior Inventory**, the **New York Teacher Rating Scale for Disruptive and Antisocial Behavior**, and the **Home and School Situations Questionnaire**, the last of which locates where the behaviour occurs. Their value is specific and bounded. Questionnaires provide quantifiable data, reliably supplement the interview, and are useful for measuring progress and outcome over the course of treatment, which is something a narrative interview does poorly. What they do not do is replace the multi-informant clinical evaluation. A score is a number attached to a rater's perception in a setting, and it acquires meaning only when the clinician

integrates it with the rest of the picture. The instruments are the measuring tape, not the diagnosis.

INSTRUMENT	TYPE	WHAT IT ADDS
Child Behavior Checklist	Broad-band	Wide behavioural and emotional coverage across informants
Eyberg Child Behavior Inventory	Disruptive-behaviour	Focused measure of conduct problems and their intensity
New York Teacher Rating Scale	Teacher-report	The classroom view of disruptive and antisocial behaviour
Home and School Situations Questionnaire	Situational	Where the behaviour occurs, across home and school settings

The instruments that supplement the interview, each contributing a different angle; none substitutes for the clinician's integration of the multiple accounts.

TRAP **A high questionnaire score is a screen, not a diagnosis.** Candidates treat a raised Child Behavior Checklist or a positive rating scale as if it made the diagnosis, when the instruments only quantify a rater's perception in one setting and are properly used to supplement the interview and to track outcome. The diagnosis remains the experienced clinician's integration of the collateral accounts; the number measures change, it does not replace judgement.

5.6 The Strengths and Difficulties Questionnaire

The workhorse behavioural screen of child mental health. The single instrument worth knowing in detail is the **Strengths and Difficulties Questionnaire**, developed by **Goodman**. It is a brief behavioural screening questionnaire of **25** items, each rated on three response options - Not True, Somewhat True and Certainly True - which makes it quick enough to use routinely. Its reach is one of its strengths: it is completed by parents and teachers, and by children and adolescents themselves as a self-report, so a single short instrument delivers the multi-informant, multi-setting perspective that the conduct disorder assessment demands. It spans roughly **ages 3 to 17**, is in the public domain, and has been translated into many languages, which is much of why it is so widely used. An optional impact supplement of up to about eight further items extends it beyond symptom counting to ask how much the difficulties actually burden the child and the family, which is often the more clinically decisive question.

5.7 SDQ structure: the five subscales and the Total Difficulties Score

The scoring architecture is examinable and elegant. The aptly named questionnaire carries both a strength scale and difficulty scales. It resolves into **five subscales of five items each**: emotional symptoms, conduct problems, hyperactivity and inattention, peer relationship problems, and prosocial behaviour. Four of these describe difficulties and one, prosocial behaviour, describes a strength, which is what the questionnaire's name announces. The scoring then does something that trips up candidates who assume all five simply add together. A **Total Difficulties Score** is generated by summing only the **four** problem subscales - emotional symptoms, conduct problems, hyperactivity and inattention, and peer relationship problems. The prosocial behaviour subscale is deliberately left out of that total and is scored separately against

its own cut point, because a low level of prosocial behaviour is conceptually a different kind of finding from a high level of difficulty. Keeping the strength scale out of the difficulty total is the design feature that distinguishes the instrument, and it is exactly the point an examiner probes.

MNEMONIC

Five by five, four make the total

Five subscales of **five** items each, and only the **four** problem scales sum to the Total Difficulties Score. The fifth scale, prosocial behaviour, is the strength and stands apart with its own cut point. The phrase fixes both the structure and the one scoring rule most often got wrong.

The must-memorise line: the SDQ Total Difficulties Score sums the four problem subscales only; the prosocial behaviour subscale is scored separately and is not part of the total.

5.8 Interpreting the scores and the banding caution

A screen produces a band, and the band is only as good as the threshold behind it. The subscale and total scores are interpreted by comparison against clinical cut points, and the familiar reporting frame sorts a child into a normal, borderline or abnormal band, with newer versions using a four-way categorisation from close-to-average through to very high. This is where discipline matters. The exact numeric thresholds that separate one band from the next are set by the instrument's own scoring instructions and are revised periodically, and they differ by informant and by version, so they are not something to reproduce from memory in a clinical or examination answer. The safe practice is to state the banding concept and to apply the current published thresholds from the questionnaire's own scoring guidance rather than to quote a boundary you cannot verify. The larger caution is the same one that governs every instrument in this topic: the SDQ, however well banded, is a screening and outcome-tracking tool. It flags children who warrant fuller evaluation and it measures change over time; it does not, on its own, make the diagnosis of conduct disorder, which remains the product of the multi-informant clinical assessment.

GOOD TO REMEMBER

Use the SDQ to open and to follow a case, not to close it. Its brevity, its public-domain availability, its coverage across parents, teachers and the young person, and its impact supplement make it an efficient front door and an honest outcome measure. Record a baseline, treat, and re-administer to show whether the difficulties have actually moved, but let the diagnosis rest on the integrated clinical picture and confirm any band you report against the questionnaire's current thresholds.

6 · Management of conduct disorder (parent training, multisystemic therapy, pharmacotherapy)

The treatment of conduct disorder is where the diagnosis earns its keep, and where the commonest instinct is the wrong one. Faced with an aggressive, rule-breaking young person, the pull toward a sedating prescription is strong, and it is almost always the second move rather than the first. The management of conduct disorder is built on a settled principle: the disorder is a problem of behaviour embedded in relationships and systems, so the treatments that change it are the ones that work on those relationships and systems. Most guidelines concur that structured psychosocial and behavioural interventions are the first line of treatment for the disruptive behaviour disorders, oppositional defiant disorder and conduct disorder alike, and that these interventions continue even where medication is later added. Marks accrue on this topic because it rewards a candidate who can name the right intervention for the right age, explain why it works, and place medication precisely where it belongs, which is at the margin and never at the centre.

This topic owns the management of conduct disorder in full: the treatment hierarchy, parent management training as the core intervention for the younger child, multisystemic and community interventions for the adolescent, and the adjunctive, aggression-directed role of medication with its dosing and monitoring. The diagnostic criteria and subtypes, the callous-unemotional specifier, the causes and risk factors, the assessment, and the long-term trajectory into adult antisocial outcomes are each developed in their own right elsewhere in this chapter and are named here only where the treatment reasoning demands them.

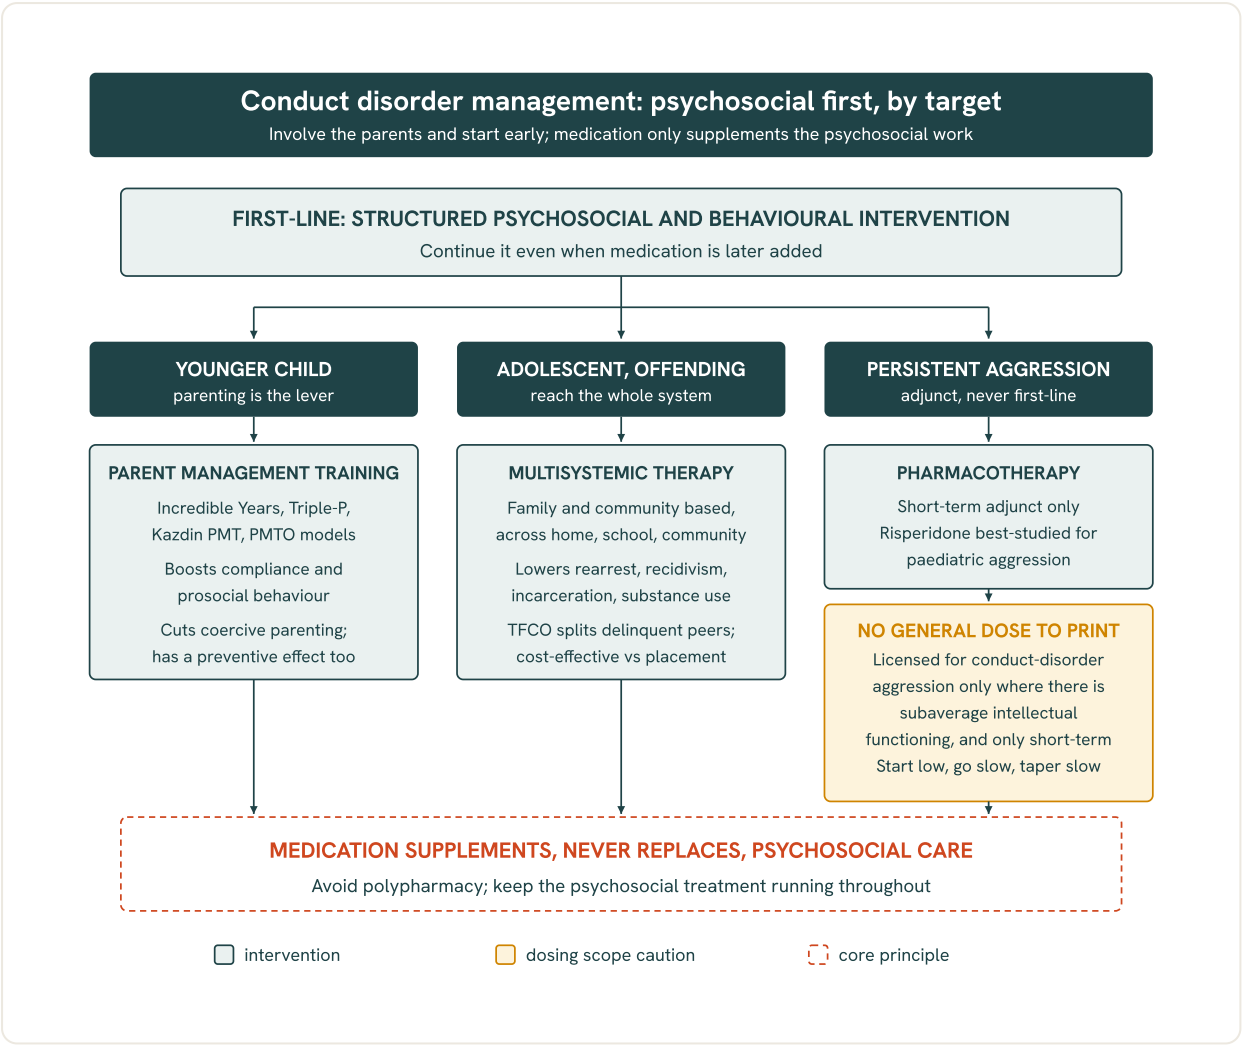

Fig 23.5. Conduct disorder management ladder: psychosocial intervention first, matched to the target - parent training for the younger child, multisystemic therapy for the offending adolescent, and short-term risperidone as an adjunct for persistent aggression. No dose is printed on the plate: the only licensed conduct-disorder dose is restricted to young people with subaverage intellectual functioning, so dosing is scope-bound and is set out in the text.

6.1 The treatment hierarchy: psychosocial first, medication as adjunct

The order of operations is itself examinable. The governing rule is that treatment leads with structured psychosocial and behavioural work and reserves pharmacotherapy for defined targets on top of it. Two features of that rule are easy to lose. The first is that the psychosocial intervention should be continued even if medication is subsequently initiated; the drug does not replace the behavioural programme, and the moment it is treated as a replacement the plan has already failed. The second is that this treatment should involve the parents, because improving parenting skills and the quality of parent-child interactions are core goals rather than incidental ones. There is also a timing effect that shapes prognosis and effort: intervention is more likely to be effective when administered early in the course, before coercive patterns and antisocial affiliations have consolidated. The clinical implication is direct. A young child brought in early is a genuine opportunity; an entrenched adolescent is harder work and the plan must be built accordingly.

RULE **Psychosocial and behavioural intervention is first-line for conduct disorder, and it continues even when medication is added.** Medication is layered onto the behavioural programme for a specific target; it never becomes the programme. An author who leads with a drug has inverted the hierarchy the evidence actually supports, and the earlier the psychosocial work begins, the more it achieves.

Carry this into the exam: for conduct disorder the first-line treatment is a structured, parent-involving psychosocial intervention, delivered early, and medication is a short-term adjunct for aggression, never a substitute for it.

6.2 Parent management training: the core intervention

The single best-evidenced treatment for the younger child works through the parent, not directly on the child. **Parent (behavioural) management training** programmes teach caregivers a set of concrete strategies that increase compliance and prosocial behaviour and reduce oppositional and aggressive behaviour. The logic is behavioural: much of the child's disruptive conduct is being inadvertently maintained by the family's own responses, and the intervention retrains those responses. Parents are coached to give clear, achievable instructions, to attend to and reinforce desirable behaviour, to use consistent and non-escalating consequences, and above all to interrupt the **coercive parenting** pattern in which harsh, inconsistent discipline and child noncompliance drive each other in an escalating loop. The change is achieved indirectly and deliberately so: rather than counselling the child, the clinician equips the parent to alter, session by session, the contingencies that surround the behaviour at home. Positive attention is shifted onto the behaviours the family wants to see, previously reinforcing responses to defiance are withdrawn, and predictable, proportionate consequences replace the cycle of threats that are not carried through. Because the parent is present for far more of the child's day than any clinician can be, a small, consistent change in the parent's response compounds across hundreds of daily interactions, which is why a treatment that never addresses the child directly can move the child's behaviour so reliably. Several programmes are well researched and share this backbone:

- Helping the Noncompliant Child, focused on younger children and instruction-following;
- Incredible Years, a structured video-based parent, child and teacher programme;
- Parent Management Training in the tradition of Kazdin, delivered to the parent as the agent of change;
- Triple-P (the Positive Parenting Programme), delivered across a tiered intensity of contact.

The evidence is not soft, and it is durable. The **Parent Management Training Oregon Model** (PMTO) reduces coercive parenting, and its benefit is measurable long after the sessions end: **nine years** post-intervention it was associated with lower teacher-rated delinquency and reduced arrest rates. Parent training is, on this evidence, an established evidence-based treatment for clinically significant disruptive and externalising behaviour, and it carries a preventive dividend as well, reducing later problems in children at risk rather than only treating those already

diagnosed. That combination, a treatment that both remediates and prevents, is why it sits at the head of the plan for the child in whom parental influence is still the dominant force.

6.3 Multisystemic therapy and the community interventions for the adolescent

When the adolescent's world has widened beyond the family, the intervention has to widen with it. By mid-adolescence the drivers of conduct problems are rarely confined to the home: school failure, delinquent peer groups, and neighbourhood factors all feed the behaviour, and a parent-only programme can no longer reach them. **Multisystemic therapy** is the intensive, family- and community-based intervention designed for exactly this situation, for antisocial behaviour in adolescent juvenile offenders. Its defining feature is that it works simultaneously across home, school and community settings rather than in a clinic room, treating the young person's behaviour as a product of the systems around them and intervening in each. The outcome data are among the strongest in this field: it is associated with decreased rates of rearrest, recidivism, incarceration, psychopathology and substance use. It is also, importantly for a resource-conscious service, a cost-effective alternative to out-of-home placement, keeping the adolescent in their own context while changing it. A related community intervention, **Treatment Foster Care Oregon** (TFCO), takes the complementary approach of placing the young person in a trained, structured foster setting that deliberately separates them from delinquent peers while the family situation is worked on. The peer emphasis is not incidental. Interventions that gather antisocial adolescents together can inadvertently strengthen the very behaviour they aim to reduce, as the group becomes a training ground for deviance and a source of mutual reinforcement, and both the multisystemic model and structured foster care are built to work with or around the peer network rather than to concentrate it. Both share the same premise that the peer group and the wider environment are not background but active ingredients of the disorder, and that an intervention confined to the individual or the clinic will not reach the systems that actually maintain the behaviour.

6.4 Matching the intervention to the developmental stage

The right treatment is a function of who still holds the levers of the child's behaviour. The two psychosocial pillars are not competitors but a developmental sequence. For the younger child, whose behaviour is still shaped chiefly within the family, the parent is the most powerful available lever, and so parent management training is the intervention of choice. For the adolescent, in whom peers, school and neighbourhood have taken on independent force and whose behaviour has often already drawn in the justice system, a family-only approach is necessary but no longer sufficient, and the multisystemic and community models that reach every system become the appropriate frame. This is why age of presentation changes the plan so decisively, and why the early-presenting child carries such a premium: the same effort applied while the family is still the dominant influence buys far more than it will a decade later. None of these interventions is a quick fix. Each asks sustained engagement of an often exhausted and demoralised family, and the clinician's task is to match intensity to the developmental reality rather than to reach reflexively for the most intensive option available.

6.5 The place of medication: adjunctive, aggression-directed, never first-line

There is no drug that treats conduct disorder; there are drugs that help a specific target within it. Medication in the disruptive behaviour disorders is deployed against aggression, and it is deployed as an addition to psychosocial treatment, not as a route around it. Antipsychotic medication for aggression in disruptive behaviour disorders is used as an adjunct in the short term and is never first-line. The framing that matters is that medication supplements, and does not replace, psychosocial treatment, and that polypharmacy should be avoided: a child accumulating agents is usually a child whose behavioural plan has been abandoned rather than one whose illness demands three drugs. Comorbidity is where pharmacotherapy earns a clearer place. Where attention-deficit/hyperactivity disorder coexists, psychostimulants help the oppositional and aggressive symptoms as the underlying ADHD is treated, which is one reason the comorbid picture must be actively sought and managed; the ADHD itself, its stimulant and non-stimulant treatment, belongs to the ADHD and specific learning/communication disorders notes.

TRAP **Treating pharmacotherapy as the primary treatment for conduct disorder.** Candidates reach for the antipsychotic as though it were the answer, because the aggression is the frightening part and a drug feels decisive. It is an adjunct for aggression only, layered onto a psychosocial programme that continues underneath it. Naming a medication before naming parent management training or multisystemic therapy is the inversion the examiner is looking for.

GOOD TO REMEMBER

Actively screen every child presenting with conduct problems for comorbid ADHD, because it is common in this group and it is treatable. Bringing the ADHD under control with a stimulant can reduce the oppositional and aggressive symptoms directly and can change the whole trajectory of the case, whereas leaving it unrecognised leaves a large, remediable driver of the behaviour untouched.

6.6 Risperidone: the best-studied agent, and the narrow scope of its licensed dose

When an antipsychotic is used there is a best-studied choice, a disciplined method, and a licence far narrower than the reflex assumes. Among the atypical antipsychotics, **risperidone** is the best-studied for aggression in paediatric populations, which is why it is the usual agent when the short-term adjunctive step is taken for severe disruptive behaviour and aggression in conduct disorder. What cannot be done is to quote a dose in the abstract, because the only licensed conduct-disorder dose in any labelling this chapter has read is tied both to a jurisdiction and to a population. The United Kingdom, the European Union and Australia license risperidone for the short-term symptomatic treatment of persistent aggression in conduct disorder, in children from five years of age and in adolescents, and only where there is subaverage intellectual functioning; the United States licenses no conduct disorder indication for risperidone at all, its paediatric approvals being schizophrenia, bipolar mania and irritability associated with autistic disorder. The restriction to subaverage intellectual functioning is part of the indication itself and can never be dropped when the dose is quoted.

Within that licensed population the labelled oral regimen is weight-banded and once daily, and it sits far below the antipsychotic doses used for paediatric schizophrenia. For a child under 50 kg the starting dose is **0.25 mg once daily**, increased in steps of 0.25 mg no more often than every other day, to an optimum of 0.5 mg once daily within a licensed range of 0.25 to 0.75 mg once daily. For a young person of 50 kg or more the starting dose is **0.5 mg once daily**, increased in steps of 0.5 mg no more often than every other day, to an optimum of 1 mg once daily within a licensed range of 0.5 to 1.5 mg once daily. The oral solution is the formulation that delivers the 0.25 mg and 0.75 mg doses, which the tablet cannot, and the licensed treatment period is **up to six weeks**, with any continuation evaluated and justified on an ongoing basis. The label itself carries the hierarchy this topic teaches: the drug is to be an integral part of a more comprehensive treatment programme including psychosocial and educational intervention, prescribing is recommended to be by a specialist in child neurology or child and adolescent psychiatry, and physical and social causes of the aggression, such as pain or an inappropriate environmental demand, are to be assessed before any prescription is written. In renal or hepatic impairment the starting and consecutive doses are halved and titration is slower. Risperidone is not recommended below five years of age, where there is no experience.

The gap that remains is the point, not a deficiency in the teaching. Outside that licensed population, which is to say for the young person who has conduct disorder with normal intellectual functioning and who is the subject of this topic, no label this chapter has read supports a risperidone dose; use there is off-label and unlicensed, no number is printed for it here, and the dosing of the antipsychotics themselves belongs to the antipsychotics chapter. Intellectual disability as a construct, and the separate risperidone indication for irritability in autism, are developed in the Intellectual disability and autism spectrum disorder notes; they are named here only because the licence for conduct-disorder aggression happens to be written around the first of them. What survives all of this unchanged is the method. The dose is reached, and later withdrawn, cautiously: begin low, increase gradually, and taper slowly when stopping, with routine monitoring throughout, so that both efficacy and adverse effects are tracked deliberately rather than discovered by accident. Because this is an antipsychotic in a growing child, the monitoring is specific: weight and metabolic parameters, and prolactin, are followed, since weight gain, metabolic disturbance and hyperprolactinaemia are the liabilities that most often force a change of plan.

MNEMONIC

Start low, go slow, taper slow

The dosing discipline for the aggression-directed antipsychotic in a child: **start low** at the bottom of the range, **go slow** in titrating upward against response and tolerability, and **taper slow** rather than stopping abruptly, all under routine monitoring. The phrase encodes the whole safety posture of adjunctive pharmacotherapy in this population.

PITFALL

Starting risperidone and then not monitoring for its metabolic cost. It is easy to prescribe and it does reduce aggression in the short term, so the follow-up drifts and the weight, metabolic indices and prolactin go unchecked. The commonest real-world harm from this agent in children is not treatment failure but unmonitored metabolic and endocrine adverse effects accumulating quietly on a drug that was only ever meant to be a short-term adjunct.

6.7 Assembling the plan, and the Indian reality

A defensible management answer names the whole staged plan, not one favourite piece of it. Put together, the plan begins with a thorough assessment of the young person and the family, leads with the psychosocial intervention matched to developmental stage, treats comorbidity actively, and adds aggression-directed medication only as a short-term adjunct with proper monitoring, keeping the behavioural work running throughout. The accompanying figure sets the modalities against the population each fits, the setting each works in, and the role each plays, and the table below does the same in summary form.

MODALITY	BEST SUITED TO	WORKS ACROSS	ROLE IN THE PLAN
Parent management training	The younger child	The family	First-line; retrains coercive interactions
Multisystemic therapy	The adolescent offender	Home, school and community	First-line for the older youth; a cost-effective alternative to out-of-home placement
Treatment Foster Care Oregon	The adolescent needing placement	A structured foster setting	Separates the young person from delinquent peers
Risperidone and related agents	Marked aggression on top of the above	Added to psychosocial care	Short-term adjunct only; never first-line

The four building blocks of management set against who each fits and what each contributes; the psychosocial rows lead, and the pharmacological row is deliberately last and conditional.

IN INDIA

The evidence base is Western, and the delivery gap is the exam-relevant point. Manualised parent management training programmes and, still more, multisystemic therapy and structured therapeutic foster care are largely unavailable in routine Indian services, which are thinly staffed and family-dependent. In practice the psychosocial first line is often delivered as pragmatic parent guidance, psychoeducation and school liaison built around the same behavioural principles rather than as a branded programme, and much of the work falls to families themselves. The mismatch this creates is a real risk: because an antipsychotic is cheap, quickly available and requires only a prescription, the temptation to lean on medication in place of the harder psychosocial work is greater here than in better-resourced settings, and that is precisely the inversion of the hierarchy the treatment principles warn against. One caution about scope belongs here rather than in a footnote: the licensing positions named above are those of the United Kingdom, the European Union, Australia and the United States, and the Indian labelling position for risperidone in conduct disorder is not stated in these notes because it was not verified for them. A prescriber here should read the current Indian package insert rather than assume that any of those licences transfers, and should not treat the drug's easy availability as evidence that a licence exists. Where conduct problems bring a young person into contact with the law, the child-protection and juvenile-justice machinery is handled in the Child psychiatry: assessment, treatment, services and protection notes.

nine years DURABILITY OF THE PMTO BENEFIT	**six weeks** LICENSED CAP ON ADJUNCTIVE RISPERIDONE, IN THE ONE POPULATION LICENSED FOR IT	**None** CONDUCT DISORDER INDICATION FOR RISPERIDONE IN THE UNITED STATES	**No dose** LICENSED FOR CONDUCT DISORDER WITH NORMAL INTELLECTUAL FUNCTIONING

7 · Prognosis and link to antisocial personality disorder

Prognosis is where conduct disorder stops being a description and becomes a prediction. Having established the diagnosis, its subtypes and its severity, the examiner now wants to know what becomes of these young people, and whether the diagnosis is the childhood face of a life-long antisocial trajectory or a phase that most will grow out of. The honest answer is that both outcomes are common, and the marks lie in being able to say which child is heading which way. The single most consequential fact about the natural history of conduct disorder is that its course is heterogeneous: it is not a uniformly grim sentence, and it is not a benign rite of passage either. A large proportion of affected young people improve, while a smaller high-risk subgroup carries the disorder into an adult life of persistent offending and personality pathology. The clinical and the examinable skill is the same one - reading, from features present in childhood and adolescence, where a given young person sits on that spread.

This topic owns the trajectory itself: the overall course into adulthood, the features that predict persistence against those that predict recovery, and the specific developmental bridge that links conduct disorder to **antisocial personality disorder**. The diagnostic criteria and the onset subtypes are established in their own right elsewhere in this chapter and are named here only as prognostic markers, not re-taught. Antisocial personality disorder as a full adult diagnosis, with

its own criteria and management, belongs to the Personality disorders notes; what is developed here is the one-way developmental corridor that runs from the childhood disorder toward it, and the fact that most children never travel down it.

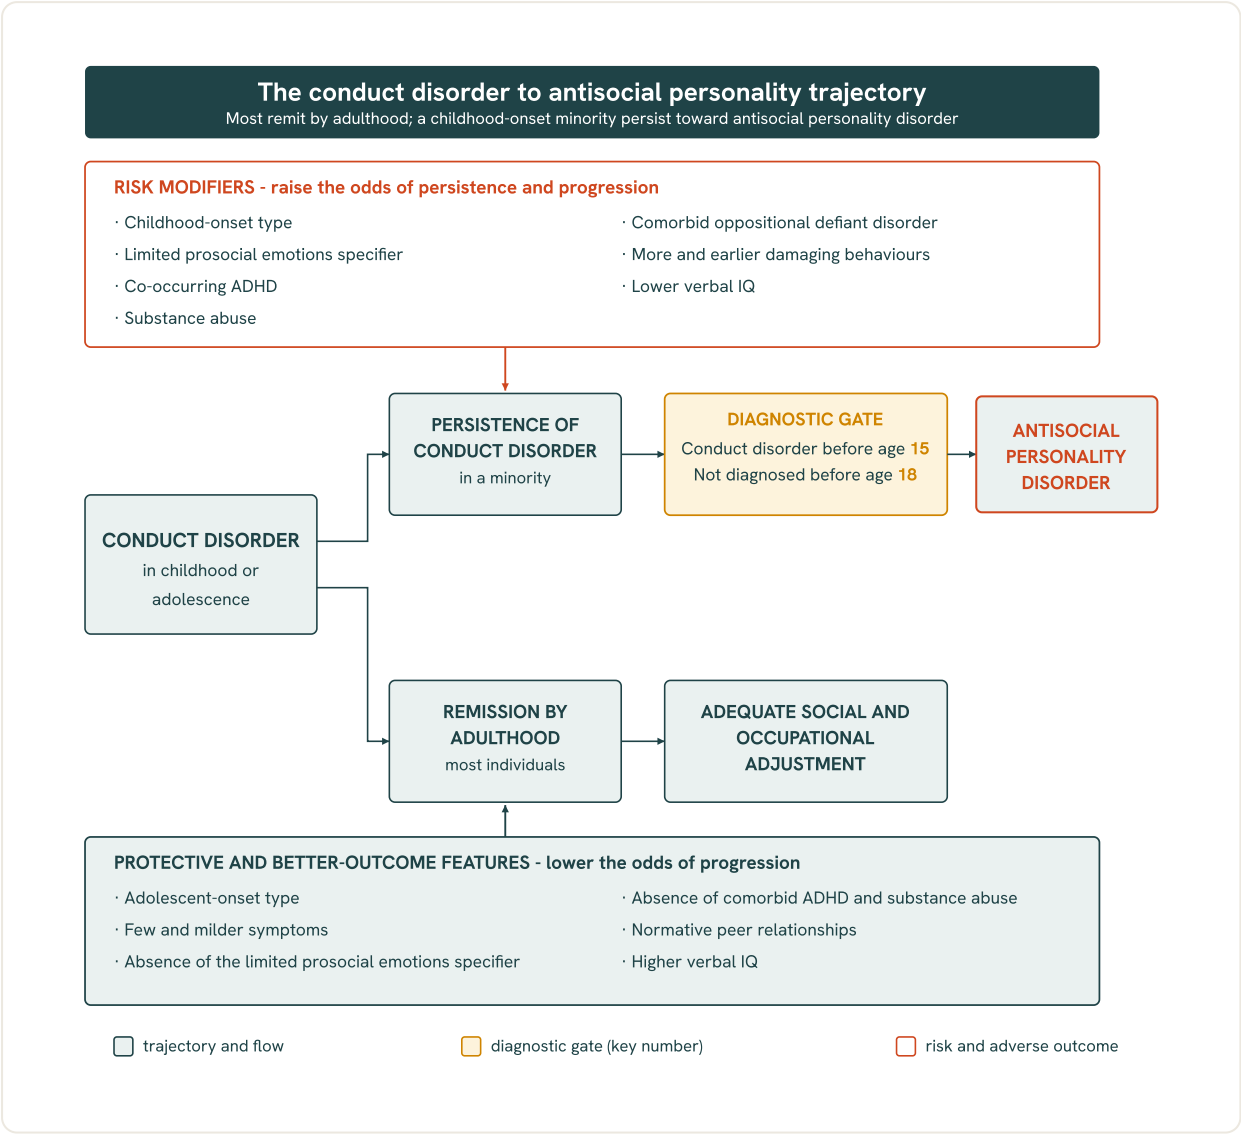

Fig 23.6. Conduct disorder to antisocial personality trajectory: most cases remit by adulthood, while a childhood-onset minority persist across the age 15 and age 18 diagnostic gates, with risk modifiers driving progression and protective features favouring remission.

7.1 The shape of the outcome: heterogeneity and remission

The default trajectory is improvement, not deterioration. The most important corrective to clinical pessimism is that in the majority of individuals the disorder **remits** by adulthood. Many young people, particularly those with the adolescent-onset course and with few and milder symptoms, go on to achieve adequate social and occupational adjustment as adults, holding down work and relationships that their teenage conduct would not have predicted. The clinical picture in early adult life is typically one of desistance: a large decline in delinquent and antisocial activity is commonly reported as the young person moves out of adolescence, matures, and acquires the stakes in conventional life - employment, a partner, responsibilities - that make offending costly and unrewarding. This does not mean the disorder is trivial, because the minority whose course does not follow this benign arc account for a great deal of harm, and

because even a self-limiting course can leave educational and legal scars. But the base rate matters enormously for how the clinician frames the problem to a family, and for resisting the pull toward writing a child off.

RULE **Conduct disorder is prognostically heterogeneous, and its commonest outcome is remission.** The disorder resolves in most affected individuals by adult life, with a marked fall in antisocial activity in early adulthood. Prognosis is therefore a question of identifying the high-risk minority who will not follow that path, not a foregone conclusion applied to everyone who carries the label.

7.2 Childhood onset as the pivot of prognosis

When the trouble began is the strongest single prognostic marker. The onset subtype is not a bookkeeping detail; it is the axis on which the outlook turns. The **childhood-onset type** predicts a worse prognosis and an increased risk of criminal behaviour, of persistent conduct disorder that does not remit on the usual schedule, and of substance-related disorders in adulthood. Alongside the age at which problems first appeared, the nature of those early problems carries weight of its own: engaging in more damaging behaviours at an early age is itself predictive of a worse outcome, so a young child whose conduct is already seriously harmful sits in a different prognostic band from one whose early problems are milder. The **adolescent-onset type**, by contrast, is the course most associated with the benign trajectory of the previous section - later onset, milder and fewer symptoms, and a stronger tendency to remit as adolescence passes. Reading onset age as a prognostic variable, and not merely as a descriptive specifier, is the reasoning a candidate is expected to show.

PITFALL

The mirror-image clinical error to over-diagnosis is therapeutic nihilism: treating a child with the childhood-onset, high-risk profile as already destined for an antisocial adult life and quietly withdrawing effort. Worse prognosis is a shift in probability, not a sealed fate. This is precisely the subgroup in which early, intensive, evidence-based intervention has the most to offer, and writing them off both misreads the evidence and forfeits the window in which the trajectory is most malleable.

7.3 What keeps the disorder going: predictors of persistence

Persistence clusters around a recognisable profile. The features that predict that conduct disorder will not remit but will run on into adult antisocial pathology are worth memorising as a set, because they recur in vignettes and in real referrals alike. **Persistence** is more likely when the young person's course meets the childhood-onset pattern and also qualifies for the limited prosocial emotions specifier - the callous-unemotional presentation whose four defining features are set out in their own right elsewhere in this chapter and are named here only as a prognostic amplifier. The risk of persistence is further increased by co-occurring **attention-deficit/hyperactivity disorder**, whose own assessment and treatment belong to the ADHD and specific learning/communication disorders notes, and by **substance abuse**, which both reflects and drives an escalating antisocial course. Comorbid ADHD and oppositional defiant disorder

each predict worse outcomes. The unifying theme is that the disorder persists when it is early, callous, comorbid and chemically fuelled: each of these adds to the load and lowers the chance of the spontaneous desistance that carries most young people out of the disorder.

- childhood-onset course rather than adolescent onset;
- the limited prosocial emotions (callous-unemotional) specifier present;
- co-occurring attention-deficit/hyperactivity disorder;
- co-occurring oppositional defiant disorder;
- substance abuse compounding the antisocial course.

MNEMONIC

Early, Callous, Hyperactive, Intoxicated

The persistence profile, in the order the features tend to appear: **E**arly onset (childhood-onset course), **C**allous (the limited prosocial emotions specifier), **H**yperactive (co-occurring ADHD, with oppositional defiant disorder alongside), and **I**ntoxicated (substance abuse). Each is a claim only about which conduct disorder runs on; none re-teaches the disorder it names.

7.4 The bridge to antisocial personality disorder

Conduct disorder is the mandatory childhood antecedent of the adult diagnosis, but it is far from a guarantee of it. The link that the examiner most wants stated precisely is the developmental corridor between the two disorders. Antisocial personality disorder cannot be diagnosed until adulthood, and it is given only where there is evidence of conduct disorder with onset **before age 15** years. That childhood requirement, written into the adult criteria themselves, is the structural reason the two disorders are taught together: conduct disorder before the mid-teens is a necessary building block of the adult diagnosis, so no one acquires antisocial personality disorder de novo in adult life without an antisocial childhood behind it. What makes the relationship so easily misremembered is that necessity runs in only one direction. A childhood history of conduct disorder is required for the adult diagnosis, yet the great majority of adolescents with conduct disorder do not go on to develop antisocial personality disorder at all. The corridor is real but narrow: most children who enter it turn off it, and only the high-risk minority identified by the persistence profile of the previous section travel its full length. The adult disorder in its own right - its criteria, its differential and its management - is the Personality disorders notes'; what belongs here is only the trajectory that connects it back to childhood.

The must-carry line: antisocial personality disorder requires evidence of conduct disorder with onset **before age 15** years, yet most adolescents with conduct disorder never develop it - necessary, not sufficient.

TRAP **The direction of the conduct-disorder-to-antisocial link is routinely reversed.** Candidates read the required childhood antecedent as though it ran the other way and assert that conduct disorder usually, or even always, becomes antisocial personality disorder. The correct statement is the opposite: conduct disorder before the mid-teens is a precondition of the adult diagnosis, but the majority of young people with conduct disorder do not progress to it. Stating the base rate as high is the single commonest error on this topic.

7.5 The other side of the ledger: protective and better-outcome features

The features that predict recovery are, for the most part, the mirror image of those that predict persistence. Prognosis is not read only from what is wrong; the examiner also expects the protective side. A better adult adjustment, and a lower likelihood of progression to antisocial personality disorder, are associated with the adolescent-onset course, with few and milder symptoms, with the absence of the limited prosocial emotions specifier, with the absence of comorbid ADHD and of substance abuse, and with **normative peer relationships** rather than an entrenched deviant peer group. Temperament contributes too: a higher verbal intelligence is protective, given that a lower verbal IQ is a recognised temperamental risk factor for the disorder. These are not a separate list to be learned in isolation but the same prognostic axis read from its favourable end, which is why they map cleanly onto the persistence predictors reversed. The clinical value of holding both columns in mind is that they convert prognosis from a vague impression into a structured judgement: the young person is placed by counting how many protective and how many adverse features are present, rather than by the emotional impression the presenting behaviour makes.

PROGNOSTIC AXIS	POINTS TOWARD PERSISTENCE AND ANTISOCIAL OUTCOME	POINTS TOWARD REMISSION AND GOOD ADJUSTMENT
Onset subtype	Childhood-onset	Adolescent-onset
Symptom load and severity	Many symptoms, damaging behaviours early	Few and milder symptoms
Limited prosocial emotions specifier	Present	Absent
Co-occurring ADHD	Present	Absent
Substance abuse	Present	Absent
Peer relationships	Deviant peer affiliation	Normative
Verbal intelligence	Lower verbal IQ	Higher verbal IQ

The prognostic ledger for conduct disorder read across shared axes; the protective column is largely the persistence column reversed, which is why the two are learned together rather than as separate lists.

7.6 Turning prognosis into practice

Prognosis is only useful if it changes what the clinician does. The reason the examiner cares about outcome prediction is that it is meant to be acted on. A structured reading of the prognostic profile does two things at once. It identifies the high-risk young person - early onset, callous-unemotional features, comorbid ADHD, emerging substance use - in whom the most

intensive, evidence-based intervention is justified and in whom the window for altering the trajectory is widest. And it gives the clinician language to hold a family's fear at the right level: neither the false reassurance that a seriously disordered child will simply grow out of it, nor the false verdict that a child is already lost. The prognostic features are also the natural targets of intervention, because several of them - the comorbid ADHD, the substance use, the deviant peer affiliations - are modifiable, and modifying them is one of the mechanisms by which good treatment shifts outcome.

GOOD TO REMEMBER

Record the prognostic profile explicitly in the formulation, not just the diagnosis. Whether the course is childhood or adolescent onset, whether the limited prosocial emotions specifier applies, and whether ADHD or substance use co-occurs, together place the young person on the outcome spread and set the intensity of the response. The same features that predict a poor outcome are the ones worth targeting, so the prognostic list doubles as an intervention checklist.

