> Reading withdrawal as relapse. When anxiety, insomnia and autonomic arousal appear during or after a reduction, they overlap almost entirely with the presentation the drug was started for, so the natural inference is that the underlying disorder has returned and the dose should go back up. Given how commonly a withdrawal reaction follows long-term use, the prior probability sits the other way. The discriminators are temporal and pharmacological rather than phenomenological: the relationship of onset to the reduction, and the half-life of the agent reduced. Getting this wrong does not merely delay a taper, it teaches the patient that they cannot manage without the drug.

23.6 The timetable is written by half-life, but not the whole of it

Onset of withdrawal tracks elimination, the most directly useful kinetic prediction here:

- After a shorter-acting benzodiazepine, effects often begin a day or two after stopping.
- After a longer-acting one they often begin several days after stopping, and delayed-onset effects are also recognised.

Severity follows the same axis in the acute phase. Short-acting benzodiazepines are associated with more severe acute withdrawal than longer-acting drugs such as diazepam, which is what the pharmacology predicts: a concentration falling steeply gives the adapted system no time to readjust, while a slow decline is a taper the drug performs on the patient's behalf. That principle explains most of the within-class variation clinicians encounter, and it is the content behind every equivalence table, since potency and half-life vary independently and a table is needed precisely because knowing one tells you little about the other. The numeric equivalences are approximations rather than conversions, and belong to the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes.

What half-life does not predict is the long tail. **A protracted withdrawal syndrome** is estimated to occur in up to 15 per cent of patients stopping long-term benzodiazepines, lasting months and

sometimes years, and both short and long acting agents can produce it. Regulation has followed the evidence: in 2020 the FDA boxed warning on marketed benzodiazepines was updated to state that withdrawal syndromes could persist for **more than 12 months** after stopping.

TRAP **Concluding that a long half-life protects against withdrawal.** It softens the acute phase, which is real and useful, and it does nothing for the protracted syndrome, which both short and long acting agents can produce. Candidates who compress the two findings into a single rank order answer confidently and wrongly. Hold them apart as two questions: how severe the acute phase is, which half-life governs, and whether a syndrome persists for many months, which half-life does not govern.

23.7 Why equal dose steps are not equal effect steps

The last piece of mechanism is the one most often missing from a candidate's account, and it explains why the end of a reduction behaves differently from the start. The relationship between benzodiazepine dose and occupancy of GABA-A is **hyperbolic**, not linear. Occupancy rises steeply at low doses and then flattens, so most of the receptor effect has already been bought by a small fraction of a typical dose.

Run the curve backwards and the clinical implication appears. Reductions made in equal linear amounts produce progressively larger reductions in effect, because each identical decrement moves further down the steep part of the curve than the one before it. A patient who tolerated the early reductions and then struggles badly on the last ones is not deteriorating or failing; they are meeting the geometry of the curve, which the pharmacology predicted before the reduction began. The corollary is that a plan reasoned in equal steps of milligrams is reasoning in the wrong currency, because the currency that matters is receptor occupancy. The schedules that follow belong to the prescribing and deprescribing lens rather than to class pharmacology, and are found in the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes.

23.8 The edges of what class pharmacology settles

Two limits deserve stating plainly, because both invite a manufactured answer. The first is that this account is built on classical benzodiazepines acting at benzodiazepine-sensitive receptors, and nothing above transfers automatically to a molecule that binds elsewhere. The second is jurisdictional: these sources record a United States regulatory warning and say nothing about scheduling in India, and a scheduling status recalled from memory is exactly the kind of confident specific that turns out to be wrong.

IN INDIA

The agent Indian practice must reason about, and that the standard textbook chapters do not cover, is etizolam, a thienotriazolodiazepine that behaves as a full benzodiazepine receptor agonist. The prescribing decision that follows is to treat it as a full member of this class for every purpose set out above: the same modulatory mechanism, the same subunit-determined split between sedation and anxiolysis, tolerance developing first to sedation, and a withdrawal reaction after long regular use. What must not be done is to borrow a half-life from another member to fill the gap, because the sources used here print none for it, and an assumed half-life silently decides how a reduction is planned. Its regulatory position needs the same discipline: read the current classification and the record-keeping it requires off the Drugs and Cosmetics Rules themselves rather than off a textbook.

What remains is compact and durable: one modulatory site with a ceiling built into the mechanism, a subunit map assigning sedation, anxiolysis and muscle relaxation to different parts of the same complex, a tolerance sequence beginning with the effect the patient notices, a withdrawal reaction that is the ordinary consequence of long exposure, and a dose-occupancy curve explaining why reductions get harder rather than easier.

A benzodiazepine cannot open the chloride channel without GABA, and the rest of the class follows from that: a ceiling that gives it perhaps the highest therapeutic index of all psychotropic drugs, a subunit map that splits sedation from anxiolysis, tolerance that takes sedation first, and a withdrawal reaction most long-term users will experience.

24 · Z-drugs and the other hypnotics compared

A hypnotic is compared with another hypnotic on two pharmacological axes and very little else. The first is which population of receptors the molecule prefers; the second is how long it persists in the plasma. Almost every question asked about this group is derived from those two axes: why one agent leaves impairment behind in the morning and another does not, why a drug with a weak anticonvulsant action is nonetheless an effective hypnotic, and why the withdrawal picture is so familiar. The **benzodiazepine receptor agonists** are the group in which the two axes separate most cleanly, which is why they repay being learned as pharmacology rather than as a list of names.

Two warnings about the label, because both are examined. The prefix in "non-benzodiazepine hypnotic" is a statement about chemical structure, not about mechanism and not about safety. And the letter Z is an orthographic accident: it groups agents that share a first letter and a binding site while differing in chemistry, in subunit preference and in the length of time they stay in the body. The GABA-A receptor itself, its subunit architecture and the biochemistry of inhibitory transmission belong to the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes and are assumed here. Benzodiazepine class pharmacology has its own section in these notes; the use of any of these agents as a clinical treatment for insomnia

belongs to the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes, and sedative-hypnotic dependence as a disorder to the Substance use disorders notes.

about 1 hour	mean 2.4 hours	5 to 6 hours	about 6 hours
ZALEPLON, ELIMINATION HALF-LIFE	ZOLPIDEM, IMMEDIATE RELEASE	ZOPICLONE, ADULT FIGURE	ESZOPICLONE

24.1 Three chemistries, one binding site

The group is named for a letter and not for a structure. Zolpidem is an **imidazopyridine**, zaleplon a **pyrazolopyrimidine** and eszopiclone a **cyclopyrrolone**: unrelated chemical families that converge on the same pharmacological place. What unites them, on the account given in Kaplan and Sadock's Comprehensive Textbook of Psychiatry, is that they act more selectively than the classical benzodiazepines on GABA-A receptors containing the alpha-1 subunit, receptors often referred to as GABA-A1 receptors. The comparison is the load-bearing half of that sentence, and the half candidates drop. Diazepam and the other classical benzodiazepines bind with equal affinity to benzodiazepine-sensitive receptors of differing subunit composition; the Z-drugs prefer one population over the others.

That one comparative statement generates most of what follows. If a classical benzodiazepine engages every benzodiazepine-sensitive receptor more or less equally, its clinical profile will be the sum of everything those receptors do, and the adaptive consequences of occupying all of them for months will be equally broad. A molecule that prefers a single population should, on the same reasoning, deliver a narrower set of effects and adapt a narrower set of receptors. The Z-drugs are the test of that prediction, and the instructive finding is that it is borne out only in part.

RULE **The prefix records chemistry; the binding site records pharmacology.** Every drug in this group is an agonist at the benzodiazepine recognition site of the GABA-A receptor. Everything that follows from occupying that site therefore remains available: sedation, psychomotor impairment, tolerance and withdrawal on stopping. What differs between the agents is which receptor populations they prefer, and for how long they stay. Nothing in the word "non-benzodiazepine" suspends the first list.

24.2 Selectivity is graded, and it belongs to the molecule

Zolpidem is the cleanest instance. Companion to Psychiatric Studies describes it as binding selectively and with high affinity at alpha-1 containing GABA-A receptors, with roughly ten-fold lower affinity for alpha-2 and alpha-3, and none at all for alpha-5. Zaleplon sits beside it: a **full agonist** at the benzodiazepine alpha-1 receptor, which it binds with high affinity, its affinity for the alpha-2 and alpha-3 subtypes being lower. Different molecules, unrelated chemical families, one preference.

The clinical translation of that binding pattern is stated by the same source and is the part to carry away: the anxiolytic, muscle relaxant and anticonvulsant properties of zolpidem are weak. KDT Essentials of Medical Pharmacology, the Indian standard pharmacology text, makes the same attribution from the opposite direction, ascribing the relatively selective hypnotic effect of zolpidem to its preferential action at the alpha-1 subunit containing benzodiazepine receptor,

with no evident anticonvulsant, muscle relaxant or antianxiety effect to accompany it and an elimination half-life of about two hours. Independent texts, opposite framings, the same pharmacological claim.

Put those statements side by side and the mechanism becomes visible without anyone having to assert a subunit-by-subunit map of function that neither source spells out here. The actions a selective agent loses are carried by receptor populations it barely engages; the action it keeps is carried by the population it prefers. That is the entire promise of subunit selectivity, and it is why these molecules were developed.

Two riders keep the account honest, and both are examinable. Selectivity is not exclusivity: despite its preference, zolpidem is still displaced from its binding sites by **flumazenil**, which is the pharmacological proof that it is sitting where a benzodiazepine sits. And the narrowing of effect is not a narrowing of every risk. KDT records that even large doses of zolpidem do not markedly depress respiration, which is a genuine and useful contrast with the older sedatives, but respiratory margin is one property among many and it says nothing about the impairment, tolerance and withdrawal discussed below.

24.3 The cyclopyrrolones, where the tidy account breaks

The neat story survives exactly as far as the cyclopyrrolones. Companion to Psychiatric Studies states that while zopiclone is chemically a cyclopyrrolone, pharmacologically it resembles the benzodiazepines in binding indiscriminately and with high affinity across the benzodiazepine site, at alpha-1, alpha-2, alpha-3 and alpha-5 containing receptors. Kaplan and Sadock's account, quoted earlier, groups eszopiclone with zolpidem and zaleplon among the agents acting more selectively at the alpha-1 population. Both statements are in print in standard texts. They cannot be reconciled by rounding, and neither is a misprint.

The defensible reading is that selectivity here is a graded property rather than a binary one, and that it is strongest and least disputed for zolpidem and zaleplon. The cyclopyrrolones are the contested case, and a candidate is safest holding them that way: as the agents whose selectivity is claimed by one authority and denied by another, rather than as agents whose selectivity is settled. It is also worth noticing that the two statements are made about two different molecules, zopiclone in one text and eszopiclone in the other. Neither source, as quoted here, states how those two molecules are related to each other, so the reader should not assume that a finding about one transfers automatically to the other.

TRAP **Treating preference for one subunit population as the definition of a Z-drug.** Candidates learn the group as "the selective ones" and then meet a question about the cyclopyrrolones, where one standard text groups the class with the selective agents and another describes indiscriminate binding across the whole benzodiazepine site. Whichever way the paper is written, the memorised equation answers it wrongly. Learn the axis, not the slogan: selectivity is graded, it is strongest for zolpidem and zaleplon, and the cyclopyrrolones are where the sources disagree.