IN INDIA

Because Indian services classify under ICD, the operative label in case files is the conduct-dissocial disorder of that system, and the prognostic principles carry across unchanged: onset age, callous-unemotional features and comorbidity still sort the persistent minority from the many who remit. The practical constraint is continuity. The desistance seen in early adulthood is easiest to support where a young person can be followed over years, but fragmented follow-up, limited child mental health services, and loss to care after a first contact mean many are seen once at a crisis and not again. Where conduct intersects with the law, the juvenile-justice interface is taken up separately in this chapter, and the wider machinery of services and protection in the Child psychiatry: assessment, treatment, services and protection notes; the prognostic point for practice is that a single contact is rarely enough to change a trajectory that is defined by its persistence.

Oppositional defiant disorder and the impulse-control disorders

8 · Oppositional defiant disorder (criteria, course, management)

The diagnosis lives in the space between a difficult temperament and a rights-violating illness. **Oppositional defiant disorder** is the syndrome of childhood and adolescence in which anger, argumentativeness, defiance and a streak of vindictiveness cohere into a pattern that is out of proportion to the child's developmental stage and that costs the child or the family something real. It is one of the commonest referrals to child mental health, and it is examined heavily for a reason that is easy to state and hard to apply: almost every young child is oppositional some of the time, so the whole art of the diagnosis is telling a disorder apart from an ordinary phase, a

temperamental extreme, or the friction of a coercive home. Marks are lost not on the symptom list, which candidates memorise, but on the thresholds, the developmental caveats and the borders with conduct disorder and the chronically irritable presentations, which is where the criteria actually do their work.

This topic owns the diagnostic architecture of the disorder: the essential feature, the symptom count and timeframe, the three symptom clusters and what each predicts, the age-graded frequency rule that separates symptom from normality, the severity grading, the local differential against conduct disorder, and the way the two major classifications part company over chronic irritability. The full conduct disorder criteria, disruptive mood dysregulation disorder, the cross-cutting normal-limits map and the attention-deficit/hyperactivity comorbidity are each developed in their own right elsewhere; here they are named where the reasoning demands it, not reopened.

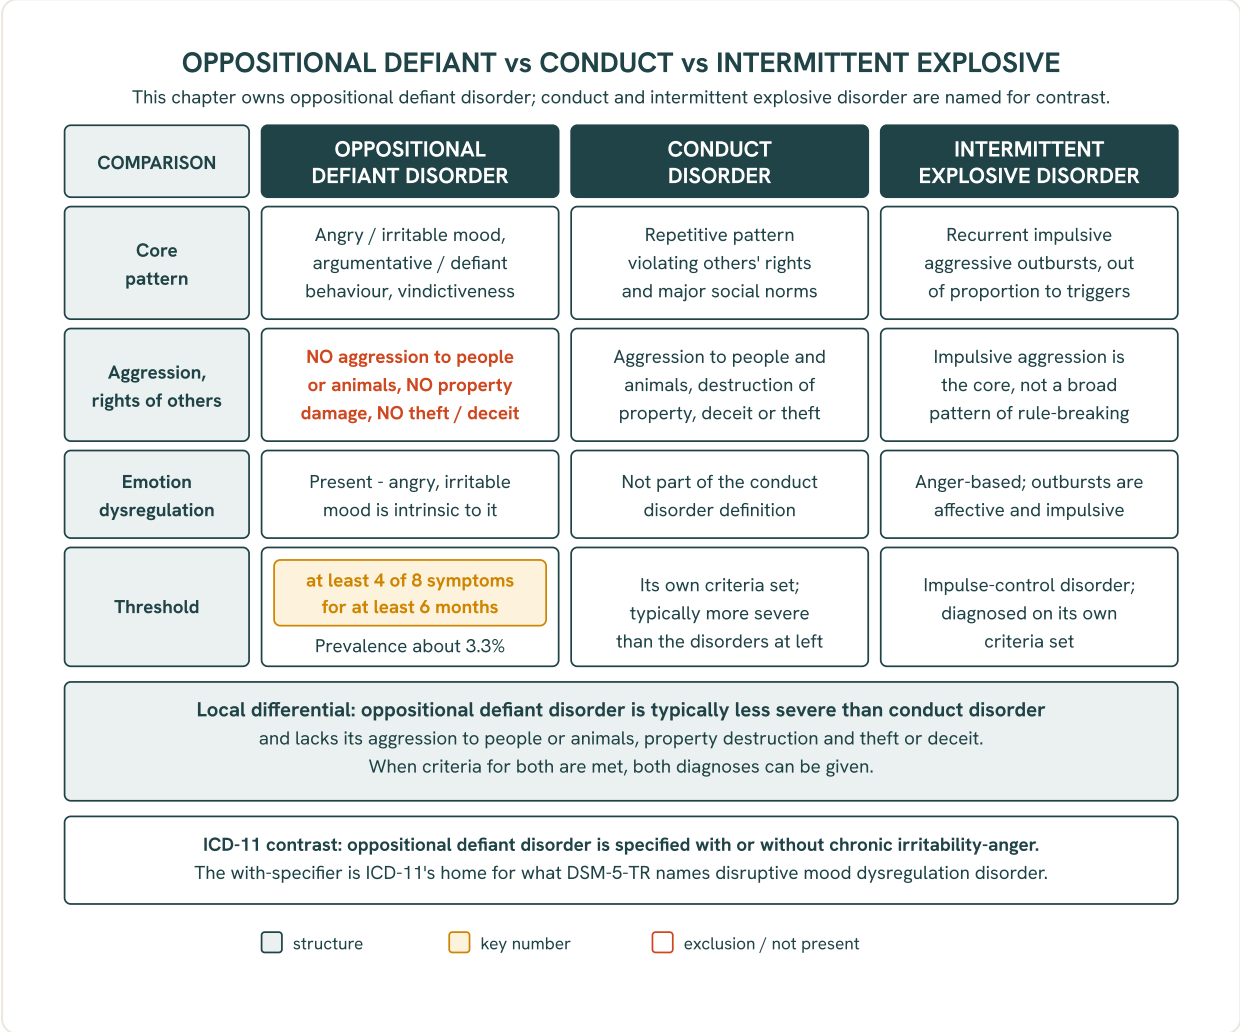

Fig 23.7. Oppositional defiant disorder against conduct disorder and intermittent explosive disorder: the same core-pattern, aggression, emotion and threshold axes that separate a persistent defiant pattern from rule-violating conduct and from impulsive aggressive outbursts.

8.1 The essential feature: a disposition, not a single scene

The unit of diagnosis is a durable pattern of three affective-behavioural dispositions. The essential feature is a recurring pattern of **angry/irritable mood**, **argumentative/defiant behaviour** and **vindictiveness**, sustained rather than sporadic and directed at the people around

the child. What makes it a disorder is not any one tantrum, argument or spiteful act, all of which are near-universal in childhood, but the consolidation of these tendencies into a stable way of relating. The framing is deliberately broader than pure behaviour: unlike the frankly antisocial syndromes, this disorder puts a mood dimension at its centre, so that the irritable, easily-provoked child who is not yet aggressive to others still belongs here. That affective core is what later separates the disorder from conduct disorder and links it to the mood and anxiety outcomes. The clinician's first task is to establish that a pattern sits behind the presenting complaint rather than be captured by the single episode that brought the family in.

8.2 Criterion A: the count, the clock and the non-sibling rule

The threshold, the timeframe and the target of the behaviour are the examinable core. The operational rule requires at least **four** symptoms drawn from a set of **eight**, present over a period of at least 6 months. Two features of the rule are quietly load-bearing. First, the four symptoms may be drawn from *any* of the three clusters, so a purely irritable child and a purely defiant child can both reach the threshold by different routes, which is why the clusters must be tracked separately rather than summed blindly. Second, the pattern must be shown during interaction with at least one individual who is not a sibling. This last clause is frequently missed and frequently tested: ordinary sibling conflict, however fierce, does not count toward the diagnosis, because rivalry and squabbling between brothers and sisters is developmentally expected and says little about a generalised oppositional disposition. The behaviour must reach beyond the sibling relationship before it becomes diagnostic.

> The core rule to carry into the exam: at least four of eight symptoms across the three clusters, for at least 6 months, shown with at least one person who is not a sibling.

8.3 The three symptom clusters and why the split predicts the future

Eight symptoms sort into three clusters that carry different prognostic freight. The criteria are not a flat list. They fall into an angry/irritable mood cluster (losing one's temper, being touchy or easily annoyed, and being angry and resentful); an argumentative/defiant behaviour cluster (arguing with authority figures, actively defying or refusing to comply with rules, deliberately annoying others, and blaming others for one's own mistakes); and a vindictiveness cluster. Grouping matters because the clusters point in different directions. The argumentative, defiant and vindictive dimension carries most of the risk for progression to conduct disorder, whereas the angry and irritable mood dimension carries most of the risk for later mood and anxiety disorders. This is the most useful prognostic reasoning the topic offers: two children who both satisfy the count can face different futures depending on which cluster dominates, so recording the profile rather than the bare tally is what lets the clinician anticipate an externalising or internalising trajectory.

CLUSTER	WHAT IT CAPTURES	WHAT IT CHIEFLY PREDICTS
Angry/irritable mood	Loses temper; touchy or easily annoyed; angry and resentful	Later mood and anxiety disorders
Argumentative/defiant behaviour	Argues with authority; defies rules; deliberately annoys; blames others	Progression toward conduct disorder
Vindictiveness	Spiteful or vindictive behaviour	

The three clusters set against what each chiefly forecasts; the affective cluster tilts toward internalising outcomes, the behavioural and vindictive clusters toward the externalising trajectory that ends in conduct disorder.

MNEMONIC

Mad, Bad and Vengeful

The three clusters in order: **Mad** (angry/irritable mood), **Bad** (argumentative/defiant behaviour) and **Vengeful** (vindictiveness). Holding them as separate axes rather than one undifferentiated pile of misbehaviour is what makes the prognostic split usable at the bedside.

8.4 The frequency rule: telling a symptom from ordinary development

Persistence and frequency, read against the child's age, are what convert a normal behaviour into a symptom. Because the raw behaviours are so common, the criteria supply an age-graded frequency floor. For a child younger than 5 years the behaviour should occur on most days across a period of at least 6 months; for a child of 5 years or older it should occur at least once per week over the same period, with an allowance for the vindictiveness item, which is expected less often. These frequencies encode a developmental truth: daily oppositionality is closer to the norm in the preschool years than later, so a higher bar is set for the younger child and a lower one for the older. The criteria also insist that the judgement be made against the individual's developmental level, sex and culture, which keeps the diagnosis from being read off behaviour in isolation from the child who produces it. Frequency, persistence and context together are what license the move from behaviour to symptom.

RULE **The threshold is set by frequency against age, not by the behaviour alone.** The same tantrum that is developmentally unremarkable on most days in a preschooler is a symptom when it recurs weekly in a school-aged child. The criteria pin the diagnosis to how often the behaviour occurs relative to what is expected at that age, which is precisely the safeguard that stops normal childhood oppositionality being pathologised.

8.5 Grading the disorder: pervasiveness across settings

Severity is read from how many settings the symptoms invade. The disorder is graded not by symptom count but by pervasiveness, on the principle that a child who is oppositional only at home is in a different clinical position from one who is oppositional everywhere. The grade is **mild** when symptoms are confined to a single setting, moderate when some symptoms appear in at least two settings, and severe when they are present in three or more. The clinical logic is sound. Symptoms limited to one relationship or place often say as much about that setting as about the child, and may respond to work targeted there; symptoms that generalise across home,

school and the wider world point to a more ingrained, more disabling disposition. Reading severity from pervasiveness also quietly instructs the assessor to gather information from more than one informant, because a grade cannot be assigned honestly from the parents' account alone.

> **GOOD TO REMEMBER**
>
> Because severity tracks the number of settings, a single-informant assessment can only ever establish the floor. If the parents describe defiance at home but the child has never been observed or reported on at school, the honest grade is provisional, and the next clinical move is to obtain the school's account before the disorder is called moderate or severe.

8.6 Epidemiology and the sex distribution

The frequency of the disorder is one of the reasons the threshold has to be strict. Cross-national estimates put the average prevalence at about **3.3%**, though the figure ranges widely, from roughly 1% to 11% across settings. Before adolescence the disorder is somewhat commoner in boys than girls, at a ratio of about **1.59 to 1**; the male preponderance is real but modest, and it attenuates with age, unlike the sharper and more persistent male excess seen in the frankly conduct-disordered group. The wide prevalence band is itself an examinable point: it is a direct consequence of how much the diagnosis depends on where the line between a difficult child and a disordered one is drawn, which varies between raters and cultures, and it is a standing argument for holding to the frequency and pervasiveness rules rather than to clinical impression.

8.7 The local differential: oppositional defiant disorder against conduct disorder

The two disorders share a family resemblance but part on rights-violation and on mood. The most consequential differential is against **conduct disorder**, whose full criteria are developed in its own right elsewhere in this chapter. Two lines separate them. First, the behaviours of oppositional defiant disorder are typically less severe and, crucially, do *not* include aggression toward people or animals, destruction of property, or a pattern of theft or deceit; those serious rights-violating and norm-violating acts are the province of conduct disorder. Second, oppositional defiant disorder additionally carries a component of emotion dysregulation, the angry and irritable mood, that has no place in the definition of conduct disorder. The two are not mutually exclusive, and when a young person genuinely satisfies the criteria for both, both diagnoses can be made.

- defiance, argument and spite without aggression, destruction, theft or deceit point to oppositional defiant disorder, not conduct disorder;
- aggression to people or animals, property destruction, or a pattern of theft or deceit moves the picture into conduct disorder territory;
- the angry and irritable mood dimension belongs to oppositional defiant disorder and is not part of the conduct disorder definition;
- when the criteria for both are met, both are diagnosed rather than one being forced to displace the other.

TRAP **Oppositional defiant disorder and conduct disorder are not mutually exclusive.** Candidates often treat them as a hierarchy in which the more severe diagnosis cancels the milder, and answer that a child meeting both sets of criteria has "only" conduct disorder. When both are genuinely satisfied, both diagnoses stand; the disorders are related but distinct, and the presence of one does not extinguish the other.

8.8 The classification split: chronic irritability and where it is housed

The two manuals agree on the disorder and disagree on what to do with chronic irritability. Under ICD-11 the entity is **oppositional defiant disorder**, coded 6C90, and the classification adds a decision the other manual makes differently. It allows the disorder to be specified **with chronic irritability-anger** (coded 6C90.0) or without it (coded 6C90.1). The with-specifier identifies a pattern of prevailing, persistent irritable and angry mood, and it is ICD-11's home for the very presentation that the other major classification carves out as a separate disorder, **disruptive mood dysregulation disorder**, which is developed in its own right elsewhere in this chapter. This is a genuine structural disagreement rather than a wording difference: one system treats chronic non-episodic irritability as a specifier hung on the oppositional diagnosis, the other as a distinct entity in its own right. Which manual a case file follows therefore decides whether a chronically irritable child is recorded as an oppositional defiant disorder with a specifier or as a separate mood-dysregulation diagnosis.

AXIS	ICD-11	THE OTHER MAJOR CLASSIFICATION
Base diagnosis	Oppositional defiant disorder (6C90)	Oppositional defiant disorder
Chronic irritable-angry presentation	A specifier: with chronic irritability-anger (6C90.0)	A distinct disorder, disruptive mood dysregulation disorder
Consequence for coding	The irritable child stays within the oppositional diagnosis	The irritable child receives a separate mood diagnosis

The same clinical presentation of chronic, non-episodic irritability placed differently by the two classifications; the load-bearing point is that ICD-11 keeps it inside the oppositional diagnosis as a specifier where the other manual gives it its own name.

IN INDIA

Because Indian services classify under ICD, the operative label in case files, referrals and official reports is oppositional defiant disorder under its ICD code, with the chronic irritability-anger specifier available for the persistently irritable child. A clinician trained on the other manual's categories should not go looking for a separate mood-dysregulation diagnosis in an ICD-coded record: the same child is recorded here as an oppositional defiant disorder with the specifier applied, and treating the two as different disorders rather than the same presentation filed differently is a recurring source of confusion in cross-referenced notes.

8.9 Course and management

Onset is early, the outlook is dimension-dependent, and the first-line treatment is delivered through the parents. The disorder typically declares itself in the preschool and early school

years, often before conduct problems proper, and for a subset it is the earliest link in a chain that runs toward conduct disorder and, beyond it, to antisocial outcomes in adulthood. But this trajectory is neither universal nor fixed, and which way a given child tends is what the cluster profile forecasts: the behavioural and vindictive dimension carries the risk of progression to conduct disorder, the irritable dimension the risk toward mood and anxiety disorders. Comorbidity is the rule rather than the exception, with attention-deficit/hyperactivity disorder the most frequent travelling companion; that disorder, its assessment and its treatment belong to the ADHD and specific learning/communication disorders notes, and its presence materially worsens the oppositional picture and complicates management.

Treatment is built on the parent-child relationship before it is built on medication. The first-line and best-supported intervention is structured **parent management training**, in which caregivers are coached to replace the escalating cycles of command, refusal and capitulation that maintain oppositional behaviour with consistent, contingent responses, clear expectations, and the deliberate reinforcement of prosocial behaviour. For an older child, individual work on problem-solving and anger management is added, and school-based consistency is enlisted so the same contingencies operate across settings, which also addresses the pervasiveness that defines severity. Pharmacotherapy has no primary role in the oppositional syndrome itself and is directed instead at treatable comorbidity, most often the accompanying attention-deficit/hyperactivity disorder, rather than at defiance as such. This is a relational and developmental problem first, so the family, not a prescription, is the main instrument of change; medication earns its place only where a comorbid disorder independently warrants it.

PITFALL

The commonest clinical error runs in both directions around the same axis: over-diagnosing the ordinary defiance of a tired, testing or newly-limit-tested young child as a disorder by ignoring the age-graded frequency floor, and, conversely, dismissing a genuinely disordered older child as "just naughty" because oppositionality is expected in the young. The corrective is the same in both cases: hold the behaviour against what is developmentally expected at that age, and against how often and in how many settings it actually occurs, rather than against the adults' exasperation.

SYMPTOMS NEEDED, AT LEAST 6 MONTHS IN DURATION	AVERAGE CROSS-NATIONAL PREVALENCE	BOYS TO GIRLS BEFORE ADOLESCENCE

9 · Intermittent explosive disorder

The disorder is defined by the loss of control, not by the size of the violence. Intermittent explosive disorder is the diagnosis given to recurrent behavioural outbursts that represent a failure to control aggressive impulses. What is disordered is not that a person becomes angry, nor even that they become violent, but that the aggressive impulse is discharged in a sudden, poorly restrained explosion that the person themselves usually regrets. The picture is of a short fuse attached to a response grossly larger than whatever lit it: a trivial provocation, a spilled drink or a delayed reply, met with screaming, threats, a thrown object or a blow. Between the episodes the

person is often unremarkable, which is precisely why families describe someone who is "fine until they snap".

Marks accrue here for a specific reason. Aggression is a final common pathway of many disorders, and the examiner wants to know that a candidate can tell impulsive, anger-driven aggression apart from the cold, instrumental aggression of conduct disorder and antisocial personality, from the chronically irritable child, and from aggression that is merely a symptom of mania, intoxication or a frontal lesion. Intermittent explosive disorder is the residual, positive diagnosis of the impulsive aggressive outburst once those other explanations have been excluded. This topic owns that diagnosis in full: its essential feature, the two thresholds of its recurrence criterion, its qualifying and exclusion rules, its course, epidemiology and differential. The wider family of impulse-control disorders, and the conditions of firesetting and stealing, are developed in their own right and named here only where the differential demands it.

9.1 The essential feature: a failure to control aggressive impulses

The unit of diagnosis is the impulsive aggressive outburst. The core disturbance is an inability to resist aggressive impulses, expressed as recurrent outbursts that are out of proportion and out of the person's control. The aggression is **impulsive** or anger-based; it is not **premeditated**, and it is not committed to secure a tangible objective such as money, power or intimidation. That single distinction carries most of the clinical and examination weight. Aggression used as a tool, to coerce, acquire or dominate, belongs to conduct disorder or antisocial personality and not here, however dramatic it looks. The aggression of this disorder is that of a system that has lost its brakes, discharged in the heat of the moment and typically followed by genuine remorse once the arousal subsides. The outburst is the disease; the person's baseline, and their regret, are part of the picture.

RULE **Impulsive and disproportionate, never instrumental.** The diagnosis requires aggression that is anger-based and unplanned and that is grossly out of proportion to its trigger. The moment the aggression is revealed to be premeditated or committed for gain, the diagnosis is not intermittent explosive disorder, and the assessor should be looking at conduct disorder, antisocial personality or another explanation instead.

9.2 Criterion A: two ways in, frequency or severity

The threshold is a dyad, and either arm alone suffices. The recurrence criterion can be met by one of two mutually alternative patterns, and understanding that they are alternatives is the examinable core of the topic. The first arm captures frequent, low-severity outbursts: **verbal aggression or non-damaging physical aggression** occurring **twice weekly**, on average, over a period of three months. These outbursts, by definition, do not damage or destroy property and do not cause physical injury, the tantrum-like verbal explosion or the shove that harms nothing being the prototype. The second arm captures infrequent but destructive outbursts: **three** outbursts that involve damage or destruction of property, or physical assault causing injury to people or animals, occurring within a 12-month period. A person qualifies on either arm; they need not meet both. The design is deliberate, catching both the individual disrupted by constant low-grade verbal explosions and the one who erupts only rarely but does real harm.

ARM OF CRITERION A	SEVERITY OF THE OUTBURST	REQUIRED FREQUENCY AND WINDOW
High-frequency arm	Verbal or non-damaging physical aggression; no property damage, no injury	Twice weekly on average, for three months
High-severity arm	Property damage or destruction, or assault causing injury	Three outbursts within a 12-month period

The two alternative routes to the recurrence criterion; a person satisfies the requirement through either arm, and the two differ in the severity of the outburst and in the counting window rather than in the nature of the underlying impulse.

9.3 The qualifying and exclusion criteria

Recurrence alone is not the disorder; the qualifiers make it one. Several further conditions must hold before the outbursts count. The aggressiveness must be grossly out of proportion to the provocation or precipitating stressor, so that a measured, if forceful, response to a genuine threat does not qualify. The outbursts must cause the person real cost, whether marked personal distress, impairment of occupational or interpersonal functioning, or financial and legal consequences. There is a developmental floor: the person must be at least **6 years** of chronological age, or the equivalent developmental level, and the diagnosis is not made below that age, where explosive behaviour is developmentally common and non-specific. Finally, the outbursts must not be better explained by another mental disorder and must not be attributable to a substance or a general medical condition. This last exclusion is what makes the condition a diagnosis of careful exclusion rather than of first impression, since aggression is so often secondary.

- the response is grossly disproportionate to its trigger;
- the outbursts cause marked distress, functional impairment, or financial or legal harm;
- the person is developmentally at least six years old;
- the aggression is not better accounted for by another disorder, a substance, or a medical condition.

> Carry this into the exam: impulsive, disproportionate, distressing aggression, either twice weekly and non-damaging for three months or three damaging outbursts in a year, in a person aged at least 6, and not explained by anything else.

9.4 The phenomenology and course of the outburst

The anatomy of the episode is characteristic and worth knowing. The typical outburst has a rapid, almost explosive onset, often with little or no prodrome, and is usually short-lived rather than smouldering for hours. Many patients describe a mounting sense of tension or arousal before the act and a sense of relief during it, followed by fatigue and, characteristically, remorse, embarrassment or guilt once it has passed. It is this remorse, and the ego-dystonic quality of the aggression, that distinguishes the picture from the unrepentant, goal-directed aggression of the antisocial patient. The disorder tends to begin in late childhood or adolescence and to run a chronic course over many years, punctuated by discrete outbursts against a comparatively normal

inter-episode baseline. That episodic structure against a well background is the signature, and it is a large part of why the condition is under-recognised: the person seeking help usually does so between outbursts, when they appear entirely well.

GOOD TO REMEMBER

Ask specifically about the shape of the episodes, not just their occurrence. Rapid onset, short duration, a build-up of tension beforehand, relief during, and remorse afterwards, all against a normal baseline, is a pattern the patient will rarely volunteer but will readily confirm. Documenting that episodic architecture is often what separates this diagnosis from a persistently irritable temperament or a mood disorder.

9.5 Epidemiology

It is commoner than its low profile suggests. Population data put the one-year prevalence in the United States at about **2.6%**, with a lifetime prevalence of around **4.0%**, figures that make it far from a rarity even if it is seldom the presenting complaint. It is more prevalent among younger people, being concentrated in those under about 35 to 40 years, in keeping with its onset in youth and its attenuation with age, and it is somewhat commoner in males. The gap between how often the disorder occurs and how rarely it is formally diagnosed is itself an examination point: patients are labelled as having an anger problem, or seen only through the marital, occupational or forensic consequences of their outbursts, rather than recognised as having a discrete, treatable impulse-control disorder.

9.6 The differential diagnosis: a crowded field

Almost every disorder that produces aggression must be set aside first. Because aggression is nonspecific, the differential is the most demanding part of the topic. The chronically irritable child whose mood is persistently angry between outbursts is better captured by **disruptive mood dysregulation disorder**, developed in its own right elsewhere in this chapter; the diagnostic convention is that where that disorder's criteria are met in a child, the explosive-disorder label is not added on top. Conduct disorder and oppositional defiant disorder, also elsewhere in this chapter, involve a broader pattern of rule-breaking or defiance in which aggression is one element, and the explosive-disorder diagnosis is reserved for impulsive aggression that is in excess of, and not fully explained by, that broader pattern. Antisocial personality is separated by the instrumental, unremorseful quality of its aggression and belongs to the Personality disorders notes. Aggression arising only during manic, depressive, psychotic or intoxicated states is a symptom of those states, and the impulsivity of untreated attention-deficit/hyperactivity disorder, taken up in the ADHD and specific learning/communication disorders notes, must be weighed as well.

CONDITION TO EXCLUDE	WHAT SEPARATES IT FROM INTERMITTENT EXPLOSIVE DISORDER
Disruptive mood dysregulation disorder	Persistent angry or irritable mood *between* the outbursts; where its criteria are met in a child, this disorder takes precedence and the explosive-disorder label is not added
Conduct disorder and oppositional defiant disorder	A broad pattern of rule-violation or defiance; the explosive diagnosis needs impulsive aggression in excess of what that pattern explains
Antisocial personality disorder	Aggression that is premeditated and instrumental, pursued for gain and without remorse
Manic, depressive or psychotic states	Aggression occurs only during the mood or psychotic episode and remits with it
Substance intoxication or withdrawal, and medical or neurological conditions	Aggression is attributable to the substance or the lesion; excluded by Criterion F

The principal competitors for the aggressive presentation; intermittent explosive disorder is what remains once each of these has been considered and set aside, which is why it is best thought of as a positive diagnosis reached through disciplined exclusion.

TRAP **Calling instrumental aggression "explosive".** The classic error is to reach for this diagnosis for any patient with a history of violence. Candidates forget that aggression committed to obtain something, or that is planned, is specifically excluded: it points to conduct disorder or antisocial personality. The disorder is impulsive, disproportionate and regretted, never a calculated means to an end.

9.7 Principles of management

Treatment targets the impulse, not merely the incident. Management combines psychological and pharmacological strategies, with the emphasis on reducing the frequency and intensity of the outbursts rather than managing each crisis after the fact. Cognitive behavioural approaches, including anger management, relaxation and coping-skills training, cognitive restructuring of the appraisals that trigger the arousal, and relapse prevention, are the psychological mainstay and have the best-established evidence. Pharmacologically, serotonergic antidepressants are the most commonly used agents, on the rationale that impulsive aggression is linked to serotonergic dysregulation, with mood stabilisers and certain anticonvulsants where affective instability is prominent; specific agents and dosing lie outside what this topic establishes and should be confirmed against a pharmacology source. Coexisting conditions, particularly depression, substance use and attention-deficit/hyperactivity disorder, must be identified and treated in their own right, since untreated comorbidity both worsens the outbursts and undermines any intervention aimed at them.

PITFALL

The commonest clinical failure is to treat only the aftermath. Clinicians manage the injury, the property damage or the legal fallout of each outburst and never step back to recognise and treat the underlying impulse-control disorder, so the patient cycles through emergency departments, marital breakdowns and forensic contacts without anyone naming the condition that drives them. Screening a patient with recurrent, regretted, disproportionate aggression for the disorder itself is what breaks that cycle.

IN INDIA

Most Indian services classify under ICD rather than DSM, where the condition sits among the impulse-control disorders, and its wider framework is developed in the Somatic-symptom, sexual, impulse-control disorders and suicide notes. The practical reality is that these patients present through their consequences, in casualty after an assault, in the marital clinic, or via a medicolegal referral after a charge, far more often than they ask for help with anger. Holding the diagnosis in mind when assessing recurrent, out-of-proportion, regretted aggression can convert a repeat forensic or emergency presentation into a treatable psychiatric problem, which is the single most useful move the topic offers here.

age 6 DEVELOPMENTAL FLOOR FOR THE DIAGNOSIS	**2.6%** ONE-YEAR PREVALENCE (UNITED STATES)	**4.0%** LIFETIME PREVALENCE

10 · Juvenile delinquency (psychiatric perspective)

The label is a verdict, not a diagnosis. A young person becomes a delinquent the moment a court adjudicates them for an offence, and nothing about that legal event tells you whether a psychiatric disorder is present. This is the first and most important idea in the topic, because the word arrives in the examination looking like a clinical entity and is nothing of the sort. Juvenile delinquency is a **legal and administrative category**, a description of what a young person has done and how the state has responded to it, not a description of a mind. The psychiatrist is called into this world not to confirm the label but to answer a separate question underneath it: what, if anything, is wrong, and is it treatable.

Marks are here for a reasoning move rather than a fact list. The examiner wants to see that a candidate can hold the legal act and the mental-health need apart, and can then say what the child and adolescent psychiatrist actually contributes to a young offender: an understanding of the antisocial behaviour, and a disciplined search for the psychiatric disorders that so often sit behind it. This topic owns that psychiatric perspective in full and names the juvenile-justice framework around it. It does not own the disorders themselves, which are taught in their own right, and it deliberately does not teach the legal machinery in detail, which belongs to the statute and to the child-services notes named at the end.

10.1 A legal category, not a psychiatric diagnosis

Delinquency is defined by adjudication, not by symptoms. The defining feature of the term is administrative: a young person has committed an act that would be an offence, and a justice system has processed them for it. There is no symptom list, no duration criterion, no exclusion clause, because it is not a diagnosis at all. This matters clinically because the same legal label covers utterly different children. One delinquent has no psychiatric disorder and has offended out of circumstance, poverty or a single bad decision; another carries **conduct disorder**, or an untreated attentional disorder, or a substance problem, or the aftermath of trauma, and offends as one expression of it. The legal category flattens all of them into a single administrative fact, and the psychiatrist's task is to reopen it. Treating the label as though it were the diagnosis is the error the whole topic is built to prevent: it leads clinicians and courts alike to assume a disorder where there is none, or, worse, to miss a treatable one because the young person has already been filed under a legal heading that seems to explain everything.

RULE **Delinquency is what the court decides; the diagnosis is what the clinician finds.** These are two independent questions asked by two different systems, and the psychiatric perspective exists to answer the second without letting the first stand in for it. A young offender may have no psychiatric disorder, or may have one that has gone unrecognised precisely because the legal label arrived first.

10.2 The psychiatric perspective: finding the disorder inside the label

The clinician's contribution is comprehension and comorbidity. Child and adolescent psychiatry is asked to do two things with a delinquent young person: to understand the antisocial behaviour in developmental terms, and to assess the psychiatric disorders that are frequently present and that contribute to the offending. This second duty is where the marks concentrate, because rates of unrecognised psychiatric illness in young people who reach the justice system are high, and much of it is treatable. The disorders that recur are a familiar cluster. Conduct disorder is the commonest and most directly relevant, developed on its own terms elsewhere in this chapter; attention-deficit/hyperactivity disorder, taken up in the ADHD and specific learning/communication disorders notes, drives the impulsivity and poor self-regulation that turn a temptation into an offence; substance use both disinhibits behaviour and generates acquisitive crime; specific learning disorders and low scholastic attainment feed the school failure and truancy that precede much delinquency; and a history of maltreatment or trauma, with its post-traumatic sequelae, is disproportionately common. None of these is the legal category, and each changes what should happen next.

CONTRIBUTING DISORDER TO SCREEN FOR	WHY IT MATTERS IN A YOUNG OFFENDER
Conduct disorder	The most direct psychiatric correlate of persistent offending; taught in its own right in this chapter, not re-established here
Attention-deficit/hyperactivity disorder	Impulsivity and poor self-regulation convert opportunity into offence; treatable, and covered in the ADHD and specific learning/communication disorders notes
Substance use	Disinhibits behaviour and generates acquisitive and violent crime; often the reversible driver
Specific learning disorders and scholastic failure	School failure and truancy commonly precede delinquency and are frequently unrecognised
Trauma and its post-traumatic sequelae	Maltreatment histories are over-represented; the offending may be one expression of the aftermath

The psychiatric disorders that recur behind the legal label; the clinical value of the psychiatric perspective lies in detecting and treating these, none of which is the delinquency itself, and several of which are directly modifiable.

GOOD TO REMEMBER

Treat entry into the justice system as a screening opportunity that would otherwise be missed. Many of these young people have never had a psychiatric assessment, and the disorders most worth finding, an attentional disorder, a substance problem, a treatable mood or post-traumatic picture, are exactly the ones that a purely legal response will overlook. The single most useful thing the psychiatric perspective offers is a low threshold for looking, because the disorder that is found is often the one that changes the trajectory.

10.3 The juvenile-justice framework and its rehabilitative orientation

The system that handles young offenders was built to rehabilitate, not to punish. The **juvenile-justice framework** is the specialised court and justice system that deals with young offenders separately from adults, and its founding logic is what a candidate must be able to state. The first juvenile court was created in **1899**, deliberately set apart from the adult criminal process so that the response to a delinquent child could be corrective rather than retributive. That rehabilitative orientation has persisted, and modern practice within the framework increasingly emphasises evidence-based psychosocial treatment over incarceration, and in particular over placements that gather delinquent young people together. The interventions that carry the best evidence are worth knowing by name:

- **multisystemic therapy**, an intensive family- and community-based treatment;
- therapeutic foster care, a structured alternative to group placement;
- diversion away from formal processing where appropriate;
- juvenile mental-health and drug courts, which route treatment needs into the justice response.

The common thread is that each keeps the young person embedded in a corrective relationship, family, foster placement or treatment programme, rather than in a peer group of other offenders.

There is also growing recognition within the framework of how much untreated psychiatric illness this population carries, which is precisely the door through which the psychiatric perspective enters. The full machinery of the framework, its statutory structure and the child-protection services that sit alongside it, is taught in the Child psychiatry: assessment, treatment, services and protection notes, and this topic names it rather than reproducing it.

PITFALL

The intuitive response, gathering delinquent adolescents together in a group placement or programme, can make antisocial behaviour worse rather than better. Placing young offenders among deviant peers tends to reinforce the very behaviour it is meant to correct, which is why the evidence-based interventions deliberately keep the young person in a family or individually structured setting. A clinician who recommends "a place with others like him" may be recommending the one thing the framework has learnt to avoid.

10.4 The Indian statutory frame, named but not quoted

The legal specifics belong to the statute, not to a textbook paraphrase. Everything above describes the general, largely Western juvenile-court model and the psychiatric role within it. The Indian legal machinery is governed by its own statute, the **Juvenile Justice (Care and Protection of Children) Act**, and this is where a candidate must be disciplined. The exact definitions, the age thresholds that determine who is treated as a child, the provisions dealing with serious offences, and the bodies constituted to decide these cases are statutory specifics that must be read from the primary Act itself, not carried over from a Western textbook or a second-hand summary. Quoting an age or a provision from memory or from a paraphrase is precisely how an error enters a candidate's answer, because the numbers differ across jurisdictions and across revisions of the law. The safe and correct move is to name the Act, to state that it governs the Indian juvenile-justice response, and to say that its provisions are read from the statute when a specific is genuinely needed.

IN INDIA

The Indian juvenile-justice response operates under the Juvenile Justice (Care and Protection of Children) Act, which establishes the dedicated bodies that adjudicate and provide for young persons in conflict with the law and children in need of care and protection. The statutory detail, the operative age definitions and the provisions for serious offences, should be read from the current Act rather than reproduced here, because these are the specifics most likely to be misquoted. For the full child-protection and juvenile-justice machinery, and for the child psychiatric services that interface with it, see the Child psychiatry: assessment, treatment, services and protection notes.

A delinquent is a young person a court has adjudicated, not a young person a clinician has diagnosed; the marks are for finding, and treating, the psychiatric disorder that so often hides inside the legal label.

TRAP **Equating delinquency with conduct disorder.** Candidates routinely treat the two as synonyms and lose the point of the topic. Delinquency is a legal status conferred by a court; conduct disorder is a clinical diagnosis conferred by a clinician. Most delinquents are not simply "conduct disorder by another name": some have no psychiatric disorder at all, and others have an attentional, substance-related, learning or post-traumatic disorder that the label conceals. Answering as though every young offender has conduct disorder both over-diagnoses and misses the treatable illness the perspective exists to find.

1899	Legal	Comorbid
FIRST JUVENILE COURT ESTABLISHED, ON A REHABILITATIVE MODEL	DELINQUENCY IS AN ADJUDICATED CATEGORY, NOT A DIAGNOSIS	CONDUCT DISORDER, ADHD, SUBSTANCE USE, TRAUMA COMMONLY PRESENT

11 · Pyromania and kleptomania (impulse-control disorders)

These are diagnoses of a captured will, not of the behaviour it produces. **Pyromania** and **kleptomania** are the classical impulse-control disorders of deliberate fire setting and repeated stealing. What makes each a psychiatric diagnosis is not the act, which is also the stuff of ordinary crime, but the internal machinery driving it: a rising, uncomfortable tension that the act discharges, followed by pleasure or relief, in the absence of any everyday motive that would explain the same behaviour in anyone else. The person does not set fires to collect insurance or steal what they cannot afford; they set fires because the setting relieves something, and they steal objects they neither need nor want.

Marks accrue here because the examiner is testing a discrimination the untrained eye gets wrong almost every time: the difference between a crime and a disorder that happens to be enacted through a criminal behaviour. A candidate who can recite that the fire setting must be purposeless, tension-driven and unexplained by gain or anger has understood the topic; one who labels every arsonist a pyromaniac and every shoplifter a kleptomaniac has missed the point. This section owns both disorders in full: their essential features, exclusion rules, rarity and differential from their criminal mimics. The wider family of impulse-control disorders is developed in the Somatic-symptom, sexual, impulse-control disorders and suicide notes and is named here only as context.