24.4 The second axis: how long the drug is there

Half-life does more comparative work in this group than receptor preference does. The **elimination half-life** of these agents spans a wide range for drugs given at the same point in the evening for the same purpose, and that range is what decides how much drug is still present when the patient has to function. The Maudsley Deprescribing Guidelines set the figures out drug by drug. Zaleplon is the extreme case, with an elimination half-life of approximately one hour and peak plasma concentration reached approximately one hour after oral ingestion, so that plasma levels fall to zero well before the next night-time dose is due. Zolpidem has a short but appreciably longer profile: a **mean of 2.4 hours** with a range of 0.7 to 3.5 hours, a duration of action of up to 6 hours, and peak plasma reached between 0.5 and 3 hours. The controlled release formulation produces a longer period of maximal dose and a half-life of 2.8 hours.

The cyclopyrrolones sit at the long end. Eszopiclone has an elimination half-life of **approximately 6 hours**, with peak plasma at approximately one hour. Zopiclone is the one figure the sources dispute. The Maudsley Deprescribing Guidelines give **approximately 5 hours**, with peak plasma at approximately 1.5 to 2 hours; Companion to Psychiatric Studies gives around six hours. The sensible teaching figure for an adult is therefore five to six hours, quoted with both sources named rather than resolved by picking one. The same text adds that the half-life is considerably longer in older people, at about nine hours, and that figure should be carried separately as an age-qualified statement rather than folded into the adult range. Prescribing in the elderly is treated in the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes.

AGENT	CHEMICAL CLASS	BINDING AT THE BENZODIAZEPINE SITE	PEAK PLASMA	ELIMINATION HALF-LIFE
Zaleplon	Pyrazolopyrimidine	Full agonist at alpha-1, high affinity; lower at alpha-2 and alpha-3	About one hour	About one hour
Zolpidem	Imidazopyridine	High affinity at alpha-1, roughly ten-fold lower at alpha-2 and alpha-3, none at alpha-5	Between 0.5 and 3 hours	Mean 2.4 hours, range 0.7 to 3.5 hours
Zopiclone	Cyclopyrrolone	Indiscriminate across alpha-1, alpha-2, alpha-3 and alpha-5, on the Companion account	About 1.5 to 2 hours	About five to six hours, sources differing
Eszopiclone	Cyclopyrrolone	Grouped with the alpha-1 preferring agents by Kaplan and Sadock	About one hour	About 6 hours

PITFALL

Reading a mean half-life as though it were the patient's own. The zolpidem figure is a mean drawn from a wide range, and the drug's stated duration of action is longer than that mean would suggest. A patient at the slow end therefore carries more drug into the morning than the textbook number predicts, and the grogginess gets attributed to poor sleep, to the illness or to anything except the tablet, on the reasoning that the half-life is short. Ask about the morning after, not only about the night.

24.5 What preference for one subunit population does not buy

If subunit selectivity delivered everything hoped of it, these agents would produce hypnosis without the residual burden of a benzodiazepine. They do not, and the evidence is at its clearest for zopiclone. Companion to Psychiatric Studies records that, like the benzodiazepines, it impairs performance motor skills; that tolerance to that impairment is only partial, so impairment continues to be evident in driving assessments with prolonged use; and that **dysgeusia**, a bitter metallic alteration in taste, is a characteristic adverse effect. The same source states that the abuse potential of the drug is clear.

The partial tolerance finding is the one that changes practice. Tolerance to sedation developing does not mean tolerance to impairment developing, and a patient who no longer feels drugged is not thereby a patient who performs normally. Abuse liability, dependence and their assessment as a disorder belong to the Substance use disorders notes; what belongs here is the pharmacological point that neither the impairment nor the abuse liability was abolished by moving away from benzodiazepine chemistry.

GOOD TO REMEMBER

Ask about driving at every review of a patient taking one of these agents, not only when the drug is started. The evidence that impairment persists comes from driving assessments in people on prolonged treatment, which is precisely the group a clinician is least likely to re-examine, because they are stable, they are not complaining, and the prescription has become a repeat. Habituation to the feeling of a drug is not evidence of recovered performance.

24.6 Receptor adaptation, and why stopping is still difficult

Here the selectivity argument does earn something measurable. Kaplan and Sadock's Comprehensive Textbook of Psychiatry reports that chronic exposure to the selective agents zolpidem and zaleplon produces less extensive change in the expression of GABA-A receptor subunits than prolonged treatment with classical benzodiazepines. That is a mechanistic result, not a marketing claim, and it is what the selectivity hypothesis predicts: fewer receptor populations occupied for months means fewer receptor populations remodelled. The important qualification travels with it. On short-term withdrawal, the changes that do occur come to resemble those seen after diazepam. Less adaptation during exposure, in other words, does not translate into a different kind of adaptation once the drug is removed.

The clinical arithmetic follows. The Maudsley Deprescribing Guidelines state that stopping these drugs, even when they have been taken exactly as prescribed, can lead to **withdrawal effects** in as many as **30 to 45 per cent** of people, and that the longer the drug has been taken and the higher the dose, the greater the risk. Two features of that statement deserve emphasis. It applies to prescribed use, so it is not a statement about misuse. And the same figure is given for each of the agents in the group, so it is not a peculiarity of one molecule that a switch within the class would solve.

TRAP **Reading "non-benzodiazepine" as "not dependence forming", and stopping abruptly on that basis.** The withdrawal frequency quoted above is not a benzodiazepine figure borrowed for effect; it is the figure given for these drugs, in people who took them as prescribed. The examination version of this error is the candidate who lists absence of dependence liability as an advantage of the class. The clinical version is the prescriber who discontinues a long-standing hypnotic without a plan, because the label said the drug was not a benzodiazepine.

24.7 The hypnotics that never touch the benzodiazepine site

The benzodiazepine receptor agonists are one family among several, and a comparison confined to them misses the axis that separates the classes. Practical Psychopharmacology sets out the wider field: beyond the benzodiazepine receptor agonists, the hypnotic families in use are the antihistamines, the **melatonin receptor agonists** and the **orexin receptor antagonists**. Read as a list of targets rather than a list of drugs, those are distinct ways of producing sleep.

- **GABA-A modulation.** The benzodiazepines and the Z-drugs, acting at the benzodiazepine recognition site, with the profile set out above.
- **Histamine blockade.** The antihistamines, several of which are available without prescription in many countries, producing sedation as an extension of a receptor action that is otherwise an unwanted effect.
- **Melatonin agonism.** Agents acting at melatonin receptors, working with the timing system rather than by depressing arousal.
- **Orexin antagonism.** Agents blocking orexin signalling, and therefore removing a wake-promoting drive rather than adding an inhibitory one.

That last distinction is the conceptual pay-off. A GABA-A modulator produces sleep by increasing inhibition; an orexin antagonist produces it by subtracting wakefulness; a melatonin agonist works through the circadian signal. Because the two newer families act nowhere near the benzodiazepine recognition site, the tolerance and withdrawal pharmacology set out above does not transfer to them by the same mechanism. What the sources quoted here do not supply are half-life or receptor-occupancy figures for the melatonin and orexin agents, so no kinetic comparison with the Z-drugs can honestly be printed, and none is attempted. The licensing position of individual agents also differs between countries, so the class names travel where product names do not. Their place in the treatment of insomnia belongs to the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes.

24.8 Comparing any two hypnotics

The comparison that examinations reward, and the one that survives the arrival of new molecules, runs in a fixed order. Establish the mechanism family first, because it decides whether the dependence and withdrawal pharmacology of the benzodiazepine site is in play at all. Within that family, establish the subunit preference, remembering that it is graded and that for the cyclopyrrolones it is disputed. Then take the half-life, which predicts how much drug is present when the patient must drive, work or supervise a child. Only then read the adverse-effect signature, which for this group includes psychomotor impairment that tolerance does not fully abolish and, for one agent, a characteristic taste disturbance.

MNEMONIC

Zaleplon, Zolpidem, Zopiclone, eszopiclone: shortest half-life first

The agents listed in ascending order of elimination half-life are also the order in which they are usually asked about, and that order predicts, other things being equal, how much drug is still present when the alarm goes off. **Za**leplon is the outlier at roughly an hour, **Zol**pidem is short but longer, and the cyclopyrrolones sit at the long end.

What none of this settles is whether a given patient should be taking a hypnotic at all. That decision belongs with the assessment of the sleep complaint. The pharmacology is what makes it executable: it tells the prescriber what the chosen molecule will still be doing at breakfast, what will happen when the patient stops it, and which of the reassuring things said about the class are properties of the drug rather than properties of its name.

The Z-drugs are benzodiazepine-site agonists whose prefix hides the fact: preference for the alpha-1 population is graded and strongest for zolpidem and zaleplon, half-life decides what is left in the morning, and withdrawal on stopping is common in people who took the drug exactly as prescribed.

25 · The non-benzodiazepine anxiolytics and the cognitive enhancers

Every drug gathered here is named for what it is not. The non-benzodiazepine anxiolytics are defined by a negative: they relieve anxiety without acting where a benzodiazepine acts, each by a different molecular route, so the group shares no receptor, no time course and no adverse-effect signature. The cognitive enhancers are the same kind of grouping seen from the other side, three drugs that inhibit an enzyme and one that plugs an ion channel, sharing a shelf rather than a mechanism. Treat either family as a single class and most questions about it become unanswerable; read each agent by its target and the answers fall out of the target.

The marks sit on dissociations, and three are worth naming in advance: a plasma half-life of a few hours against an onset measured in weeks; a plasma half-life that says nothing about how long an enzyme stays inhibited; and one mechanism the standard textbooks label with two different words. Whether any of these agents is the right treatment for a particular anxiety disorder belongs to the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes, and their

indication, staging and efficacy in dementia belong to the Dementias and neurocognitive disorders notes. Cross-class interaction tables and monitoring schedules belong to the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes.

2 to 4 hours	10 days	1.6 hours	about 70 hours
BUSPIRONE PLASMA HALF-LIFE	BEFORE ITS ANXIOLYTIC EFFECT BECOMES APPARENT	RIVASTIGMINE MEAN ELIMINATION HALF-LIFE	DONEPEZIL HALF-LIFE, HENCE ONCE-DAILY DOSING

25.1 An azapirone, and the receptor it never touches

Buspirone is an **azapirone**, also written as an azaspirodecanedione, and the single most important fact about it is a negative one: it does not act on the GABA-A benzodiazepine chloride ionophore at all. That one statement generates most of what follows, because every property a benzodiazepine derives from modulating a chloride channel is one buspirone has no route to.

Where it does act is on a serotonin receptor. Buspirone is a **partial 5-HT1A agonist** and a relatively weak dopamine antagonist, apparently at predominantly presynaptic sites. The dopaminergic component is worth holding separately: it is the weaker action, and its site is qualified rather than asserted. What partial agonism does to a prescribing decision is developed where receptor theory is treated in this chapter, and the underlying receptor biology sits in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes.

Two cautions belong with that receptor address. The Companion to Psychiatric Studies, having given the profile, describes buspirone's complex actions as incompletely understood, so the profile is a location and not a completed explanation. And candidates who have learnt that anxiolysis means a chloride channel will translate a serotonergic anxiolytic back into GABAergic language, then predict sedation, anticonvulsant activity and cross-tolerance that this drug does not have. The mechanism is not a paraphrase of the benzodiazepine mechanism; it is a different one that happens to earn the same therapeutic label.