11.1 The shared architecture: tension, act, relief

Both disorders run on the same three-beat cycle, and recognising it is half the topic. Before the act there is a mounting sense of **tension or affective arousal**; the act discharges it; and in its aftermath there is pleasure, gratification or relief. This is the signature of an **impulse-control disorder**: the behaviour is not a means to an external end but a way of managing an internal state, which is why it feels compelling to the person and senseless to the observer. The impulse is difficult to resist, often ego-dystonic, and the relief is short-lived, so the cycle repeats. Holding this architecture in mind is what lets a clinician ask the right questions, because the tension-then-relief pattern is rarely volunteered but readily confirmed once specifically sought.

MNEMONIC

Tension - Act - Relief

The common spine of both disorders: an uncomfortable build-up of arousal before the behaviour, its discharge in the act of fire setting or stealing, and a transient sense of pleasure, gratification or relief afterwards. If that cycle is absent, and the behaviour is fully explained by an external motive, neither diagnosis applies.

RULE **The diagnosis is the impulse, never the act.** Fire setting and stealing are behaviours, not disorders. Pyromania and kleptomania are made only when the behaviour is driven by an irresistible, tension-relieving impulse and is not accounted for by profit, ideology, concealment, anger, need or another psychiatric condition. The moment an ordinary motive is found, the impulse-control diagnosis falls away.

11.2 Pyromania: the core criteria

Four positive features must be present together. The behavioural core is **deliberate and purposeful fire setting** on more than one occasion, so a single episode never suffices. Around it sit three affective features that make it a disorder: the tension or affective arousal that precedes the act; a genuine **fascination with, interest in, curiosity about or attraction to fire** and its contexts, uses and paraphernalia; and the pleasure, gratification or relief experienced when setting fires or witnessing their aftermath. The person is often a familiar face at fires, drawn to alarms, equipment and the fire service. The internal state carries the weight: the fire is set not to destroy a target but because the setting and its spectacle satisfy something in the person.

11.3 Pyromania: the exclusions and the arson differential

The exclusions do most of the diagnostic work, because instrumental fire setting is common and pyromania is not. The fire setting must not be done for a rational or comprehensible external reason: not for monetary gain, not in the service of a sociopolitical ideology, not to conceal a crime, not to express anger or vengeance, not to improve one's living circumstances, not in response to a delusion or a hallucination, and not as a product of impaired judgement such as in a major neurocognitive disorder or intellectual disability. Beyond these motive-based exclusions, the fire setting must not be better explained by a broader disorder in which it is one symptom among many.

- excluded if set for monetary gain, ideology, concealment of crime, anger or vengeance, or to improve living circumstances;
- excluded if set in response to a delusion or hallucination, or as a result of impaired judgement;
- excluded if better explained by **conduct disorder, a manic episode, or antisocial personality disorder**.

These exclusions are precisely what separate the diagnosis from ordinary or **instrumental arson**, and from fire setting that is a symptom of conduct disorder, developed in its own right elsewhere in this chapter. The great majority who set fires do so for a reason, which is itself the disqualifier. Antisocial personality disorder, where fire setting can be one facet of a broader exploitative

pattern, belongs to the Personality disorders notes; fire setting only during a manic episode is a symptom of that episode.

TRAP **Equating fire setting with pyromania.** The classic examination error, and the classic clinical one, is to call any repeated fire setter a pyromaniac. Candidates forget that the diagnosis is one of exclusion: it requires that every ordinary motive be absent and that the behaviour not be part of conduct disorder, mania or antisocial personality. Most fire setting is instrumental or symptomatic, and true pyromania is a small residue left once those are stripped away.

11.4 How rare pyromania really is

The number examiners want is a warning against over-diagnosis. Pyromania as a primary diagnosis appears to be very rare, and its true population prevalence is simply not known. The most quoted figure comes from a forensic study of repeated fire setters, among whom only **3.3%** met full criteria for the disorder; even in the population most enriched for fire setting, the overwhelming majority did not qualify. It is essential to separate this from fire-setting behaviour in general, whose lifetime prevalence is of the order of **1.0% to 1.1%** and which is only one component of the disorder and never sufficient for it. In children and adolescents, fire setting is usually associated with conduct disorder, attention-deficit/hyperactivity disorder or an adjustment disorder rather than pyromania, so the paediatric diagnosis should be made with great caution.

11.5 Kleptomania: the core criteria

The defining feature is theft of the useless. Kleptomania is a recurrent failure to resist impulses to steal objects that are **not needed for personal use or for their monetary value**. As with pyromania, an increasing sense of tension precedes the theft, and pleasure, gratification or relief accompanies the act of committing it. The tell is in what is taken and what becomes of it: the objects are typically of little value to the person, who could usually have afforded them, and who then gives them away, discards, hoards or even returns them. The stealing is not driven by want but by the impulse, and the goods are almost incidental. Between episodes the person is frequently distressed and ashamed, the ego-dystonic quality that marks the impulse-control disorders and separates them from a settled criminal disposition.

11.6 Kleptomania: exclusions and the ordinary-theft differential

The single most important discrimination is from ordinary theft. The stealing must not be committed to express anger or vengeance and must not occur in response to a delusion or a hallucination, and it must not be better explained by conduct disorder, a manic episode or antisocial personality disorder. The pivotal contrast is with **ordinary theft**, which is deliberate and motivated by the usefulness or monetary worth of the object. In kleptomania the object is not wanted; in ordinary theft it is the whole point. Shoplifting driven by need, resale value or peer pressure is not kleptomania; nor is the calculated stealing of the antisocial patient, which belongs to the Personality disorders notes, nor the disinhibited acquisitiveness of a manic episode, which remits with the mood state.

- not committed to express anger or vengeance, and not a response to a delusion or hallucination;
- not better explained by conduct disorder, a manic episode, or antisocial personality disorder;
- distinguished from ordinary theft, where the object is taken for its use or its worth.

PITFALL

The commonest clinical failure is to stop at the label of thief and never look for what travels with kleptomania. These patients carry a heavy burden of comorbid mood, anxiety, eating and substance-use disorders, and present through shame and legal jeopardy rather than a request for help. Treating the person as merely delinquent, without screening for the treatable picture behind the stealing, misses both the diagnosis and its companions.

11.7 Kleptomania: epidemiology and the sex ratio

Rare in the population, over-represented among the caught. Kleptomania is very rare in the general population, with a prevalence of about **0.3% to 0.6%**. It shows a female preponderance, with women outnumbering men by a ratio of about **3 to 1**, one of the few impulse-control disorders that is commoner in women. Its visibility is greatest at the point of apprehension: it is found in roughly 4% to 24% of people arrested for shoplifting, a wide band that reflects how variably it is sought. That combination, genuine rarity in the community but a real minority presence among shoplifters, is the examinable shape of its epidemiology, mirroring pyromania, where the disorder is a small fraction even of fire setters.

AXIS	PYROMANIA	KLEPTOMANIA
The behaviour	Deliberate, purposeful fire setting on more than one occasion	Recurrent stealing of objects not needed for use or value
The internal cycle	Tension before, fascination with fire, relief after	Tension before, pleasure or relief at the theft
Its criminal mimic	Instrumental or ideological arson	Ordinary, need-driven or profit-driven theft
Sex distribution	Not established by an owned figure here	Female preponderance, about 3 to 1
Frequency	Very rare even among fire setters (3.3%)	Very rare in the population (0.3% to 0.6%)

The two disorders side by side; they share an identical internal architecture and differ chiefly in the behaviour through which the impulse is discharged and the criminal act each must be told apart from.

11.8 Assessment and management principles

The task is to find the impulse behind the offence and to treat what surrounds it. Because both present far more often through their consequences than a request for help, assessment begins with a deliberate search for the tension-relief cycle and a careful exclusion of every ordinary motive, followed by a systematic screen for the accompanying comorbidities. Management is not established here by an owned protocol, and specific agents and doses should be confirmed against a pharmacology source; in broad terms it combines psychological work

aimed at the impulse, such as cognitive and behavioural strategies that interrupt the tension-to-act sequence, with treatment of coexisting mood, anxiety and substance-use disorders, which frequently improves the impulse-control behaviour as a byproduct. The evidence base for both is thin, a consequence of their rarity, and treatment is individualised rather than protocolised.

GOOD TO REMEMBER

When a patient reaches you through a charge for fire setting or shoplifting, ask three things first: what they felt in the minutes before the act, what they felt during it, and what they did with what they took or what target they chose. A build-up of tension, relief in the act, and a fire set at nothing in particular or an object neither needed nor kept is what turns a medicolegal referral into a treatable diagnosis. The motive question is the whole assessment in miniature.

IN INDIA

Most Indian services diagnose under ICD, where both conditions sit among the impulse-control disorders and their broader framework is developed in the Somatic-symptom, sexual, impulse-control disorders and suicide notes. In practice these patients almost never present asking for treatment; they arrive through the criminal-justice route, after a fire or a shoplifting charge, often for a medicolegal opinion on responsibility. Holding the diagnosis in mind in that forensic setting, and enquiring carefully into motive and the tension-relief cycle, is what distinguishes a treatable disorder from ordinary crime.

Carry this into the exam: pyromania and kleptomania are diagnoses of a tension-relieving impulse, made only when fire setting or stealing is purposeless and every ordinary motive - gain, anger, ideology, need - and every competing disorder is excluded.

Childhood anxiety, OCD and trauma disorders

12 · Separation anxiety disorder (criteria, course, management)

Almost every toddler protests when a parent leaves the room, so the whole clinical art of this diagnosis is knowing where an ordinary developmental protest ends and a disorder begins. **Separation anxiety disorder** is the syndrome in which fear or anxiety about being parted from those to whom the child is attached becomes developmentally inappropriate, excessive and persistent, and starts to cost the child a normal life. It is the most frequent anxiety disorder of early childhood, and it earns its marks not from the symptom list, which candidates memorise easily, but from the two discriminations that sit on either side of it: telling the disorder apart from the heightened separation anxiety that is a normal, even reassuring, feature of early

development, and recognising that the same disorder no longer stops at the nursery door but runs on into adolescence and adult life.

This topic owns the diagnostic architecture of the disorder: the essential feature and its symptom threshold, the eight anxieties the criteria enumerate, the duration and impairment rules, the way the disorder is graded against the child's developmental stage, its epidemiology across the lifespan, its heritable and temperamental roots, the split between the two major classifications over how long symptoms must last, and the screening instrument most used to detect it. School refusal, the childhood anxiety family, selective mutism and the somatisation of distress each belong to their own accounts elsewhere in this chapter and are named here only where the reasoning demands, never reopened.

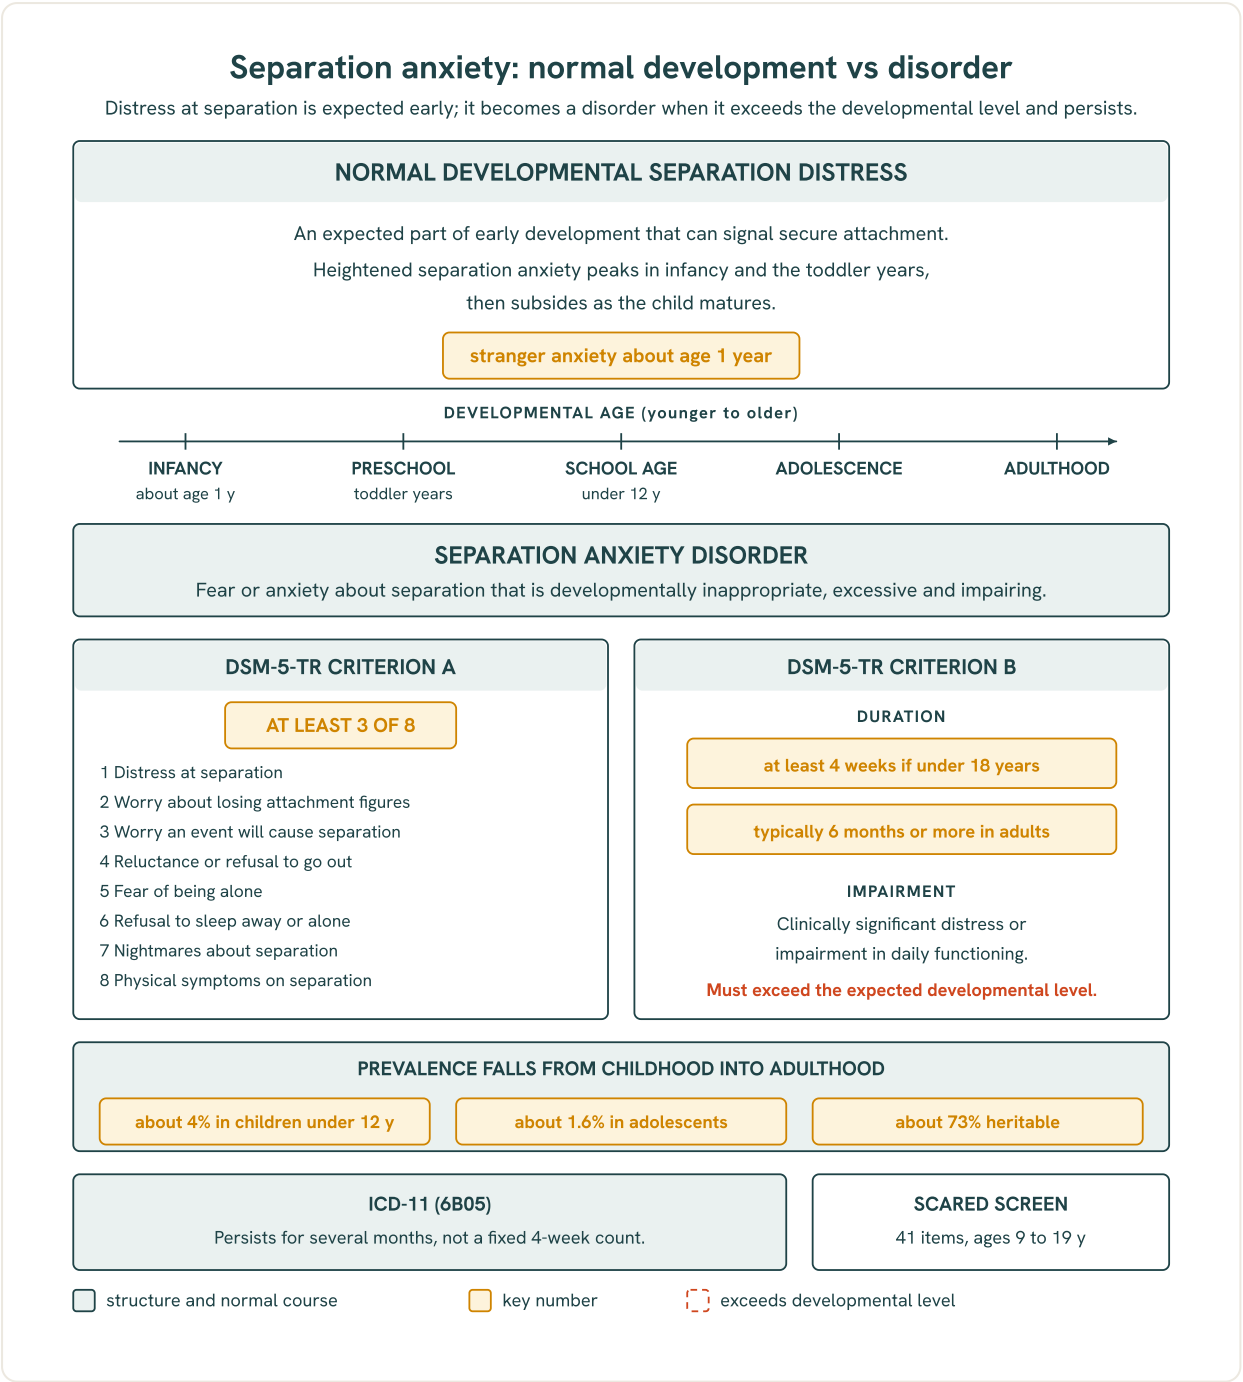

Fig 23.8. Separation anxiety across development: normal early distress that signals secure attachment versus separation anxiety disorder, defined by the DSM-5-TR count and duration thresholds, with prevalence falling from childhood into adulthood.

12.1 Normal separation anxiety and where the disorder begins

Separation fear is a normal developmental achievement before it is ever a disorder. A period of heightened distress on separation is an expected part of early development, appearing as **stranger anxiety** around the age of one year and reflecting the very cognitive and attachment gains that let an infant hold a caregiver in mind and register their absence. Far from being pathological, its presence can signal a securely formed attachment. The disorder is diagnosed only when the anxiety exceeds what is developmentally expected for the child's age and, in addition, meets the duration and impairment thresholds the criteria set. That two-part test - out of proportion to development, and functionally costly - is the safeguard that keeps a normal

phase from being pathologised, and it is the SAD-specific corner of the broader question of when childhood behaviour is within normal limits, which is drawn together as a cross-cutting map in its own right elsewhere in this chapter.

PITFALL

The commonest clinical error runs in both directions around the same axis. A clinging, tearful preschooler at the school gate is over-called a disorder when the distress is age-appropriate and transient; conversely, a genuinely impaired older child is dismissed as merely "attached" or "shy" because separation fear is assumed to belong only to the very young. The corrective is to read the anxiety against the child's developmental level and against how much it actually derails schooling, sleep and family life, rather than against the parents' worry alone.

12.2 Criterion A: the count and the eight anxieties

The diagnosis requires a developmentally excessive fear of separation evidenced by a defined minimum of symptoms. The operational rule is that the fear or anxiety concerning separation from attachment figures be shown by **at least three** of eight enumerated symptoms. Those eight are not a random inventory: they cluster around a small number of themes. Three are forms of anticipatory **worry** - distress at actual or anticipated separation, persistent worry about losing attachment figures or that harm will befall them, and worry that some untoward event will bring about separation. Two are forms of refusal and avoidance - reluctance or refusal to leave home, go to school or go out because of the separation it entails, and reluctance or refusal to be alone. Two concern sleep - reluctance or refusal to sleep away from home or without being near an attachment figure, and repeated nightmares whose theme is separation. The eighth is bodily: repeated **physical complaints** such as headaches, stomachaches, nausea or vomiting when separation occurs or is anticipated. The last of these is easy to miss because it presents to the paediatrician, not the psychiatrist; the recurrent abdominal pain and headache through which anxiety and low mood so often speak in children is developed as a presentation in its own right elsewhere in this chapter, but here the point is narrower - somatic complaints tied specifically to separation are one of the eight diagnostic symptoms and must be counted as such.

THEME	DIAGNOSTIC SYMPTOMS TIED TO SEPARATION
Anticipatory worry	Distress at separation; worry about losing or harm coming to attachment figures; worry about an event causing separation
Refusal and avoidance	Reluctance or refusal to go out or to school; fear of being alone
Sleep	Reluctance or refusal to sleep away or without an attachment figure near; nightmares of separation
Bodily	Physical symptoms - headaches, stomachaches, nausea, vomiting - on separation

The eight Criterion A symptoms grouped by theme; the child needs at least three of the eight, and the bodily symptoms are the ones most likely to be routed to a physician before a psychiatrist.

MNEMONIC

Worry, Won't-go, Won't-sleep, and the body

The eight anxieties fall into four holdable groups: three **worries** about separation and harm, two forms of **won't-go** refusal to leave or be alone, two forms of **won't-sleep** away from an attachment figure, and one **bodily** cluster of physical complaints. Carrying the themes rather than a flat list of eight is what makes the count usable at the bedside.

12.3 Criteria B to D: duration, distress and the differential

Duration is where the criteria are age-graded, and it is the most examinable single rule. The fear, anxiety or avoidance must be persistent, lasting **at least four weeks** in children and adolescents younger than eighteen years, and typically six months or more in adults. The four-week floor is deliberately short because childhood distress on separation can be so intense that a longer wait would leave an impaired child untreated; the longer adult convention reflects that a disorder first surfacing or persisting in adulthood must be distinguished from transient reactions to real life stress. Beyond duration, the disturbance must cause clinically significant distress or impairment in social, academic or other important areas, and it must not be better explained by another disorder. Several conditions mimic it and must be excluded:

- the refusal to leave home in autism, driven by a need for sameness rather than separation fear;
- the diffuse worry of generalised anxiety, which is not anchored to separation;
- a fear driven by delusion in a psychotic illness;
- the reluctance to go out in agoraphobia, where the fear is of the situation, not the parting.

The diagnosis, in other words, is not made from the separation fear alone but from separation fear that persists, disables and is not a better fit somewhere else.

The core rule to carry into the exam: at least three of eight symptoms of developmentally excessive separation fear, persisting at least four weeks in the under-eighteens, with clinically significant impairment.

RULE **The threshold is developmental inappropriateness plus duration plus impairment, never the fear alone.** Separation anxiety is normal; separation anxiety that exceeds the child's developmental level, lasts beyond the criterion period and demonstrably impairs schooling, sleep or family function is the disorder. Each of the three conditions is load-bearing, and dropping any one of them is how normal childhood distress is over-diagnosed.

12.4 A lifespan disorder: epidemiology and course

The single most important shift in how this disorder is now understood is that it does not end with childhood. It is the most common anxiety disorder in children younger than twelve years, with a six-to-twelve-month prevalence of **approximately four per cent**. Prevalence then falls steadily from childhood through adolescence and into adult life; by adolescence the twelve-month figure is down to **about 1.6 per cent**. The older teaching that the condition is purely a

disorder of childhood has been abandoned: it can persist across development, can wax and wane with periods of stress and transition, and can have its first onset in adulthood, which is why the criteria carry a separate adult duration convention at all. The typical childhood course is one of exacerbation around developmental hurdles - starting school, a family move, a parental illness or a bereavement - and the disorder is a recognised antecedent of later anxiety and depressive disorders, so it is worth treating rather than waiting out.

12.5 Etiology: temperament, attachment and a strongly heritable core

The disorder sits at the meeting point of a fearful temperament, the quality of attachment and a substantial genetic loading. Behavioural inhibition - the temperamental tendency to withdraw from, and to react with distress to, the unfamiliar - is the constitutional soil, and an anxious or overprotective parenting style, parental anxiety disorder, and stressful life events involving loss or threat of separation are the environmental accelerants. Onto that clinical picture the genetics map cleanly: in a community sample of six-year-old twins, heritability was **estimated at 73 per cent**, with higher rates in girls. That is a high figure for a childhood emotional disorder: it signals that the condition is not simply a learned response to an anxious home but carries a strong constitutional contribution, and it fits the observed familial aggregation, in which children of parents with anxiety and panic disorders are over-represented. Etiology here is genuinely biopsychosocial: temperament sets the threshold, attachment and parenting shape the expression, and life events involving separation pull the trigger.

12.6 The classification split: a fixed count against a clinical judgement of duration

The two major manuals agree on the disorder and disagree on how much numerical precision to demand. One system fixes an explicit symptom count and an explicit minimum duration, the four-week floor for the under-eighteens being the clearest example. The other, the ICD-11 clinical descriptions and diagnostic requirements, deliberately avoids that kind of artificial precision, asking instead that symptoms persist for at least several months rather than for a fixed four-week count, and leaving the clinician to judge severity and persistence against the whole picture. In ICD-11 the disorder is coded **6B05**, and, unlike its predecessor, it is no longer confined to childhood. Where the individual is under six years of age, the ICD-11 mortality and morbidity statistics map the condition to the older category of separation anxiety disorder of childhood, F93.0. The disagreement is not cosmetic: a count-and-clock system prizes reliability and reproducibility between raters, while the descriptive system prizes clinical validity and warns against reifying an arbitrary threshold, and knowing which philosophy a given case file follows tells the reader why one record insists on four weeks and another speaks of several months.

AXIS	FIXED-CRITERIA SYSTEM	ICD-11 CLINICAL DESCRIPTIONS
Symptom count	An explicit three-of-eight threshold	No fixed count; a clinical judgement
Duration	At least four weeks in the under-eighteens	At least several months, not a fixed count
Code	Separation anxiety disorder	6B05 (mapping to F93.0 under age six)

The same disorder handled by two classificatory philosophies; the load-bearing contrast is the fixed four-week count against a clinical judgement that symptoms have lasted several months.

IN INDIA

Because Indian services classify under ICD, the operative label in case files, referrals and official reports is the ICD entity, and the clinician is not obliged to satisfy an exact four-week count so much as to judge that the separation anxiety has persisted, is developmentally excessive and is impairing. A trainee schooled on the count-and-clock manual should not treat a record that speaks of several months rather than four weeks as incomplete: it is following the classification actually in force here, and the two systems are describing the same child.

12.7 Assessment and the screening instruments

Assessment is multi-informant, developmentally framed and helped, but never replaced, by a rating scale. The history is taken from the child and, separately, from the parents, because a young child's account and a caregiver's account of the same anxiety frequently diverge, and school information anchors the impairment. Among structured aids the most widely used is the **Screen for Child Anxiety Related Emotional Disorders**, the SCARED, developed by Birmaher and colleagues. It is a 41-item questionnaire yielding five factors - panic or somatic symptoms, generalised anxiety, separation anxiety, social phobia and school phobia - so that it screens not only for this disorder but across the childhood anxiety family, whose members are developed in their own account elsewhere in this chapter. It has matched child and parent report versions, is intended for roughly ages nine to nineteen, is freely available, and takes under fifteen minutes to complete; a short five-item version also exists for rapid screening. Its value is precisely that it captures the separation factor within a broader anxiety screen, which suits a disorder that rarely travels alone.

GOOD TO REMEMBER

Use the SCARED as a screen and a way of structuring the interview across the anxiety factors, not as a diagnostic verdict. A scale flags where to look; the diagnosis still turns on the developmental-inappropriateness, duration and impairment judgement made from the history, and a high separation-anxiety factor score in a child whose function is intact is a prompt to reassess, not a diagnosis.

12.8 Management and the borders that matter

Treatment is psychological first, pharmacological second, and always delivered partly through the parents. The best-supported first-line intervention is a structured, exposure-based **cognitive behavioural therapy**, in which the child is helped to face graded separations while the accompanying catastrophic cognitions about harm and loss are tested and revised, and in which caregivers are coached out of the accommodation - the reassurance, the sleeping-in, the staying at home - that inadvertently maintains the fear. For more severe or refractory presentations, pharmacotherapy is added, with the serotonergic antidepressants the usual choice; the specific agents, doses and the youth-specific safety monitoring that any antidepressant in a young person requires are the province of the paediatric mood and antidepressant accounts and are not

reproduced here. The clinically decisive point is that medication supplements, and does not replace, the psychological and family work, because the disorder is sustained by a learned cycle of avoidance and accommodation that only exposure can unwind.

The management borders are as examinable as the treatment itself. Separation anxiety disorder is the single commonest engine of **school refusal**, but the two are not the same thing - school refusal has other causes, from social anxiety and depression to bullying and learning difficulty, and its assessment and management are developed in their own right elsewhere in this chapter. It must also be held apart from selective mutism, another childhood anxiety condition treated separately here, and from the frank school truancy of the conduct-disordered child, who stays away from school without anxiety and usually without the parents' knowledge, rather than clinging to a caregiver in fear. The anxious child who cannot get to school and the defiant child who will not are two different clinical problems, and the exam reliably rewards the distinction.

TRAP **School refusal is not a diagnosis, and separation anxiety disorder is not its only cause.** Candidates conflate the two, answering "separation anxiety disorder" whenever a child will not attend school. The anxious, home-clinging non-attender whose parents know exactly where he is points to this disorder; the child who leaves for school and never arrives, without anxiety and without the parents' knowledge, is truant, which belongs to the disruptive rather than the anxious spectrum.

13 · School refusal and school phobia (assessment and management)

The single most useful thing this topic teaches is that "not going to school" is a behaviour, not a diagnosis. A child who is repeatedly absent has told you almost nothing about why, and the entire clinical and examination value of the subject lies in taking that one observable fact apart into the very different problems that produce it. Absenteeism sits at the meeting point of psychiatry, paediatrics, the family and the school, and the marks are here because the assessor wants to see a candidate move from the presenting behaviour to the mechanism underneath it, and then to a management plan that follows from the mechanism rather than from the behaviour.

The vocabulary is where candidates lose easy marks, because the words are used loosely in ordinary speech and precisely in the exam. This topic owns the terminology of school non-attendance, the assessment that separates its varieties, and the management that flows from that separation. The individual anxiety disorders that so often lie beneath school refusal are each developed in their own right elsewhere in this chapter and are named here only at the point where the differential needs them, because the skill being tested is not the re-recitation of separation anxiety criteria but the ability to recognise which disorder is driving the child to the door and turning them back.

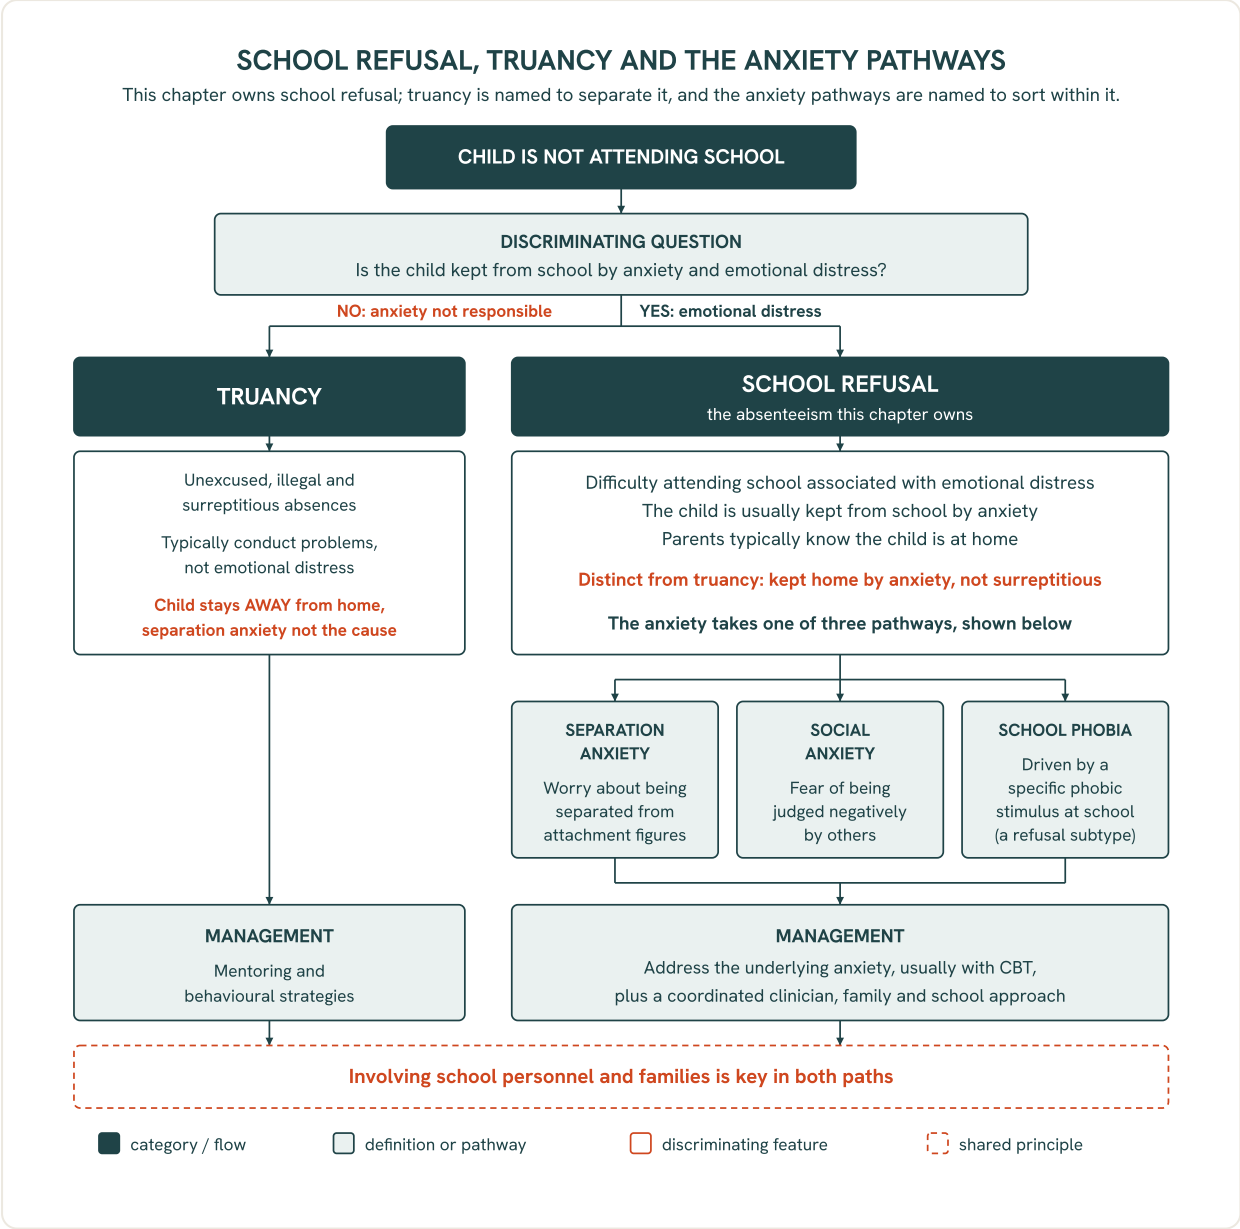

Fig 23.9. School refusal against truancy and the three anxiety pathways: one discriminating question splits anxiety-driven school refusal from surreptitious truancy, school refusal then sorts into separation anxiety, social anxiety or school phobia, and the management path diverges - mentoring and behavioural strategies for truancy, addressing the underlying anxiety for school refusal - while school and family involvement stays key in both.

13.1 Three problems wearing one presentation

The same empty desk has at least three quite different explanations. The first is **truancy**, which is absence that is unexcused, concealed and often against the rules, in a child who characteristically does not want to be in school and shows no particular emotional distress about staying away. Truancy is typically embedded in a wider pattern of conduct problems rather than in anxiety, and the child usually hides the absence from parents. The second is **school refusal**, difficulty attending school that is bound up with emotional distress: the child is not skipping school for something more enjoyable but is being kept from it by fear, dread or misery, and the distress is real and visible. The third and narrowest is **school phobia**, which is difficulty attending because of a specific phobia, a phobic stimulus located in or on the way to the school itself. These three are not points on a single spectrum of severity; they are different problems with different engines, and the first task of assessment is to say which one is in front of you.

RULE **Distress is the pivot on which the differential turns.** The absence that is comfortable, concealed and tied to rule-breaking points to truancy and its conduct-problem context; the absence that is distressing, known to the parents and driven by fear points to school refusal and an anxiety disorder beneath it. Every later decision, assessment and management alike, follows from which side of that line the child falls.

13.2 Why "school refusal" is a symptom and not a disorder

School refusal is a final common pathway, and the diagnosis lives one layer down. No classificatory system carries "school refusal" as a disorder, and that is the conceptual heart of the topic. It is a presenting behaviour produced by any of several anxiety disorders, and the clinical job is to identify which one. Three pathways account for most cases. In the youngest children the driver is most often separation anxiety, the fear not of school itself but of being apart from an attachment figure, so that the child would be equally reluctant to go anywhere that meant separation; separation anxiety disorder is developed in its own section of this chapter and is only named here. In older children and adolescents the driver is frequently social anxiety, where the avoidance is generated by **fear of being judged negatively by others** rather than by worry about leaving home, so that the feared object is the classroom, the corridor and the crowd rather than the parent's absence. The third pathway is the true school phobia, in which a discrete phobic stimulus connected with the school compels avoidance. Social anxiety disorder and specific phobia are themselves taught elsewhere in this chapter; what belongs here is the recognition that each can surface as the identical behaviour of a child at the school gate who cannot go in.

PATHWAY BENEATH THE REFUSAL	WHAT THE CHILD IS ACTUALLY AFRAID OF	WHERE THE FEAR POINTS
Separation anxiety	Being apart from an attachment figure; harm befalling them or the self while apart	Away from the parent, not at the school as such; reluctance to sleep away or be left anywhere
Social anxiety	Being negatively evaluated by others rather than separation from home	The peer group, being watched, performing, the corridor and the classroom
Specific phobia (school phobia)	A discrete phobic stimulus located in or en route to the school	The particular object or situation, avoidance narrowing onto it

The three anxiety routes to the same behaviour. Naming the route is the diagnosis; the behaviour of non-attendance is shared and by itself distinguishes none of them.

13.3 Truancy versus school refusal: the fork that decides everything

The two look alike from the school register and diverge on almost every clinical axis. Distinguishing conduct-driven truancy from anxiety-driven school refusal is the examinable core of assessment, and it is done from a handful of discriminating features rather than from the fact of absence. The most reliable single discriminator concerns where the child is while not in school. In truancy, and in the school avoidance that goes with conduct disorder, the child or adolescent typically stays away from the home rather than returning to it, and separation anxiety is not what is keeping them out; the absence is spent elsewhere, often with a peer group, and is concealed

from the parents. In school refusal the opposite holds: the child is usually at home, and the parents usually know it, because the child cannot bear to leave and the distress is directed at going, not at being caught. Conduct disorder, within which truancy characteristically sits, is developed in its own section of this chapter and is named here only as the context that truancy points towards.

FEATURE	TRUANCY (CONDUCT-LINKED)	SCHOOL REFUSAL (ANXIETY-LINKED)
Emotional state about attending	Little distress; the child prefers not to attend	Marked distress, fear or dread centred on going
Where the child is during absence	Away from home, often with peers	At home, close to the attachment figure
Parental knowledge	Usually concealed from parents	Usually known to the parents
Associated pattern	Broader conduct problems and rule-breaking	An underlying anxiety disorder
Schoolwork attitude	Often accompanied by loss of interest in schoolwork	Often a conscientious child who wants to keep up

The clinical axes that separate the two great categories of absence. No single row is infallible, but the pattern across them is what the assessor is testing.

TRAP **Treating "school phobia" as a synonym for all school refusal.** The older literature used "school phobia" loosely for any anxious non-attendance, and candidates inherit the habit. In precise use it is the narrow subtype in which a specific phobia drives the avoidance; most school refusal is not a true phobia of the school at all but separation or social anxiety wearing the school as its stage. Answering that a young, separation-anxious child has "school phobia" misnames the mechanism and, worse, points management in the wrong direction.

13.4 Assessment: reading the pattern, not just the absence

The history is built to expose the mechanism, and its shape is characteristic. A useful assessment establishes the onset and its triggers, the daily pattern, the somatic accompaniments and the family response. Onset is often tied to a transition or a discrete stressor: starting a new school, moving up a stage, returning after an illness or a holiday, a bereavement, bullying, or a humiliation in class. The daily pattern is a strong clue, with distress and physical symptoms mounting on school mornings, on Sunday evenings and at the start of term, and easing markedly at weekends, in the holidays and once the child is allowed to stay home, a Monday-to-Friday rhythm that anchors the problem to school rather than to a generalised illness. A meticulous account of what the child does during the day, and of whether the parents know where they are, does much of the work of separating refusal from truancy on its own.