25.2 A short half-life against a slow onset

The kinetics are unremarkable, and worth learning because they explain so little. Buspirone is rapidly absorbed, undergoes extensive presystemic metabolism and has a half-life of only **two to four hours**. A drug cleared that quickly rises and falls several times a day, which on the reasoning used everywhere else should predict a rapid, easily titrated effect.

It predicts nothing of the sort. Buspirone's action is not instantaneous, requiring some 10 days to become apparent and up to 3 weeks to develop fully. Set those two figures side by side and the arithmetic is unavoidable: the effect cannot be a simple function of plasma concentration, because the concentration has completed hundreds of cycles before the effect appears. Whatever produces anxiolysis here is downstream of receptor occupancy and is timed like an antidepressant response, not like a sedative.

The exact figure is not agreed. Tasman's psychiatry text puts the effect at least two weeks away and reports clinical experience suggesting three to four weeks before a truly beneficial effect is seen, while the Companion gives the shorter figure above. Nothing turns on which is right: the

teachable envelope runs from about ten days to about four weeks, and the contrast that earns the mark, against the very rapid onset of a benzodiazepine, survives either.

One vulnerability follows from the presystemic step. Buspirone's metabolism is inhibited by naringenin in grapefruit juice, which produces substantial increases in blood levels. That is a class-level property rather than an interaction table; the tables belong to the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes.

TRAP **Quoting a single onset figure for buspirone.** Two standard texts give different numbers, and an answer key built on either will mark the other wrong. Say that the effect takes days to weeks rather than minutes, give the envelope, and name the contrast with the benzodiazepine; that answer is correct against both sources and is what the question is actually testing.

25.3 One effect where a benzodiazepine has four

Buspirone's spectrum of action is restricted to anxiety, with little or no hypnotic, anticonvulsant or muscle relaxant component. A benzodiazepine carries all four actions on one molecule because all four descend from the same channel; buspirone carries one, because it is not at that channel. The practical corollary is the hardest single rule here: it should not be used to substitute for benzodiazepines or alcohol in withdrawal regimes, and the same text warns that it has a mild proconvulsant action and should be avoided in those at risk of fits and in combination with monoamine oxidase inhibitors. Benzodiazepine dependence as a disorder belongs to the Substance use disorders notes.

That same absence of agonist activity puts buspirone at the far end of the misuse-liability spectrum. Buspirone is essentially devoid of benzodiazepine agonist activity and has little or no misuse liability in the predictive human models used to rank sedative-hypnotic drugs, placing it below the benzodiazepines and far below methaqualone and the barbiturates. Read the qualification with the claim: those rankings come from laboratory paradigms of drug liking and from the ARCI-MBG scale, not from field data, so what has been shown is an absence of reinforcing subjective effect, not an absence of misuse in the world.

Stopping the drug behaves accordingly. Discontinuation of buspirone has not been associated with the development of withdrawal symptoms, although patients discontinued from pharmacotherapy tend to relapse over time. That pairing is the honest version of the class advantage: relapse and withdrawal are different events, and a drug can be free of one while remaining fully subject to the other.

PITFALL

Starting buspirone to cover a benzodiazepine taper, then reading the patient's distress as anxiety returning. A drug with no action at the benzodiazepine site cannot occupy the receptor the patient is withdrawing from, so the taper runs unopposed while an agent that will not work for another two weeks is credited with holding it. The error is attractive because the two drugs share the word anxiolytic, and the proconvulsant caution makes it worse, since the population being tapered is the population with a lowered seizure threshold.

25.4 Beta-adrenergic blockade, the gabapentinoids, and onset as the axis

The other non-benzodiazepine routes are narrower than their reputation. Beta-adrenergic blockers such as propranolol may achieve short-term control of tremor and palpitations, which can be the most handicapping symptoms of specific social phobias such as performance anxiety among musicians, and it is doubtful whether they are more generally effective in social phobia. That sentence is the whole of what the Shorter Oxford Textbook of Psychiatry supports: two target symptoms, one narrow situation, and no mechanism at all.

Two things commonly taught alongside it are absent from the sources here, and both should be omitted rather than reconstructed. The familiar division of anxiety into somatic symptoms that a beta-blocker treats and psychic symptoms that it does not is not in this passage. Neither is the lipophilicity argument, the claim that propranolol is preferred over atenolol because it enters the central nervous system: no source here supports choosing a beta-blocker for its degree of central penetration, so that reasoning should not be offered as the pharmacological basis for the choice.

The gabapentinoids are the third route and the most often misfiled. Pregabalin binds to a subunit of voltage-gated calcium channels in the central nervous system, is unusually not protein bound and undergoes virtually no metabolism, so its interactions are few, and the Companion is explicit that how that binding relates to the drug's mode of action is unknown. The subunit is named elsewhere: **the alpha-2-delta protein** of the voltage-sensitive calcium channel is the target of pregabalin and gabapentin, and that protein may regulate conformational changes that alter how the channel opens and closes. The name gabapentinoid records a chemical resemblance, not a receptor: there is no action at the GABA-A receptor here, and a candidate who assumes one predicts the wrong interactions and the wrong withdrawal.

On a single axis of onset the group organises itself, and the axis is mechanism, not indication.

AGENT OR CLASS	MOLECULAR TARGET AS STATED	ONSET OF ANXIOLYTIC EFFECT
Buspirone	5-HT1A partial agonist	Delayed, at about two weeks
Beta-adrenergic blockers	Blockade of beta-adrenergic receptors	Rapid
Pregabalin	GABAergic by a mechanism not fully known	Rapid
Benzodiazepines	Modulation of the GABA-A receptor	Rapid to very rapid

25.5 The cognitive enhancers: two mechanisms, not one class

The second family is smaller than it looks and splits cleanly in two. Three cholinesterase inhibitors are currently available in the United States: donepezil, rivastigmine and galantamine, with tacrine, the first agent approved, no longer on that market. Standing apart from them, memantine is an NMDA receptor antagonist approved for moderate to severe Alzheimer disease. Both approval statements are specific to the United States and should be quoted as such. Which agent is indicated at which stage, and what either family achieves clinically, belongs to the Dementias and neurocognitive disorders notes.

The cholinergic three share a target that is more divisible than the class name suggests. Two enzymes hydrolyse acetylcholine, **acetylcholinesterase** and **butyrylcholinesterase**, and the cholinesterase inhibitors differ in the extent to which they selectively inhibit each. The second enzyme is the minor partner centrally, making up about 10 per cent of the total cholinesterase in the central nervous system according to the same source, which is why a drug that also blocks it is doing something additional rather than something more.

That split is what makes the within-class comparison tractable: there is no single quantity called cholinesterase inhibition to rank these drugs on, only two enzymes, a duration of binding, a nicotinic action that one agent has, and a set of kinetics.

25.6 What actually separates the three cholinesterase inhibitors

The enzyme selectivities are the first column and they are stated cleanly. Donepezil inhibits acetylcholinesterase with higher selectivity, rivastigmine inhibits both acetylcholinesterase and butyrylcholinesterase, and galantamine selectively inhibits acetylcholinesterase while also producing allosteric modulation of nicotinic receptors. The withdrawn agent completes the range in the opposite direction: tacrine inhibited butyrylcholinesterase 18 times more potently than acetylcholinesterase, which shows that selectivity within this class is a real variable.

Galantamine's second action is a genuinely different mechanism and is examined as such. **Allosteric modulation of nicotinic receptors** is distinct from the action of acetylcholine and from that of nicotinic agonists or antagonists, and it upregulates or potentiates nicotinic ion channel activity in response to acetylcholine, so cholinergic transmission is enhanced by a route that never passes through the enzyme.

The second axis is time on the enzyme rather than affinity for it. Cholinesterase inhibitors are classified as reversible, pseudo-irreversible or irreversible according to how long they bind the enzyme, and the three arms are worth separating explicitly.

- Reversible inhibitors bind the enzyme for seconds to minutes, so inhibition tracks the plasma concentration closely.
- **Pseudo-irreversible inhibitors** bind for hours, so inhibition outlasts the concentration that produced it.
- Irreversible inhibitors sit at the far end of the same axis, where the enzyme is not available again until new enzyme has been made.

MNEMONIC

Donepezil one, rivastigmine both, galantamine plus nicotinic

Three agents, three answers to one question about the target. **Donepezil** acts on acetylcholinesterase preferentially. **Rivastigmine** takes both enzymes. **Galantamine** is selective for the same enzyme as donepezil but adds a nicotinic action nobody else in the class has. The line records what each one does, never which is better.

25.7 Kinetics, and why the plasma half-life is the wrong question

The elimination half-lives inside this small class span a very wide range, and each must be read against the binding classification rather than on its own. Rivastigmine is rapidly absorbed orally with a mean time to maximum plasma concentration of one hour, range 0.8 to 1.7 hours, and has a mean elimination half-life of **1.6 hours**. Read naively, that predicts a drug present for only part of the day. It does not, because rivastigmine's inhibition is pseudo-irreversible, and for such an inhibitor the plasma half-life and the duration of enzyme inhibition are different quantities that need not resemble each other.

Galantamine sits in the middle and carries the class's one metabolic complication. Galantamine immediate release has an elimination half-life of about seven hours, and galantamine is mainly metabolised by hepatic CYP2D6 and CYP3A4, with the CYP2D6 metabolite sanguinine accounting for 20 per cent of the parent drug and being three times more potent than the parent drug at inhibiting acetylcholinesterase. An active metabolite more potent than its parent, formed by a polymorphic enzyme, is the classic setting for a genotype-driven difference in effect, though the source's own position is that the poor-metaboliser difference is probably not significant given the large variation between patients. The enzymology sits in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes, and the cross-class interaction consequences in the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes.

The two long-acting agents anchor the other end. Donepezil's schedule is derived from its kinetics: the Indian pharmacology standard attributes its once-daily administration at bed time to a long half-life of about 70 hours, a distinct advantage over rivastigmine and galantamine, both of which need twice-daily dosing, and the Comprehensive Textbook of Psychiatry gives the same order of half-life for the same reason. Memantine is longer again: it reaches peak plasma concentration within three to seven hours, has an elimination half-life of **between 60 and 80 hours**, and is largely excreted unchanged in the urine, the remainder being converted to three minimally active polar metabolites, with steady state reached separately at about 21 days.

AGENT	ENZYME OR RECEPTOR ACTION	ELIMINATION HALF-LIFE	KINETIC CONSEQUENCE
Donepezil	Inhibits acetylcholinesterase with higher selectivity	About 70 hours	Once daily at bed time
Rivastigmine	Inhibits both acetylcholinesterase and butyrylcholinesterase	1.6 hours, mean	Twice-daily dosing
Galantamine	Selective for acetylcholinesterase, plus nicotinic allosteric modulation	About seven hours, immediate release	Twice-daily dosing
Memantine	NMDA receptor antagonist	60 to 80 hours	Steady state at about 21 days
Tacrine, withdrawn	Inhibited butyrylcholinesterase 18 times more potently than acetylcholinesterase	Not stated in these sources	Withdrawn from the United States market

GOOD TO REMEMBER

A half-life answers how often the drug must be given and how long it takes to reach steady state. It does not answer how long the target stays engaged, which for a pseudo-irreversible enzyme inhibitor is a separate measurement. With an agent whose steady state is three weeks away, anything assessed in the first fortnight measures the titration rather than the medicine.

RULE **A short half-life buys neither a fast onset nor a short action.** Buspirone is cleared in a few hours and takes weeks to work; rivastigmine is cleared faster still and inhibits its enzyme for longer than it is present. Onset is set by whatever process actually mediates the effect, and offset by how long the target stays engaged. The plasma curve sets the dosing interval and nothing else.

25.8 Memantine, and the block that works only while the channel is open

Memantine is the one agent here that is not a cholinergic drug, and its mechanism is the most precisely specified claim in the section. It is an **uncompetitive open-channel NMDA receptor antagonist**, and Stahl's account gives the four properties together: low to moderate affinity, voltage dependence, and fast blocking and unblocking kinetics, with the drug working at the same site as magnesium, plugging the ion channel where the magnesium ion normally blocks it at rest. Each clause does work. Because the drug occupies the channel rather than the glutamate recognition site, it can bind only once the channel has been opened, which is what voltage dependence means here; and because affinity is low and the kinetics fast, a barrage of glutamate from normal neurotransmission readily and quickly reverses the block.

The therapeutic logic follows directly. Chronic blockade of the NMDA receptor would hypothetically interfere with memory formation and neuroplasticity, so a drug meant to damp excessive tonic activation without abolishing phasic signalling has to be this kind of antagonist

and no other. Tasman's text describes the same mechanism independently, as an uncompetitive antagonist binding the NMDA receptor-operated cation channels and acting by inhibiting calcium influx.

One caution about the literature is worth carrying into the examination hall. At least one printing of a major psychiatry textbook carries a sentence that reads as though memantine blocked glutamate binding at the receptor. That is incompatible with open-channel block and with the surrounding paragraph, which describes selective uncompetitive blockade and strong voltage dependence. Where one sentence contradicts the mechanism its own paragraph describes, take the paragraph.

TRAP **Treating uncompetitive and noncompetitive as a factual disagreement about memantine.** Every source that spells the mechanism out in prose calls the drug uncompetitive, and the same books print noncompetitive in figure legends and passing mentions. The mechanism described is identical in both: binding inside the channel at the magnesium site, only while the channel is open, with low affinity and fast kinetics. Learn the mechanism, use uncompetitive, and treat a mismatch against an answer key on this one word as a labelling difference rather than an error of fact.

25.9 Nootropic: a claim about a category, not a mechanism

The word that ends this section is not a pharmacological description at all. Piracetam is a cyclic GABA derivative with no GABA-like activity, and the word **nootropic** denotes a drug said to selectively improve the efficiency of higher telencephalic integrative activities. Both halves repay attention. The molecule resembles a transmitter it does not act like, which is the trap the gabapentinoid name sets earlier; and the label names a hoped-for functional outcome rather than a target, so nothing about a receptor, an enzyme or a channel can be derived from it. A category defined by its intended effect is a claim awaiting evidence, not a mechanism.

The evidence has been examined and the verdict is unambiguous. Piracetam has long been promoted in India and some other countries for cognitive impairment and dementia in the elderly and for intellectual disability in children, but a Cochrane Database review of 2004 concluded that published data do not support such use, and in the United Kingdom it is approved only as adjunctive treatment of cortical myoclonus. The narrow surviving approval is the tell: the demonstrable effect was licensed, the broad cognitive claim that named the category was not.

IN INDIA

This is the one agent here where the prescribing decision is made against local practice rather than with it. Piracetam is promoted in this country for exactly the two populations in which the evidence was examined and found wanting, so it should not be started as a cognitive enhancer for an older adult with cognitive impairment or for a child with intellectual disability, and a request to add it to an existing regimen has no pharmacological argument behind it.

When a patient arrives already taking it, ask which claim it was started on. If the answer is cognition, say plainly that the licensed indication surviving review is a movement disorder rather than a cognitive one. The drug is well known in Indian households, and quietly stopping the tablet reads as a treatment being taken away.

Nothing in this section shares a mechanism with the drug it is offered as an alternative to, so nothing in it inherits that drug's speed, its spectrum or its behaviour on withdrawal.

26 · Psychostimulants and atomoxetine: onset, duration and diversion

What separates one stimulant preparation from another is almost entirely kinetic. The molecules in routine use are few: methylphenidate, dexamfetamine and the mixed amphetamine salts all raise synaptic catecholamines at the monoamine transporters. What differs between the products, and what is examined here, is rate. How fast the drug arrives, how long its effect lasts and how quickly it occupies a transporter determine both the shape of the therapeutic day and the probability that the tablet is swallowed by somebody other than the patient. Atomoxetine belongs in the same section for the opposite reason: it is not a stimulant at all, and set against the stimulants it demonstrates that abuse liability is a property of where and how fast a transporter is occupied rather than of which transmitter is raised. The mechanism itself, reuptake blockade against transporter-mediated release, and the indication-specific dosing, titration and adverse-effect monitoring of these agents, belong to the ADHD and specific learning/communication disorders notes; stimulant misuse as a disorder belongs to the Substance use disorders notes.

within 30 minutes	4 to 6 weeks	up to 12 hours	15 per cent
ORAL STIMULANT ONSET OF ACTION	ATOMOXETINE TIME TO EFFECT	LISDEXAMFETAMINE DURATION OF ACTION	METHYLPHENIDATE PLASMA PROTEIN BINDING

26.1 The one property the whole class is organised around

The class begins at the gut wall. Tasman Psychiatry puts it simply: psychostimulants are rapidly absorbed from the gut and therefore act quickly, an oral dose beginning to work **within the first 30 minutes** of ingestion. Almost nothing else in psychiatric pharmacology behaves like this: an antidepressant or an antipsychotic is judged over weeks, a stimulant before the patient has left the waiting room.

Three consequences organise the rest of the topic. First, the therapeutic trial is short, so response and non-response are both visible quickly rather than inferred from a plasma level. Second, because the effect appears and disappears within a single day, the clinically interesting number is

not the elimination half-life but the **effect duration**, the length of time a single administration continues to do useful work. Third, a drug that reaches the brain fast enough to be felt can by that same property reinforce its own consumption. Speed is at once the therapeutic advantage of the class and the reason it is regulated.

26.2 Onset, peak, half-life and duration are four different numbers

Residents lose marks by collapsing four independent parameters into one. Tasman Psychiatry tabulates them separately for the immediate-release preparations.

IMMEDIATE-RELEASE PREPARATION	EFFECT ONSET (MINUTES)	ELIMINATION HALF-LIFE (HOURS)	EFFECT DURATION (HOURS)
Methylphenidate	30 to 60	2 to 4	3 to 5
Dexamfetamine	30 to 60	3 to 5	4 to 6
Mixed amphetamine salts	30	3 to 5	4 to 6

The time to peak concentration is the fourth parameter and it separates the preparations least: the same table gives a time to peak of one to three hours for methylphenidate, for dexamphetamine and for the mixed salts alike. What does separate them is the pair at the right of the table. Methylphenidate has both the shortest elimination half-life, at **two to four hours**, and the shortest effect duration; the amphetamine preparations sit a step longer on both axes. That within-class ranking is the durable teaching point, and it is why immediate-release methylphenidate has needed more frequent administration than an amphetamine to cover the same waking day. Notice too that duration is not read off the half-life: for methylphenidate the tabulated effect outlasts the tabulated half-life, as you would expect of a drug whose action depends on transporter occupancy rather than plasma concentration. A half-life predicts how long a drug takes to leave the body, not how long the patient feels better, and here the second question is the clinical one.

TRAP **Quoting one methylphenidate half-life as though the standard texts agreed, and then treating that figure as the duration of action.** Two errors travel together. The first is that Tasman Psychiatry is internally inconsistent about the elimination half-life: its parameter table gives two to four hours, while the prose of the same chapter reports that methylphenidate peaks in plasma at 2 to 2.5 hours and falls to half the peak after 3 hours. This is one book disagreeing with itself, and because the prose point estimate sits inside the tabulated range, the range is the safer figure to carry into an answer. Declare the discrepancy rather than resolving it silently. The second error is the more consequential: candidates who have memorised a short half-life conclude that every methylphenidate product needs several administrations a day, which is false the moment a modified-release preparation is prescribed. Half-life belongs to the molecule; duration of action belongs to the product.

26.3 Where methylphenidate actually goes

Methylphenidate has an unusual disposition for a psychotropic, and its interaction profile falls straight out of it. The parent compound is hydrolysed at its ester group to yield **ritalinic acid**, an inactive product, and approximately 20 per cent is oxidised by the liver to secondary metabolites.

The dominant route is an esterase reaction rather than a cytochrome one, which is why this drug does not sit at the centre of the psychotropic substrate map that the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes set out.

The second peculiarity is how little of it needs to be there. Its low plasma protein binding, of about 15 per cent, makes it highly available to cross the blood-brain barrier, which is part of why relatively low plasma concentrations are effective. The comparison the source draws is striking: clinically effective oral methylphenidate produces plasma concentrations as low as 7 to 10 nanograms per millilitre, against dexamfetamine concentrations between 40 and 120 nanograms per millilitre in children with ADHD. Such a gap suggests a large **first-pass effect**, and the reported oral bioavailability has itself moved: once given in the 80 per cent range, it is placed by more recent studies close to 30 per cent. A drug largely destroyed before it reaches the circulation, which nonetheless works an order of magnitude below its comparator, is one whose plasma concentration tells you very little.

The site of that metabolism is contested inside a single book, and the honest position is to say so. Tasman Psychiatry states in prose that methylphenidate is primarily metabolised extrahepatically by **de-esterification** to an inactive metabolite, while the parameter table of the same chapter records its metabolism as hepatic, and the passage above assigns a fifth of the drug to hepatic oxidation. Teach the mechanism, not the compartment: clearance is mainly by de-esterification to inactive ritalinic acid with a minor oxidative route, and the extrahepatic claim is not settled enough to offer as though it were.

26.4 The release mechanism, not the molecule, sets the duration

Formulation is the principal therapeutic variable in this class, and it is engineering rather than chemistry. The same molecule can be built to act for a third of a working day or for the whole of one, and the design that achieves it is stated on the product, not deduced from the drug. Tasman Psychiatry maps the **release mechanism** of each preparation onto the duration it buys.

PREPARATION	MECHANISM OF DRUG RELEASE	DURATION OF ACTION (HOURS)
Mixed amphetamine salts	Single pulse	4 to 6
Mixed amphetamine salts, long acting	Two pulses	8 to 10
Methylphenidate, sustained release	Wax matrix	3 to 8
OROS methylphenidate	Three pulses	10 to 12
Transdermal methylphenidate patch	Transdermal	10 to 12
Lisdexamfetamine	Delayed single pulse	Up to 12

Read down the duration column. One pulse delivers a single bolus and buys the shortest cover; two pulses buy roughly double; three pulses, or a transdermal system that bypasses the gut and releases continuously, buy the longest. The wax matrix is the outlier: its band is the widest of any

design here, so such a product is the least predictable and the least suitable when the timing of cover matters. The prodrug reaches a long duration by another route, its delay being metabolic rather than physical.