The somatic presentation deserves particular emphasis because it is how many of these children first reach a doctor. Recurrent abdominal pain, headache, nausea and non-specific malaise, appearing on school mornings and resolving when attendance is not required, are the common currency of anxious school refusal, and the child is frequently worked up for a physical illness before the pattern is recognised. This somatisation of distress is itself developed elsewhere in this

chapter, and the point to carry here is only that a negative physical work-up in a child whose symptoms keep the timetable of the school week should redirect the assessment towards anxiety rather than prolong the search for organic disease. Corroborating history from the school, and from several informants, is essential, and the fuller apparatus of child psychiatric assessment and the involvement of services is developed in the Child psychiatry: assessment, treatment, services and protection notes.

- onset and its trigger: a school transition, an illness, a bereavement, bullying or a classroom humiliation;
- the weekly rhythm: worse on school mornings and at term's start, better at weekends and in holidays;
- somatic symptoms timed to attendance and clearing when the child stays home;
- where the child spends the day and whether the parents know, the discriminator from truancy;
- the family's response, and whether accommodation has quietly become the pattern.

GOOD TO REMEMBER

Ask the parents to narrate a single school morning in detail, from waking to the point at which the child either leaves or does not. That one concrete account usually reveals the mechanism faster than any checklist: the pleading and the physical complaints, the exact moment the distress peaks, whether it is the parting or the classroom that is dreaded, and how the household has learned to respond. The pattern of who does what at that moment is also the raw material for the behavioural plan that follows.

13.5 Management follows the mechanism

The management splits exactly where the diagnosis split, and the two paths are not interchangeable. Because truancy and school refusal have different engines, they call for different interventions. Truancy is best met with mentoring and behavioural strategies, whereas school refusal is best managed by treating the anxiety underneath it, usually with cognitive behavioural therapy and a coordinated approach across clinician, family and school. In both, the involvement of school personnel and the family is decisive, because the behaviour is enacted in the space between home and school and cannot be shifted from the clinic alone. For the anxious school refuser the therapeutic centre of gravity is a **graded return to school**: a planned, stepwise re-exposure that begins below the point of overwhelming anxiety and advances as tolerance builds, so that avoidance is not reinforced by escape and the child relearns that the feared situation can be survived. The longer a child is out, the harder re-entry becomes, which is why an early, structured, sympathetic push to return generally serves the child better than an open-ended wait for the anxiety to pass on its own.

The work is necessarily done by a triad. The clinician formulates the driving disorder and delivers or directs the anxiety treatment; the family is coached to hold the plan at the difficult morning moment and to stop inadvertently rewarding non-attendance; and the school arranges the graded

timetable, a point of safety within the building and the flexibility that a stepwise return requires. Where the underlying disorder is severe, medication for the anxiety disorder may be added to therapy, but the specific agents and their dosing belong with the pharmacology of the individual anxiety disorders and are not settled by this topic. Comorbid conditions and the family's own difficulties are addressed in parallel, since an unaddressed parental anxiety or an unrecognised depression in the child will quietly undo the best-laid return plan.

PITFALL

The recurring clinical failure is to misread the category and then apply the wrong lever. An anxious school refuser handled as a truant, with sanctions, threats and a purely disciplinary response, is punished for a fear they cannot simply choose to drop, and the anxiety and the avoidance both deepen. The mirror error, treating a conduct-driven truant with gentle, anxiety-focused accommodation, rewards the very absence it means to cure. Naming the mechanism first is not an academic nicety; it is what decides whether the intervention helps or harms.

IN INDIA

Several features of Indian practice sharpen this topic. These children very often present first to a paediatrician or a general practitioner with recurrent abdominal pain or headache, and the psychiatric mechanism is reached only after a physical work-up, so the index of suspicion has to be carried by the first doctor. The intense weight placed on academic performance, tuition and board examinations can both precipitate anxious refusal and make families read it as laziness or defiance, which pushes them towards a punitive response and away from the graded, collaborative plan that actually works. Coordinated clinician, family and school management, straightforward to prescribe, is harder to deliver where schools have little counselling provision and mental-health literacy is low, so a large part of the clinician's task is patient liaison and psychoeducation with parents and teachers who may never have heard the behaviour named as anxiety.

13.6 Course, complications and why the marks are here

Left unaddressed, the problem compounds. School refusal tends to entrench: avoidance is self-reinforcing, each absence makes the next one harder, and prolonged absence brings secondary losses that outlast the original fear. Academic slippage, social withdrawal from a peer group the child no longer sees daily, erosion of confidence and, in the family, a slow accommodation that hardens around the absence are the characteristic complications, and the anxious school refuser who never returns is at risk of carrying anxiety disorders and impaired functioning into adult life. The prognostic levers are the ones assessment and management have already identified: the earlier the recognition and the shorter the time out of school, the better the outlook, while long-standing refusal in an older child with a well-established pattern is harder to reverse. This is why the topic rewards a candidate who can move cleanly from the shared behaviour to the specific mechanism and then to a mechanism-matched plan, because that sequence is exactly what changes the trajectory.

Not-going-to-school is a behaviour, not a diagnosis: separate the concealed, distress-free absence of truancy from the distressing, parent-known absence of school refusal, find the anxiety disorder driving the refusal, and manage each along its own path, with a graded return to school at the centre of the anxious child's plan.

14 · Anxiety disorders in children (generalized, social, specific phobia)

Anxiety is the commonest form of childhood psychopathology, and the marks here reward the candidate who can hold three disorders apart while remembering what binds them. This topic covers the childhood presentations of generalized anxiety disorder, social anxiety disorder and specific phobia. These are ordinary human states of worry and fear that have crossed a threshold: they have become excessive for the child's developmental stage, persistent rather than passing, and costly to functioning at home, at school or among peers. The examinable difficulty is not the existence of these disorders, which every candidate can name, but the child-specific modifications the classifications make to their adult criteria, the developmental content of the fear, and the border between a disorder and the fears and worries that are normal in growing up.

What is owned here is the child-specific criteria and epidemiology of these three disorders. The wider family of childhood anxiety - separation anxiety disorder, selective mutism, and the anxiety that drives school refusal - is developed in its own right elsewhere in this chapter, as are paediatric obsessive-compulsive disorder and childhood post-traumatic stress disorder; here they are named as relatives, not reopened. The general adult anxiety disorders, their neurobiology and their pharmacology are not the business of this chapter. The accompanying figure places these disorders as one anxiety family so that their overlap and comorbidity can be seen at a glance.

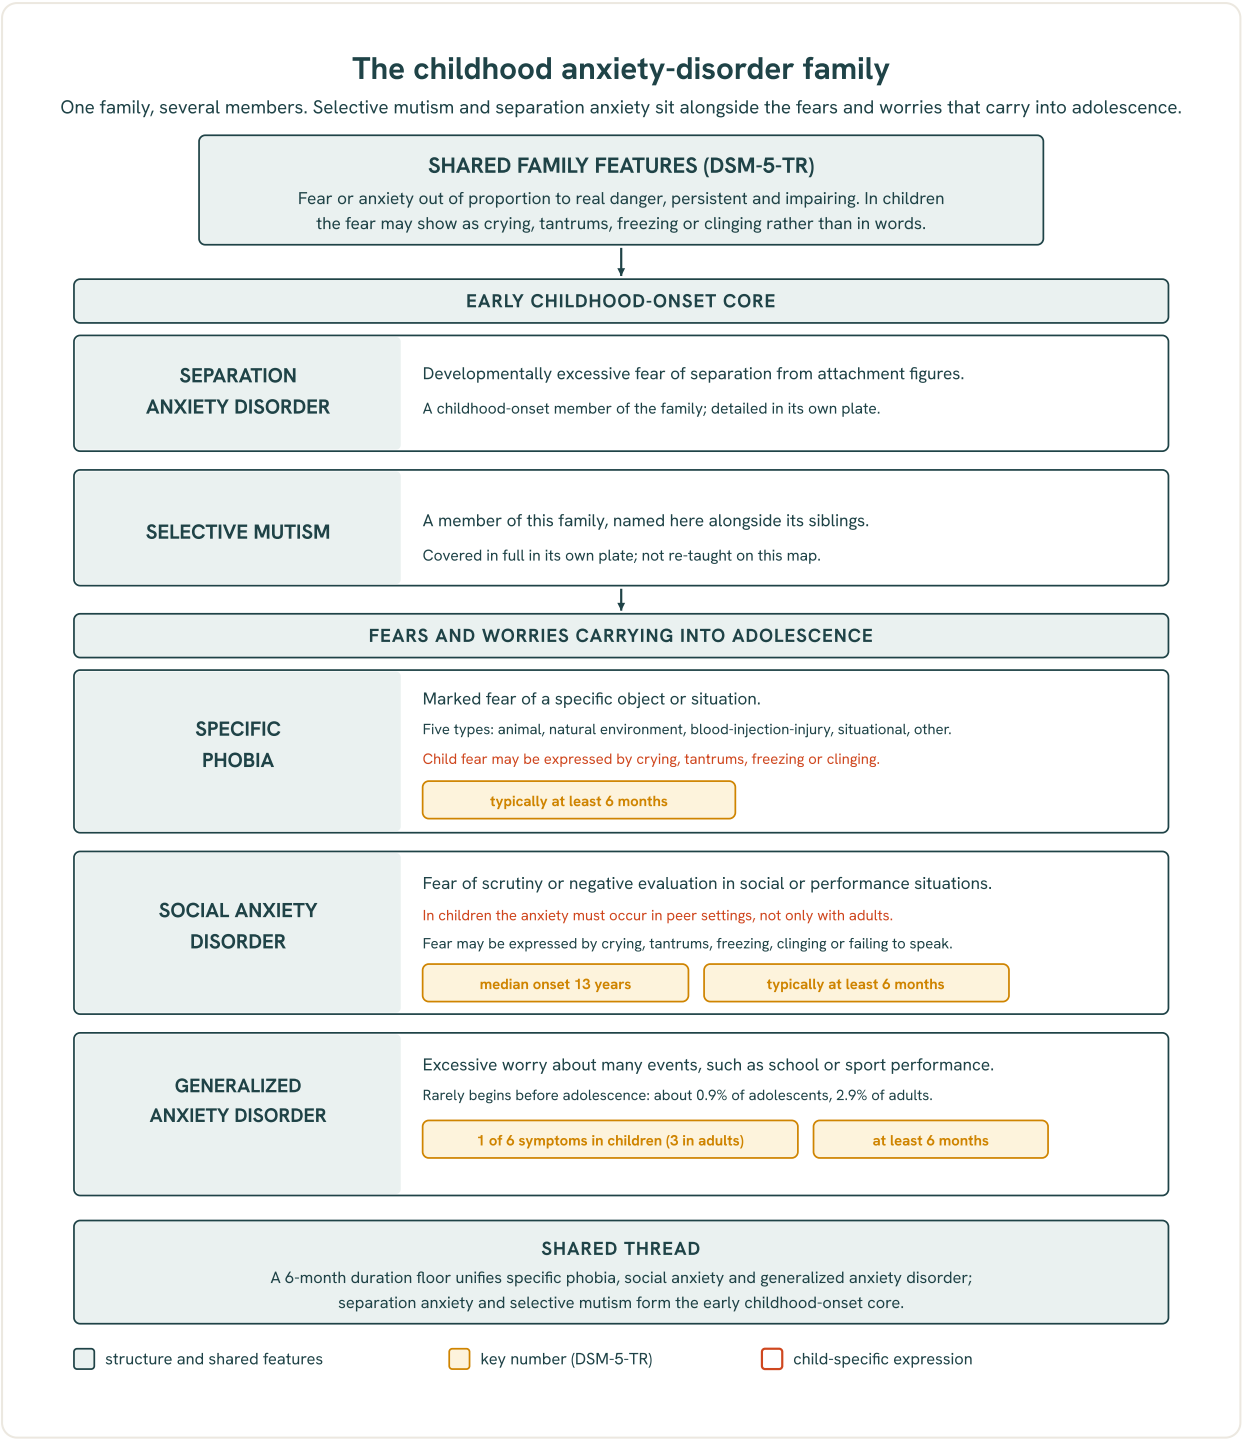

Fig 23.10. The childhood anxiety-disorder family: an early childhood-onset core (separation anxiety disorder and selective mutism, the latter named only) alongside specific phobia, social anxiety disorder and generalized anxiety disorder, unified by a fear out of proportion to danger, a typical 6-month duration floor and a child-specific expression through crying, tantrums, freezing or clinging.

14.1 The shared architecture: what makes childhood fear a disorder

Across all three disorders the diagnosis turns on the same three qualities: the fear is excessive, it is persistent, and it impairs. A young child who is frightened of the dark, shy with strangers or worried before an examination is not thereby ill; fear and worry are adaptive and developmentally expected. The classifications convert these normal states into disorders only when the response is out of proportion to any real danger, endures well beyond the situation that provoked it, and interferes with the child's life. This is why each of the three carries a minimum

duration and an impairment requirement, and why the clinician's first move is always to weigh the presentation against what is normal for that age. The core pathology is not different from the adult form; what differs is how a developing child expresses fear and how the thresholds are set for someone who cannot yet regulate or articulate distress. Holding this shared frame in mind is what stops a candidate from memorising three unconnected symptom lists and losing the reasoning that actually earns the marks.

RULE **Childhood anxiety disorders differ from their adult forms in expression and threshold, not in essence.** The fear is the same fear; the child shows it through behaviour rather than words, and the criteria are modified to fit a developing person. Diagnose when the fear or worry is excessive for the child's stage, persistent rather than transient, and genuinely impairing, and not before.

14.2 Generalized anxiety disorder: the worry and its childhood content

The essential feature is excessive, hard-to-control worry, and in children its content is characteristically about performance. **Generalized anxiety disorder** requires excessive anxiety and worry, occurring more days than not, about a number of events or activities, sustained for at least **6 months**. What marks the childhood form is the subject matter of the worry. Affected children **worry excessively about their own competence and the quality of their performance** at school or in sport, and they do so even when their performance is not being evaluated by anyone. Such children are often overly conforming, perfectionistic and unsure of themselves, and they tend to seek repeated reassurance about their work and their worth. This reassurance-seeking is diagnostically useful and clinically double-edged: it briefly relieves the child but draws the parent into providing it again and again, maintaining the very worry it is meant to settle. The worry is not tied to a single feared object, which separates it from specific phobia, nor to separation or to social scrutiny specifically.

14.3 The associated-symptom criterion and the child modification

The single most tested point in this disorder is that children need far fewer associated somatic-cognitive symptoms than adults. The worry must be accompanied by physical and cognitive symptoms drawn from a fixed set of six. In adults, at least three of the six must be present; in children, however, only **one** of the six is required. This is a deliberate developmental concession: a worried child may not yet report or recognise the full cluster of arousal symptoms an adult can describe, so the bar is set lower to avoid missing genuine cases. The **six associated symptoms** are the familiar mix of arousal and its consequences.

- restlessness or feeling keyed up or on edge;
- being easily fatigued;
- difficulty concentrating or the mind going blank;
- irritability;
- muscle tension;
- sleep disturbance.

MNEMONIC

Restless, Run-down, Distracted, Irritable, Tense, Sleepless

The six associated symptoms in order: **R**estless (restlessness or feeling keyed up), **R**un-down (easily fatigued), **D**istracted (difficulty concentrating or mind going blank), **I**rritable, **T**ense (muscle tension) and **S**leepless (sleep disturbance). In a child, remember that any single one of these, alongside the worry, satisfies the criterion.

14.4 Generalized anxiety disorder: epidemiology and course

The disorder is uncommon before adolescence, and that fact carries clinical weight. Twelve-month prevalence among adolescents is around **0.9%**, and the disorder rarely occurs before adolescence, with rates rising as the child moves through the teenage years toward the higher figures seen in adulthood. The developmental point behind the numbers is that the sustained, future-oriented, self-evaluative worry that defines this disorder depends on cognitive capacities - anticipating, comparing oneself against a standard, projecting consequences forward - that mature through late childhood and adolescence. A genuinely generalised, chronic worry in a very young child is therefore unusual and should prompt a careful look for another explanation: a more circumscribed anxiety disorder such as separation anxiety, a response to an ongoing stressor, or worry anchored to a specific feared situation. The disorder tends to be chronic and to fluctuate, and it is a frequent forerunner of, and companion to, depressive disorders as the young person grows.

14.5 Social anxiety disorder: the fear and its child-specific expression

Two child-specific rules define this disorder in the young: the fear must reach peers, and it may be shown as behaviour rather than spoken as fear. **Social anxiety disorder** is a marked fear of social situations in which the child is exposed to possible scrutiny by others, driven by a fear of acting in a way, or showing anxiety symptoms, that will be negatively evaluated. The first modification is a safeguard against overdiagnosis: in children the anxiety must occur in settings with peers and not only during interactions with adults. Many children are reticent with unfamiliar grown-ups while being entirely comfortable among other children, and that pattern is not this disorder; genuine social anxiety disorder shows itself with age-mates, in the playground and the classroom, not merely in the consulting room. The second modification concerns how the fear surfaces. A young child rarely says that they fear negative evaluation; instead the fear may be expressed by crying, tantrums, freezing, clinging, shrinking, or failing to speak in social situations. The clinician must read these behaviours as the child's language of fear rather than as defiance or as a separate problem.

GOOD TO REMEMBER

A child who freezes, clings or falls silent when peers are present is telling you about fear, not staging a protest. Because the same child may speak freely at home, the diagnosis is easily missed if the assessment relies only on the parents' account of a "shy" or "stubborn" child; ask specifically about behaviour in the presence of other children, and gather a report from school before the shyness is dismissed.

14.6 Social anxiety disorder: duration, onset and trajectory

The duration requirement is what separates the disorder from the ordinary and often intense social fears of childhood. The fear, anxiety or avoidance must be persistent, typically lasting 6 months or more. This floor matters more in the young than in adults precisely because transient social fears - a phase of clinginess, a spell of reluctance to perform, a wariness after a change of school - are so common in children and so often self-limiting. The persistence requirement forces the clinician to wait past the passing phase before affixing a diagnosis. In its course, social anxiety disorder has a characteristically early onset: the median age at which it begins is about **13** years, and it frequently emerges out of a childhood history of **behavioural inhibition** or marked shyness, the temperamental tendency to withdraw from the unfamiliar that can be observed from the earliest years. That developmental continuity, from an inhibited temperament in the toddler to a diagnosable disorder in the adolescent, is a favourite theme of examiners and a real target for early intervention.

14.7 Specific phobia: the phenomenon, the childhood expression and the five types

A specific phobia is fear out of proportion to a circumscribed object or situation, and in children it too speaks through behaviour. **Specific phobia** is a marked, disproportionate fear or anxiety about a specific object or situation, which is actively avoided or endured with intense distress, and which is out of keeping with any actual danger. As in social anxiety, the young child's fear may be expressed by crying, tantrums, freezing or clinging rather than described. The phobias are grouped by the nature of the feared stimulus into **five** specifier types.

SPECIFIER TYPE	TYPICAL FEARED STIMULUS
Animal	Dogs, insects, snakes
Natural environment	Heights, storms, water
Blood-injection-injury type	Needles, injections, the sight of blood
Situational	Enclosed spaces, aeroplanes, the dark
Other	Choking, vomiting, costumed figures

The five phobic-stimulus specifiers by which specific phobia is coded. The blood-injection-injury type is set apart by its distinctive physiology.

One type behaves unlike the rest. The blood-injection-injury type is associated with a vasovagal fainting response: rather than the sustained sympathetic arousal of the other phobias, exposure provokes an initial rise and then a sharp fall in heart rate and blood pressure, and the person faints. This is why the child who passes out at the sight of a needle or blood belongs in a

physiological category of their own, and why the applied relaxation used for other phobias is combined here with applied tension to counter the drop in blood pressure.

14.8 Specific phobia: duration and the border with normal childhood fear

Because circumscribed fears are near-universal in childhood, the persistence requirement is the safeguard that keeps a normal fear from being called a disorder. Fear of the dark, of animals, of strangers and of imaginary creatures follows a well-described developmental sequence, each fear appearing and then fading as the child matures; these are part of normal development, not pathology. What converts such a fear into a specific phobia is that it is persistent, typically lasting 6 months or more, disproportionate to real danger, and productive of real impairment or avoidance. The threshold is therefore not the presence of the fear but its persistence and its cost. The normative sequence of childhood fears belongs to the Normal child development and milestones notes; the diagnostic line drawn here is simply that a fear which has outlasted its developmental window, and which is now distorting the child's life, has become a disorder. This is the specific threshold this topic owns; the broader map of normal-versus-disordered childhood behaviour is drawn elsewhere in this chapter.

> **PITFALL**
>
> The error runs both ways. On one side, an anxious parent and clinician pathologise the developmentally ordinary fear of the dark or of dogs in a preschooler, ignoring that the fear is age-appropriate and will pass; on the other, a genuinely impairing, persistent phobia in an older child is waved away as "a phase" long after the phase should have ended. The corrective in both directions is the same: measure the fear against the developmental norm and against the twin tests of persistence and impairment, not against the family's level of alarm.

14.9 Assessment, comorbidity and management

Find one childhood anxiety disorder and look for the others, because they cluster, and treat first with graded exposure. These three disorders are highly comorbid with one another, with the rest of the anxiety family, and with depression as the child grows, so the discovery of one should trigger a screen for the rest. Assessment is necessarily multi-informant: child, parents and school each see a different slice of the anxiety, and the criterion that the fear reach peers, or that worry persist across settings, cannot be judged from one source. Childhood anxiety also hides behind other complaints. It commonly presents through recurrent physical symptoms such as abdominal pain and headaches, and through reluctance or refusal to attend school; those presentations are developed in their own right elsewhere in this chapter and are flagged here only so the anxiety behind them is not missed. The first-line treatment across all three is **exposure**-based cognitive behavioural therapy, in which the child, supported by parents, is helped to approach the feared situation in graded steps while the avoidance that maintains the fear is dismantled; parental accommodation, the well-meaning reassurance and avoidance that families build around an anxious child, is a specific target. Medication is reserved for more severe or refractory presentations and is layered onto the psychological work, never a substitute for it.

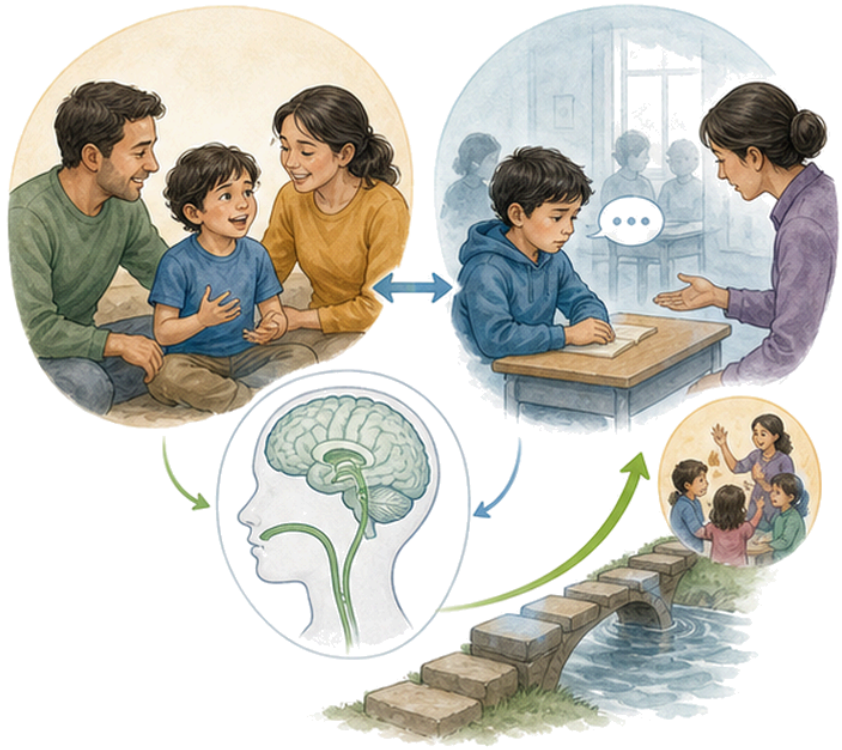
IN INDIA

Two realities shape presentation here. First, services classify under ICD, so these disorders appear in case files under their ICD labels rather than the DSM ones, and the clinician reads across the two systems. Second, childhood anxiety is under-detected: it surfaces in paediatric and general clinics as unexplained abdominal pain, headache or school refusal rather than as a complaint of worry, and the intense cultural emphasis on academic performance can both feed the performance-focused worry of generalized anxiety disorder and cause it to be normalised as ordinary diligence. Trained delivery of exposure-based cognitive behavioural therapy remains scarce outside specialist centres, which places a premium on equipping parents and schools to carry the graded-exposure approach.

FEATURE	GENERALIZED ANXIETY	SOCIAL ANXIETY	SPECIFIC PHOBIA
Focus of fear	Diffuse worry about competence and performance	Scrutiny and negative evaluation by others	A single circumscribed object or situation
Child modification	Only one associated symptom required	Must occur in peer settings, not only with adults	Fear shown as crying, tantrums, freezing or clinging
Behavioural expression in the young	Reassurance-seeking, perfectionism, conforming	Crying, freezing, clinging, mutism	Avoidance, distress on exposure
Duration floor	at least 6 months	at least 6 months	at least 6 months

The three disorders on shared axes; the shared six-month persistence floor sits beneath all of them, and each carries its own developmental modification to the adult criteria.

TRAP **Candidates apply the adult criteria to the child and lose the modifications.** The two most frequently missed are that generalized anxiety disorder in a child requires only *one* associated symptom rather than the adult three, and that social anxiety in a child must be present in *peer* settings and not only with adults. Reproducing the adult thresholds verbatim either excludes a genuinely anxious child or counts ordinary adult-directed reticence as a disorder.



Carry into the exam: all three disorders share a persistence floor of about 6 months plus impairment, and each modifies the adult criteria for the child - generalized anxiety needs only one associated symptom, social anxiety must reach peers, and specific phobia and social anxiety may be shown as crying, freezing or clinging rather than spoken.

6 months SHARED PERSISTENCE FLOOR	**1 of 6** ASSOCIATED SYMPTOMS NEEDED IN A CHILD (GAD)	**0.9%** 12-MONTH PREVALENCE IN ADOLESCENTS (GAD)	**13 yrs** MEDIAN ONSET OF SOCIAL ANXIETY

15 · Selective mutism

The child can speak, and that single fact is the whole diagnosis. **Selective mutism** is the condition of a child who talks fluently and comfortably in the settings where they feel safe, most often at home with immediate family, yet consistently fails to speak in particular social situations

where speech is expected of them, the classroom being the prototype. The speech apparatus is intact, the vocabulary is present, and the child demonstrates both every evening at home; what fails is the ability to produce speech under the specific social pressure of being watched, addressed or expected to answer. This is not shyness that a warm teacher can coax away in a week, nor a refusal that a firm one can command out of the child. It is a persistent, situation-bound silence that the child cannot simply choose to break, and understanding it as an anxiety phenomenon rather than a wilful or a linguistic one is the key to the entire topic.

- Speech is intact
- Speaks in safe settings
- Silent where speech is expected
- Anxiety—not defiance
- Graded participation

Fig 23.11 Selective mutism is persistent, situation-bound failure to speak where speech is expected despite comfortable, fluent speech in safer settings. It is understood as an anxiety phenomenon rather than defiance or absence of language.

The marks here are discriminative. An examiner uses this diagnosis to test whether a candidate can separate an anxiety-driven, situational mutism from the several conditions it superficially resembles: ordinary developmental shyness, the silent settling-in of a child learning a new language of instruction, a primary communication or language disorder, a hearing impairment, and the social muteness that can accompany autism spectrum disorder. This topic owns selective

mutism in full: its defining criterion, its duration and exclusion rules, its standing as an anxiety disorder, its epidemiology, onset and course, and its management. The wider childhood anxiety family of which it is a member is developed in its own right elsewhere in this chapter and named here only where the reasoning needs it.

15.1 The essential feature: a situational, not a global, failure of speech

The diagnosis lives in the contrast between the two settings. The core requirement is a consistent failure to speak in specific social situations in which there is an expectation to speak, present at the same time as normal speech in other situations. It is the coexistence of the two that defines the disorder: a child who is mute everywhere has a different problem, but a child who chatters at home and falls silent at school shows the characteristic split. The failure must be consistent, not the occasional off day, and it must occur where speech is genuinely expected, so that a child who happens to be quiet in a setting that makes no demand on them is not captured. Because the child can and does speak elsewhere, the clinician has direct evidence that the machinery of speech is unimpaired; the deficit is one of performance under a particular kind of social threat, not of competence.

RULE **Speech preserved in one setting, absent in another, is the disorder.** Selective mutism requires demonstrated normal speech in a comfortable setting alongside a consistent failure to speak where speech is expected. If the child is mute in every setting, the diagnosis is not selective mutism, and the assessor should be considering a language disorder, a hearing deficit, autism spectrum disorder or a global mutism instead.

15.2 The duration rule and why the first month of school does not count

The one-month floor exists to exclude normal settling-in. The disturbance must last for **at least one month**, and, importantly, that qualifying month is explicitly not the first month of school. This is not an arbitrary threshold. It is entirely normal for a child to be reticent, subdued or briefly silent in the first weeks of a new class, a new school or a new language environment, and that transient reserve settles on its own as the child habituates. Requiring the mutism to persist beyond that initial settling-in period screens out this benign, self-limiting reticence and reserves the diagnosis for a silence that has proven itself durable. A candidate who forgets the exclusion of that first month will over-diagnose the ordinarily anxious new entrant, which is precisely the error the criterion is written to prevent.

15.3 The exclusion criteria: language, communication and pervasive disorders

The silence must be anxiety, not an artefact of language, speech or a broader disorder. Two exclusions do most of the diagnostic work. First, the failure to speak must not be attributable to a lack of knowledge of, or comfort with, the spoken language the situation demands. A child newly arrived into a school taught in an unfamiliar tongue may pass through a normal **silent period** while they acquire it, and that child does not have the disorder however complete their classroom silence. Second, the mutism must not be better explained by a **communication disorder** such as a childhood-onset fluency disorder, and it must not occur exclusively during the course of autism spectrum disorder or a psychotic disorder. Where the muteness is fully accounted for by one of

those conditions, that condition is the diagnosis. These exclusions are what convert selective mutism from a description of a silent child into a specific, anxiety-based entity.

- not due to a lack of knowledge of, or comfort with, the required spoken language;
- not better explained by a communication disorder such as a fluency disorder;
- not occurring only within autism spectrum disorder or a psychotic disorder;
- separable, clinically, from ordinary shyness and from a hearing impairment.

CONDITION TO DISTINGUISH	WHAT SEPARATES IT FROM SELECTIVE MUTISM
The silent period of a new-language learner	The muteness reflects unfamiliarity with the language of the setting, not anxiety; the language-knowledge exclusion removes it
Communication or fluency disorder	A primary difficulty producing speech itself, present across settings, rather than a setting-bound silence with normal speech elsewhere
Autism spectrum disorder	The muteness sits within a pervasive social-communication deficit and a restricted, repetitive repertoire; selective mutism is not diagnosed if the silence occurs only within autism
Ordinary developmental shyness	Transient, coaxable and not functionally impairing; selective mutism is consistent, durable and disabling

The conditions the situational silence is most often confused with; each is separated by the source of the muteness rather than by its appearance, which is why the exclusion criteria carry the diagnosis.

TRAP **Diagnosing the bilingual child in a silent period.** The classic examination error is to label a recently immigrated or newly enrolled child, silent in a classroom taught in a language they are still acquiring, as having selective mutism. The language-knowledge exclusion exists precisely for this child: until they are comfortable in the language of the setting, their silence is not the disorder, and time and exposure, not treatment, are what they need.

15.4 An anxiety disorder in its own right

The company it keeps settles what kind of disorder it is. Children with selective mutism seen in clinical settings are almost always given an additional anxiety diagnosis, and the one that accompanies it most often is **social anxiety disorder**. That near-constant coincidence is the strongest argument that the mutism is a manifestation of anxiety rather than a communicative or an oppositional problem: the child who cannot speak at school is very often the same child who is intensely frightened of scrutiny and negative evaluation. Both major classifications now place the condition accordingly. It sits among the anxiety disorders in current DSM classification, and ICD-11 lists it as an **anxiety or fear-related disorder** under code **6B06**. This is not a filing detail; it directs treatment, because it tells the clinician to target the anxiety and not to treat the silence as a speech problem or a behaviour to be disciplined.

Carry this into the exam: a child who speaks freely at home but consistently not at school for at least a month, and not explained by language or a communication disorder, is showing an anxiety disorder, almost always alongside social anxiety.

15.5 Epidemiology

A rare disorder, and commoner in the young. Selective mutism is uncommon. Point-prevalence estimates across clinic and school samples fall in the range of **0.03 to 1.9 per cent**, the width of that range reflecting how much the figure depends on the setting sampled and on the age of the children studied. It is more likely to manifest in young children than in adolescents and adults, in keeping with its early onset and its tendency to attenuate with age. The rarity has a practical consequence: because most clinicians see very few cases, the condition is easily missed or misattributed, and the child who is silent at school but never at home is often written off as merely shy long before anyone names the disorder.

15.6 Onset and course

Early to begin, late to be noticed, and it leaves something behind. Onset is usually before **age five**, but the condition frequently goes unrecognised until the child enters school, where the demand to speak in front of others suddenly exposes a silence that at home had looked like nothing more than a quiet temperament. School entry, in other words, does not cause the disorder so much as reveal it. The course is instructive: in many children the mutism itself fades with time, but the underlying social anxiety commonly persists, so that the disorder is better understood as an early, visible expression of an anxiety diathesis than as a self-contained childhood problem that resolves without trace. That residual anxiety is why early, anxiety-directed intervention matters, rather than simply waiting for the child to grow out of the silence.

15.7 Principles of management

Treat the anxiety, lower the pressure, and let speech be shaped, not forced. Because the disorder is anxiety-based, management is built on behavioural and family-and-school interventions that reduce the anxiety around speaking rather than demand speech directly. The mainstay is graded behavioural work: techniques such as stimulus fading, in which a person the child already speaks to slowly brings a new listener into the setting, and shaping, in which any communication is rewarded and successively closer approximations to speech are encouraged, together with graded exposure to the feared speaking situations. Close collaboration with the school is essential, since the classroom is usually where the silence lives and where any gain has to be generalised. Where the disorder is severe or does not respond to behavioural work, a selective serotonin reuptake inhibitor is the pharmacological option most commonly added, on the same anxiety rationale that governs its use across the childhood anxiety disorders; specific agents and dosing lie outside what this topic establishes and should be confirmed against a pharmacology source.

GOOD TO REMEMBER

The single most useful instruction to give the parents and the teacher is to stop asking the child to speak. Direct pressure, coaxing, and rewards made contingent on an immediate spoken answer all raise the very anxiety that produces the silence. Removing the spotlight, accepting non-verbal responses at first, and letting a trusted adult widen the circle gradually does more than any amount of encouragement to talk.

PITFALL

The commonest clinical failure is to read the silence as oppositionality. A child who speaks fluently at home but says nothing to the teacher looks, to an untrained eye, as though they are choosing not to cooperate, and the response, more pressure, discipline or a battle of wills, predictably worsens matters. The child is not refusing; they are unable to speak under that specific anxiety, and treating it as defiance both misses the diagnosis and deepens the problem.

IN INDIA

Two features of Indian practice are worth holding in mind. Most services diagnose under ICD, where the condition now sits among the anxiety or fear-related disorders, which usefully reinforces the anxiety-directed approach. And the multilingual classroom makes the language-knowledge exclusion especially live: a child schooled in English, or in a state language different from the mother tongue spoken at home, may be silent simply because they are still acquiring the language of instruction. Establishing which languages the child speaks freely, and where, is the first step before the diagnosis is even entertained, and it is often what separates a genuine case from a child in a normal silent period.

16 · Paediatric OCD and PANDAS

Obsessive-compulsive disorder in a child is the same disorder as in an adult, but it wears a developmental disguise. A young child rarely arrives complaining of intrusive thoughts. The family notices the behaviour first: the handwashing that will not stop, the bedtime routine that must be repeated until it feels right, the questions asked again and again for reassurance. Marks accrue here because the examiner wants to know that a candidate can recognise the disorder through that behavioural surface, grade its severity with the standard paediatric instrument, and hold a disciplined, sceptical line on the one piece of this territory that generates more heat than light, the proposed link between streptococcal infection and abrupt-onset childhood OCD. The general adult disorder, its full criteria set and its pharmacology, are developed in the Anxiety, OCD and trauma-related disorders notes; this topic owns the child-specific presentation, the standard rating scale, and the PANDAS and PANS story in full.

The structure to carry into the exam is simple. First, what OCD is and how its two building blocks behave in a child. Then how it is measured and how common it is. Then the post-infectious hypothesis, taught as a named, contested proposal rather than as settled fact, because that scepticism is itself the examinable point.