PITFALL

Switching a patient between two preparations of the same drug on total daily dose alone. Methylphenidate is not one product but several, and the tabulated durations of a wax-matrix and an osmotic three-pulse preparation do not overlap at their extremes. A switch made on the drug name changes the shape of the day even when the total dose is unchanged, and the complaint that follows is usually loss of afternoon efficacy or a new evening problem, neither a failure of the molecule. Name the preparation, not just the drug, on every prescription and in every handover note.

26.5 Why speed, and not the molecule, is the abuse variable

The pharmacology of diversion is the core of this topic, and it is a story about rate. Tasman Psychiatry records that the slow reversal of methylphenidate binding to the dopamine transporter has been interpreted to mean that methylphenidate is not as reinforcing as cocaine, and is therefore less likely to lead to self-administration, even though therapeutic oral doses significantly increase extracellular dopamine. That last clause is the part candidates miss. The dopamine rises; reinforcement does not follow, because it tracks how abruptly occupancy changes rather than how much transmitter is present.

Stahl's Essential Psychopharmacology generalises the principle into a class statement, and flags it throughout as hypothetical. Extended-release oral stimulants, the transdermal methylphenidate patch and the prodrug lisdexamfetamine are considered **slow-dose stimulants**: three quite different pieces of engineering converging on one kinetic result.

- an oral extended-release system, which meters the drug out of the tablet;
- a transdermal patch, which meters it through the skin and never presents a gut bolus at all;
- a prodrug, which meters it by requiring an enzymatic step before any active drug exists.

The shared mechanism is regional. These preparations occupy noradrenaline transporters in the prefrontal cortex with slow enough onset, and for long enough duration, to enhance tonic signalling, but they do not occupy dopamine transporters in the nucleus accumbens quickly or extensively enough to increase **phasic signalling** at D2 receptors, and it is that failure to drive the accumbens phasically that hypothetically reduces abuse potential. Tonic cortical signalling is what the therapeutic effect is thought to need, phasic accumbens signalling is what reinforcement needs, and formulation supplies the first while withholding the second.

Lisdexamfetamine is the purest expression of the idea. It is a **prodrug** in which dexamfetamine is complexed with the amino acid lysine and is inactive in that form, and it is broken down in red blood cells so that dexamfetamine is gradually made available, which is why it is unlikely to be abused for recreational or dependency-driven purposes. Because the rate-limiting step lives inside the erythrocyte rather than the capsule, crushing, snorting or injecting the contents

defeats nothing: the route changes, the conversion step does not. The source applies the same practical logic to extended-release methylphenidate preparations.

RULE **Abuse liability in this class is set by the rate and the site of transporter occupancy, not by the identity of the drug or by the amount of dopamine released.** Every fact in this section applies that one sentence. Therapeutic oral methylphenidate raises extracellular dopamine and is still poorly reinforcing, because its binding to the transporter reverses slowly. A modified-release and an immediate-release preparation of the same molecule carry different risk, differing in nothing but rate. A prodrug is safer than its own active metabolite, because a conversion step is inserted between the mouth and the accumbens.

MNEMONIC

Slow in, long on, cortex not accumbens

Slow in: the onset must be gradual, which is what every extended-release, transdermal and prodrug design is engineered to achieve. **Long on**: occupancy must be sustained rather than spiky, because tonic signalling is what the therapeutic effect requires. **Cortex not accumbens**: the transporters to occupy are the noradrenaline transporters of the prefrontal cortex, not the dopamine transporters of the nucleus accumbens.

26.6 The regulatory expression of a kinetic fact

Regulation follows the pharmacology, and the examinable content is the reasoning rather than the schedule. The Maudsley Prescribing Guidelines record that both methylphenidate and dexamfetamine are Schedule 2 Controlled Drugs in the United Kingdom, that prescriptions should be written appropriately, with the total amount in words and figures, and that they should cover **a maximum supply of 30 days**. The same source makes a within-class discrimination worth carrying: dexamfetamine is probably more likely than methylphenidate to be diverted and misused. The source states the ranking without giving a mechanism, so carry it as an empirical comparison rather than as something deduced from the kinetics above, and comparative rather than a licence to regard methylphenidate as safe.

The scheduling quoted here is one jurisdiction's and should be labelled as such whenever it is used. The corresponding Indian position, the schedule these drugs occupy in Indian law and the prescription requirements that follow, is not established in the sources behind this section and is deliberately not asserted; take it from current Indian statute and current drug-controller requirements, which change more often than pharmacology does. What transfers across jurisdictions is the underlying claim: a preparation is regulated because of how fast it reaches the brain, so a preparation engineered to reach the brain slowly is making a regulatory argument as well as a therapeutic one.

26.7 Atomoxetine: the negative control for the whole argument

Atomoxetine is best taught as the experiment that isolates the variable. KDT Essentials of Medical Pharmacology defines it precisely: a **selective noradrenaline reuptake inhibitor**, unrelated to amphetamine and to imipramine, which does not enhance dopamine release in the brain, and is neither a central nervous system stimulant nor an antidepressant. Every element of

that definition works. It is not an amphetamine derivative, so structural analogy predicts nothing. It is not a tricyclic, so that class's receptor promiscuity does not apply. And it is not an antidepressant despite inhibiting a monoamine transporter, a useful reminder that mechanism does not confer class membership.

How it avoids being reinforcing is a matter of regional anatomy. Stahl's Essential Psychopharmacology explains that by blocking noradrenaline transporters, atomoxetine raises both noradrenaline and dopamine in the prefrontal cortex, where the inactivation of both transmitters is largely by those transporters, while the relative lack of noradrenaline transporters in the nucleus accumbens prevents it from raising either transmitter there, and that regional difference reduces the risk of abuse. This is the slow-dose argument by another road: the stimulant preparations avoid the accumbens by being slow, atomoxetine because the transporter it blocks is scarce there. Other noradrenaline transporter inhibitors would be expected to have the same effects.

Its disposition introduces the topic's one pharmacogenetic variable. Atomoxetine is absorbed orally, hydroxylated by CYP2D6 and excreted in the urine mainly as the glucuronide, and while the majority of individuals are extensive metabolisers, a few are **poor metabolisers** because of polymorphism of CYP2D6. The enzymology belongs to the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes, and co-prescription with a CYP2D6 inhibitor to the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes. What belongs here is the class-level consequence: a drug cleared through a polymorphic enzyme has a wider spread of exposure across a population than one cleared by an esterase.

The clinical headline is the timescale. The Maudsley Prescribing Guidelines give the time to effect for atomoxetine as **approximately four to six weeks**, and note in the same breath that it is not a controlled drug and may be useful where the diversion of stimulants is a problem. Held against an oral stimulant working inside the first half hour, that is an enormous gap in time to effect between two drugs given for the same purpose, and it is the comparison most likely to be examined here.

TRAP **Treating atomoxetine as a slow stimulant, and abandoning it early because nothing has happened.** The stem describes a patient started on atomoxetine who is unchanged after a fortnight, and offers a switch or a dose increase as the tempting answer. Both are premature. A stimulant declares itself the same day, so an unhelpful stimulant trial is over quickly; a noradrenaline reuptake inhibitor is assessed over weeks, and the quoted interval has not elapsed. The deeper version is classificatory: candidates who file atomoxetine under stimulants expect it to carry stimulant liability, and are then unable to explain why it is the agent recommended where diversion is the problem.

GOOD TO REMEMBER

Three questions convert this section into a prescribing conversation. What does the day need to look like, which is a question about effect duration and therefore about the release mechanism rather than the drug name. What happens to the tablets between the clinic and the patient, which kinetics answers: a prodrug or a patch where supervised immediate-release dosing cannot be guaranteed. And how long is everybody prepared to wait, because a family told that timescale in advance behaves very differently from one told nothing.

In this class the kinetics are the pharmacology: onset, effect duration and half-life are separate numbers that must never be substituted for one another, the release mechanism rather than the molecule sets how long a preparation works, and both the therapeutic effect and the abuse liability follow from how fast and where transporter occupancy changes, which is why a prodrug, a patch and a non-stimulant reuptake inhibitor all reduce diversion risk by the same argument.

Consolidate and apply

27 · Worked vignettes

A pharmacology vignette asks what the drug is doing, not what the diagnosis is. The examiner rarely asks a candidate to define a receptor. Far more often a short stem describes a patient already on treatment, or about to start it, plants one pharmacological fact, and waits to see whether the candidate reasons from it. That planted fact is almost always one of four things: a binding profile, an elimination half-life, an enzyme that some other drug has just inhibited or induced, or a margin between the concentration that works and the concentration that harms. This closing section teaches no new agent and no new class. It rehearses the pharmacology assembled across this chapter as a reading skill, moving from a paragraph of history to the mechanism that explains it.

The discipline that earns marks here is resisting the reflex to answer with a treatment algorithm. A stem that describes a patient whose sedation is intolerable is not asking which antipsychotic treats schizophrenia; it is asking which receptor family the current agent occupies and what a within-class move would change. Where a stem genuinely asks which drug to choose for a disorder, the reasoning belongs to that disorder's own chapter, and the antipsychotic and antidepressant selection decisions are set out in the Schizophrenia: management, antipsychotics and adverse effects notes and the Mood disorders: pharmacotherapy notes respectively. What this chapter supplies, and what a good vignette answer uses, is the layer underneath those decisions.

27.1 Four questions read almost any pharmacology stem

Before deciding what a stem is asking, run the same four questions across it. They are the four axes on which psychotropic agents actually differ, and between them they account for most of the

discriminating information an examiner can plant in a short paragraph.

Binding	Duration	Company	Margin
WHAT IT OCCUPIES	HOW LONG IT LASTS	WHAT ELSE IS ON BOARD	HOW MUCH ERROR IT FORGIVES

Binding asks which receptors and transporters the agent touches and with what relative affinity, because a drug's unwanted effects are largely the affinities that were not the point of prescribing it. Duration asks how long the drug persists, which governs how quickly it accumulates, how forgiving it is of a missed dose, and how quickly anything at all can be judged. Company asks what else the patient is taking, including the drugs a psychiatrist did not prescribe and the habits that behave like drugs, because a concentration can move without anyone changing the prescription. Margin asks how much distance sits between a useful concentration and a harmful one, which decides whether the drug can be managed by clinical judgement alone or needs a measured level. The single feature a stem plants to make one of these questions decisive is its **pharmacological discriminator**, and well-written stems are built around exactly one.

RULE **In a pharmacology stem, the answer is the mechanism, not the diagnosis.** If your answer to a stem in this territory can be written without naming a receptor, a half-life, an enzyme or a therapeutic margin, you have almost certainly answered the wrong question. The diagnosis in the stem is usually scenery: it tells you which class the patient is on, and nothing more. What earns the marks is the pharmacological property that makes this patient's problem inevitable and the within-class or within-schedule move that follows from it.

27.2 The vignette that resolves on a binding profile

The commonest stem in this territory describes a patient who is responding to treatment but cannot tolerate it. She is sedated all morning, or has gained weight steadily, or feels her heart racing when she stands, or has a dry mouth and constipation, or has developed galactorrhoea, or cannot sit still. Every one of those complaints is a receptor being occupied, and the reading move is **reverse inference**: take the symptom the patient reports, ask which receptor family generates it, then ask whether the prescribed agent has meaningful affinity there. The full map from binding profile to predicted adverse effect is developed in its own right within this chapter, and the biochemistry of the transmitter systems underneath it belongs to the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes.

What makes the stem answerable rather than merely descriptive is that the receptor families cluster into recognisable symptom groups. Histaminergic and cholinergic occupancy produce one kind of complaint, adrenergic occupancy another, dopaminergic occupancy a third, and the serotonergic actions a fourth. Once the symptom has been mapped back to a family, the answer is a within-class move to an agent whose affinity at that family is lower, not a change of class and not a change of diagnosis. That is why the comparative profiles assembled elsewhere in this chapter are worth learning as a ranked shape rather than as a list of drugs: the vignette is asking you to substitute along one axis while holding the others.

TRAP **Treating members of a class as interchangeable because they share a label.** Candidates who have learned the classes as boxes will answer that any agent in the box will do, and lose the mark. Agents within a single class differ in what else they bind, how long they last and which enzymes clear them, and those differences are precisely what the stem is testing. **Binding promiscuity** is the reason two drugs with the same primary mechanism produce entirely different complaints, and the reason a within-class switch is a real therapeutic manoeuvre rather than a cosmetic one.

27.3 The vignette that resolves on a half-life

A second family of stems turns entirely on how long the drug stays. The patient misses a few doses and becomes unwell in a characteristic way; or stops the drug abruptly and develops symptoms that could be relapse or could be discontinuation; or has a level checked soon after a dose change and the clinician acts on it; or is switched from one agent to another and something goes wrong in the overlap. In every case the discriminator is the elimination half-life and the accumulation that follows from it, developed in full among this chapter's pharmacokinetic principles, with the underlying kinetic derivations in the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes.

Three consequences do most of the work in vignettes. A drug that is eliminated slowly buffers itself: missed doses matter less, the plasma concentration changes gradually, and symptoms on stopping are muted and delayed, so a picture arising soon after cessation is more likely to be something other than withdrawal. A drug eliminated quickly does the opposite, producing interdose symptoms, an abrupt **offset** and a withdrawal picture that arrives fast. And accumulation takes several half-lives whatever the drug, which means any judgement made before the concentration has plateaued, whether clinical or laboratory, is a judgement about a moving number. The interval a clinician must leave empty between stopping one agent and starting another, the **washout**, is the same arithmetic used in the opposite direction, and it is the reason some switches are simple and others are not.

PITFALL

Sampling a drug level before the concentration has plateaued, and then changing the dose on the result. A level drawn too early after starting or after a dose change is not a steady-state level, it is a point on a rising curve, and treating it as though it were the patient's true exposure leads to a dose increase in a patient who was already on their way to an adequate concentration. The same error in reverse explains apparently unstable levels in a patient whose adherence is intermittent. The remedy is arithmetic, not repetition: know the drug's half-life, know when the plateau is due, and sample against it.

27.4 The vignette that resolves on an enzyme

The third family of stems is the one where nothing about the psychotropic prescription changed and the patient changed anyway. A physician added an antimicrobial or an antifungal; a cardiologist started something new; the patient bought a herbal preparation over the counter; the patient stopped smoking on admission to a ward where smoking is not allowed. Then a drug that had been tolerated for months becomes toxic, or a drug that had been working stops working, and the stem waits to see whether the candidate looks past the psychiatric drug list.

The direction of reasoning is simple and it is worth having automatic. An added inhibitor reduces the clearance of a substrate, so the substrate's concentration rises, and it rises promptly, because inhibition acts at an enzyme that is already present. An added inducer increases the amount of enzyme, so the substrate's concentration falls, and it falls with a lag, because new enzyme has to be synthesised, and it recovers over a comparable but somewhat longer interval when the inducer is withdrawn, the figures for both directions being carried by this chapter's cytochrome P450 section. That asymmetry of tempo is itself a discriminator: an abrupt deterioration points toward inhibition, a loss of effect that develops over days rather than hours toward induction. The clinically important variant is **phenoconversion**, in which a patient with entirely normal metabolic capacity is turned by a co-prescribed inhibitor into the functional equivalent of a poor metaboliser. The psychotropic substrate map itself is developed within this chapter; the interaction matrix spanning several classes at once belongs to the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes.

GOOD TO REMEMBER

When a stable patient destabilises, date the change against the whole drug list, not the psychiatric one. Ask what a non-psychiatric colleague started or stopped, what the patient bought without a prescription, and whether tobacco use changed, because admission to hospital silently removes an inducer from many patients. A symptom whose onset lines up with a change somewhere else in the list is an interaction until proved otherwise, and the question that resolves it is which enzyme both drugs share.

27.5 The vignette that resolves on the margin

Some stems are constructed so that the pharmacology is unremarkable except for one property: the drug has very little distance between the concentration that treats and the concentration that harms. Then a modest kinetic disturbance, one that would be trivial for a forgiving drug, carries the patient across the line. A **narrow therapeutic index** is what converts an ordinary intercurrent illness, a change in fluid balance, or a new co-prescription into a toxic presentation, and it is the single property that justifies routinely measuring a concentration at all. This chapter develops the index itself, and which psychotropics need a measured level, as a principle; the target concentrations, and the monitoring framework built on them, belong to the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes.

The reading move is to notice that the stem has told you about the patient's physiology rather than about the psychiatry. Anything that alters volume status, reduces renal clearance or competes for the elimination route will move the concentration of a narrow-index drug while the prescription stays identical, and for a drug with a wide margin the same events pass unnoticed. Which precipitants matter for which agent is developed within this chapter's sections on the narrow-index drugs, and the answer a stem wants is rarely to stop the drug reflexively; it is to name the kinetic precipitant, state that the concentration will have moved, and act on that. Toxic presentations themselves, and the psychotropic emergencies more broadly, are recognised and managed under the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes.

27.6 The vignette that resolves on intrinsic activity

A subtler stem describes a patient in whom a drug was added and something got worse rather than better, or in whom two agents acting on the same system produced an effect neither would have produced alone. The property being tested is **intrinsic activity**: whether the agent at a given receptor is a full agonist, a partial agonist, a plain antagonist or an inverse agonist. A partial agonist behaves in opposite directions depending on what the receptor is already seeing, damping the system where tone is high and supporting it where tone is low, which is why adding one to a patient already maintained on a full antagonist can produce an apparent loss of effect. This chapter teaches partial agonism as a prescribing variable in full, and the receptor theory beneath it belongs to the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes.

The same reasoning explains a second stem shape, in which an agent modulates the action of an endogenous ligand rather than blocking it, so its behaviour depends on the state of the system rather than on the dose alone. With this axis in hand, the question is not how much drug is present but what the receptor was doing before it arrived.

27.7 The vignette that resolves on tempo

When a problem starts is often more informative than what it looks like. Adverse effects have characteristic latencies, and the **latency** a stem specifies is frequently the discriminator that assigns the phenomenon to a mechanism. Something that appears within hours of a first exposure, before any accumulation has occurred, is a direct pharmacodynamic effect of occupancy. Something that emerges over the first weeks, as the concentration plateaus and adaptive changes begin, is typically dose-related and often modifiable by dose. Something that appears only after months or years of continuous exposure implies receptor adaptation rather than occupancy alone, and is the tempo of the late movement disorders whose spectrum this chapter develops in full. Something whose onset bears no relation to dose or duration at all is **idiosyncratic**, and cannot be titrated around.

Tempo also separates the two commonest look-alikes in this whole territory. Symptoms that appear within a short and predictable interval of stopping a drug, an interval read against that drug's half-life, and that resolve when the drug is reinstated, are a withdrawal or discontinuation phenomenon. Symptoms that appear later, at a remove the kinetics do not account for, and that do not remit promptly on reinstatement, are relapse. Do not separate them by what they look like. Where a drug was prescribed for the very state it suppresses, withdrawal reproduces the original presentation almost exactly, a trap the benzodiazepine section works through in detail. The discrimination is kinetic and pharmacological: the interval from cessation, and the response to reinstatement. Where the phenomenon is a substance use disorder in its own right rather than a pharmacological adaptation, the assessment and treatment belong to the Substance use disorders notes, and the clinical use of the anxiolytics and hypnotics belongs to the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes.

27.8 Look-alike stems and the reading spine

Consolidation is easiest as pairs. The table sets out the stems most often confused, against the property that separates them and the axis the reasoning lands on.

TWO STEMS THAT LOOK ALIKE	THE PHARMACOLOGICAL DISCRIMINATOR	THE AXIS IT LANDS ON
Symptoms soon after stopping a drug against symptoms emerging later, the two pictures looking much alike	Interval from cessation, and whether reinstatement resolves it	Half-life and offset
Loss of effect over weeks against abrupt toxicity in a stable patient	Whether the added agent induces or inhibits	Enzyme interaction
Intolerable sedation against intolerable restlessness on the same class	Which receptor family the agent occupies most avidly	Binding profile
An apparently unstable drug level against a genuinely rising one	Whether the sample was drawn at plateau	Accumulation kinetics
Toxicity after an intercurrent illness against toxicity after a dose increase	Whether a kinetic precipitant altered clearance	Therapeutic margin
Worsening after adding a second agent to an established one against worsening on the first alone	Full antagonism against partial agonism at the shared receptor	Intrinsic activity
An adverse effect present from the first exposure against one emerging after prolonged treatment	Latency, and its relation to dose	Tempo of onset

MNEMONIC

What it binds, How long it lasts, Alongside what else, Tolerance of error

The four questions to run across any pharmacology stem: **W**hat does the agent bind, and with what relative affinity; **H**ow long does it last, and has it reached plateau; **A**longside what else is the patient taking, prescribed or not; and what **T**olerance of error does the drug allow between a useful and a harmful concentration. They spell WHAT, which is the question the stem is really asking, and each one is a door to a different section of this chapter.

With the discriminator identified, a marks-winning answer follows four moves in order.

- Name the pharmacological property the stem has planted, in pharmacological language.
- State the mechanism that connects that property to the patient's problem.
- Choose the move that acts on that mechanism: a within-class substitution, a change of interval or schedule, a washout, or a measured concentration.

- Say explicitly what you would not do, and why the obvious algorithmic answer does not address the mechanism.

That final move is where the pharmacology becomes visible to an examiner. A candidate who says the drug should be stopped has answered a question about a patient; one who says it should not, because the problem is an inhibitor that will wash out or a withdrawal effect that reinstatement will resolve, has answered a question about pharmacology. Every vignette here rewards the second answer, worked from the four axes without a treatment algorithm.

> In a pharmacology vignette, identify the property the stem has planted - binding, duration, company or margin - and answer with the mechanism it implies, not with a treatment algorithm.

28 · Consolidation and quick review

Every class in this chapter holds several agents that share a mechanism and differ in what they cost the patient. That sentence is the chapter compressed. Each class was assembled around one shared action: blockade of the dopamine receptor, inhibition of monoamine reuptake, potentiation of the inhibitory chloride channel, inhibition of the metabolising enzyme. The shared action makes the agents members of a class and explains why they work at all. Everything else about them, what else the molecule binds, how long it stays in the body, and how much room lies between the exposure that helps and the exposure that harms, is where the members separate. A reader who knows the class knows why the drugs work and still cannot say which of them to give.

This closing section teaches no new agent, because every drug has already been taught in the section that owns it. What remains is to state the argument those sections were arranged to make, and to convert it into something that can be produced from a blank page. The argument is that **within-class selection** is a prediction rather than a preference: given a drug's binding profile, its handling by the body and the width of its safety margin, most of what separates it from its neighbours in the same class can be worked out before any of it is observed in a patient. The pharmacology needed to make that prediction is small, finite, and the same for every class here.