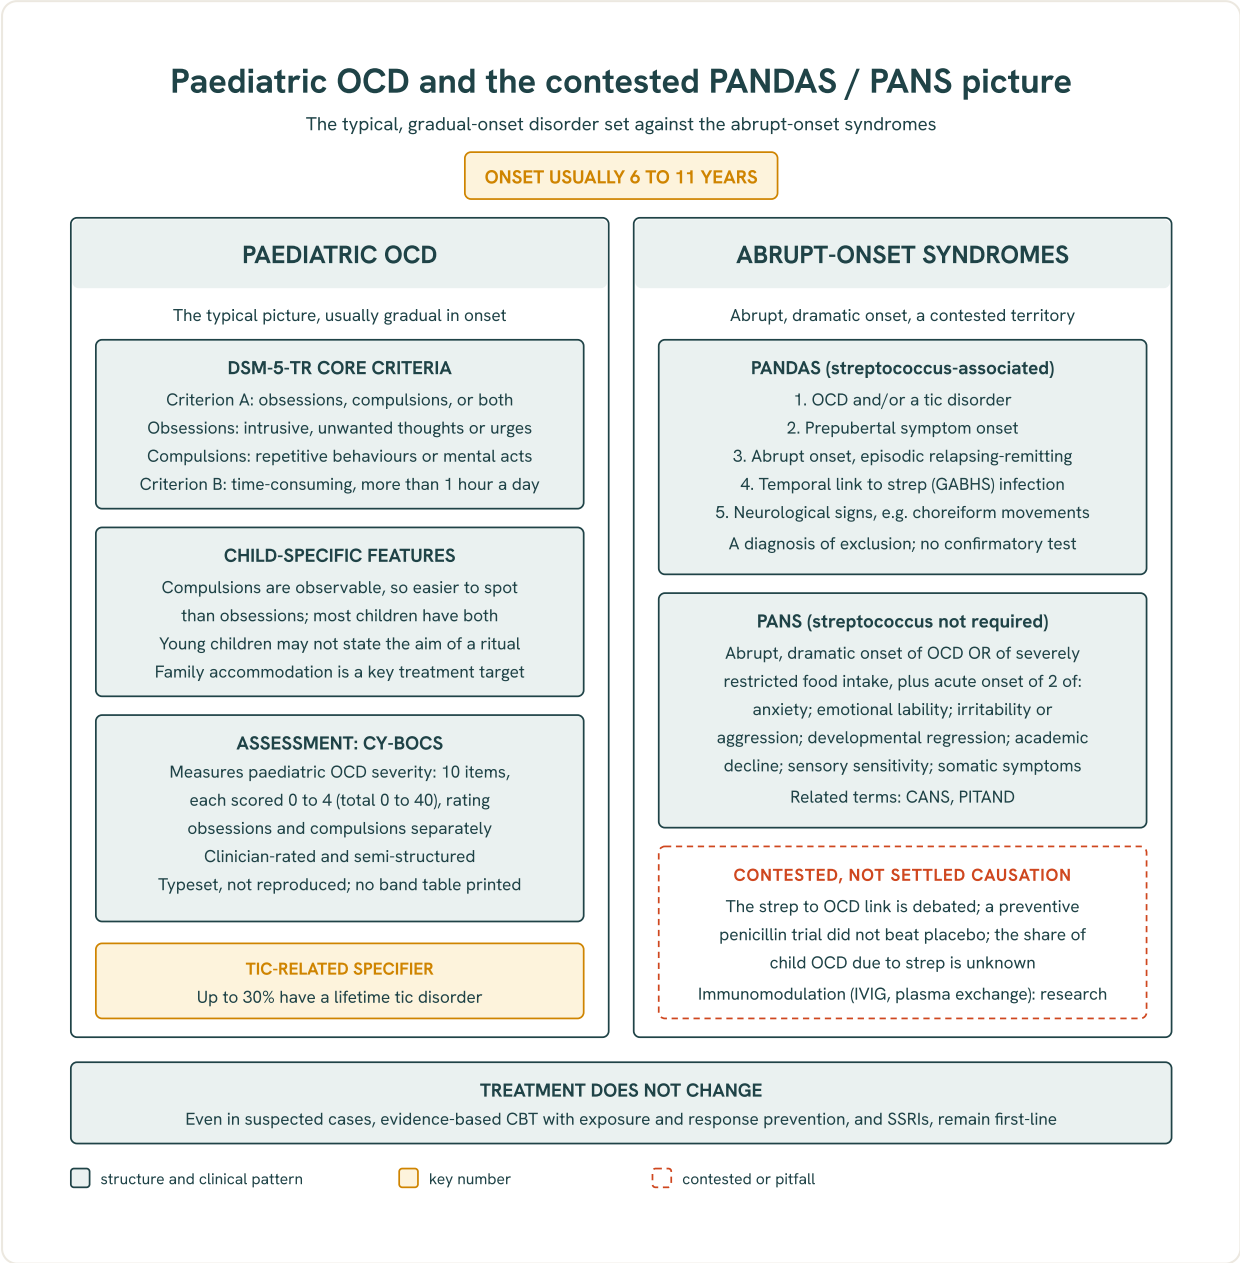

Fig 23.12. Paediatric OCD and the contested PANDAS and PANS abrupt-onset picture: the typical gradual-onset disorder with its DSM-5-TR criteria and its CY-BOCS severity assessment, set against the abrupt-onset syndromes whose streptococcal cause remains contested and whose treatment stays evidence-based CBT with exposure and response prevention, and SSRIs.

16.1 The defining features and how they present in a child

The disorder is built from two elements, and either can stand alone. The core diagnostic requirement is the **presence of obsessions, compulsions, or both**. Obsessions are recurrent, intrusive and unwanted thoughts, urges or images that the person experiences as distressing; compulsions are the repetitive behaviours or mental acts performed in response to an obsession, or according to rigid self-imposed rules, that are meant to reduce that distress or to prevent some feared event. The compulsion is functionally tethered to the obsession even when the child

cannot articulate the link. The second requirement is that these symptoms exact a real cost. They must be time-consuming, taking **more than one hour a day**, or else cause clinically significant distress or impairment of functioning. That threshold is what separates a diagnosable disorder from the ordinary superstitions, rituals and preoccupations of normal childhood, which the reader will find mapped against their pathological counterparts elsewhere in this chapter.

RULE **Obsession drives, compulsion relieves.** The compulsion is not a random tic or habit; it is performed to neutralise the anxiety of an obsession or to satisfy a rigid rule. When you cannot see an obsession, ask what the child fears will happen if the ritual is stopped, and the obsession usually appears.

16.2 Why the child looks different from the textbook adult

In children the compulsion is the visible half of the disorder. Younger children often cannot describe the aims of their compulsions, so the **compulsions**, being observable, are more readily diagnosed than the obsessions that drive them, even though most affected children in fact have both. This inverts the adult stereotype of a patient who can narrate a tormenting thought. A second developmental feature carries genuine clinical weight: **family accommodation**, the involvement of parents or siblings in the child's rituals, providing the reassurance, performing the checks, or reorganising the household around the symptoms. Accommodation feels kind in the moment and is almost universal, but it maintains the disorder by removing every opportunity for the anxiety to fall on its own, and it is therefore an important treatment target, more so in children than in adults.

PITFALL

The commonest management failure is to leave family accommodation untouched. Parents who have spent months answering the same reassurance-seeking question, or supervising a two-hour bedtime ritual to keep the peace, are unwittingly holding the disorder in place. Unless the treatment plan explicitly coaches the family to withdraw accommodation in a graded, agreed way, exposure work with the child alone will keep failing at home.

16.3 Epidemiology, onset and sex

It is neither rare nor a purely adult disease. The most widely accepted six-month prevalence of OCD in the general paediatric population is **0.5 to 1 per cent**. The disorder is strongly developmental in its origins: **up to 80 per cent** of adults with OCD had their onset in childhood or adolescence, so the paediatric presentation is not a minor tributary of the adult disorder but its headwater. Mean age at onset falls between 6 and 11 years, with a bimodal pattern peaking around puberty and again in young adulthood. The prepubertal, early-onset group has a distinctive profile: it shows a male preponderance and a higher rate of family history, whereas the sex ratio tends to even out by adolescence. That early-onset, male-predominant, familial, often tic-associated form is the one to keep in mind when the post-infectious hypothesis is raised.

16.4 The tic-related specifier and OCD-tic comorbidity

Childhood-onset OCD and tics travel together. DSM-5-TR carries a **tic-related specifier**, applied when the individual has a current or past tic disorder, precisely because the overlap is substantial: **up to 30 per cent** of people with OCD have a lifetime tic disorder, an association most common in males with childhood onset. The clinical importance is that tic-related OCD tends to present with a particular symptom flavour, with more just-right, symmetry and touching compulsions than pure contamination-and-washing pictures, and it sits at the crossroads of OCD and Tourette syndrome. The tic disorders themselves, their classification and management, are developed in their own right elsewhere in this chapter; here the specifier matters because it flags the early-onset, familial subtype and because it is the same subtype invoked by the streptococcal hypothesis below.

16.5 Measuring severity: the CY-BOCS

The standard paediatric instrument is worth knowing in structural detail. The **Children's Yale-Brown Obsessive Compulsive Scale** is a ten-item clinician-administered, semi-structured scale, each item anchored on an ordinal scale from 0 to 4. It precedes the rated items with a broad symptom checklist and then rates obsessions and compulsions separately across five dimensions each: the time occupied, the interference with life, the subjective distress, the internal resistance mounted against the symptom, and the degree of control the child retains over it. What it measures is paediatric OCD severity across those two halves, and severity is read off the summed total. No interpretive band table is printed here: the exact cut-offs separating mild from moderate from severe illness could not be confirmed against a primary source, and a wrong cut-off is worse than none, so learn the structure and the dimensions rather than a number line. The instrument is a licensed one, typeset from its published description rather than reproduced as a form. Because it is administered by the clinician rather than self-reported, it sidesteps the very problem that defines paediatric OCD, the child who cannot put the obsession into words, and it is the scale used both to grade severity at intake and to track response over treatment.

> **GOOD TO REMEMBER**
>
> Use the CY-BOCS as a change measure, not a one-off label. A total at intake, repeated at review, converts a vague impression that the child is "a bit better" into a defensible figure that tells you whether exposure therapy and, where used, a serotonergic agent are actually working, and whether family accommodation is falling as it should.

16.6 PANDAS: the proposed post-streptococcal syndrome

PANDAS names a hypothesised subgroup, not an established disease. **PANDAS**, paediatric autoimmune neuropsychiatric disorders associated with streptococcus, denotes OCD-like and tic symptoms proposed to be triggered by group A beta-haemolytic streptococcal infection. The proposed mechanism is **molecular mimicry**: antibodies raised against streptococcal antigens are held to cross-react with, and inflame, the basal ganglia, producing an acute neuropsychiatric picture. The model is deliberately built on Sydenham chorea, the recognised post-streptococcal movement disorder of rheumatic fever, and it was first described by Swedo and colleagues in a

small putative subgroup of children. The concept is attractive because it offers a mechanism and, tantalisingly, a treatable cause; the difficulty, taken up below, is that the evidence has never firmly closed the loop from infection to symptoms.

16.7 The working diagnostic features, and PANS

The clinical description is a checklist of features and a diagnosis of exclusion. The working features proposed for PANDAS are the presence of OCD or a tic disorder; prepubertal onset; an abrupt onset with an episodic, relapsing-remitting course; a temporal association with streptococcal infection; and associated neurological signs such as motoric hyperactivity and choreiform movements. There is no confirmatory test, so the diagnosis rests on this pattern and on excluding other causes.

- OCD or a tic disorder is present;
- onset is prepubertal;
- onset is abrupt and the course is episodic;
- there is a temporal link to streptococcal infection;
- neurological abnormalities, such as choreiform movements, accompany the presentation.

A broader term was later coined to escape the demand for a proven streptococcal cause. **PANS**, paediatric acute-onset neuropsychiatric syndrome, requires an abrupt, dramatic onset either of OCD symptoms or of severely restricted food intake, together with the acute onset of at least two of a wider list, anxiety, emotional lability, irritability or aggression, developmental regression, academic deterioration, sensory sensitivity, or somatic symptoms. The crucial contrast is that PANS, unlike PANDAS, does not require any link with or presumed cause by streptococcal infection; it is defined by the abrupt neuropsychiatric onset alone, and it too has no definitive test.

FEATURE	PANDAS	PANS
Streptococcal link	Required: a temporal association with streptococcal infection	Not required; no presumed streptococcal cause
Core symptom	OCD or a tic disorder	Abrupt OCD, or severely restricted food intake, plus acute onset of at least two further neuropsychiatric symptoms
Onset and course	Prepubertal, abrupt, episodic and relapsing-remitting	Abrupt and dramatic
Confirmatory test	None; diagnosis of exclusion	None; diagnosis of exclusion

PANS is the wider, streptococcus-agnostic term: it keeps the abrupt neuropsychiatric onset of PANDAS but drops the requirement for a streptococcal trigger, which is precisely the requirement that has proved hardest to substantiate.

16.8 The controversy, and why it does not change the treatment

This is the part the examiner is really testing. The causal claim behind PANDAS is **contested and not established**. The association between streptococcal infection and childhood OCD remains debated; efforts to establish a reliable biological marker have been inconclusive; the

proportion of paediatric OCD actually attributable to streptococcus is unknown; and a prophylactic penicillin trial failed to separate from placebo, while several groups could find no dependable temporal association between infection and symptom flares. In the current literature PANDAS is described as one of the most **controversial** conditions in paediatric practice, with epidemiological data still lacking and few randomised studies to anchor any recommendation. The honest position, and the one to write, is that this is a proposed, contested autoimmune mechanism, never settled causation.

The practical consequence is reassuringly clear. Whatever one believes about the trigger, the treatment of a child who presents with OCD or tics does not change: evidence-based cognitive behavioural therapy with exposure and response prevention, together with a serotonergic agent where indicated, remains the mainstay even in suspected post-infectious cases. Immunomodulatory treatments such as intravenous immunoglobulin and plasmapheresis remain experimental and belong to research protocols, not to routine care.

TRAP **Presenting PANDAS as a settled, antibiotic-treatable cause of OCD.** The seductive error is to hear "abrupt-onset OCD after a sore throat" and reach for a streptococcal work-up and antibiotics as if the diagnosis were proven. It is not. Reproduce the contested status, keep the child on exposure-based therapy and, where indicated, a serotonergic agent, and reserve immunomodulation for research settings.

Paediatric OCD is diagnosed through observable compulsions and treated with exposure and response prevention plus an SSRI; PANDAS and PANS are contested, test-free hypotheses that never displace that treatment.

IN INDIA

Two local realities sharpen this topic. First, Indian services classify predominantly under ICD, and the CY-BOCS remains the workhorse severity measure across child psychiatry units. Second, the background rate of streptococcal disease and rheumatic fever is higher here than in the Western data that framed the PANDAS debate, which makes it tempting to over-attribute abrupt childhood OCD to infection. The discipline is the same as everywhere: a positive throat swab or a raised antistreptococcal titre in a child with new OCD proves exposure, not causation, and it must not divert the family from exposure-based therapy and, where indicated, a serotonergic agent.

17 · Post-traumatic stress disorder in children

A child is not a small adult with the same symptoms writ small. Post-traumatic stress disorder after a traumatic event is recognisable in a school-aged child or adolescent along broadly the same lines as in an adult, but in the youngest children it hides. A traumatised two-year-old does not describe a flashback; a traumatised four-year-old does not report emotional

numbing. They repeat the event in their play, wake screaming from dreams whose content no one can trace, lose words they had already learned, and cling to a parent as though the world has become unsafe. Applying the standard adult symptom list to such a child systematically under-diagnoses them, and that under-recognition is the whole reason this topic carries marks.

- Traumatic play
- Non-specific nightmares
- Regression
- Clinging
- Developmentally modified assessment

Fig 23.13 Post-traumatic stress in young children may appear through repetitive traumatic play, frightening dreams without recognisable content, developmental regression and new clinging rather than through an adult verbal account of re-experiencing and numbing.

The general trauma-related disorders, including the adult form of post-traumatic stress disorder, acute stress disorder, adjustment disorders and the underlying neurobiology of the fear circuitry, are developed in the Anxiety, OCD and trauma-related disorders notes; they are named here and not re-taught. What this topic owns is the paediatric problem: how trauma presents developmentally in young children, and the separate, developmentally modified diagnostic set that the current classification provides for them. The examinable core is that a child of a certain age is read against a different rulebook, and knowing which criteria change, and why, is what a candidate must show.

17.1 A separate rulebook for the youngest children

The main criteria are written for anyone older; the very young get their own set. The current classification splits the diagnosis by developmental stage. The principal post-traumatic stress disorder criteria are intended for adults, adolescents and children older than six years, and are read as they would be for an adult. For children who are **six years and younger**, a distinct and developmentally modified **preschool subtype** is applied instead. This is not a mere footnote softening the adult criteria; it is a genuinely separate set, with fewer required symptoms and with several clusters rewritten to match what a preverbal or barely verbal child can actually show. The single most useful thing to carry into the assessment room and the examination hall is the age boundary itself, because it decides which of two different diagnostic templates you are entitled to use.

RULE **Age decides the template.** A child of six years or younger is diagnosed on the preschool subtype, which lowers and re-shapes the symptom requirements to fit developmental expression. Reading such a child against the adult criteria, which demand more symptoms and more verbal reporting, is how a genuinely traumatised toddler is wrongly cleared.

17.2 Criterion A: the exposure, seen through the caregiver

For a young child the caregiver is the centre of the traumatic world. The exposure criterion in the preschool subtype is deliberately narrower and more caregiver-focused than the older-than-six version. A young child qualifies by directly experiencing the event, by witnessing it in person as it happened to others (particularly to primary caregivers), or by learning that the event happened to a parent or other caregiving figure. The logic is developmental: a small child's sense of safety is organised almost entirely around the attachment figure, so a threat to that figure is a threat to the child, whereas the more abstract routes that count for older individuals do not yet have the same force. This differs from the criterion used for anyone older than six, which additionally counts learning of violent or accidental events happening to any close relative or friend, and repeated or extreme exposure to aversive details of trauma. Naming that contrast is often the mark: the young child's exposure is anchored to the people who care for them.

17.3 Criterion B: intrusion expressed as play

Reexperiencing in a young child is enacted, not narrated. The intrusion cluster requires one or more symptoms, but the crucial point is how they show. Intrusive memories in a young child **may appear as repetitive play** that refers, directly or symbolically, to the trauma, and this play need not look distressing to an observer; the child may seem absorbed or even calm while re-enacting a car crash or an assault with toys. Frightening dreams are common, but their content often cannot be tied to the event, so a new pattern of night terrors without an obvious theme still counts. Trauma-specific re-enactment may spill into behaviour and games. Because the child cannot say "I keep seeing it happen", the clinician must infer the intrusion from what the child does, which is why detailed collateral about play, sleep and behaviour is not optional here but is the actual data of the criterion.

17.4 Criterion C: avoidance and negative cognition, merged

Two adult clusters become one, and a single symptom will do. This is the structural heart of the subtype and the point most likely to be tested. In the version for anyone older than six, persistent avoidance and negative alterations in cognitions and mood are two separate clusters, each requiring its own symptoms. In the preschool subtype these are collapsed into a single Criterion C, and only one symptom from the combined list is needed, whether that is avoidance of reminders or a negative change such as social withdrawal, restricted play, or a marked reduction in the expression of positive emotions. The consequence to memorise is arithmetic: the preschool set is built on **three** symptom clusters rather than the four of the older version. The merge exists because a young child cannot reliably report the cognitive content, the persistent distorted blame or the sense of a foreshortened future, that fills out the adult negative-cognition cluster, so the classification asks only for the observable behavioural change.

FEATURE	OLDER THAN SIX YEARS	SIX YEARS AND YOUNGER (PRESCHOOL SUBTYPE)
Exposure (A)	Includes learning of events to any close person, and repeated exposure to aversive details	Direct experience, witnessing in person (especially to caregivers), or learning it happened to a parent or caregiving figure
Intrusion (B)	Reexperiencing, often reportable	One or more; often expressed as play re-enactment, not overt distress
Avoidance and negative cognition	Two separate clusters	Merged into a single Criterion C requiring one symptom
Arousal and reactivity (D)	Full cluster	Two or more symptoms, tantrums count as irritability
Number of symptom clusters	Four	Three
Duration	More than one month	More than one month

The preschool subtype set against the version used for everyone older; the changes all move in one direction, lowering and re-shaping the requirements to fit what a developmentally young child can show.

TRAP **Counting a preschooler against the four-cluster adult set.** Candidates apply the older-than-six structure to a young child, look for two separate avoidance and negative-cognition clusters and the full adult symptom counts, find them absent, and conclude there is no disorder. The preschool child is diagnosed on three clusters with lower thresholds, so the adult arithmetic wrongly excludes a genuine case.

17.5 Criterion D: arousal, and the tantrum as a symptom

Hyperarousal in a young child wears the face of behaviour problems. The **arousal and reactivity** cluster requires two or more symptoms, and here the developmental translation matters as much as the count. Irritable behaviour and angry outbursts may be expressed as extreme temper tantrums, and this is precisely where a traumatised preschooler is misread as merely oppositional or as having a behavioural disorder. Alongside the tantrums the cluster includes hypervigilance, an exaggerated startle response, problems with concentration, and

disturbed sleep. The reason this cluster is a trap in daily practice is that every one of its manifestations, the tantrums, the poor attention, the broken sleep, is nonspecific and common in early childhood, so the arousal cluster is only informative when it is new, when it clusters with the other criteria, and when it dates from an identifiable trauma.

PITFALL

The commonest clinical failure is to stop at the presenting behaviour. A young child brought in for new tantrums, defiance, poor sleep and clinginess is labelled with a behavioural or oppositional problem, medicated or sent for behaviour management, and never asked what happened to them. Because young children do not spontaneously report trauma and may not even have shown fear at the time of the event, the history has to be sought actively from caregivers; without that question, the arousal cluster reads as naughtiness and the diagnosis is missed.

17.6 Duration, delayed expression and the developmental picture

The clock is the same, but the symptoms may take time to declare themselves. The duration requirement does not change with age: symptoms must persist for **more than one month** before the diagnosis is made, which separates the disorder from the expected, self-limiting distress of the first weeks after a frightening event. Where the full criteria are not met until **at least six months** after the event, the delayed-expression specifier applies, a pattern that is clinically real in children whose symptoms crystallise only as development proceeds. The wider developmental picture rounds out the assessment: before the age of six, children more often express reexperiencing through play that refers to the trauma directly or symbolically, may develop new frightening dreams without trauma-specific content, and may show developmental regression such as loss of previously acquired language. Young children may not have shown a fearful reaction at the moment of exposure at all, and their negative alterations tend to be changes in mood rather than the articulated guilt or self-blame of an older patient, simply because the capacity to label and attribute emotion is still forming.

- reexperiencing enacted in repetitive, trauma-referring play rather than described;
- new frightening dreams whose content cannot be tied to the event;
- developmental regression, including loss of language or of toileting skills;
- mood change and withdrawal in place of verbalised negative beliefs.

In a child of six or younger, diagnose on the modified set: three symptom clusters not four, one intrusion symptom, one merged avoidance-or-negative-cognition symptom, two arousal symptoms, persisting for more than one month.

17.7 Assessment, management and the Indian setting

The diagnosis is only useful if it changes what happens next. Assessment leans heavily on caregiver report and on structured observation of the child's play, because the child is not a reliable narrator of internal states. The clinician gathers a clear trauma history, maps the current symptoms onto the developmental criteria, and screens the caregiving environment, since

ongoing threat or a distressed, unavailable caregiver both perpetuates the disorder and limits any treatment. The first-line treatment is a **trauma-focused psychotherapy**, delivered in a developmentally graded and caregiver-inclusive form; the general evidence base and the pharmacological questions for post-traumatic stress disorder belong to the Anxiety, OCD and trauma-related disorders notes and are not restated here. Where the trauma is abuse, neglect or exposure to violence, safeguarding and the statutory child-protection response are inseparable from treatment, and the machinery for that is set out in the Child psychiatry: assessment, treatment, services and protection notes.

GOOD TO REMEMBER

Interview the caregiver as your primary instrument and watch the child's play as your second. Ask specifically about new fears, sleep, tantrums, clinginess, regression and any change dated to a frightening event, because none of these will be offered spontaneously by a young child. A single well-placed question about what happened often converts a vague "behaviour problem" referral into a treatable, developmentally-typed post-traumatic presentation.

IN INDIA

Young children in Indian practice carry a heavy and often unspoken trauma load, from road-traffic and burn injuries, natural disasters, domestic and community violence, and physical or sexual abuse, yet the preschool presentation is routinely read as a phase or a discipline problem and reaches services late, if at all. Most public services classify under ICD rather than DSM, and access to a trained trauma-focused child therapist is scarce outside a few centres, so the practical yield of this topic is recognition: asking the trauma question of a regressed or newly tantrumming young child, and routing genuine cases into whatever child mental-health and protection services exist locally.

6 and younger	3 clusters	over 1 month	6 months
AGE FOR THE PRESCHOOL SUBTYPE	PRESCHOOL SET, NOT FOUR	REQUIRED SYMPTOM DURATION	DELAYED-EXPRESSION SPECIFIER

Childhood mood disorders, disruptive mood dysregulation, early-onset psychosis and paediatric suicidality

18 · Childhood depression (presentation, masked depression, management)

The whole difficulty of the topic is that the illness rarely announces itself the way it does in an adult. **Childhood depression** is the same major depressive syndrome recognised in later life, but its surface presentation is bent by development: a young child cannot always name low mood, is more likely to show it as irritability or bodily complaint, and depends on the adults around to notice that something has changed. This is why the marks cluster where they do. Candidates who can recite the adult symptom list still lose ground on the two questions that actually decide the

diagnosis in a child, which is how the presentation shifts with age, and how a depressive disorder is told apart from the disruptive and behavioural pictures it can hide behind.

This topic owns the developmental presentation of the disorder - the irritable-mood variant, the age-dependent symptom expression, and the older idea of a depression that is masked behind other complaints - together with the assessment instruments used to detect and track it and the shared minimal duties of its management. The general neurobiology of depression, the detailed suicide-risk tools, the paediatric antidepressant-suicidality warning, disruptive mood dysregulation disorder and the somatic presentation of childhood distress are each developed in their own right elsewhere; here they are named where the reasoning demands it, not reopened.

Fig 23.14. Childhood depression, developmental presentation: irritable mood and age-adjusted criteria as the picture shifts toward the adult form with development.

18.1 Why the disorder is missed: development conceals the mood

The core clinical problem is under-recognition, and it is a developmental problem before it is a diagnostic one. Depression in children was for a long time thought not to exist, on the reasoning that an immature personality could not sustain the sense of guilt and hopelessness that defines the adult illness. That view has been abandoned - the disorder is real, impairing and recurrent in the young - but the reason it was ever plausible remains clinically live. A child's capacity to identify and report an internal state is limited, so the depression tends to be inferred

from what the adults around the child observe rather than declared by the child. Pervasive **anhedonia**, a loss of the ordinary pleasure in play, friends and activities, is often the most reliable observable sign, precisely because it does not depend on the child being able to articulate sadness. The practical consequence is that the assessor must actively look for the disorder in a child whose difficulty is showing up as falling grades, withdrawal, somatic complaint or a change in temper, rather than wait for a spontaneous complaint of low mood that a young child may never produce.

18.2 Irritability as the depressed mood

The single most examinable adaptation of the criteria is that irritability can stand in for sadness. The diagnostic rules for a major depressive episode carry an explicit developmental note: **in children and adolescents the depressed-mood criterion can be satisfied by an irritable mood** rather than by a subjectively sad or dejected one. This is not a softening of the threshold but a recognition that the same underlying mood disturbance surfaces differently earlier in life, so that a young person who is persistently cranky, touchy and easily provoked may be depressed even though they never say they are sad. The clinical instruction that follows is a discrimination, not a relabelling: an irritable or cranky mood may develop in place of a sad or dejected one, and it must be differentiated from the ordinary irritability a child shows when frustrated. What converts irritability into a depressive sign is its pervasiveness and persistence, its company with anhedonia, sleep and appetite change and a drop in functioning, and its independence from a specific frustrating trigger. The irritability of the depressed child is a background weather, not a reaction to being told no.

RULE **In a child, an irritable mood can meet the depressed-mood criterion in place of sadness.** The examiner is testing whether the candidate knows that a persistently irritable young person can be experiencing a major depressive episode, and can separate that sustained, pervasive irritability from the situational crossness of a frustrated child. Miss the developmental note and the whole diagnosis is missed with it.

18.3 The age-graded shift in symptoms

The same disorder wears different clothes at different ages. Beyond the mood itself, the neurovegetative criteria are read differently in a growing child. Where an adult is expected to lose weight, the criteria direct that in a child one should instead consider a failure to make the expected weight gain: a still-growing child who is depressed may not lose weight but may fall off their expected growth trajectory, so the clinician reads the growth chart rather than the scale reading alone. More broadly, the presenting complaint tends to track development. Younger children more often present with somatic distress, clinginess, irritability and a flattening of play; adolescents move closer to the adult picture of low mood, hopelessness, guilt and articulated suicidal thinking, but with a heavier loading of irritability, interpersonal sensitivity and behavioural change than an adult would show. The recurrent bodily complaints - the aching stomach, the headache with no organic cause - are a genuine and frequent vehicle for depressive and anxious distress in the young, but that somatic presentation is developed in its own right elsewhere in this chapter and is only named here as one of the forms the disorder can take.

FEATURE	YOUNGER CHILD	ADOLESCENT
Predominant mood surface	Irritability, crankiness	Low mood and irritability, closer to the adult picture
Appetite and weight criterion	Failure to make expected weight gain	Weight loss or gain, as in adults
How distress is voiced	Somatic complaints, clinginess, loss of play	Hopelessness, guilt, articulated suicidal thoughts
Chief route to detection	Adult observation of change	Self-report becomes more available

The developmental presentation set out age against age; the load-bearing points are that irritability can be the mood and that a failure to gain expected weight can replace weight loss in the still-growing child.

Carry two developmental substitutions into the exam: in children and adolescents the depressed-mood criterion can be met by irritable mood, and the appetite criterion by a failure to make expected weight gain.

18.4 Masked depression: the concept and its careful reading

Masked depression is the older name for a depression whose mood is hidden behind a non-mood complaint. The term **masked depression** was coined for presentations in which the depressive affect is not the presenting feature at all, and the disorder instead shows itself through what were called **depressive equivalents**: recurrent somatic complaints, school refusal, a fall in academic performance, aggression, or in older children substance use and antisocial behaviour. In a child, for the developmental reasons already given, the depression is more often masked than in an adult, and the idea earns its keep as a reminder to hold depression in mind when the complaint on the referral letter is behavioural or physical. It should nonetheless be read critically. The concept is imprecise and historically over-extended, and the safer modern position is not that any behavioural disturbance is a hidden depression, but that a depressive disorder must be actively excluded when a child presents with an unexplained change in conduct, function or bodily state. The mask is a prompt to look underneath, not a licence to diagnose depression behind every difficult behaviour.

PITFALL

Diagnosing a child from the child's self-report alone. Depressed children, especially younger ones, under-report their own symptoms and may deny sadness outright, while a parent or teacher sees the irritability, withdrawal and functional decline plainly. A single-informant assessment built on the child's account can therefore return a falsely reassuring picture; the diagnosis in this age group is a multi-informant one, and the account of the adults who see the child across settings is not optional.

18.5 Detecting and tracking it: the rating scales

Because the disorder is inferred rather than declared, a structured instrument earns its place. Rating scales do not make the diagnosis, which remains clinical, but they standardise detection, quantify severity and let the clinician track change over treatment. The best known in

this age group is the **Children's Depression Inventory**, a **27-item** self-report scale built as a downward extension of the adult Beck inventory for younger respondents. The original version resolved into five subscales - dysphoric mood, acting out, loss of personal and social interest, self-deprecation and vegetative symptoms - though the total score is what is generally used, and it is brief enough to complete in a single short sitting. Its structure tells you what a good paediatric depression scale must do: sample mood, the behavioural surface, anhedonia, self-worth and the neurovegetative signs together, because any one of these alone can be the way the disorder shows.

The current second edition is designed as a **multi-informant** instrument, pairing the child's self-report with parent and teacher forms, which is exactly the correction the single-informant pitfall demands. It remains modelled on the Beck Depression Inventory, is a widely used self-report measure that includes an item on suicidality and is sensitive to treatment effects, so it doubles as an outcome measure across a course of care; its limitation is that results are mixed for distinguishing depression from other disorders, so it screens and monitors but does not adjudicate the diagnosis. It is applicable across the school-age and adolescent years, in the region of 7 to 17 years depending on the source consulted, and being a proprietary instrument it must be purchased for use.

> **GOOD TO REMEMBER**
>
> Choose the scale for the job. A self-report inventory with a suicidality item and known sensitivity to change is well suited to tracking a known case across treatment and to prompting a suicide conversation, but a scale that does not reliably separate depression from other disorders cannot be used to confirm the diagnosis. Score it, act on the suicidality item at once, and re-score it to judge response - but let the clinical formulation, not the number, make the diagnosis.

18.6 Management: severity decides the first move

Management is stepped to severity, and the first line for a mild presentation is deliberately not a drug. The organising principle is that treatment intensity should match illness severity, and the sharpest examinable edge is at the mild end. For **mild depression the first-line approach is supportive care or a psychological intervention, and an antidepressant should not be prescribed**. The reasoning is twofold: mild childhood depression has a substantial rate of spontaneous improvement and response to non-drug support, so a period of active watchful support with a psychological therapy captures many recoveries without exposing a child to medication; and the risk-benefit balance of antidepressants in the young is only favourable once the illness is severe enough to warrant it. As the picture moves to moderate or severe, a structured psychological therapy is offered either alone or in combination with an antidepressant. Involving the family and the school is not an optional extra but part of the treatment itself, because the child's environment carries much of the maintenance and much of the recovery.

- mild depression: supportive care and a psychological therapy first-line, with medication actively withheld;
- moderate to severe depression: a psychological therapy alone or combined with an antidepressant;

- family and school engaged throughout as part of the intervention, not as an afterthought;
- severity, suicide risk and comorbidity reviewed at the outset and again as treatment proceeds.

18.7 Pharmacotherapy: which drug, what dose, what evidence

When an antidepressant is indicated, the choice, the dose and the evidence behind it are all examinable. The first-line agent is **fluoxetine**, and the reason it holds that place is specific rather than generic: it is the one antidepressant for which the trial evidence shows benefits outweighing risks in this age group, and it is approved for use from **age 8**, with escitalopram approved from age 12 as the other option. Dosing is cautious and stepwise: start at 10 mg daily, increase after one week to 20 mg daily, with a usual range of 20 to 60 mg daily, the lower end being the minimum therapeutic dose and the higher end reserved for the older or higher-weight child or where an early response is a priority. The general pharmacology of the antidepressants belongs to the Mood disorders: pharmacotherapy notes and is not reopened here; what is childhood-specific is that fluoxetine is chosen first on evidence, and that the youth-specific antidepressant-suicidality question and its monitoring schedule are developed in their own right elsewhere in this chapter.

The evidence that anchors the choice is worth knowing as a figure. The Treatment of Adolescents with Depression Study, which compared fluoxetine, cognitive behavioural therapy, their combination and placebo in adolescents with major depression, found over its acute phase a response of **61 percent** to fluoxetine against 35 percent to placebo, a number needed to treat of 4. That separation is the quantitative backbone of the recommendation, and the trial is also the source most often cited for the combined-treatment finding that adding a psychological therapy to medication does best of all, though the combination figures are not reproduced here.

> **IN INDIA**
>
> Fluoxetine is inexpensive, off-patent and among the most widely available antidepressants in the country, which makes the evidence-based first choice also the pragmatic one in a resource-limited service. The greater Indian constraint is not the drug but access to the psychological therapies that should precede and accompany it: specialist child mental health services are concentrated in a few centres, so much childhood depression is first seen in general adult psychiatry, paediatrics or primary care. The stepped principle still holds - a mild presentation is managed with support and psychological input, not a prescription - but its delivery leans heavily on family work and the school, and on task-shared counselling under the national mental health programme, where a full child psychiatry team is out of reach.

18.8 The safety floor every case carries

Whatever the severity, childhood depression management carries a minimum safety duty. Depression is the commonest diagnosis behind youth suicide, so every assessment of a depressed child carries a baseline screen for suicidality and early, close monitoring, and when an antidepressant is started the risk of harm must be carefully monitored in the early weeks. This is the shared minimal duty owned by the management of the disorder itself. It deliberately stops short of the detailed content that sits elsewhere: the full risk-assessment and safety-planning

tools are developed in their own right elsewhere in this chapter, as is the paediatric antidepressant-suicidality warning with its absolute-risk figures and its structured early-monitoring schedule. The point to hold here is the floor, not the detail - that a suicide screen and early monitoring are not add-ons to be remembered for severe cases but the baseline of every depressed child's care, and that starting a drug raises rather than removes the monitoring obligation.

18.9 Course, comorbidity and the differential that catches candidates

Getting the diagnosis right means getting the boundaries right. Childhood depression is recurrent, carries forward into adult mood disorder in a substantial proportion, and rarely travels alone: anxiety disorders, the disruptive behaviour disorders and attention problems are frequent companions, and comorbidity both worsens the outlook and complicates treatment. The general neurobiology and life-course of mood disorder belong to the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes; what is examinable here is the local differential. The chronic, non-episodic irritability that in a child can look like depression is also the territory of a separate chronic-irritability diagnosis, disruptive mood dysregulation disorder, which is developed in its own right elsewhere in this chapter and must be distinguished from a discrete depressive episode with an irritable mood. The behavioural surface of a masked depression can equally be read as a purely disruptive disorder. The discipline in every case is the same: establish whether a genuine, pervasive and persistent change in mood and functioning underlies the presenting behaviour, because that change is what separates a mood disorder from the conduct and irritability syndromes it can imitate.

TRAP **Reading an irritable, declining child as "just behavioural" and stopping there.** The classic error is to take the irritability, the falling grades or the acting-out at face value as an oppositional or conduct problem and never screen for the depression underneath. The developmental note that irritability can be the depressed mood exists precisely to stop this: a persistent, pervasive irritability with anhedonia and functional decline is a reason to assess for a depressive disorder, not a reason to close the file on a behavioural label.

19 · Somatic symptom, conversion and pain disorders in children

A child in distress often has no words for it, so the distress finds a body to speak through. The recurring tummy ache before school, the morning headache that lifts by lunchtime, the exhaustion no blood test explains: these are among the commonest ways emotional trouble reaches a paediatrician, and they are examinable because a candidate must do two quite different things well. The first is to recognise ordinary somatisation, the healthy child whose anxiety or low mood is being felt in the gut rather than named as a feeling. The second is to recognise the two formal disorders that sit beyond it, somatic symptom disorder and conversion disorder, and to grade and reason about them without falling into the traps that have been deliberately built into the modern criteria. The general adult forms of these conditions, their full nosology and their

treatment, are developed in the Somatic-symptom, sexual, impulse-control disorders and suicide notes; this topic owns the child-specific presentation and teaches the two disorders in their own right.