28.1 One argument, tested five times

The chapter moves through receptor and kinetic principles, then the antipsychotics, the antidepressants, the mood stabilisers, and the anxiolytics, hypnotics and remaining agents. Read as five territories they are a long list to be survived. Read as one argument they are a single claim tested five times, and the claim is that the difference between two members of a class is generated by pharmacology that can be stated in advance. The principles are not an introduction to the four drug bands; they are the instrument those bands are read with.

The claim has a testable shape, which is what makes it worth holding. Take two agents from one class and set out, for each, what it binds beyond the shared target, how quickly it is cleared and by what route, and how much distance lies between the dose that works and the dose that harms.

Those three statements anticipate most of what the patient reports, most of what the prescriber has to manage, and most of the practical difference in how the two drugs are started, stopped and exchanged. What they do not anticipate is which agent a unit happens to stock, or which one the reader saw used most often as a junior, and those two considerations decide a great many real prescriptions.

Each pairwise difference runs along a **separating axis**: one pharmacological property on which the members of a class can be ranked against each other. The axes are few and they recur. Sedation, weight, prolactin and movement liability rank the antipsychotics. Half-life, enzyme inhibition and binding beyond the transporter rank the antidepressants. Index width, elimination route and reproductive risk rank the mood stabilisers. Receptor subunit selectivity and half-life rank the hypnotics. Naming the axis rather than the drug converts a remembered preference into a defensible choice.

RULE **The shared mechanism explains the effect; everything that separates the members of a class is a side action, a kinetic difference or a margin.** Establish what two agents have in common only to confirm they belong to the same class. The clinical question is always what they do not share, and that question has a small and recurring set of answers.

28.2 Five questions asked of every agent

Because the separating axes recur, a single **retrieval card** serves the whole chapter. Rather than storing each agent as an unstructured block of facts, the reader learns one set of prompts and answers them for the drug in hand, which reduces the memory load and guarantees that no limb of an answer is dropped under time pressure. They spell CLASS, which is the level this chapter works at and the level at which an answer here should be pitched.

MNEMONIC

Clearance, Ligand behaviour, Adverse-effect signature, Safety margin, Selection

For any agent in any class, retrieve: **C**learance, meaning the half-life, the route of elimination and the enzymes that handle the drug; **L**igand behaviour, meaning whether the molecule acts as a full agonist, an antagonist, a partial agonist, a reuptake inhibitor or an enzyme inhibitor, and whether that action is reversible; **A**dverse-effect signature, meaning what else the molecule binds and therefore what the patient will report; **S**afety margin, meaning the distance between the exposure that treats and the exposure that harms; and **S**election, meaning the within-class choice that all four preceding answers were gathered to justify. Read together they spell CLASS, which is exactly the level this chapter teaches.

The card is built out of constructs the chapter has already supplied, so nothing in it has to be learned separately. Its value is that it disciplines an answer. A reader who has produced all five prompts for the agent in front of them has generated a structured response: how the drug is handled, what it does at the receptor, what the patient will feel, how much room for error exists,

and what follows for the choice. An examiner reads that as pharmacological reasoning rather than as recall of a list.

Binds	**Stays**	**Margin**	**Chooses**
WHAT ELSE IT TOUCHES	HOW LONG IT LASTS	ROOM BEFORE HARM	THE AGENT THAT FOLLOWS

28.3 What each question actually predicts

The card is only useful if each prompt is attached to the decision it settles, because a prompt that returns a fact without a consequence is one more thing to memorise. Set out this way, the four pharmacological questions each buy a different practical answer and the fifth is the answer itself. The table is a retrieval index rather than a teaching table: the full account of each property lives in the section that owns it.

THE PROMPT	WHAT THE ANSWER PREDICTS	WHERE MEMBERS OF A CLASS DIVERGE
Clearance: half-life, elimination route, metabolising enzyme	Dosing interval, time to a steady concentration, whether a measured level means anything yet, how abruptly the drug may be stopped, and how a switch is staged	Agents sharing a mechanism still differ on stopping and on switching, because the shorter-acting member falls away faster
Ligand behaviour: agonist, antagonist, partial agonist, reuptake inhibitor, enzyme inhibitor, and reversibility	Whether the effect has a ceiling, how the system behaves on withdrawal, and whether one molecule can look stimulating in one state and blocking in another	A partial agonist and a full antagonist at the same receptor share a class and are not interchangeable
Adverse-effect signature: what else the molecule binds	The symptoms the patient will report, anticipated before any appear, and the tolerability conversation held before the first prescription	Promiscuous binding predicts a broad adverse-effect signature; a cleaner profile predicts a narrower one at the same efficacy
Safety margin: distance between effective and toxic exposure	Whether the drug is titrated to clinical effect or to a measured concentration, and how much a small change in fluid balance or renal handling matters	A narrow margin makes an ordinary event dangerous where a wide margin absorbs it
Selection: the member that fits this patient	The actual prescription, defended by the four answers above rather than by habit	This is the output, not another property to memorise

Worked in both directions, given an agent produce its properties and given a property produce the agents at either end of it, the index becomes a network rather than a sequence.

28.4 Retrieve across the classes, not down one

A chapter learned in the order it was read is fragile, because recall then depends on starting at the top of a class and running down it. Durable retrieval comes from asking the same question of every class in turn, which is **interleaved retrieval**: deliberately mixing the classes during practice

instead of drilling one to exhaustion. It feels slower than working through a single class at a time, and that difficulty is why it works, because it trains the discrimination a stem actually tests.

Two prompts are worth interleaving across all five sub-areas. The first is the separating axis. The second is the **class-defining hazard**: the adverse consequence characteristic of the whole class rather than of one member, which therefore has to be considered whenever any member is prescribed. Together they explain both why a class is used and why choosing carelessly inside it has consequences.

CLASS	WHAT SEPARATES THE MEMBERS	THE CLASS-DEFINING HAZARD
Antipsychotics	Sedation, weight, prolactin and movement liability, each read off the binding profile rather than off the older typical and atypical labels	Movement disorder from dopamine blockade, and metabolic burden from the wider binding profile
Antidepressants	Half-life, inhibition of the metabolising enzymes, and how much the molecule binds beyond its intended transporter or enzyme	Disturbance on stopping, which tracks the half-life, and interaction risk, which tracks enzyme inhibition
Mood stabilisers	Width of the therapeutic index, route of elimination, whether the agent induces its own metabolism, and reproductive risk	Toxicity in a narrow-index agent, and harm to a developing fetus with the agents that carry it
Anxiolytics and hypnotics	Receptor subunit selectivity and half-life, which together set both the daytime residue and the rebound	Tolerance, dependence and withdrawal as pharmacological consequences of sustained receptor exposure
Stimulants and the non-stimulant agents	Speed of onset, duration of action, and what the formulation does to the concentration curve	Misuse and diversion, which follow rapidity of onset rather than the molecule alone

As a drill this means posing the class as the question and producing the axis and the hazard from memory, then reversing it: given an axis, name the class it ranks; given a hazard, name the receptor action that generates it. That movement, from a mechanism to its consequences and back, is what a viva is built to elicit.

28.5 The failure mode this chapter exists to correct

Set against the pharmacological method is the alternative most prescribing actually runs on, the **familiarity heuristic**: choosing the agent one has used before, seen used, or been taught by whoever supervised the first ward. Familiarity is not worthless, since a drug the prescriber knows well is monitored better than one they do not. It is simply not a reason, and it cannot be defended when the choice turns out badly. The remedy is not to abandon experience but to state the axis experience was tracking.

The examination version of the same failure is answering a within-class question with a name instead of a property. The stem describes a patient who cannot tolerate sedation, or who is

unlikely to attend for a blood test, or in whom a missed dose is likely; the answer that scores states the axis first and reaches the agent second. The antidote is **cold retrieval**, producing the card from a blank page with the book closed rather than reviewing an answer already written, because recognising a correct choice on the page is a far weaker skill than generating one from a bare stem.

TRAP **Answering a within-class question with a drug name instead of the property that selects it.** Candidates do this because the name is what they revised and because it feels decisive. The examiner is testing whether the choice can be derived, so an answer that names the separating axis and then lands on an agent earns marks an unsupported name does not, even when both arrive at the same drug.

PITFALL

Switching within a class and expecting the troublesome adverse effect to disappear, when the two agents share the binding that generated it. A switch is worth making only when the profiles genuinely differ on the axis causing the problem; where they do not, the patient endures a second titration and arrives at the same complaint. Before any within-class switch, state which property is expected to change and by what mechanism. If that sentence cannot be completed, the switch is being made on familiarity.

28.6 Where this chapter stops

Consolidating a chapter includes consolidating its edges, because a disciplined answer is defined as much by what it hands over as by what it teaches. The **handover boundary** matters unusually here, since the systematic pharmacology of a class sits beside several chapters that treat the same drugs from a different angle. Each of the following should be retrieved as an interface: named where it touches the question, handed to its owner, and left there.

- The underlying science of receptor theory, the kinetic equations and the enzymology of drug metabolism belongs to the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes; this chapter uses those principles as instruments rather than deriving them.
- Choosing and managing an antipsychotic for a patient with a psychotic illness, including the management of movement disorder in that setting, belongs to the Schizophrenia: management, antipsychotics and adverse effects notes.
- Choosing an antidepressant or a mood stabiliser for a depressive episode or for bipolar disorder, and the clinical monitoring that goes with it, belongs to the Mood disorders: pharmacotherapy notes.
- The clinical use of anxiolytics and hypnotics belongs to the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes, while sedative dependence as a diagnosable disorder, with its assessment and detoxification, belongs to the Substance use disorders notes.
- Indication-specific dosing for attention deficit hyperactivity disorder belongs to the ADHD and specific learning/communication disorders notes; the antiepileptic lens on the

anticonvulsant mood stabilisers belongs to the Epilepsy and psychiatry notes; and the cognitive enhancers as treatments belong to the Dementias and neurocognitive disorders notes.

- Interactions spanning classes, prescribing in physical illness and in pregnancy, monitoring schedules running across psychotropics, therapeutic target ranges, and the drug emergencies all belong to the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes.

Retrieved as a rehearsed set, the boundary supplies a ready-made handover sentence: name the neighbouring construct, say why it matters to the case in front of you, point to where it is taught, and return to the pharmacological question actually asked.

28.7 Weighting the comparison to the practice you will work in

Not every within-class comparison carries the same weight at the bedside you will actually stand at. Consolidation is finite, so the last allocation decision is where to spend the retrieval that remains. Weight it toward the comparisons that recur locally and the agents genuinely available to prescribe, rehearsing those pairs until the axis separating them comes without effort, and let rarely used agents sit at lower priority.

IN INDIA

Two pharmacogenetic differences taught in the sections that own them change a within-class decision on Indian ground, and both should be retrieved as decisions rather than as facts. Where a variant that slows clearance is documented as common in Asian populations, the decision is to open at the lower end of the range and titrate against response rather than to start at a standard dose and react to the adverse effect afterwards. Where a genetic test is recommended before a specific anticonvulsant is started in people of South-East Asian ancestry, the decision is to test before prescribing rather than after a reaction has occurred. Both remain within-class decisions, because in each case a differently handled member of the same class stays available.