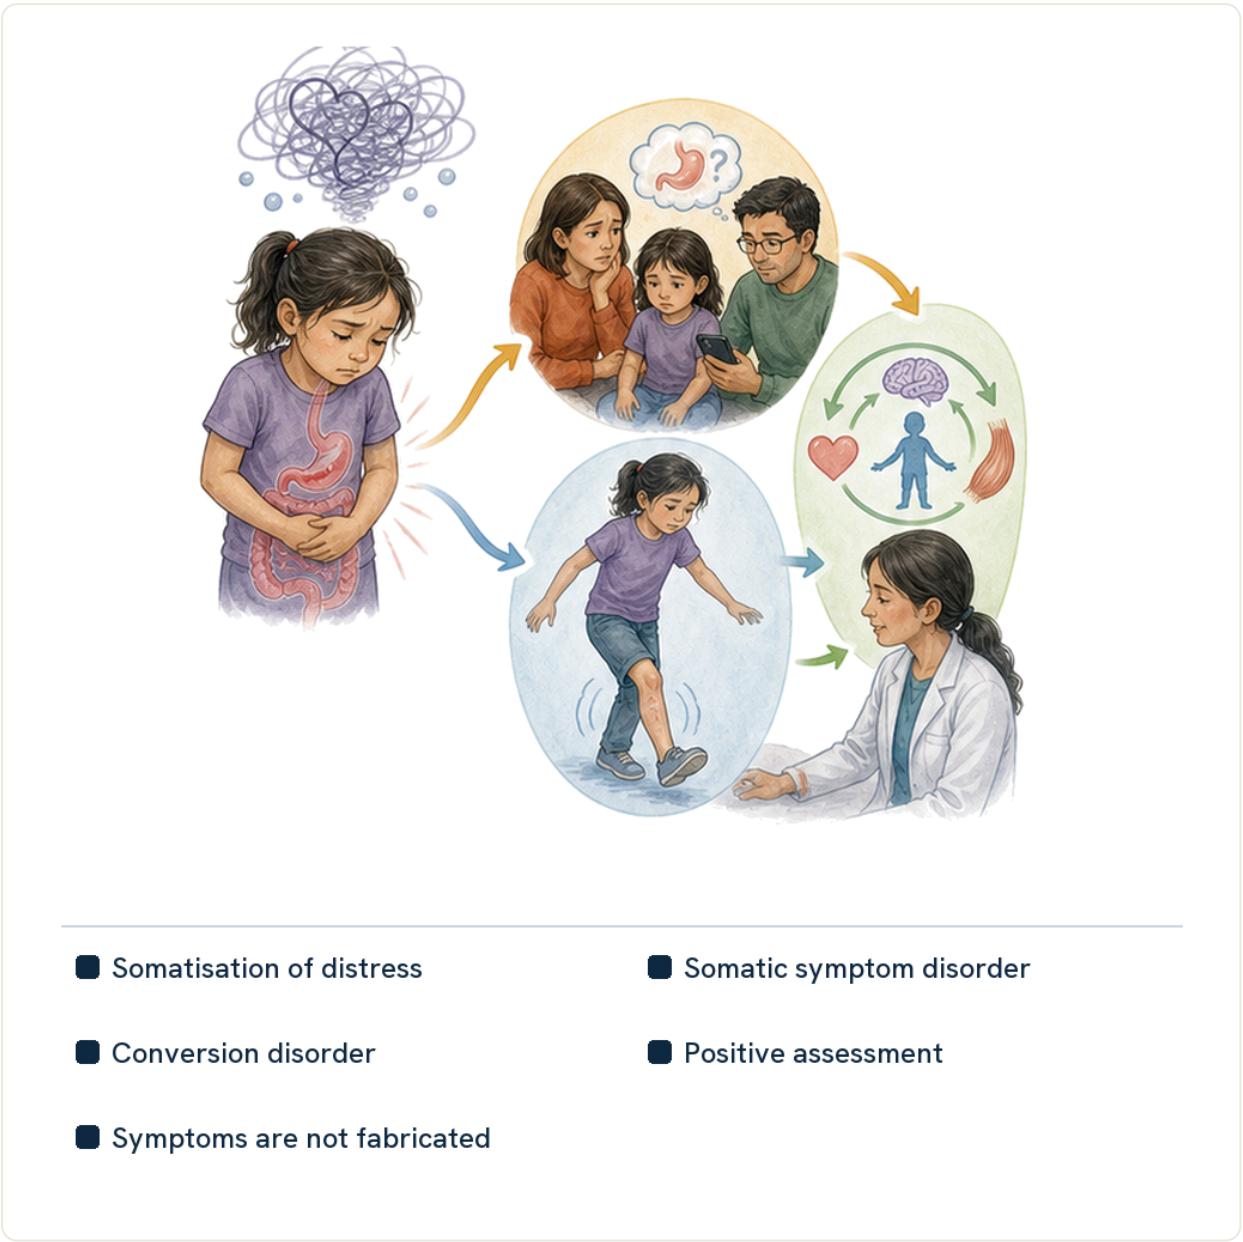

Fig 23.15 Childhood bodily symptoms lie on a clinical sequence from somatisation of distress to formal somatic symptom or conversion disorder. Assessment validates the symptom, looks for positive clinical features and functional impact, and does not equate unexplained symptoms with fabrication.

The order to hold runs from the softest to the hardest edge: first the somatisation of distress, a presentation and not yet a disorder; then somatic symptom disorder, defined by how the child and family respond to symptoms rather than by whether those symptoms are explained; then conversion disorder, which turns on a positive neurological sign and is not a diagnosis reached by exclusion.

19.1 The body as the voice of distress

Before any disorder is diagnosed, know how ordinary childhood distress somatises. When children are anxious or depressed, the complaint that reaches the clinic is frequently physical.

The characteristic symptoms of childhood **somatisation** are recurrent abdominal pain, headache, fatigue and nausea, and a useful developmental point is that a single prominent symptom is commoner in a child than the elaborate multi-system picture more typical of an adult. This is the presentation that separation anxiety, school refusal and childhood depression each borrow when they surface in the body rather than in mood or thought; those conditions are taught in full in their own places in this chapter, and here the point is only that the abdominal pain or the headache is the surface, and the affect underneath it is what the interview must reach.

19.2 Recurrent abdominal pain as the paradigm

One symptom carries most of the marks here. **Recurrent abdominal pain** is one of the most common medical complaints of childhood, and in the majority of children who present with it no organic pathology is ever identified. That single fact does most of the clinical work. It tells you that a careful history and examination, rather than a widening battery of tests, is the right first move, and that in a child with recurrent pain, normal growth and no alarm features, an emotional contributor is statistically the likeliest story. The pain is real, felt exactly where the child points; it is the meaning, not the sensation, that is misattributed. The discipline is to hold two truths together: most such pain is functional, and yet the minority with organic disease must not be missed, which is why red-flag features such as weight loss, nocturnal waking, bleeding or a localising sign always earn investigation regardless of how anxious the child seems.

> **PITFALL**
>
> The repeated normal investigation can itself become the disease. Each fresh scan that comes back clear is meant to reassure, but for an anxious child and a frightened family it often does the opposite: it confirms that something serious is being hunted for and has not yet been found. The result is escalating investigation, school absence and an entrenched sick role. Deciding early that the picture is functional, and saying so with conviction while keeping a light safety net, protects the child better than another test.

19.3 Somatic symptom disorder: the DSM-5 entity

Somatic symptom disorder is a formal diagnosis, distinct from the presentation above. Its architecture is worth carrying exactly. **Somatic symptom disorder** requires one or more somatic symptoms that are distressing or that cause significant disruption of daily life. The defining requirement, however, is not the symptom but the reaction to it: there must be **excessive thoughts, feelings or behaviours** about the symptoms, demonstrated by at least **one** of three features.

- disproportionate and persistent thoughts about the seriousness of the symptoms;
- a persistently high level of anxiety about health or about the symptoms;
- excessive time and energy devoted to the symptoms or to health concerns.

The symptomatic state must be persistent, typically lasting **more than six months**, although any one symptom need not be continuously present across that time. Severity is graded by how many

of the three response features are met, which keeps the grading anchored to the psychological burden rather than to the count of bodily complaints.

MNEMONIC

Symptom, Story, Staying-power

A distressing bodily **symptom** (Criterion A); the excessive **story** the child and family build around it, in thought, health anxiety or time consumed (Criterion B); and the **staying-power** of a persistent symptomatic state (Criterion C). The middle term is the diagnosis.

19.4 The pivot away from medically unexplained symptoms

This is the single most tested conceptual point. The older somatoform category was built on the idea that the symptoms were medically unexplained. DSM-5 abandoned that foundation. Having **medically unexplained symptoms** is no longer sufficient to make the diagnosis; the diagnosis rests on the excessive thoughts, feelings and behaviours, and the somatic symptoms may or may not accompany a diagnosable medical condition. A child with genuine asthma or migraine can also have somatic symptom disorder if the response to those real symptoms is disproportionate and disabling. This reframing stops the diagnosis from being a label of last resort applied when the tests come back normal, and it protects the truth that the child's suffering is authentic whether or not medicine can explain the sensation.

RULE **Somatic symptom disorder is diagnosed by the response, not by the absence of a cause.** Ask not whether the symptom is explained but whether the thoughts, anxiety and behaviour around it are out of proportion and are consuming the child's life. A real diagnosis can sit alongside a real disease.

19.5 Applying the criteria to children

The adult criteria transfer, but the assessment does not. The somatic symptom disorder criteria appear suitable for use in children and adolescents, though the entity is far less studied in the young than in adults. The practical consequence is that a child cannot be assessed alone. Distress in childhood is co-authored: how a parent interprets a stomach ache, whether it is met with alarm or with calm, shapes how the child comes to experience and report it, and the same symptom can be trivial in one household and disabling in another. Assessment therefore gathers the child's account, the family's, and the school's, because the pattern of missed lessons and the child's function among peers reveals disability the consulting room cannot. The full child psychiatric assessment battery and its services are set out in the Child psychiatry: assessment, treatment, services and protection notes.

19.6 Conversion disorder and the incompatibility criterion

Conversion disorder is a different animal, defined by a positive examination. In **functional neurological symptom disorder**, also called conversion disorder, the presenting problem is altered voluntary motor or sensory function: a weak or paralysed limb, an abnormal gait, non-epileptic attacks that resemble seizures, or a sensory loss. The pivotal requirement is that the clinical findings provide evidence of incompatibility between the symptom and recognised

neurological or medical conditions. Incompatibility is a specific and technical idea: it means the signs are internally inconsistent, behaving in a way no organic lesion could produce, rather than simply being unexplained or unusual. That internal inconsistency, demonstrated at the bedside, is what carries the diagnosis, and it is why the neurological examination in a suspected conversion disorder is an active search for positive signs rather than a screen for disease to rule out.

19.7 A rule-in, not a rule-out, diagnosis

Conversion disorder is not made because the scans are clean. This deserves its own place because getting it wrong is the classic failure. The diagnosis is not one of exclusion; it is made on positive clinical signs of incompatibility. The examples worth knowing are **Hoover's sign**, in which apparent leg weakness normalises when the opposite hip is flexed against resistance, and the tremor entrainment test, in which a functional tremor takes on the rhythm the examiner asks the other hand to tap. Because these signs demonstrate the symptom directly, conversion disorder can coexist with genuine neurological disease, and it must never be diagnosed merely because investigations are normal or because a symptom looks bizarre. A symptom that is odd is not thereby functional, and a normal scan proves the absence of the lesions it images, not the presence of conversion.

TRAP **Treating conversion disorder as a diagnosis of exclusion.** The tempting shortcut is to order the investigations, watch them return normal, and conclude by elimination that the paralysis or the non-epileptic attack must be psychological. That reasoning is unsafe in both directions: it misses the organic disease the tests did not cover, and it fails to demonstrate the positive incompatibility the diagnosis actually requires. Show the sign, do not merely fail to find a lesion.

19.8 Telling the three apart

The examinable discrimination is between three near neighbours. The somatisation of distress, somatic symptom disorder and conversion disorder are related but distinct, and a candidate is expected to separate them cleanly. The sharpest line runs between the two formal disorders: in **functional neurological symptom disorder the presenting problem is a loss of function**, of a limb or a sense, whereas in somatic symptom disorder the focus is the distress that the symptoms cause and the disproportionate response to them. The somatisation presentation sits before both, describing how childhood anxiety and depression speak through the body without necessarily reaching the threshold of either disorder. Persistent pain, once carved out as a separate pain disorder, is now captured within somatic symptom disorder when the response to it is excessive. For the general adult versions of all of these, and their management, the general somatic-symptom and conversion disorders are taught in the Somatic-symptom, sexual, impulse-control disorders and suicide notes.

FEATURE	SOMATISATION OF DISTRESS	SOMATIC SYMPTOM DISORDER	CONVERSION DISORDER
Status	A presentation, not a disorder	DSM-5 disorder	DSM-5 disorder
Core focus	Anxiety or low mood felt in the body	The distress and excessive response to the symptoms	A loss of voluntary motor or sensory function
Typical symptom	Recurrent abdominal pain, headache	Any distressing bodily symptom, explained or not	Weakness, abnormal gait, non-epileptic attacks
What secures it	Reaching the affect beneath the complaint	The excessive thoughts, feelings and behaviours	A positive sign of clinical incompatibility
Cardinal trap	Dismissing real suffering as fabrication	Reading it as merely "medically unexplained"	Diagnosing by exclusion

The three run from a presentation towards two disorders defined on opposite grounds: somatic symptom disorder by the response to a symptom, conversion disorder by a positive sign that the symptom is incompatible with disease.

GOOD TO REMEMBER

What changes practice on Monday is the stance, not a new test. Validate the symptom as genuinely felt, name the emotional contributor without implying the child is inventing anything, set a firm ceiling on investigation, and enlist the family and school in a graded return to normal function. For a suspected conversion presentation, gently demonstrate the incompatibility sign to the family, because a diagnosis they can see explained is one they can work with.

IN INDIA

Somatic presentation is arguably the default idiom of distress across much of Indian practice, where emotional vocabulary is often somatic and the first contact is a physician or paediatrician rather than a mental health clinician. Conversion presentations, including non-epileptic attacks framed by families in idioms of possession or spiritual affliction, are seen frequently in Indian child and adolescent services. Two habits follow. Screen for anxiety and depression behind the persistent tummy ache or headache rather than reaching only for another investigation, and, in a country where organic infective and nutritional disease is common, keep the safety net for red-flag features firmly in place even once a functional cause looks likely.

Somatic symptom disorder is diagnosed by the excessive response to symptoms, not by their being unexplained; conversion disorder is ruled in by a positive sign of incompatibility, never ruled in by exclusion.

20 · Disruptive mood dysregulation disorder

The diagnosis was built to solve a problem the field had created for itself. **Disruptive mood dysregulation disorder** names the child who is chronically, grindingly irritable and who erupts into severe temper outbursts many times a week, every week, for a year or more. It exists because a generation of chronically irritable children had been swept into a diagnosis of paediatric bipolar disorder on the strength of their rages, treated with mood stabilisers and antipsychotics, and followed into an adulthood that turned out to hold not mania but depression and anxiety. The construct was introduced to give that presentation a home of its own, in the depressive rather than the bipolar family, and to stop the reflex that read every explosive child as bipolar. For the examination the marks sit almost entirely on two things: the exact criteria, which are long and easily half-remembered, and the reasoning that separates this chronic, non-episodic irritability from the episodic mood elevation of bipolar disorder.

This topic owns the diagnostic architecture of the disorder and the operational rule that distinguishes it from paediatric bipolar disorder: the temper-outburst criterion, the frequency and inter-outburst mood requirements, the duration, pervasiveness, age-window and onset rules, the manic-exclusion clause, its placement among the depressive disorders, its differential against oppositional defiant disorder, its prevalence, its position in the two major classifications, and its indication-scoped pharmacotherapy. The historical over-diagnosis debate itself, the narrow-phenotype argument and the reasons the category was contested are developed in their own right elsewhere in this chapter; here they are named as the backdrop, not reopened.

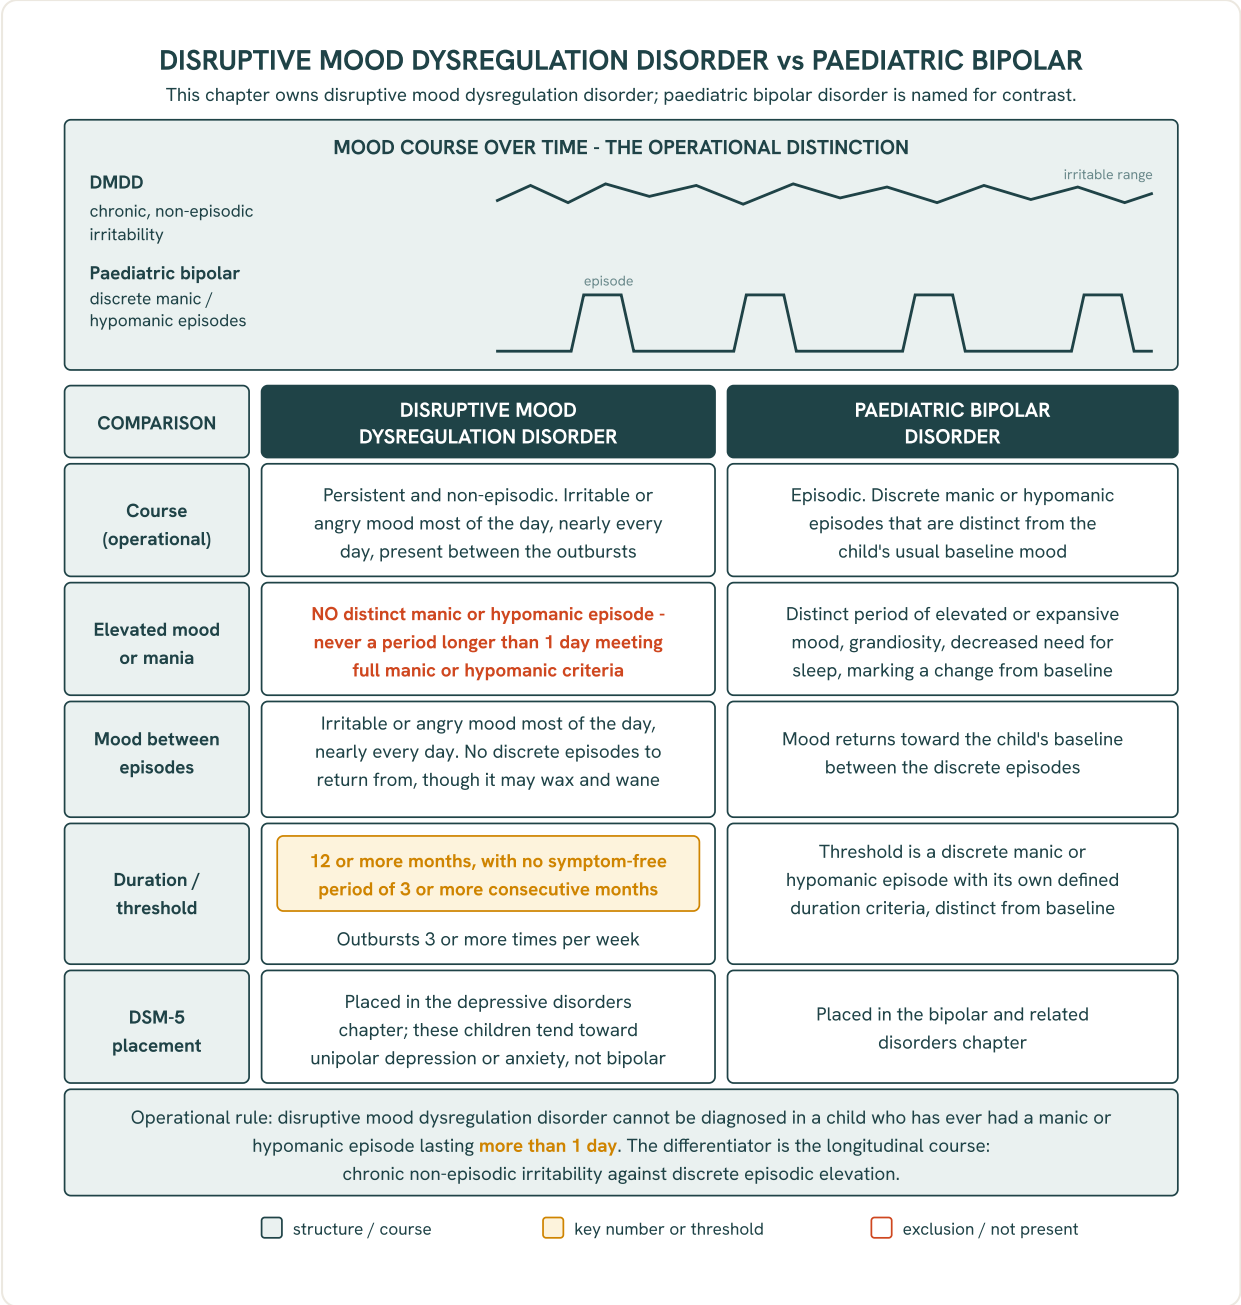

Fig 23.16. Disruptive mood dysregulation disorder against paediatric bipolar disorder: a mood-course timeline and a paired criteria grid showing chronic non-episodic irritability against discrete episodic mania, the 12-month duration floor, the manic-episode exclusion boundary of more than 1 day, and the depressive-chapter placement that carries the operational distinction.

20.1 What the disorder is, and why it sits among the depressive disorders

The placement is the argument in miniature. The classification files this disorder among the **depressive disorders**, and that decision carries the whole rationale for the category. Longitudinal work found that children with chronic, non-episodic irritability do not, as a rule, grow into adults with bipolar disorder; they grow into adults with unipolar depressive and anxiety disorders. The irritability is therefore read as a depressive-spectrum phenomenon expressed in a developmentally immature way, not as a prodrome of mania, and the disorder is housed accordingly. This is worth holding onto because it explains everything downstream: why the manic exclusion is written into the criteria, why lithium is not the answer, and why the differential that matters is not against conduct problems but against bipolar disorder. The name

itself is a compromise, splitting the presentation into two visible components - the **persistently irritable or angry mood** that forms the baseline, and the severe outbursts that punctuate it.

20.2 Criterion A: the temper outburst as the core symptom

The disorder is anchored on outbursts that are grossly disproportionate to their trigger. The core criterion is **severe recurrent temper outbursts**, which may be verbal, behavioural, or both, and which are grossly out of proportion in intensity or duration to the situation or provocation that set them off. In practice this is the verbal rage - screaming, shouting - and the physical aggression toward people or property that families describe as coming out of nowhere and lasting far longer than the small frustration that triggered it. Two qualities do the diagnostic work. The first is disproportion: the reaction is wildly larger than the provocation, so a minor "no" produces a twenty-minute destructive storm. The second is that the outbursts are inconsistent with developmental level; the tantrum of a two-year-old denied a sweet is expected, the same storm in a school-aged child is not. It is the pairing of severity, disproportion and developmental inappropriateness, not the mere fact of a tantrum, that makes an outburst count.

MNEMONIC

Storms on a stormy sky

The whole picture is two components at once: the **storms** are the severe temper outbursts, and the **stormy sky** is the persistently irritable, angry mood that persists between them. A child who has the storms but a calm sky between them does not have this disorder, and neither does the child who is merely irritable without the outbursts. Requiring both is the single feature that keeps the category tight.

20.3 Frequency and the mood between outbursts: the two thresholds that define the syndrome

An outburst threshold and a baseline-mood threshold must both be crossed. The frequency rule requires the outbursts to occur, on average, at least **three** times a week. This is a demanding bar and it is deliberate: it filters out the child who erupts occasionally under stress and captures only the pattern of repeated weekly explosiveness. The second threshold is the mood between the storms. The criteria require that, in the intervals between outbursts, the mood is persistently irritable or angry, present most of the day, nearly every day, and - crucially - observable by others such as parents, teachers and peers. This inter-outburst irritability is what separates the disorder from a simple explosive-behaviour problem. The child is not calm and pleasant between rages; the baseline itself is angry. Requiring the irritability to be observable by others, rather than merely reported, guards against a diagnosis built on a single exhausted parent's account, and it is a frequently examined clause.

RULE **Both the outbursts and the mood between them must be abnormal.** The defining structure of this disorder is a persistently irritable or angry baseline punctuated by severe, frequent temper outbursts. The outbursts alone are not enough, and the irritable baseline alone is not enough; the diagnosis lives precisely in the requirement that both be present, together, over a long stretch of time. This is what makes the irritability chronic rather than episodic, and chronicity is the whole point.

20.4 Duration, pervasiveness and the age rules

Four gating rules turn a cross-sectional picture into a diagnosis. The criteria then wrap the two core thresholds in a set of qualifying rules whose job is to enforce chronicity and to keep the diagnosis inside a defined developmental band. The symptoms must have been present for at least **twelve** months, with no symptom-free stretch of three or more consecutive months, so a transient irritable phase cannot qualify. They must be present in at least two of three settings - home, school and with peers - and be severe in at least one, which enforces the pervasiveness that separates a disorder from a reaction to one difficult environment. The diagnosis must not be made for the first time before age 6 or after age 18, because the outburst-plus-irritability picture is neither reliable nor distinctive at the extremes of that range. And by history or observation the onset of the symptoms must be before **age 10**. Together these rules are what make this a disorder of chronic, pervasive, early-onset irritability rather than a label for any child who is having a bad month.

REQUIREMENT	THE RULE	WHAT IT GUARDS AGAINST
Outbursts	Severe, disproportionate, at least three per week on average	The occasional stress-driven eruption
Baseline mood	Persistently irritable or angry between outbursts, observable by others	Explosive behaviour without a mood disturbance
Duration	Present at least twelve months, no gap of three or more months	A transient irritable phase
Pervasiveness	In at least two of three settings, severe in one	A reaction confined to one setting
Age window	Not diagnosed before age 6 or after age 18	Unreliable diagnosis at the developmental extremes
Onset	Symptoms begin before age 10	An adolescent-onset mood or behavioural disorder in disguise

The gating rules read against the failure mode each one is designed to exclude; the accompanying figure lays the same structure out as the two core thresholds wrapped in the chronicity and age constraints.

20.5 The manic exclusion and the chronic-versus-episodic distinction

This is the reasoning the whole category was built to force. The criteria carry an explicit exclusion: a child who has ever had a manic or hypomanic episode - a distinct period meeting the full symptom criteria, except duration - is, by definition, on the bipolar spectrum and cannot receive this diagnosis. The load-bearing distinction is longitudinal and it is the single most examined point in the topic: the irritability of this disorder is **persistent and non-episodic**, a chronic background state that may wax and wane without ever resolving into episodes, whereas bipolar disorder is **episodic**, defined by discrete manic or hypomanic episodes that stand out clearly from the child's usual baseline. You are not comparing two cross-sectional pictures; you are comparing a flat, chronically irritable course against a course marked by episodes with a beginning and an end. The bipolar controversy in children - the historical over-diagnosis, the

narrow-phenotype debate - is taken up in its own right elsewhere in this chapter; the operational discriminators the clinician actually applies are these:

- a chronic, non-episodic irritable baseline, present most of the day and nearly every day though it may wax and wane, favours this disorder; irritability that arrives and departs in discrete spells favours bipolar disorder;
- any distinct period, longer than one day, that met full manic or hypomanic criteria bars this diagnosis outright;
- a developmentally appropriate surge of high spirits at a genuinely exciting event is not mania and does not count toward it.

TRAP **Chronic severe irritability is not paediatric mania.** The classic error, and the very error the diagnosis was created to correct, is to see a child with frequent explosive rages and a short fuse and reach for bipolar disorder. Irritability is not episode-defining; it is the non-specific affect this disorder makes chronic. The question is never how angry the child is but whether the anger comes in discrete episodes distinct from baseline. If it does not, this is chronic irritability, and the manic-exclusion clause bars the bipolar label outright.

20.6 The differential against oppositional defiant disorder

The two overlap heavily, and the diagnostic-hierarchy rule resolves it. The other disorder this presentation is constantly confused with is **oppositional defiant disorder**, whose diagnostic architecture is developed in its own right elsewhere in this chapter. The overlap is substantial: roughly **15%** of children who meet criteria for oppositional defiant disorder also meet criteria for this disorder. The two share the angry, irritable, easily-provoked child, but this disorder demands more: severe, recurrent temper outbursts and a persistently disturbed inter-outburst mood, at a severity and chronicity that the oppositional diagnosis does not require. Because the presentations nest, the classification imposes a hierarchy: when a child meets criteria for both, only this disorder is diagnosed. That rule is the reverse of the usual instinct to give the "milder" oppositional label, and it reflects a judgement that the chronic mood disturbance is the more clinically significant fact about the child. The practical upshot is that a chronically irritable, explosive child who could be called oppositional is called by this disorder's name instead, once the outburst and mood thresholds are genuinely met.

PITFALL

Clinicians who anchor on the tantrums alone slide toward one of two wrong homes for this child: oppositional defiant disorder, if they read the outbursts as defiance, or bipolar disorder, if they read them as mania. Both misreadings share a single cause - attending to the explosive behaviour and neglecting the shape of the mood over time. The corrective is to characterise the baseline between outbursts and the longitudinal course before choosing a label, because it is the persistent, non-episodic irritability, not the outbursts, that actually discriminates this disorder from its neighbours.

20.7 Epidemiology

The prevalence figures carry a warning about the diagnosis itself. Community estimates vary substantially with the age of the sample and the instrument used, which is itself the

epidemiological headline. A population-based cohort of Brazilian eleven-year-olds, assessed with a dedicated diagnostic module, put the prevalence at about 2.5%, while a United States community sample of six-year-olds returned a figure closer to **8.2%**. Reading the two together, the diagnosis appears commoner in younger children, consistent with the general truth that irritability and tantrums are more prevalent, and less specific, earlier in childhood - which is part of why the criteria refuse the diagnosis below the lower age bound. Unlike several externalising disorders of childhood, a consistent sex difference has not been reported in population samples.

20.8 The two classifications part company

One major system created the disorder; the other declined to. The two international classifications disagree at the level of whether this entity exists at all. One houses it as a standalone diagnosis within the depressive disorders. ICD-11 **has no equivalent category**; the corresponding presentation is coded instead as oppositional defiant disorder with chronic irritability-anger, under the code 6C90.0. In other words, where one manual carves the chronically irritable child out as a separate depressive-spectrum disorder, the other keeps the child inside the oppositional category and attaches a specifier to mark the irritability. That system also holds that irritability-anger on its own is neither necessary nor sufficient for the oppositional diagnosis. This is a genuine structural disagreement, not a difference of wording, and it decides how the same child is recorded depending on which manual a service follows.

> **IN INDIA**
>
> Because Indian services classify under ICD, there is no disruptive mood dysregulation disorder to code in routine case files, referrals or official reports. The chronically irritable, explosive child is recorded as oppositional defiant disorder with the chronic irritability-anger specifier under its ICD code. A clinician trained on the other manual's categories should not go hunting for a separate mood-dysregulation diagnosis in an ICD-coded record: the same presentation lives here inside the oppositional diagnosis, and treating the two systems as describing different children, rather than the same child filed differently, is a recurring source of confusion in cross-referenced notes and in examination answers.

20.9 Management: what is established, and what is not

The honest teaching point is the absence of a specific evidence base. There is, as yet, **no established treatment** for this disorder as such. Two negatives and two provisional positives should be carried. First, lithium is ineffective here - a direct consequence of the disorder not being bipolar, and a useful confirmation that the depressive-spectrum placement is more than a filing decision. Second, SSRIs together with psychological and parenting interventions may be considered, though the supporting data specific to this indication are thin. Beyond that, treatment is genuinely investigational: trials of stimulant and adjunctive SSRI treatment for these children are in progress, and adjunctive SSRIs are in practice used for the irritable child with comorbid attention-deficit/hyperactivity disorder without a firm evidence base behind that use. The comorbid disorder itself, its stimulant and non-stimulant treatment, belongs to the ADHD and specific learning/communication disorders notes; here it is named only as the common travelling companion whose treatment sometimes carries the irritability with it. Benzodiazepines

are disfavoured, because they can increase disinhibition and aggression in this population. The examinable posture is therefore one of therapeutic humility, kept carefully distinct from the pharmacotherapy of aggression in conduct disorder, which is a separate indication with its own evidence and is developed elsewhere in this chapter.

The one line to carry: this is chronic, non-episodic irritability with severe frequent temper outbursts on a persistently angry baseline, placed among the depressive disorders precisely because it is not bipolar.

GOOD TO REMEMBER

Before this label changes anything you prescribe, characterise the course. If the irritability is chronic and non-episodic and the outbursts frequent on an angry baseline, you are in this disorder's territory and lithium and antipsychotics are not the reflex; if the irritability comes in discrete episodes distinct from baseline, you are not, and the assessment turns toward bipolar disorder. The clinical move that protects the child is to map the mood over months, not to weigh the size of the last tantrum.

3+ / week	12 months	before 10	~15%
TEMPER OUTBURSTS, ON AVERAGE	MINIMUM SYMPTOM DURATION	AGE AT SYMPTOM ONSET	OF ODD ALSO MEET CRITERIA

21 · Childhood bipolar disorder controversy

Few debates in child psychiatry have caused as much diagnostic harm as the question of whether young children can have bipolar disorder. The topic earns its marks not because paediatric bipolar disorder is common, but because a generation of children were labelled with it who did not have it, and a candidate is expected to understand exactly how that happened, why a new diagnostic category was created to stop it, and where the honest line now lies. The general bipolar syndrome, its full episode criteria and its neurobiology, belongs to the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes; what this topic owns is the controversy itself, the reasoning behind it, and the discipline it demands at the bedside. The single most examinable idea is that a diagnosis with sharp, episodic boundaries was quietly stretched to cover children whose problem was not episodic at all.

The structure to carry into the exam is a short causal chain. A diagnostic upsurge occurred; it was driven by a specific conceptual move; that move collided with the defining requirement of the disorder; and the classification responded by carving out a separate home for the children who had been swept in. Each link is teachable, and each is where the marks sit.

21.1 The shape of the controversy

A rare disorder became, briefly, a common diagnosis. Over a relatively short span, bipolar disorder came to be applied to large numbers of children, first and most dramatically in the United States and afterwards, more cautiously, in other countries. The concern that grew out of this was not academic hair-splitting: it was that the disorder was being **over-diagnosed and**

over-treated in children, with young patients placed on mood stabilisers and antipsychotics on the strength of a label many of them did not warrant. That worry became formal enough that a new category, **disruptive mood dysregulation disorder**, was written into the classification for the express purpose of giving these children a more accurate diagnostic home. The whole controversy, in other words, is documented inside the classification that resolved it, which is why examiners treat it as settled teaching rather than open opinion.

21.2 How the upsurge happened: two presentations merged into one

The rise did not come from better detection of true mania; it came from a conceptual merger. The mechanism of the upsurge was that clinicians combined **two** genuinely distinct clinical pictures into a single category. On one side sat **episodic mania**, the classic, discrete elevation or expansion of mood that defines the adult disorder. On the other sat **non-episodic severe irritability**, a chronic, grinding crossness punctuated by explosive outbursts, with no discrete episode at all. Once these two were treated as versions of the same illness, the pool of eligible children expanded enormously, because chronic irritability is common and non-specific in the clinic while true episodic mania is not. The classification's answer was to draw the boundary sharply: in **DSM-5** the term bipolar disorder is explicitly reserved for the episodic presentation, so that the mere presence of a chronically irritable, explosive child can no longer be read as a mood-cycling illness.

RULE **Bipolar disorder is defined by episodes, not by irritability.** Irritability is a symptom that appears in mania, in depression, in anxiety and in ordinary childhood distress. What makes a presentation bipolar is a discrete change from baseline with an onset and an offset, not the intensity of a child's temper. Strip the episode away and you have not made a milder bipolar disorder; you have a different condition.

21.3 The crux: is chronic irritability a form of mania?

This is the question the whole debate reduces to. The crux is whether severe, **non-episodic irritability** should count as a paediatric form of mania. The answer written into the diagnostic rules is no, and the reasoning is structural rather than a matter of taste. Both DSM-IV and DSM-5 require distinct **a distinct manic episode** for a diagnosis of bipolar I disorder. A child whose irritability is present most of the day, most days, without ever resolving into and out of a bounded episode does not meet that requirement, however severe the presentation looks. This is why the debate was often framed as a contest between a narrow and a broad reading of the disorder. The **narrow phenotype** holds the episode requirement intact and keeps the diagnosis close to its adult form; the **broad phenotype** loosened it to include persistent irritability, and it was the broad reading that generated the over-diagnosis. The operational criteria for the disruptive mood dysregulation disorder that now houses these children are developed in their own right elsewhere in this chapter; here the point is only that the episode requirement is the fault line the two phenotypes fall on.

AXIS OF CONTRAST	NARROW PHENOTYPE (TRUE BIPOLAR)	BROAD PHENOTYPE (CHRONIC IRRITABILITY)
Mood pattern	Distinct manic episodes with a clear onset and offset	Persistent, non-episodic irritability with no discrete episode
Core disturbance	Episodic elevation or expansion of mood and energy	Chronic crossness with reactive, explosive outbursts
Diagnostic home	Bipolar I and the bipolar spectrum	Disruptive mood dysregulation disorder, placed among the depressive disorders
Longitudinal course	Continuity with adult bipolar disorder	Very low conversion to bipolar; risk of unipolar depression and anxiety

The two columns are not two grades of one illness; they are different conditions that were briefly filed together, and the episode requirement is what separates them.

21.4 Why a new category was created, and where it sits

The classification did not simply forbid the diagnosis; it built somewhere for the children to go. Removing the broad phenotype from bipolar disorder would have left a large group of genuinely impaired, chronically irritable children with no diagnostic label at all, and no clinician will leave such a child unnamed. The purpose of the new category was therefore twofold: to protect the bipolar diagnosis from erosion, and to give chronic paediatric irritability its own honest home. Crucially, that home was placed among the **depressive disorders** rather than in the bipolar section. That placement is not arbitrary filing. It is a claim about the underlying nature of the condition, and it is defended by the longitudinal evidence taken up next: these children do not travel toward bipolar disorder, so housing them beside it would repeat the very error the category was built to correct.

- it preserves the episodic meaning of the bipolar label;
- it gives severe non-episodic irritability a specific diagnosis of its own;
- it signals, by its placement, a depressive rather than a bipolar trajectory;
- it discourages the reflex prescription of mood stabilisers to irritable children.

21.5 What the follow-up data actually show

The longitudinal evidence is the strongest single argument against the broad phenotype. If chronic non-episodic irritability were really an early form of bipolar disorder, then children who show it should convert to bipolar disorder as they grow. They largely do not. The **rates of conversion** from severe non-episodic irritability to bipolar disorder are very low. What these children are at increased risk of, instead, is unipolar depressive and anxiety disorders in adulthood. This is a decisive discrimination for the exam, because it converts a question of definition into a question of prognosis: the two phenotypes do not share an outcome, and an illness is known partly by where it leads. The trajectory data are precisely what justify filing chronic irritability with the depressive disorders and keeping it out of the bipolar section.

GOOD TO REMEMBER

When a chronically irritable, explosive child is in front of you, the useful question is not "how severe is the temper" but "is there a discrete change from baseline". Hunt for a bounded period of elevated, expansive or unusually energised mood, distinct from the child's usual self, with a beginning and an end. If you cannot find one, you are not looking at bipolar disorder, and the treatment that follows a bipolar label does not follow.

21.6 The traps, and the position to defend

The examiner is testing discipline, not knowledge of a rare disorder. The safe position to write is the narrow one: bipolar disorder in children exists but is uncommon, it requires the same discrete episodes demanded in adults, and chronic irritability is not a substitute for those episodes. The candidate who can state that cleanly, name the category built to house the displaced children, and cite the low conversion rate as the reason for its placement has shown the whole reasoning chain the marks reward.

TRAP **Reading chronic irritability, or "very frequent mood swings", as paediatric rapid-cycling bipolar disorder.** The seductive move is to hear that a child is irritable "all the time" and explosive "several times a day" and translate that into ultra-rapid cycling. Frequency within a day is not cycling; cycling means discrete episodes. Label the presentation as chronic irritability, look for a true episode before you invoke bipolar disorder, and do not let severity stand in for episodicity.

PITFALL

The clinical harm of the broad phenotype was pharmacological. A bipolar label on a chronically irritable child leads almost automatically to a mood stabiliser or an antipsychotic, carrying metabolic and neurological burden, to treat a condition the child does not have. Naming the presentation accurately is not a semantic nicety; it is what keeps a child off years of unnecessary medication.

Episodic mania is bipolar disorder; chronic non-episodic irritability is not, and it was the conflation of the two that drove the over-diagnosis a separate diagnostic category was created to end.

IN INDIA

Indian child psychiatry classifies predominantly under ICD, which never carried the broad paediatric-bipolar phenotype the way American practice briefly did, so the over-diagnosis surge was largely a Western phenomenon that Indian trainees read about rather than lived through. The discipline it teaches still applies here. A chronically irritable, explosive child brought to an Indian clinic is common, and the temptation to reach for a bipolar label and a mood stabiliser is real; the correct response is to reserve the bipolar diagnosis for genuine episodic illness and to resist importing the broad reading that the international debate has already discredited.

22 · Early-onset schizophrenia and childhood psychosis

Psychosis in a child is not a smaller version of an adult illness; it is the same illness arriving early, on a brain that was already developing atypically. This topic is about schizophrenia and related psychotic states that declare themselves before adulthood, and it carries marks out of all proportion to how often the condition is seen, because it forces a candidate to do three things at once: recognise that true psychosis can begin in childhood, place it correctly on the neurodevelopmental continuum with the adult disorder, and separate it from the far commoner non-psychotic phenomena that mimic it. Get any one of those wrong and a well child is labelled schizophrenic, or a genuinely psychotic child is dismissed as imaginative, and both errors are examined.

The essential message is one of continuity with severity. Early-onset schizophrenia is uncommon, but where it occurs it is a harsher, more neurodevelopmentally saturated expression of the same process that produces adult schizophrenia. This topic owns that account in full: the definitions and the onset-age spectrum, the premorbid picture, the phenomenology, the neurocognition, the course and outcome, and the differential from the psychosis-mimics of childhood. The general neurobiology and pharmacology of schizophrenia belong to the adult chapters and are named here only where the reasoning demands them.

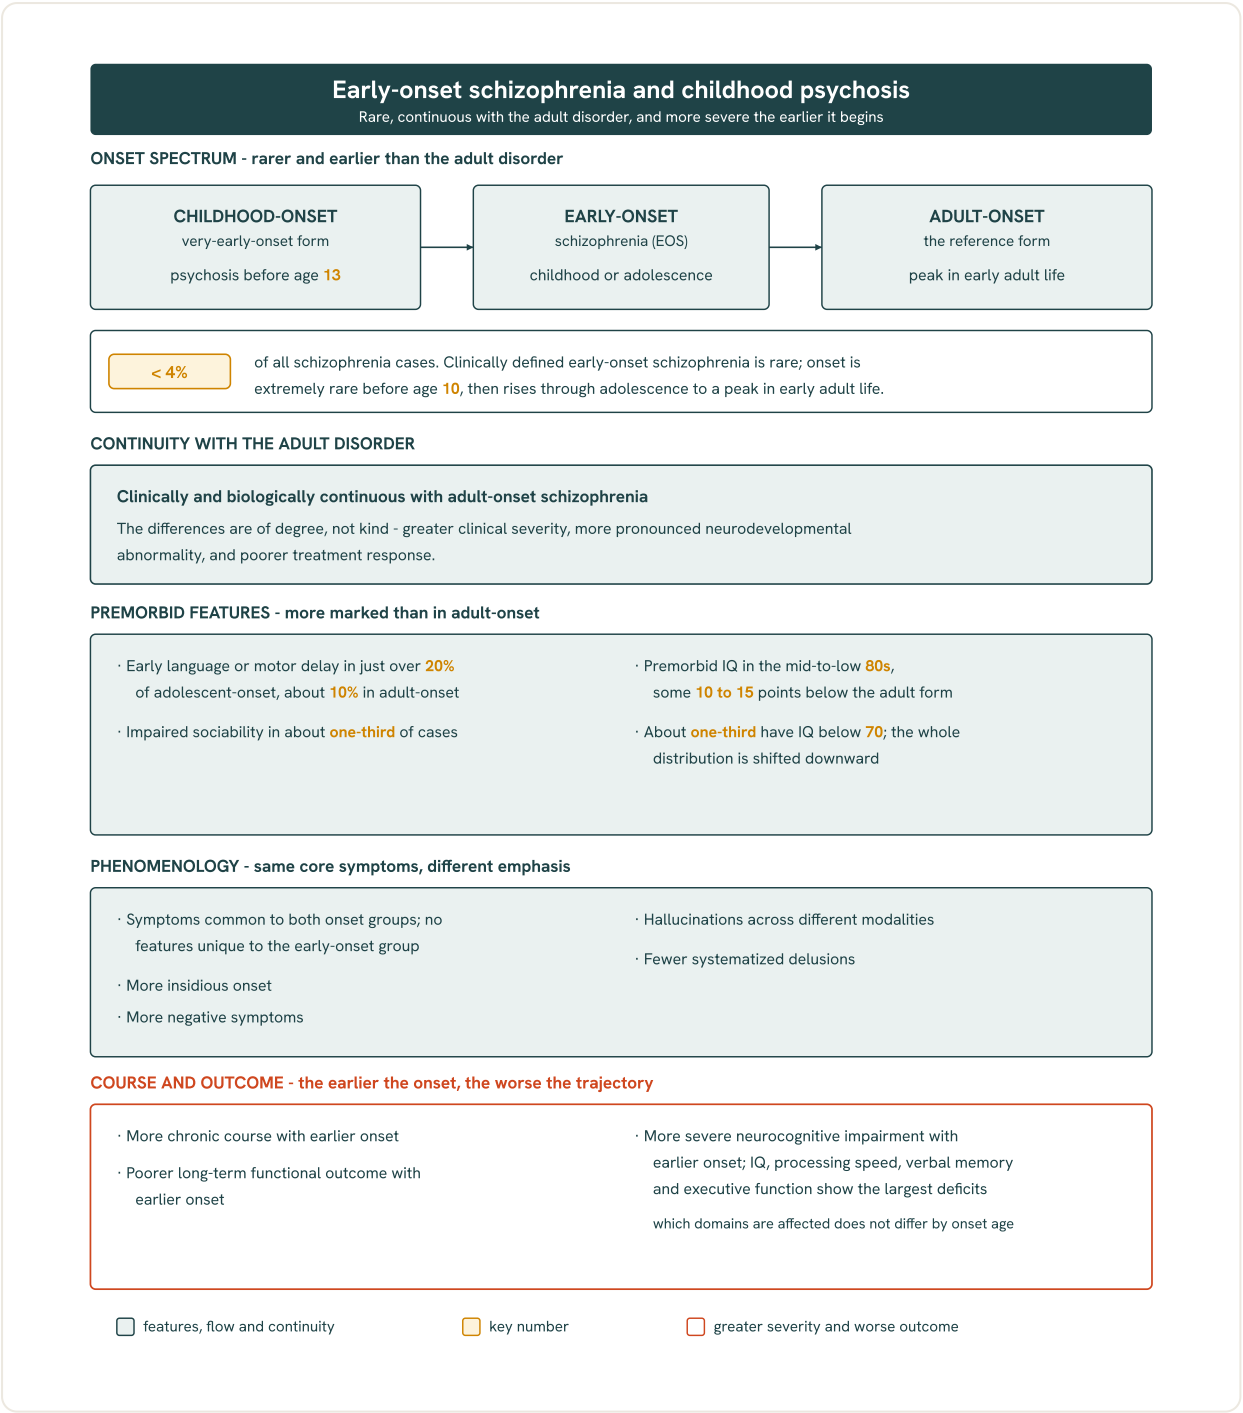

Fig 23.17. Early-onset schizophrenia and childhood psychosis: a rare disorder (under 4% of all cases, extremely rare before age 10) that is continuous with the adult form but more severe - childhood-onset psychosis begins before age 13, premorbid delay and low IQ are more common, phenomenology is broadly shared, and earlier onset predicts a more chronic course, poorer functional outcome and more severe neurocognitive impairment.

22.1 Definitions and the onset-age spectrum

Onset age is not a footnote; it defines the entities. The same diagnostic criteria used for adults are applied, unchanged, at every age, so what distinguishes these conditions is purely the age at which the full syndrome first appears. Two thresholds are worth holding. **Early-onset schizophrenia** refers to onset before adulthood, in the adolescent years, while the rarer **childhood-onset** or very-early-onset form is conventionally defined by onset of psychosis before the age of **13**, the boundary used by the National Institute of Mental Health childhood-onset cohort, which additionally required a near-normal premorbid intelligence and the absence of

significant neurological disease so that a primary psychosis was being studied rather than a secondary one.

Rarity is itself examinable. Clinically defined early-onset schizophrenia is genuinely rare, accounting for fewer than **4%** of all schizophrenia, even though self-reported psychotic-like experiences are far commoner in the general youth population and must not be equated with the disorder. Rarity increases sharply the younger the child: schizophrenia is extremely uncommon before the age of 10, and its incidence then rises steadily through adolescence towards a peak in early adult life. That gradient is why any convincing psychosis in a young child should prompt a careful search for a secondary cause before schizophrenia is accepted.

22.2 Continuity with the adult disorder

The default assumption is one illness across the lifespan, not two diseases. A large body of evidence indicates that early-onset schizophrenia is clinically and biologically **continuous** with the adult-onset disorder: the same diagnostic construct, broadly the same genetic and neuroimaging findings, the same treatment logic. What changes with earlier onset is quantitative, not categorical. Three differences stand out and are the ones to reproduce in an answer: earlier onset carries greater clinical severity, more pronounced neurodevelopmental abnormality, and a poorer response to treatment. The developmental framing follows directly. If schizophrenia is in part a disorder of aberrant brain maturation, then a case that surfaces during childhood or adolescence is one in which that aberration has been more marked, or has expressed itself sooner, and the child accordingly carries more of its developmental fingerprints.

RULE **Earlier onset is a more neurodevelopmental, more severe form of the same disorder, not a different one.** Do not present early-onset schizophrenia as a distinct childhood disease. Present it as adult schizophrenia declaring itself early, on a more compromised developmental substrate, which is precisely why its premorbid impairment is heavier, its symptoms more insidious, its cognition more affected and its outcome worse.

22.3 Premorbid functioning: the developmental fingerprint

The illness is usually visible, in retrospect, long before the first psychotic symptom. This is the single richest examination seam in the topic, because the premorbid abnormalities are more frequent and more severe than in adult-onset disease and they map cleanly onto the neurodevelopmental account. Careful histories find early **premorbid** difficulties across several domains, and they are worth carrying as a set because it is the pattern across all four, rather than any one of them, that points to a neurodevelopmental illness.

- **Language or motor delay.** Significant early delay is present in just over **20%** of adolescent-onset cases, markedly more than in adult-onset schizophrenia.
- **Impaired sociability.** The child who was always solitary, odd or poorly connected to peers: about a third of cases.
- **Premorbid IQ.** The group sits lower than the adult-onset group from the outset, averaging in the **mid-to-low 80s**, some 10 to 15 points below the adult-onset average.

- **Intellectual disability range.** Around a third of early-onset patients have a premorbid IQ below 70, with the whole distribution shifted downward rather than a small tail pulling the mean.

The clinical use of this is diagnostic, not merely descriptive. A convincing premorbid history of language delay, motor clumsiness, social isolation and academic struggle, followed by an insidious decline into psychosis, is far more consistent with a neurodevelopmental early-onset schizophrenia than with an acute reactive or drug-induced state, and it should raise rather than lower the index of suspicion.

> **GOOD TO REMEMBER**
>
> Always reconstruct the premorbid trajectory before you commit to a diagnosis. Ask the parents, and the school, about early speech and motor milestones, friendships, and the timing of any change. A lifelong drift of subtle developmental impairment that then steepens into positive symptoms supports a primary neurodevelopmental psychosis; a previously well child who becomes acutely psychotic over days should push you harder towards an organic, substance-related or mood-driven cause first.

22.4 Clinical phenomenology

The symptoms are the adult symptoms, with a shift in emphasis, not a new set. There are no phenomena unique to the early-onset group; the clinical symptoms are common to both. What differs is the balance and the presentation. Onset tends to be more **insidious** than in adults, creeping in over months of withdrawal, deteriorating function and blunting rather than announcing itself in a sudden florid break. The burden of **negative symptoms**, the avolition, flattening and social retreat, is heavier. Hallucinations tend to occur across different sensory modalities rather than being confined to the auditory, and delusions are typically less **systematized**, more fragmentary and less elaborately constructed than the organised delusional architecture of the older patient, in keeping with the cognitive immaturity and heavier cognitive impairment of the child. That combination, an insidious slide dominated by negative symptoms and disorganisation, is exactly what makes the diagnosis easy to miss early, when the picture can look like depression, oppositionality or simple failure to thrive at school.

22.5 The differential diagnosis of childhood psychosis

Far more children report psychotic-like phenomena than are psychotic, and this is the crux of the topic. The examiner is testing whether a candidate will resist the pull to over-diagnose. The first task is to establish that the phenomena are truly psychotic at all: developmentally normal imaginary companions, vivid fantasy, hypnagogic experiences and the misreported perceptions of a frightened or tired child are not psychosis, and isolated self-reported hallucinatory experiences in youth are common and usually transient. The second task is to exclude secondary and non-schizophrenic causes: delirium, epilepsy, central nervous system infection, substance intoxication, and the psychotic phenomena that can accompany severe mood disorder or trauma. The chronic irritability of disruptive mood dysregulation disorder, the mood-congruent phenomena and episodicity of the childhood bipolar disorder question, and the re-

experiencing and dissociation of childhood post-traumatic stress disorder are each developed elsewhere in this chapter and must be set against a psychotic presentation before schizophrenia is accepted. Distinguishing schizophrenia from autism spectrum disorder rests on the presence of genuine positive psychotic symptoms and a clear deterioration from a previously attained baseline, whereas the social-communication difficulties of autism are lifelong and non-psychotic; the disorder itself is taught in the Intellectual disability and autism spectrum disorder notes and is only named here.

TRAP **Reading normal or non-psychotic childhood experience as schizophrenia.** The classic error is to take a child's imaginary companion, vivid fantasy, or an isolated report of hearing a voice as evidence of psychosis and reach for schizophrenia. Such experiences are common, usually developmentally normal or transient, and clinically defined schizophrenia in childhood is rare. True psychosis requires sustained positive symptoms, disorganisation and functional deterioration, not a single frightening perception in an otherwise well child.

AXIS	EARLY-ONSET SCHIZOPHRENIA	ADULT-ONSET SCHIZOPHRENIA
Frequency	Rare, under 4% of all cases; increasingly rare the younger the child	The great majority of cases; peak incidence in early adult life
Premorbid development	Language and motor delay, impaired sociability and lower IQ far commoner	Premorbid impairment present but less frequent and milder
Onset and symptoms	More insidious onset, more negative symptoms, fewer systematized delusions	Often more acute; more organised, systematized delusions
Neurocognition	Same domains affected, more severe impairment	Same domains affected, less severe on average
Course and outcome	More chronic course, poorer functional outcome	Comparatively better course and outcome

The comparison is one of degree along shared axes rather than of kind; earlier onset shifts every axis in the direction of greater severity, which is the unifying idea of the whole topic.

22.6 Neurocognition

The cognitive deficit is qualitatively the same as in adults but quantitatively worse.

Neurocognitive impairment is a core, not incidental, feature, and it is more severe the earlier the onset. Importantly, which domains are affected does not change between the groups: the largest deficits fall on **neurocognitive** measures of general intelligence, processing speed, verbal memory and executive function in both early- and adult-onset disease. The message for an answer is precise. Early onset does not produce a different cognitive profile, it produces a deeper one, and because it strikes during the years of active learning and skill acquisition, that deeper deficit compounds over development into a heavier functional handicap than the same absolute impairment would cause in a fully matured adult.

22.7 Course, outcome and principles of management

Age of onset is one of the more reliable prognostic markers available. The relationship is consistent and directional: the earlier the onset, the more **chronic** the course tends to be, and the poorer the long-term functional **outcome**. Early-onset schizophrenia thus sits at the more severe end of the schizophrenia spectrum on almost every measure that matters, which is why the poorer treatment response noted earlier is so consequential. Management follows the same principles as in adult schizophrenia, combining antipsychotic pharmacotherapy with family work, educational support and psychosocial rehabilitation, but with heightened attention to developmental needs, schooling and the greater sensitivity of the young to adverse effects; the specific agents, doses and monitoring lie outside what this topic establishes and should be taken from a pharmacology source and the antipsychotics chapter. What the topic does establish is the stance: treat early and adequately, support development actively, and hold realistic expectations shaped by the worse prognosis that early onset confers.

PITFALL

Because the onset is insidious and negative-symptom-dominated, the commonest clinical failure is not over-diagnosis but delay. The gradual withdrawal, falling grades and blunted affect are attributed to depression, laziness or oppositionality, and months pass before the psychosis is recognised and treated. In a young person with an unexplained, sustained decline in function and social contact, actively ask about attenuated psychotic phenomena rather than waiting for a florid presentation to force the diagnosis.

IN INDIA

Most services here classify under ICD, and the same criteria are applied irrespective of age, so the entity is recognised even where a dedicated child psychiatry service is not available. Two realities shape practice. First, specialist child and adolescent psychiatry capacity is thin outside the larger centres, so a psychotic child often reaches an adult general psychiatry clinic, where the developmental history is easy to under-take. Second, secondary and organic psychoses, including those of neuroinfection, epilepsy and metabolic disease, carry a meaningful load in Indian children and must be excluded with particular care before a primary early-onset schizophrenia is diagnosed. The practical rule is to invest in the premorbid and organic history, which is exactly the part that a rushed clinic is tempted to skip.

Carry this into the exam: early-onset schizophrenia is the same disorder as the adult form, arriving before adulthood on a more neurodevelopmentally impaired brain, and it is more premorbidly abnormal, more insidious, more cognitively affected, more chronic and poorer in outcome the earlier it begins.

23 · Suicide and self-harm in children and adolescents

The act is the alarm, not the intent behind it. The single most useful move a clinician makes when a young person presents after hurting themselves is to stop trying to read their mind about whether they "really meant it" and to treat the act itself as the signal. **Self-harm** in children and adolescents is deliberately defined without reference to motive: it is any nonfatal act of self-poisoning or self-injury, whatever the degree of wish to die, and it is the doorway through which almost every completed youth suicide has first passed. This section owns the youth-specific tools for that presentation - what the act is, how common it is, how young people do it, what raises the danger, how the risk is assessed, and how it is managed once identified.

Marks accrue here because paediatric suicidality is where a candidate's judgement is tested rather than their recall. There is no criteria set to recite; there is a way of thinking. The examiner wants to see that you can define self-harm without collapsing it into "suicide attempt", that you know the risk factors and the structure of a risk assessment, and that you can turn that assessment into a concrete plan rather than a reassuring note. The wider adult framework and the pharmacovigilance question of antidepressants in the young are developed in their own right elsewhere; this topic teaches the child and adolescent detail in full.

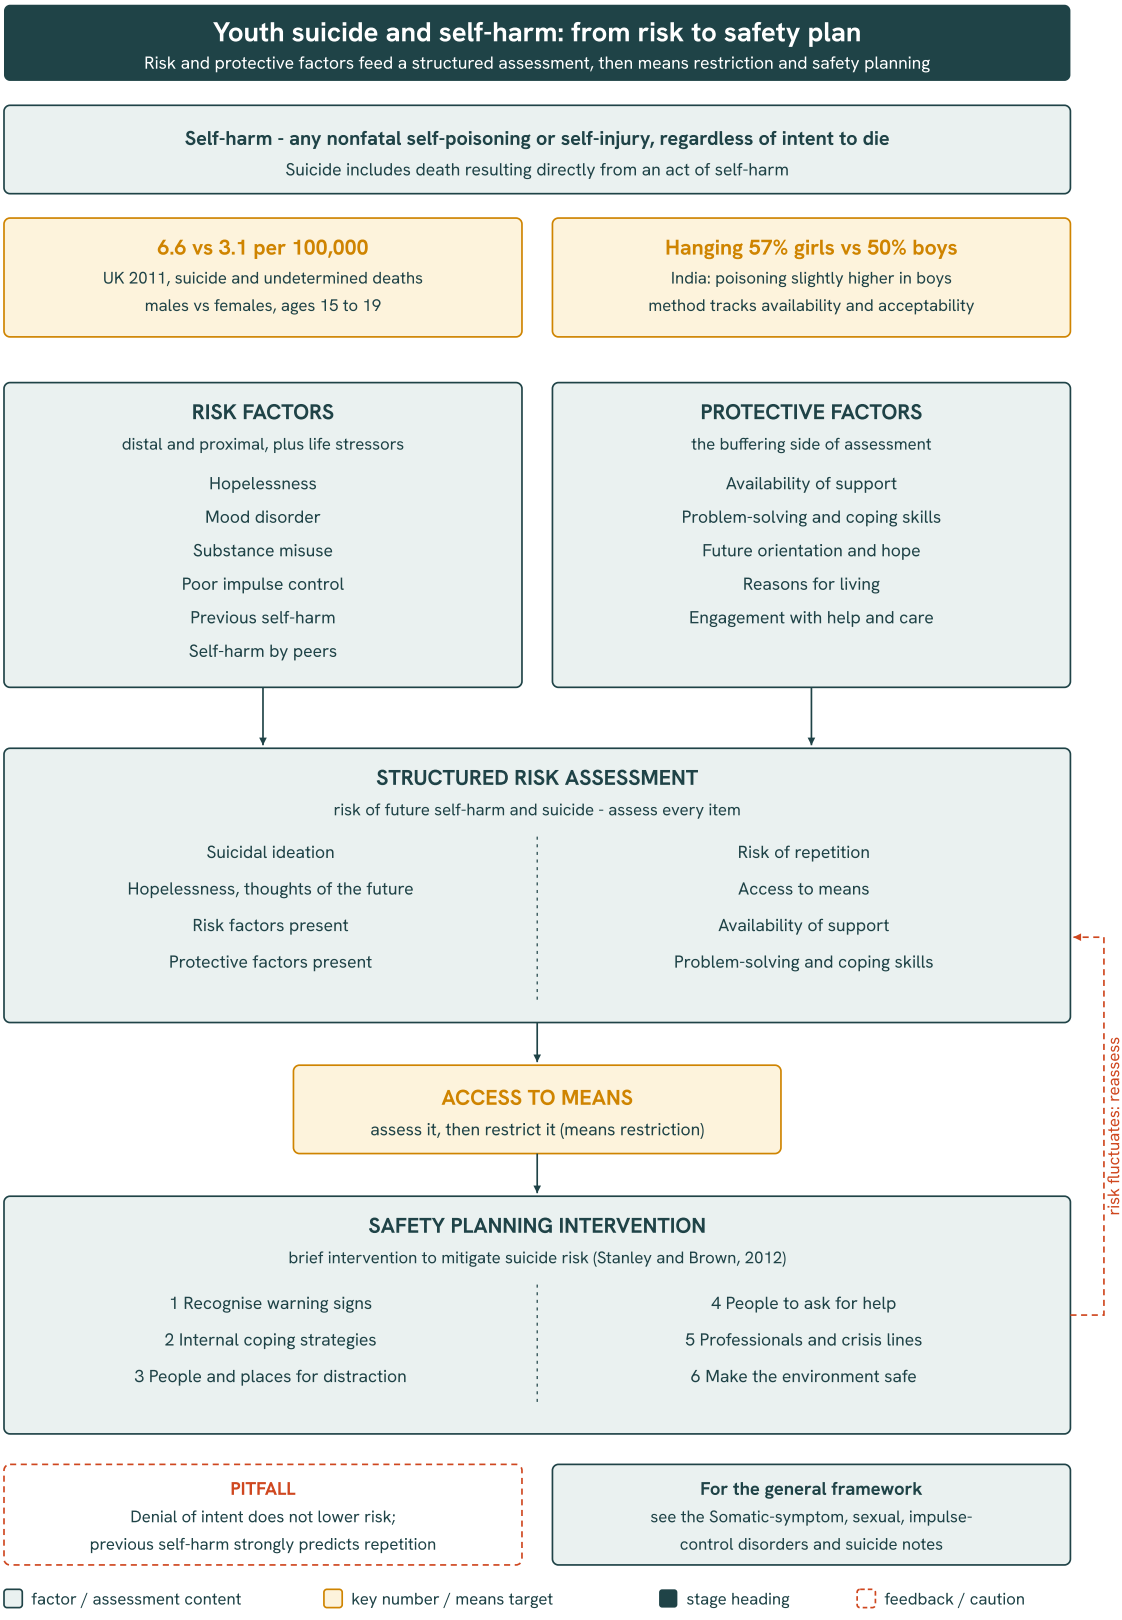

Fig 23.18. Youth suicide and self-harm pathway: risk and protective factors feed a structured risk assessment, then means restriction and a safety plan (Stanley and Brown), with reassessment as risk fluctuates.

23.1 What counts as self-harm, and how it relates to suicide

Self-harm is defined by the act, deliberately divorced from intent. The operational definition is broad on purpose. It takes in any form of nonfatal **self-poisoning or self-injury**, and it does so regardless of the motivation or the degree of intent to die that lay behind it. The cut made in private with no thought of dying, the impulsive overdose taken in front of a parent, and the near-lethal act interrupted by chance all fall under the one term, because the alternative - grading acts by inferred intent at the point of contact - is exactly where clinical assessment fails. Intent in an adolescent is fluid, poorly recalled and easily minimised, and an act that carried little wish to die today is still the strongest single marker of the act that may kill next year. Suicide sits at the fatal end of the same continuum: it is best understood as death resulting directly from an act of self-harm, not as a categorically different behaviour. Holding the definition this wide is what stops a clinician discharging a "minor" cut as unrelated to suicide risk.

- self-cutting and other self-injury;
- self-poisoning and overdose;
- hanging and self-strangulation;
- other dangerous acts such as running into traffic.

RULE **Assess the act, not the story about the act.** Because self-harm is defined without reference to intent, the clinician's job is never to decide whether the young person "meant it" and then act on that verdict. Every nonfatal act of self-poisoning or self-injury is taken as a marker of risk and assessed as such, whatever motive the young person or the family offers for it.

23.2 Epidemiology and the developmental gradient

Rare before puberty, then a sharp adolescent rise, with sexes that diverge. Completed suicide is uncommon before puberty and climbs steeply through adolescence, which is why the condition is a problem of the teenage years rather than of childhood proper. The pattern by sex is the examinable point and it reverses depending on which end of the continuum you count. For completed suicide the male rate runs higher: national figures for the United Kingdom put the rate of suicide and undetermined deaths in those aged 15 to 19 at **6.6 per 100,000** in males against **3.1 per 100,000** in females. Non-fatal self-harm shows the opposite skew, being commoner in girls, so that the same population produces more female acts but more male deaths - a reversal that turns on method and impulsivity rather than on distress. A methodological caution belongs here too: undetermined verdicts are not applied to those aged 10 to 14, so recorded rates in the youngest band understate the true burden and cross-country comparison must allow for how each coroner system counts.

23.3 Methods, and why the method is a clinical fact

Method is not incidental; it is where prevention gets its purchase. How a young person harms themselves is driven by what is culturally acceptable and what is physically available, and it varies by sex and by country in ways that matter at the bedside. The Indian pattern is a standing examination contrast. Where in many countries hanging predominates among males, Indian data show hanging to be somewhat more frequent in girls than in boys, and self-poisoning slightly

commoner in boys, so the Western default cannot simply be transposed. The clinical significance is that method choice is modifiable at the population level: restrict access to the lethal means that are locally common and you reduce deaths, because much youth self-harm is impulsive and a barrier at the moment of crisis buys the time in which the impulse passes.

METHOD	PATTERN BY SEX IN INDIAN YOUTH
Hanging	More frequent in girls (**57%**) than in boys (50%)
Self-poisoning	Slightly commoner in boys (**50%**) than in girls

Method distribution by sex in Indian youth; the contrast with the male-hanging predominance reported in many other countries is itself the teaching point, and it exists because acceptability and availability, not biology, set the method.

IN INDIA

Two locally common methods carry most of the mortality of youth self-harm: hanging and the poisons that sit within reach in Indian homes, above all agricultural pesticides and household chemicals. That makes means restriction a concrete, culturally specific task rather than an abstraction - securing or removing pesticides and medicines, and counselling families on storage, is often the highest-yield intervention available and one that does not depend on a scarce specialist. It also reframes the assessment: asking what is physically accessible to this particular young person in this particular home is not a formality but the part of the interview that most directly changes the odds.

23.4 Risk factors: a distal-proximal pathway

Suicidality is the endpoint of accumulating risk, not a single cause. No one factor explains a suicidal act; the useful model is a pathway in which longstanding vulnerabilities and immediate precipitants combine against a background stressor to push a young person over threshold. The core risk factors an examiner expects, read as one set, are **hopelessness**, an underlying mood disorder, substance misuse, poor impulse control, a history of previous self-harm, and self-harm among the young person's peers. They separate naturally along a time axis. The more distal contributors are the standing conditions - a depressive illness, a substance problem, a temperamentally impulsive style - that raise baseline vulnerability over months and years. The more proximal are the near-term markers, above all a recent act of self-harm or exposure to it in a close friend, and these fire in the setting of an acute life stressor such as a humiliation, a loss, a relationship rupture or a disciplinary crisis. Previous self-harm deserves particular weight as the strongest behavioural predictor of a further act, which is why a history of it reframes the whole assessment. The depressive illness that so often underlies the picture is developed as childhood depression in its own right elsewhere in this chapter, and the separate question of whether starting an antidepressant itself alters suicidality in the young is taken up as a distinct topic; here the mood disorder is named as a risk domain, not re-taught.

23.5 Assessing the risk of future self-harm

Structured content beats prediction. No instrument predicts which individual will die, and a candidate who promises the examiner a risk score has missed the point. What a good assessment does is systematically cover the domains that inform judgement and disposition, so that nothing

decisive is left unasked. The content the young person's assessment must reach is definable and this topic owns it: current suicidal ideation and its intensity; hopelessness and how the young person pictures their future; the risk factors present; the protective factors that pull the other way; the **risk of repetition**; **access to means**; the availability of support around them; and their problem-solving and coping capacity. Two of these do double duty as intervention targets rather than mere descriptors - access to means, because it can be restricted, and support, because it can be mobilised - which is what makes the assessment continuous with the plan rather than a separate exercise that precedes it.

DOMAIN OF THE ASSESSMENT	WHAT IT ESTABLISHES
Suicidal ideation	Whether thoughts are present, and their frequency, intensity and specificity
Hopelessness and view of the future	The affective marker most tied to intent; can the young person imagine things improving
Risk factors	The distal and proximal contributors and the precipitating stressor
Protective factors	Reasons for living, attachments and responsibilities that pull against the act
Risk of repetition	Prior self-harm and the features that predict a further act
Access to means	What lethal means are physically available; an explicit target for restriction
Availability of support	Who can watch, contain and respond; can it be mobilised now
Problem-solving and coping	The young person's capacity to tolerate and resolve the crisis

The content a youth suicide-risk assessment must cover; it is a structure for gathering the information that informs disposition and a plan, not a scale that outputs a probability of death.

TRAP **Reading a denial of ideation as an absence of risk.** The classic error is to accept "I don't want to die" at face value and stand down. A young person may minimise or genuinely fluctuate, and low intent at interview coexists with high danger when the means are lethal and to hand. Risk is judged from the whole assessment - prior acts, hopelessness, access to means and support - never from the single question about current wish to die.

PITFALL

Labelling self-harm of apparently low intent as "attention-seeking" and treating it as a behaviour to be ignored is a recurrent and dangerous clinical failure. The framing licenses the clinician to skip the assessment and the means-restriction conversation, yet low-intent acts are precisely the population from which impulsive deaths emerge. Communicative or interpersonal function and lethal risk are not alternatives; an act can be both a signal to others and a genuine hazard, and it is assessed on its danger regardless of what it also communicates.

23.6 Managing the risk: safety planning and means restriction

The plan is an intervention, not a promise extracted from the patient. Management of the identified risk turns on a small number of high-yield actions taken with the young person and their family. Chief among them is a **safety planning intervention** - the brief, structured safety plan described by **Stanley and Brown** - which works with the young person to recognise their own warning signs, to name internal coping strategies and people and settings that provide distraction, to identify who to contact in a crisis, and to reduce the danger of the immediate environment. It is deliberately distinct from the discredited "no-suicide contract", which asks for a promise and changes nothing. Coupled to it is **means restriction**: because access to means is both an assessment item and a modifiable target, removing or securing the lethal means available to this young person is a direct reduction in risk and a routine, non-negotiable component of the plan. Around these sit the treatment of the underlying mood, substance or impulse-control disorder, the mobilisation of family supervision and support, and clear, explicit arrangements for follow-up and re-assessment, since risk is not a fixed quantity settled at one interview but a state that shifts with circumstance and must be reviewed.

The general suicide-risk framework that applies across the lifespan - the wider theory of assessment and the adult evidence base - is developed in the Somatic-symptom, sexual, impulse-control disorders and suicide notes; what this section adds is the child and adolescent application of it, where developmental fluidity of intent, dependence on the family, and culturally specific means make the youth version its own competence.

GOOD TO REMEMBER

Every young person who has harmed themselves leaves the consultation with two things done, not one: a completed risk assessment and a concrete plan that includes means restriction. The assessment without the plan is an observation; the plan without honest means restriction is a document. Doing both, and arranging who reviews the young person and when, is the deliverable the examiner and the parent are both looking for.

Self-harm is defined by the act and not the intent behind it; take every nonfatal self-poisoning or self-injury as a risk marker, assess it across its full content, and convert that assessment into a safety plan with means restriction.

6.6 per 100,000 SUICIDE AND UNDETERMINED DEATHS, ADOLESCENT MALES (UK)	**3.1 per 100,000** SUICIDE AND UNDETERMINED DEATHS, ADOLESCENT FEMALES (UK)	**57%** HANGING AS A METHOD IN GIRLS (INDIA)	**50%** SELF-POISONING AS A METHOD IN BOYS (INDIA)

24 · Antidepressant use and suicidality warning in youth

This is the most politically charged prescribing decision in child psychiatry, and the examiner knows it. A young person with moderate to severe depression stands to gain from an antidepressant, yet the same drug carries a regulatory warning that it may increase suicidal

thinking in exactly this age group. Marks accrue here because the topic tests something harder than a fact: it tests whether a candidate can hold two true statements at once, that the risk signal is real and that the treatment is still, for the right patient, correct. The general pharmacology of antidepressants, their classes and mechanisms, belongs to the Mood disorders: pharmacotherapy notes; the assessment of suicide risk itself, its structured tools and safety planning, is developed elsewhere in this chapter. What this topic owns is the pharmacovigilance story: where the warning came from, how large the risk actually is, the adverse effects unique to starting these drugs in the young, and how the child must be monitored once the prescription is written.

The reasoning to carry into the exam runs in a fixed order. First the signal and the trials that produced it. Then the single most important move in the whole topic, converting an alarming relative risk into a small absolute one. Then the regulatory response, the youth-specific adverse effects, and the monitoring that the warning demands.

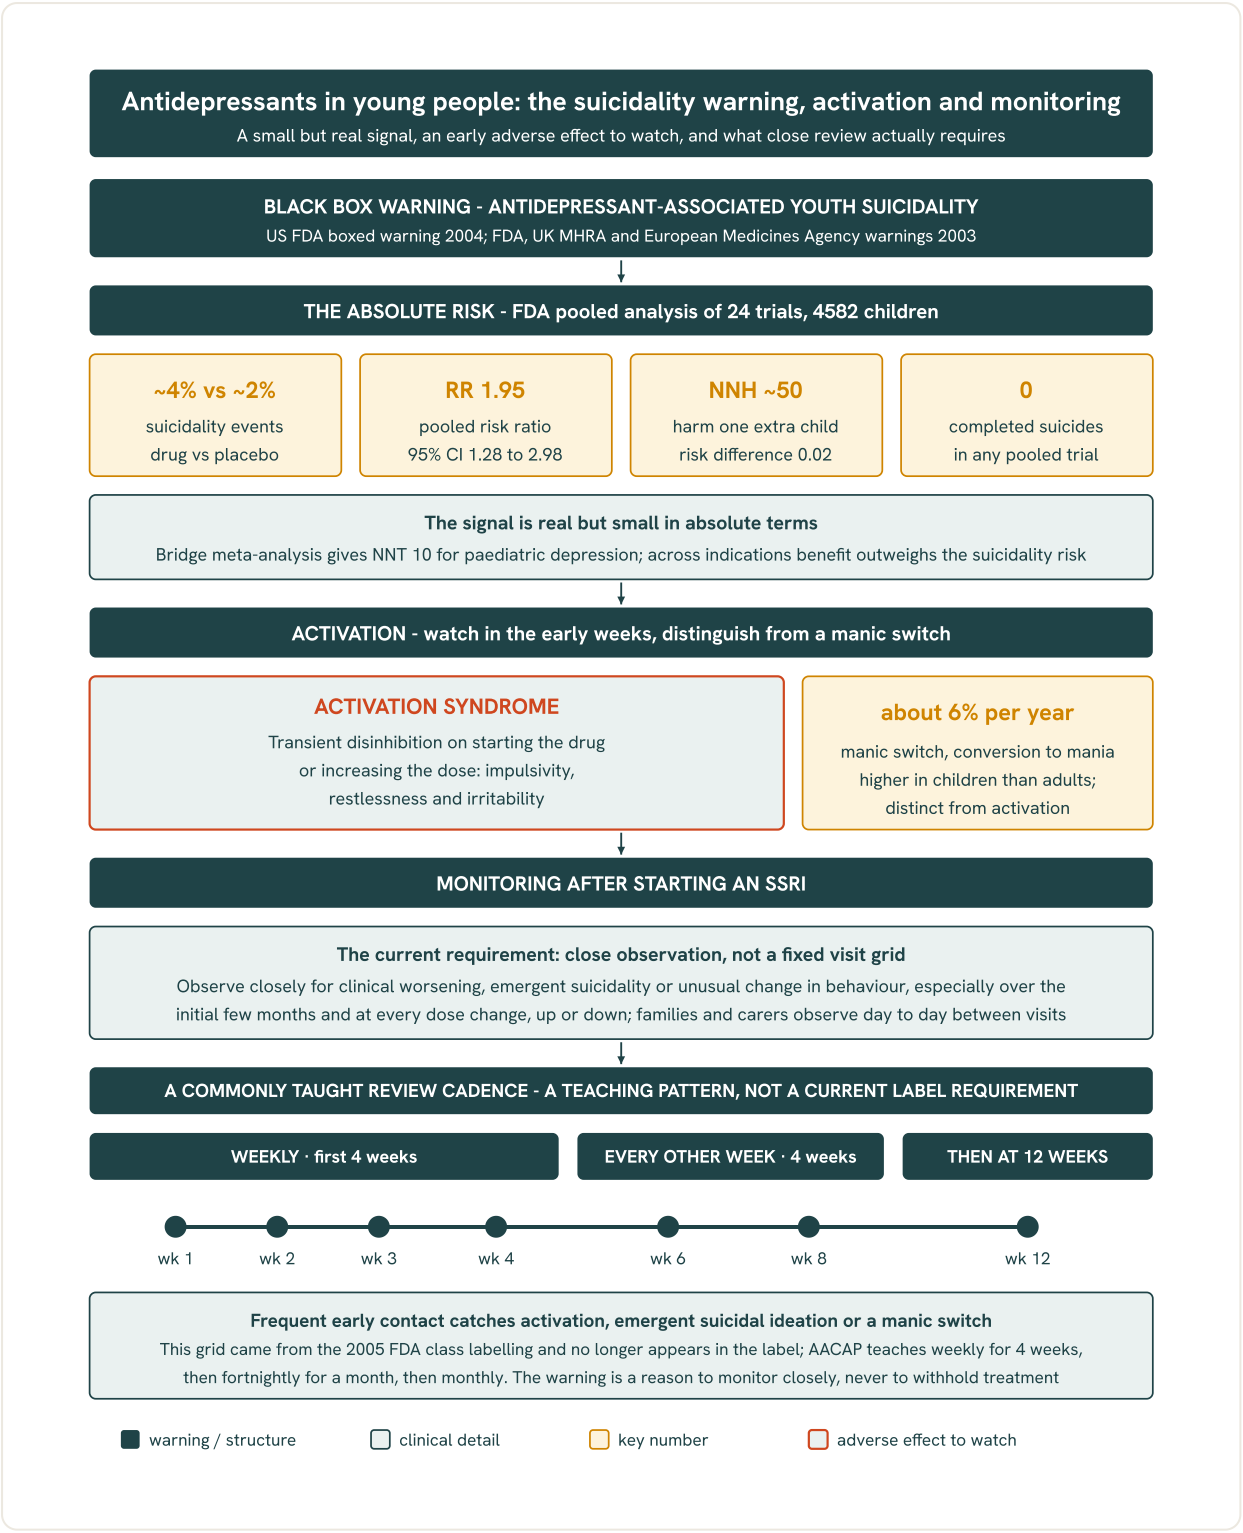

Fig 23.19. Antidepressants in young people: the paediatric suicidality warning quantified (absolute risk, risk ratio and number needed to harm), activation as the early adverse effect to distinguish from a manic switch, and what the label requires after starting an SSRI: close observation through the initial few months and at every dose change, with daily family observation between visits, rather than a fixed visit grid.

24.1 The signal and where it came from

The warning rests on a pooled analysis, not on a stream of deaths. When regulators grew concerned, the United States regulator assembled the paediatric placebo-controlled antidepressant trials and pooled their **suicidality** events, meaning suicidal ideation and suicidal behaviour recorded as adverse events, not completed suicide. Across 24 trials enrolling some 4582 children and adolescents, the pooled risk of a suicidality event on active drug against

placebo gave a risk ratio of **1.95** across all drugs and all indications. Restricted to the selective serotonin reuptake inhibitors used in depression trials, the risk ratio was 1.66. Those numbers are the origin of the entire controversy, and two features of them must be reproduced. They describe emergent suicidal ideation and behaviour, and the crucial fact that anchors every sensible reading of the data is that there were no completed suicides in any of the pooled trials.

24.2 Relative against absolute: the number that actually matters

A doubled relative risk sounds catastrophic until you see the base rate it doubles. A risk ratio near two means the event became about twice as likely, but on a rare event twice a small number is still a small number. The quantity that a clinician and a family can actually use is the **absolute risk difference**, and here it was 0.02, roughly two percentage points. In the regulator's cell rates that appears as approximately **4 per cent on antidepressant versus 2 per cent on placebo**. Inverting that risk difference gives a **number needed to harm** of approximately 50, meaning that for every fifty young people treated, one additional patient reports emergent suicidal thinking or behaviour who would not have on placebo. The teaching point is that the alarming headline and the modest reality are the same finding stated two ways.

The estimate is a range, not a point. Different pooled datasets used slightly different denominators and produced different absolute figures, and the exam rewards a candidate who can bound the signal rather than parrot one number. A meta-analysis cited in the standard formulary gives a lower estimate, roughly 2 per cent versus 1 per cent, with a number needed to harm of 112. A separate meta-analysis of 27 trials found a pooled risk difference of 0.7 per cent and a number needed to harm of 143, with the within-indication differences not reaching statistical significance and, again, no completed suicides. These are not competing truths to be adjudicated; they are the lower and upper bounds of a single small signal.

SOURCE	RELATIVE MEASURE	ABSOLUTE MEASURE	NUMBER NEEDED TO HARM
Regulator's pooled analysis	risk ratio 1.95, all drugs and indications	risk difference 0.02; about 4 per cent versus 2 per cent	approximately 50, derived
Formulary meta-analysis	lower estimate	2 per cent versus 1 per cent	112
27-trial meta-analysis	within-indication differences not significant	risk difference 0.7 per cent	143

The same suicidality signal, expressed by three groups. The relative risk is what alarmed regulators; the absolute risk difference and the number needed to harm are what a clinician weighs against benefit at the bedside.

RULE **Never quote the relative risk without the absolute risk beside it.** A risk ratio near two, stated alone, implies a doubling of deaths and is the single commonest misstatement of this evidence. Stated with its absolute risk difference of two percentage points and its origin in ideation rather than completed suicide, the same finding becomes a manageable, monitorable adverse effect.

24.3 The regulatory response: the boxed warnings

The warning is a class-wide regulatory act, and its dates and wording are examinable. The concern was taken up by regulators on both sides of the Atlantic: warnings on antidepressant-associated youth suicidality were issued by the American regulator, the United Kingdom medicines regulator and the European Medicines Agency in 2003. The American regulator then formalised the strongest label available to it, a **boxed (black box) warning**, in 2004, flagging worsening depression, agitation and suicidal ideation linked to these drugs and drawn from the review of adolescent depression studies. What the warning did NOT say is as important as what it said: it did not withdraw the drugs, did not forbid their use, and did not claim that they cause completed suicide. It mandated informed prescribing and close monitoring, which is the spirit a candidate should convey. Whether the warning was subsequently extended upward to young adults is a separate regulatory question that the sources used here do not settle, and a candidate should not assert an upper age boundary they cannot source.

> **GOOD TO REMEMBER**
>
> The warning changed the conversation with families more than it changed the pharmacology. Before starting an antidepressant in a young person, the modern standard is an explicit, documented discussion: that emergent suicidal thoughts are an uncommon early adverse effect, that they are usually transient, that the family should watch for them in the first weeks and report them immediately, and that this is precisely why review is scheduled early and often. A prescription written without that conversation is the one that gets challenged.

24.4 Why benefit still outweighs risk

The warning is a reason to prescribe carefully, not a reason to withhold. The same body of trials that produced the suicidality signal also demonstrated efficacy: the 27-trial analysis found a **number needed to treat** for paediatric major depressive disorder of **10**, and the authors judged that the benefits outweighed the suicidality risk across indications. Set the two frequencies side by side and the logic is stark: roughly one young person benefits for every ten treated, while the additional suicidality events run at one in fifty to one in a hundred and forty, and none of those events was a death. Against this sits the risk that the warning itself can do harm, because untreated adolescent depression is itself a leading driver of suicidal behaviour, and a chilling effect that reduces prescribing without reducing illness can raise the very outcome everyone fears. The examinable synthesis is therefore not "avoid antidepressants in the young" but "treat the depression that needs treating, and build the monitoring in".

TRAP **Reading the signal as an increase in completed suicide.** Candidates hear "antidepressants increase suicide risk in youth" and picture deaths. The pooled trials recorded emergent suicidal ideation and behaviour as adverse events and contained no completed suicides at all. Stating that antidepressants were shown to increase completed suicide in these trials is factually wrong and marks the answer as unsafe.

24.5 Activation, and its separation from a manic switch

Two early adverse phenomena are constantly confused, and distinguishing them is a favourite station. The first is **activation**, a transient disinhibitory response to starting an antidepressant or increasing its dose, characterised by impulsivity, restlessness and irritability. It is dose-related, it appears early, and it typically settles when the dose is reduced or the drug is withdrawn. Its clinical danger is that in an impulsive, disinhibited adolescent it can be the substrate on which emergent suicidal behaviour is enacted, which is one plausible route from the drug to the suicidality signal above. The second phenomenon is the **manic switch**, a conversion to a manic or hypomanic state, which is reported at approximately **6 per cent per year** in young people taking antidepressants and appears to be commoner in children than in adults, although there is no clear evidence that the antidepressant actually causes the switch rather than unmasking a latent bipolar diathesis. Activation must be differentiated from a manic switch, because the two demand different responses.

FEATURE	ACTIVATION	MANIC SWITCH
Nature	transient disinhibition with impulsivity, restlessness and irritability	sustained elevated or expansive mood, reduced need for sleep, grandiosity, pressured behaviour
Timing and course	early, dose-related, settles on dose reduction or withdrawal	may persist and may herald an underlying bipolar disorder
Frequency	a recognised early effect of initiation and titration	about 6 per cent per year, apparently higher in children
Response	reduce or stop the drug; the phenomenon reverses	reassess the diagnosis; a mood stabiliser may be needed

Activation is a reversible, dose-linked disinhibition; a manic switch is a syndromic mood change that questions the diagnosis. Confusing the two leads either to needless drug withdrawal or to a missed emerging bipolar disorder.

PITFALL

The frequent clinical error is to read early activation as the depression worsening and respond by pushing the dose higher, which amplifies the very disinhibition driving the problem. The mirror error is to see any early agitation as an emerging bipolar switch and stop the antidepressant altogether, abandoning a treatment the child needed. The safe move is to recognise activation as its own transient, dose-related entity, hold or reduce the dose, and reassess, reserving a diagnostic rethink for genuinely sustained, syndromic mood elevation.

24.6 The monitoring the warning demands

The warning converts into a concrete schedule of contact. Because the suicidality signal and activation both cluster in the early weeks, the regulator paired the label with a monitoring schedule following initiation of a serotonergic antidepressant in a child, front-loaded to catch trouble when it is most likely:

- weekly review over the first four weeks;
- then a review every other week for a further four weeks;

- then a review at week twelve.

The academic child psychiatry literature concurs with a schedule of the same shape, weekly for the first month, then fortnightly for a month, then monthly thereafter. Two honesties should accompany this in an exam answer. The schedule is expert consensus rather than a proven intervention, and there is no firm evidence that adhering to this exact calendar changes outcome; and "monitoring" means active enquiry into mood, suicidal ideation, activation and any switch to elevated mood, not a passive repeat prescription. Reproducing the schedule earns the mark; adding that it is consensus and defining what is actually monitored earns the rest.

The youth antidepressant signal is a doubling of emergent suicidal ideation, not of completed suicide, over a base rate of a few per cent; the response is careful prescribing, early front-loaded monitoring, and a family who know what to watch for, not withholding an effective treatment.

IN INDIA

The warning translates awkwardly into Indian practice. Antidepressants in children are largely prescribed off-label, most often fluoxetine, and frequently by non-specialists, because child psychiatry services are scarce and concentrated in a few tertiary centres. The front-loaded monitoring schedule, which assumes weekly face-to-face review through the first month, is difficult to deliver when families travel long distances and follow-up is irregular. The practical adaptation is to make the family the monitor: to explain activation and emergent suicidal thinking in plain language, to give an explicit instruction to return or telephone at once if either appears, and to use telephone or teleconsultation contact to approximate the weekly review the label intends. The signal itself is not Indian or Western; the ability to monitor for it is where the local reality bites.

Attachment disorders of childhood

25 · Reactive attachment disorder (criteria, etiology)

This is the one childhood diagnosis whose very definition points a finger at the caregiving environment rather than at the child. **Reactive attachment disorder** is the syndrome in which a young child, having been denied the ordinary experience of a responsive caregiver, fails to develop the normal behavioural signs of a **selective attachment**: when frightened, hurt or ill, the child neither turns to an adult for comfort nor takes much comfort when it is offered. What makes the disorder examinable is not the symptom picture of a flat, withdrawn, joyless child, but the demanding structure of its criteria - a specific behavioural pattern, a required history of grossly inadequate care, an explicit causal link between the two, a set of exclusions, and two age gates - all of which must hold together before the label can be used.

Its placement in the classification carries the whole argument. Rather than sitting with the neurodevelopmental disorders, where a naive reader might expect a disorder of early social behaviour to live, it is classified among the **Trauma- and Stressor-Related Disorders**, because the disturbance is understood as a response to an identifiable adverse experience. This topic owns the diagnostic criteria of reactive attachment disorder, its specifiers, its epidemiology, the etiological role of neglect, its associated features and course, and its within-section differentials. Its mirror-image sibling, **disinhibited social engagement disorder**, in which the same deprivation produces an indiscriminately over-familiar rather than a withdrawn child, is taught in its own account here and is named only as the contrasting pattern. The attachment-side comparison with autism, and the effects of institutional care with the management of these disorders, each belong to their own accounts elsewhere in this chapter.

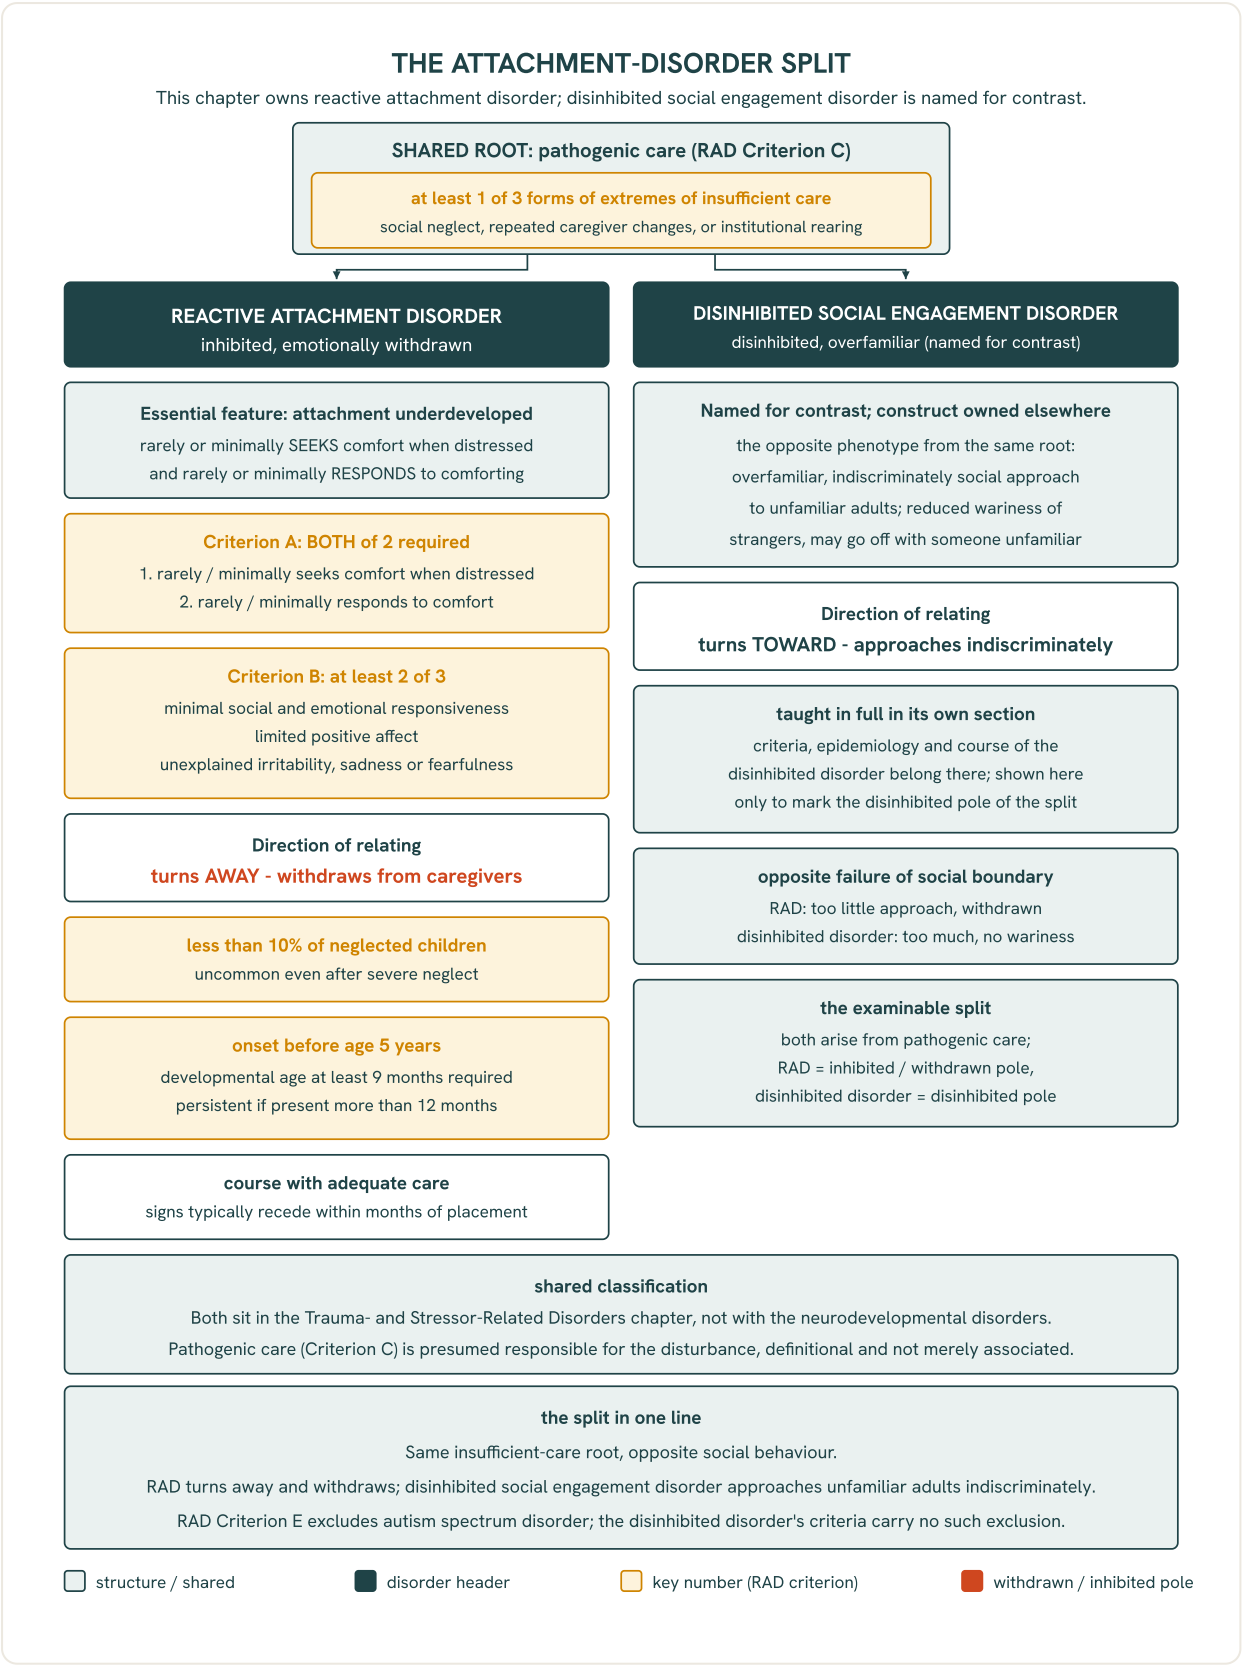

Fig 23.20. The attachment-disorder split: reactive attachment disorder (inhibited, withdrawn) against disinhibited social engagement disorder (disinhibited, overfamiliar, named for contrast), both arising from the same pathogenic care, with RAD turning away from caregivers and the disinhibited disorder turning toward unfamiliar adults.

25.1 The essential feature: an attachment that never took hold

The core of the disorder is an absent or grossly underdeveloped attachment to caregiving adults. A typically developing infant, by the second half of the first year, begins to show a

preferred attachment figure - seeking that person out when distressed and using the caregiver as a secure base. In reactive attachment disorder these behaviours are missing. The prevailing understanding is that these children retain the underlying **capacity to form selective attachments** but, deprived of the early relational opportunity to do so, do not show the behavioural manifestations of one; when distressed they rarely or only minimally seek comfort, and rarely or only minimally respond to comfort when it is given. The clinical impression is of a child who has learned that adults do not reliably answer need, and who has stopped asking. This separates the disorder at its root from a primary disorder of social capacity, and is why better caregiving can change the picture at all.

25.2 Criterion A: the inhibited, emotionally withdrawn pattern

Criterion A defines the behavioural signature, and it is a conjunction, not a menu. The child must show a consistent pattern of inhibited, emotionally withdrawn behaviour toward adult caregivers, evidenced by both of two features: the child rarely or minimally seeks comfort when distressed, and rarely or minimally responds to comfort when distressed. The word "both" is load-bearing. A child who seeks no comfort but is soothable once held, or who cannot be soothed but still turns to the caregiver, does not satisfy Criterion A. The pattern captured is a two-sided failure of the comfort transaction - the child neither initiates the bid for care nor completes it by being reassured - and it is this doubled withdrawal, present consistently rather than in a single frightened moment, that marks the inhibited attachment presentation the disorder is named for.

25.3 Criterion B: the persistent social and emotional disturbance

Criterion B broadens the picture from the attachment relationship to the child's general emotional life. Alongside the withdrawn attachment behaviour there must be a persistent social and emotional disturbance shown by at least two of three features: minimal social and emotional responsiveness to others; limited positive affect; and episodes of unexplained irritability, sadness or fearfulness that are apparent even during non-threatening interactions with caregivers. The third feature is the most clinically telling and the most easily overlooked, because it locates distress where there should be none - the flashes of misery or fear surface in ordinary, safe exchanges, not only under threat, which is what separates this from a child who is simply frightened by a specific stressor. Where Criterion A describes what the child fails to do within the attachment bond, Criterion B describes the pervading flatness and dysregulation that colour every relationship.

25.4 Criteria C and D: the pathogenic care and the causal link

This pair of criteria is what makes reactive attachment disorder unlike almost any other diagnosis in the manual. Criterion C requires that the child has experienced a pattern of extremes of insufficient care, evidenced by at least one of three recognised forms of deprivation:

- social neglect or deprivation, a persistent lack of having basic emotional needs for comfort, stimulation and affection met by caregiving adults;
- repeated changes of primary caregiver that limit the child's opportunity to form a stable attachment, as with recurrent moves through foster placements;

- rearing in unusual settings that severely limit the chance to form selective attachments, such as institutions with high child-to-caregiver ratios.

Criterion D then does the work that no associated risk factor could: it requires that the inadequate care in Criterion C is **presumed responsible** for the disturbed behaviour in Criterion A, as when the disturbance is seen to have followed the onset of neglect. This is what elevates **pathogenic care** from a mere correlate to a definitional requirement: the diagnosis is not "a withdrawn child who happens to have been neglected" but "a withdrawn child whose withdrawal is judged to arise from that neglect".

MNEMONIC

The three N's of Criterion C

The pathogenic care takes three recognised forms, each beginning with an **N**: social **N**eglect of the child's emotional needs, repeatedly **N**ew caregivers whose turnover prevents a stable bond, and iN**N**stitutional or otherwise unusual rearing that starves the child of any selective figure. Only one of the three need be present, but at least one must, and Criterion D then requires that it be judged the cause.

RULE **Pathogenic care is definitional to reactive attachment disorder, not merely associated with it.** A child cannot receive this diagnosis without a documented history of grossly insufficient care, and the criteria go further in demanding that the care be presumed to have caused the disturbance. Remove the neglect and the diagnosis dissolves, which is exactly why the disorder is filed with the trauma- and stressor-related conditions rather than with disorders of innate social development.

25.5 Criteria E to G: the autism exclusion and the two age gates

The final three criteria are exclusions and thresholds that keep the diagnosis honest. Criterion E is an explicit exclusion built into the disorder's own criteria set: the presentation must not meet the criteria for autism spectrum disorder. It is worth noting that this exclusion sits inside reactive attachment disorder but has no counterpart in the criteria of its disinhibited sibling. The fuller attachment-side reasoning for telling these disorders apart from autism, and autism itself, are taught elsewhere; here the point is only that the exclusion exists and must be cleared. Criterion F sets the upper age gate: the disturbance must be evident **before age five years**. Criterion G sets the lower, developmental gate: the child must have a developmental age of **at least nine months**. The rationale for that floor is precise and examinable - around this developmental level the capacity to form a selective attachment normally emerges, so a child who has not reached it cannot be said to have failed at a task they were not yet equipped to attempt. The gate is developmental, not chronological, which matters in a population where developmental delay is common.

GOOD TO REMEMBER

Before diagnosing reactive attachment disorder in a slow-to-develop or neglected infant, establish the child's developmental age, not just the age in months. A child functioning below the nine-month developmental level has not yet reached the stage at which a selective attachment would normally form, so the absence of comfort-seeking cannot be read as the disorder. Screening developmental level first prevents the diagnosis being pinned on a child who is simply not developmentally ready to attach.

25.6 The specifiers: persistence and severity

Two specifiers refine the diagnosis once it is made. The condition is specified as **persistent** when it has been present for **more than twelve months**, marking a presentation that has not resolved with time or with any change of circumstance and that therefore carries a heavier prognostic weight. Current severity is specified as severe when the child exhibits all of the symptoms of the disorder, with each manifesting at relatively high levels. Both specifiers matter because the disorder is, in favourable circumstances, recoverable; a presentation persisting beyond a year despite the chance of better care, or severe across every symptom, marks a child in whom the deprivation has bitten deep and for whom a change of environment alone may not suffice.

25.7 Epidemiology and etiology: neglect necessary, but far from sufficient

The single most important etiological fact is a paradox. Serious social neglect is at once a diagnostic requirement and the only established risk factor for the disorder, and yet the great majority of severely neglected children never develop it. The disorder is seen relatively rarely even in clinical settings; its general-population prevalence is unknown, and even among neglected children it is uncommon, arising in **fewer than one in ten** of them even where the neglect has been severe. That combination - neglect is necessary but not sufficient - is the whole of the etiological teaching a candidate can state with confidence. Pathogenic care sets the stage, but something further, some pattern of individual vulnerability or some specific quality of the neglectful environment, decides which deprived child develops the disorder and which does not, and those vulnerability factors and the critical ingredients of the neglect remain incompletely defined, with no confident biological mechanism assertable beyond the requirement of neglect itself.

25.8 Associated features, comorbidity and course

What travels with the disorder travels with it because of the shared root in neglect. The associated problems are largely those of a deprived early environment: **developmental delays**, particularly in cognition and language, together with stereotypies and the physical stigmata of severe neglect such as malnutrition. Internalising symptoms may co-occur; a relationship with externalising problems or with attention-deficit/hyperactivity disorder has been suggested but is not clearly established, and the reader should hold it loosely. The course is the most hopeful part of the picture and the part most dependent on what happens next. Signs of the disorder typically recede within months once the child is placed in an adequate caregiving environment; in the absence of that enhanced caregiving the signs may persist for several years. Prognosis, in short,

tracks the quality of the post-neglect caregiving far more than any property of the child. The full evidence on institutional deprivation and its remediation, and the interventions themselves, are the province of the attachment-disorder management account elsewhere in this chapter.

PITFALL

When a child's withdrawn signs persist after placement in what looks like a good home, the reflex is to call the treatment a failure or the child untreatable. The more useful reading is that a withdrawn, unrewarding child is genuinely hard to warm to, and can quietly elicit less engaged caregiving even from willing carers - a continuing de facto neglect that keeps the disorder alive. The clinical task then is not to abandon the placement but to support the caregiver's sensitivity, because persistence is often a sign that the child is still not, in practice, receiving the responsive care the diagnosis presumes was missing.

25.9 ICD-11, and telling the disorder apart from its mimics

The two classifications converge, and the differentials are where marks are won or lost. The ICD-11 clinical descriptions mirror the manual approach with closely similar requirements - a history of grossly insufficient care, a persistent and pervasive pattern of inhibited, emotionally withdrawn behaviour toward caregivers with both the minimal comfort-seeking and the minimal response to comfort, and the insufficient care presumed responsible - coding the disorder as **6B44**, its ICD-10 predecessor having been the reactive attachment disorder of childhood, F94.1. Where the neglect has taken the form of repetitive maltreatment such as chronic physical or sexual abuse, the child is additionally at risk of co-occurring post-traumatic stress disorder or complex post-traumatic stress disorder, so the same pathogenic care can generate a frank trauma disorder alongside the attachment disturbance. Two differentials recur in examinations:

CONDITION	ATTACHMENT BEHAVIOUR	THE DISCRIMINATING POINT
Reactive attachment disorder	Comfort neither sought nor accepted	Requires a history of pathogenic care and a developmentally excessive failure of selective attachment
Childhood depression	Comfort still sought and accepted	Reduced positive affect and withdrawal overlap, but the depressed child's attachment is intact; consider this disorder only with significant social neglect and absent comfort-seeking
Intellectual developmental disorder	Selective attachment forms with development	The child with intellectual disability forms selective attachments once a developmental age of about seven to nine months is reached, with social-emotional skills matching cognitive level

The two examination differentials of reactive attachment disorder; in both the pivot is whether attachment behaviour - the seeking and accepting of comfort - is preserved.

The depression differential is genuine because both conditions show blunted positive affect and withdrawal, so the discriminator must be the attachment behaviour itself: the depressed child still turns to a caregiver and is soothed, and the neurovegetative signs and excessive guilt of depression are not features of the attachment disorder. The intellectual disability differential matters because developmental delay so often accompanies neglect; the resolution is that a child whose social-emotional functioning tracks their cognitive level has delay rather than an attachment disorder, and this disorder is diagnosed only when the failure to attach is out of step with the child's developmental level.

Carry into the exam: reactive attachment disorder is the inhibited, withdrawn child who neither seeks nor accepts comfort, arising from a documented history of pathogenic care presumed to be its cause, evident before age five in a child of at least a nine-month developmental age, with autism excluded.

TRAP **The two attachment disorders are mirror images, and candidates reliably swap them.** Reactive attachment disorder is the internalising, inhibited, emotionally withdrawn pattern - the child who will not turn to an adult. Its disinhibited sibling, taught separately here, is the externalising, indiscriminately sociable pattern - the child who wanders off with any stranger. Both spring from the same pathogenic care, but a vignette describing an over-familiar, boundary-less child is not this disorder, and answering "reactive attachment disorder" to it is the classic error.

IN INDIA

Because Indian services classify under ICD, the operative label in case files and referrals is the ICD entity coded 6B44, and the clinician works from its clinical descriptions rather than a separate criteria manual. The pathogenic-care contexts the criteria describe are far from rare here: children reared in institutions with high child-to-caregiver ratios, and children moved repeatedly between placements before adoption, are exactly the settings Criterion C names, so the caregiving history must be documented carefully, because the diagnosis stands or falls on it. The deprivation evidence and the interventions themselves belong to the attachment-disorder management account elsewhere in this chapter.

<10%	Before 5	9 months	>12 months
OF NEGLECTED CHILDREN, EVEN WHEN NEGLECT IS SEVERE	YEARS: THE ONSET GATE	MINIMUM DEVELOPMENTAL AGE TO DIAGNOSE	DEFINES THE PERSISTENT SPECIFIER

26 · Disinhibited social engagement disorder

A child who never learned that a stranger is a stranger. **Disinhibited social engagement disorder** turns on one arresting behaviour: the child walks up to adults they have never met, engages them with warmth and physical closeness, and will wander off with them showing none of the wariness a securely reared child of the same age keeps in reserve for the unfamiliar. Its essential feature is a manner of **culturally inappropriate, overly familiar** conduct with relative strangers that violates the social boundaries the child's own culture sets for that age. It is the

outward, sociable, boundary-crossing face of early adversity, and it is the mirror image of the withdrawn, comfort-refusing picture of the other attachment disorder of childhood, **reactive attachment disorder**, which is developed in its own right elsewhere in this chapter.

The examiner's interest here is discriminative and conceptual. This is a disorder that looks, to an untrained eye, like nothing worse than a friendly temperament, and the marks reward the candidate who can explain why an approach that charms an adult is in fact a marker of disturbed early development, who can hold the picture apart from the general impulsivity of attention-deficit/hyperactivity disorder, and who can name the specific ways it parts company from its sibling attachment disorder. This topic teaches disinhibited social engagement disorder in full: its phenomenology, its diagnostic criteria, the caregiving history it requires, its epidemiology, its comorbidity and differential, its course and its place in the two classifications. Reactive attachment disorder itself, the comparison of both attachment disorders with autism spectrum disorder, and the management of attachment disorders and the effects of institutional care are each owned elsewhere and are named here only where the reasoning needs them.

26.1 The essential feature: indiscriminate sociability that crosses boundaries

The abnormality is not that the child is friendly, but that the friendliness has no discrimination in it. The healthy toddler is sociable too, but their sociability is calibrated: warmth for the familiar, a checking wariness for the stranger, and a caregiver used as a secure base from which to venture and to which to return. In this disorder that calibration is absent. The child treats the unfamiliar adult as though they were a trusted figure, with a lack of the reticence that age and culture would ordinarily impose. Crucially, and unlike its withdrawn sibling, this pattern does not require or imply a failure of attachment. It can appear in children whose attachments range from clearly disturbed to apparently secure, which is the single most counter-intuitive fact about the condition and the one an examiner most likes to test. The behaviour is a marker of a particular kind of early experience rather than a direct readout of the child's bond with any one caregiver, and the sign frequently persists even after other, more obvious markers of neglect have resolved.

GOOD TO REMEMBER

Because the disinhibited approach can coexist with a formed and even secure attachment, the fact that a fostered or adopted child is visibly bonded to the new caregiver does not exclude the diagnosis. Clinicians who reason "but the child is attached to the parents, so this cannot be an attachment disorder" miss it routinely. Watch how the child behaves toward the unfamiliar adult in the room, not only toward the parent.

PITFALL

The most consequential clinical error is to read the overfamiliarity as endearing charm and to reassure the family that the child is simply outgoing. The willingness to go off with an unknown adult is a genuine safeguarding concern, not a personality quirk, and framing it as sociability both misses the disorder and leaves a vulnerable child unprotected.

26.2 Criterion A: the behavioural signature

The diagnosis is built on a pattern of actively approaching and engaging unfamiliar adults. The child must show at least **two** of four characteristic behaviours, so that no single incident carries the diagnosis and the requirement is for a genuine pattern. The four are drawn from the same underlying failure of stranger-wariness expressed at different moments of an encounter.

- Reduced or absent reticence in approaching and interacting with unfamiliar adults;
- Overly familiar verbal or physical behaviour, out of keeping with culturally sanctioned, age-appropriate social boundaries;
- Diminished or absent checking back with the caregiver after venturing away, even in unfamiliar settings;
- Willingness to go off with an unfamiliar adult with minimal or no hesitation.

MNEMONIC

Approaches, over-Familiar, no Checking-back, goes Off willingly

The four behaviours track a single encounter with a stranger from start to finish: the child moves in without hesitation, is too familiar too fast, does not glance back to the caregiver for reassurance, and will leave with the stranger. Any two of the four, sustained as a pattern, satisfy this criterion.

26.3 Criterion B: the disinhibition is social, not merely impulsive

This criterion is what keeps the diagnosis from collapsing into general impulsivity. The behaviours must reflect **socially disinhibited** conduct and not be limited to the impulsivity seen in attention-deficit/hyperactivity disorder. A child who blurts, interrupts and acts without forethought across every domain is showing a broad behavioural impulsivity; the child captured by this disorder shows a specific loss of the social brake that governs approach to unfamiliar people. The distinction is drawn inside the criteria set itself precisely because the two can look alike at a glance and because they genuinely co-occur. Attention-deficit/hyperactivity disorder is developed as its own entity in the ADHD and specific learning/communication disorders notes; the point of Criterion B is only to insist that the disinhibition on display is of the social, stranger-directed kind rather than a general failure of impulse control.

26.4 Criteria C and D: the required history of pathogenic care

No amount of overfamiliar behaviour makes the diagnosis without the caregiving history behind it. The child must have experienced a pattern of **extremes of insufficient care**, evidenced by at least one of three circumstances: social neglect or deprivation, in the form of a persistent lack of having basic emotional needs met by caregiving adults; repeated changes of primary caregiver that prevent stable attachments from forming, as with successive foster placements; or rearing in unusual settings that severely limit the opportunity to form selective attachments, the institutional nursery being the archetype. The accompanying criterion requires that this care is presumed responsible for the disturbance, so that the abnormal behaviour is tied causally to the deprivation and not merely coincident with it. This pathogenic-care requirement is shared, word for word, with the sibling attachment disorder, and the effects of deprivation and

institutional rearing are themselves the subject of a separate topic in this chapter; here the history is named as the necessary etiological gate through which the diagnosis must pass.

26.5 Criterion E, and the two things this disorder does not require that its sibling does

Here the two attachment disorders separate on the page of criteria, not just in clinical feel. The developmental requirement is modest: the child must have a **developmental age** of at least **9 months**, which simply ensures the child is developmentally capable of the selective attachment whose failure the disorder describes. What is far more testable is what the criteria do NOT contain. This disorder carries no criterion demanding onset before a particular age, and it carries no exclusion for autism spectrum disorder, whereas the sibling attachment disorder's criteria include both an onset requirement and an autism exclusion. A candidate who imports those two conditions into this diagnosis from the neighbouring one is making the error the examiners write the question to catch.

TRAP **Importing the sibling disorder's onset and autism rules.** Because the two attachment disorders share their pathogenic-care requirement, candidates assume the rest of the criteria match too, and wrongly demand an onset-before-age-five and rule the diagnosis out in a child with autism. Neither belongs here: this disorder has no onset-age criterion and no autism-spectrum exclusion. The attachment-versus-autism discrimination itself is owned by a separate topic in this chapter.

26.6 The specifiers: persistent and severe

Two specifiers record chronicity and intensity. The disorder is designated **persistent** when it has been present for more than **12 months**, marking the presentation as an entrenched rather than a transient one, which matters because a durable course carries different prognostic weight. It is designated severe when the child exhibits all of the criterion behaviours, each expressed at relatively high levels, rather than the minimum two that satisfy the diagnosis. The specifiers are not idle bookkeeping: an examiner may use them to check that a candidate grasps that this is a dimensional, persisting phenomenon and not a one-off observation, and the persistence specifier in particular foreshadows the disorder's tendency to endure.

26.7 Epidemiology