28.8 Carrying the frame into the examination

If cold retrieval is the engine, **spaced retrieval** is the schedule that makes it last: returning to a class after a deliberate gap rather than in one continuous block. A memory retrieved just as it begins to fade is strengthened more than one retrieved while still fresh, so letting a class cool between attempts is a feature of the method rather than neglect. Across a revision period the gaps before returning to a secure class lengthen while a shaky one is brought forward, which concentrates limited hours on the gaps the reader actually has.

GOOD TO REMEMBER

Finish every within-class decision with a spoken sentence: this agent rather than that one, because of this property, at this cost. Said aloud in clinic it exposes a choice made on familiarity in a way that thinking it silently does not, and the same sentence is the one that earns marks in a viva. A decision that cannot be finished in that form has not yet been made pharmacologically.

Carried into the examination, the chapter collapses to a sequence that survives when detail fails. Identify the class from the mechanism, run the card for the agent in question, name the axis that separates the members, and state the class-defining hazard that constrains all of them. What consolidation buys is not more facts but faster and more reliable access to the facts already learned, so that under pressure the pharmacology arrives as a method rather than as a set of half-remembered associations about individual drugs.

> Within a class the mechanism is shared, so the choice is made from what differs: what else the agent binds, how fast it clears, and how much room lies between the exposure that helps and the exposure that harms.

Sources and further reading

Every dose, threshold, half-life and frequency in this chapter is grounded in one of the works below; where two sources set different figures, both are named in the text as a conflict rather than reconciled. Rating scales and monitoring instruments are described and cross-referred, never reproduced. Editions and publication years here were read from each work's own title and copyright pages rather than recalled.

Taylor DM, Barnes TRE, Young AH.
The Maudsley Prescribing Guidelines in Psychiatry. John Wiley and Sons. The 15th edition, first published 2025, is the chapter's principal prescribing source; the 14th edition, first published 2021, is retained where it carries a statement the 15th drops. The Maudsley Deprescribing Guidelines, first published 2024, is the source for withdrawal and tapering.

Sadock BJ, Sadock VA, Ruiz P.
Kaplan and Sadock's Comprehensive Textbook of Psychiatry. Eleventh edition, Wolters Kluwer, 2025. The principal reference across the chapter: receptor pharmacology, the antipsychotic and antidepressant classes, and the mood stabilisers. Its India chapter is cited separately where local prescribing practice is at issue.

Stahl SM.
Stahl's Essential Psychopharmacology: Neuroscientific Basis and Practical Applications, and the companion Prescriber's Guide, seventh edition, Cambridge University Press, 2021. Receptor mechanism and the profile-to-effect reasoning that organises this chapter.

Meyer JM, Stahl SM.
Stahl's The Clozapine Handbook, Cambridge University Press, first published 2020; and The Lithium Handbook, Cambridge University Press and Assessment, first published 2023. The two single-drug monographs behind the clozapine and lithium sections.

Brunton LL, Knollmann BC (Goodman and Gilman).
Goodman and Gilman's The Pharmacological Basis of Therapeutics, fourteenth edition. Receptor theory, dose-response and the therapeutic index as pharmacology rather than as prescribing. The publisher and year are deliberately not printed: the parsed copy held in this project has no title page and no copyright page, so neither could be read from the record, and neither is stated here from memory.

Tripathi KD.
Essentials of Medical Pharmacology. Eighth edition, Jaypee Brothers Medical Publishers, 2019. The pharmacology reference in widest use in Indian training, cited for class mechanism and for agents whose Indian use differs from the Western default.

Johnstone EC, Owens DGC, Lawrie SM, et al.
Companion to Psychiatric Studies. Eighth edition, Elsevier, Churchill Livingstone imprint, 2010. Class structure and the comparative pharmacology of the antidepressants.

Tasman A, Kay J, Lieberman JA, et al.
Tasman's Psychiatry. Fourth edition, John Wiley and Sons, first published 2015. Comparative within-class parameters, including the stimulant duration-of-action table.

Martin A, Bloch MH, Volkmar FR (Lewis).
Lewis's Child and Adolescent Psychiatry: A Comprehensive Textbook. Fifth edition, Wolters Kluwer, 2018. Cited for pharmacokinetic principle and for the stimulant pharmacology this chapter teaches at class level.

Indian Psychiatric Society.

Also cited, in single passages.
Practical Psychopharmacology: Clinical Topics in Psychology and Psychiatry; the Shorter Oxford Textbook of Psychiatry; Stahl's Substance Use; and The Maudsley Prescribing Guidelines for Mental Health Conditions in Physical Illness. Each grounds one or two claims only, and each is named here by title alone because its edition and publisher were not read from the copy held in this project.

PART VIII

VIII

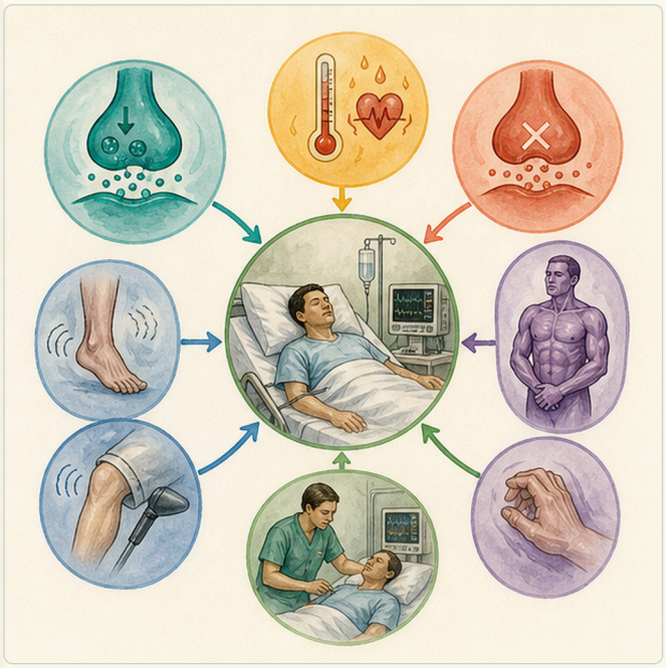
Psychopharmacology II: Emergencies, Resistance, Monitoring and Interactions

Prescribing when it goes wrong or will not work: the emergencies, treatment resistance, monitoring, and the interactions that cause both.

01 Drug emergencies

02 Treatment resistance and augmentation

03 Drug monitoring, pharmacovigilance and pharmacogenomics



04 Interactions and prescribing in physical illness

05 Neurostimulation and device-based treatments

06 Pharmacogenetic and structural drug-reaction syndromes

07 Consolidate and apply

VISUAL 8.1

Serotonin syndrome versus neuroleptic malignant syndrome

- Serotonergic exposure
- Clonus and hyperreflexia
- Dopamine blockade
- Rigidity
- Temperature and autonomic change
- Immediate stabilisation

Serotonin syndrome and NMS are separated by exposure, onset and neuromuscular pattern while both require urgent stabilisation and culprit withdrawal.

Source lock: day-37.final.html#sec-t04

VISUAL 8.2

Treatment resistance begins with verification

- Verify
- Adequate trial
- Switch or combine
- Augment
- Rapid or neurostimulation option
- Measure outcomes

Treatment resistance is defined only after diagnosis, adherence, dose, duration and outcome have been verified, after which strategies are sequenced and measured.

Source lock: day-37.final.html#sec-t07

VISUAL 8.3

Monitoring turns risk into actionable information

- Therapeutic drug monitoring
- Blood and metabolic
- ECG and QTc
- Liver and renal
- HLA and pharmacogenomics
- Pharmacovigilance

Monitoring is useful when each test has a defined indication, timing, interpretation and action.

Source lock: day-37.final.html#sec-t12

VISUAL 8.4

Neurostimulation is a family of prescriptions

- ECT
- rTMS
- Theta-burst
- tDCS
- VNS and DBS
- Selection and monitoring

Neurostimulation modalities differ in invasiveness, target, dosing parameters, evidence and monitoring; they are prescriptions, not interchangeable devices.

PAPER IV

Psychopharmacology II: emergencies, resistance, monitoring and interactions

Six bands . one complete notes document

Drug emergencies

1 · Psychopharmacology II for the psychiatrist: what this chapter owns, and what it points to

A psychotropic that was correct for the diagnosis can still be the wrong drug for the patient in front of you. The agent that suits a depressive episode meets a patient who is already taking several other medicines, whose kidneys clear the drug more slowly than any textbook assumed, whose inherited enzyme complement handles it at an unusual speed, who has already had adequate trials fail, or who returns with rigidity and fever that the prescription itself produced. In none of these has the pharmacology of the molecule changed. What has changed is that a second variable now sits between the drug and the patient, and every decision has to be made through it.

That is the whole subject of these notes. The systematic pharmacology that precedes them studies the drug class as an object in its own right: what it binds, what binding there produces, how the body handles the molecule, and what separates the members of a class from one another. This chapter takes those same molecules and asks what happens when something else is in the room. The marks here are not given for reciting a mechanism. They are given for a decision made under a named constraint, and the constraint is written into the question. Which concentration do you measure, and at what point in the dosing interval. Which agent do you avoid in this organ. Which test do you order before this prescription is written. What do you do when adequate treatment has already failed. What is this new sign, and did you cause it.

1.1 The lens: pharmacology under a second variable

What this chapter studies is the psychopharmacology of the complicated case, and its unit of teaching is the decision rather than the drug. The organising idea is **the second variable**: anything present alongside the psychotropic that changes what the correct action is. Five of them recur, and between them they account for almost every question this territory can ask. Another drug, which competes for the same clearing enzyme or adds its own effect at the same receptor. Another organ, when a heart, a liver, a kidney or a brain with an established disease alters either the exposure the patient achieves or the harm that exposure can do. Another genome, when inherited variation alters either pharmacokinetic exposure or immune susceptibility to a specific reaction. A failed trial, when adequate treatment has been given and the illness has not moved. And a syndrome the drug itself produced, when the presenting problem is no longer the disorder but the treatment.

Each of these turns a settled pharmacological fact into an unsettled clinical question. A half-life that is a property of a molecule becomes a question about this patient's clearance. A therapeutic

range that is a property of an assay becomes a question about when the sample was drawn. A familiar adverse effect becomes a question of attribution. Reading the whole chapter through that lens keeps its very different sections coherent, because the emergencies, the resistance decisions, the monitoring framework, the interaction matrix, the device-based treatments and the idiosyncratic reactions are all the same operation performed on different second variables.

RULE **No decision in this territory is made about the drug alone.** Before answering any question here, name the second variable the question has put in front of you, and say what it changes: the exposure the patient actually achieves, the harm that exposure can do in this particular organ, the susceptibility to a reaction the dose does not predict, the interpretation of a measured value, or the attribution of a new sign. A correct pharmacological statement about the molecule that ignores the second variable answers a question nobody asked.

1.2 Four operations, performed again and again

Beneath the sections lie four operations, and a reader who recognises which one a question is asking for has usually found the answer's shape before finding its content. The first is **anticipation**: predicting, before a drug is given, what a co-prescription, an organ, a genome or a pregnancy will do to it, and adjusting the choice rather than the aftermath. The second is measurement: deciding when a clinical judgement should be replaced by a number, which number, and at what moment in the dosing cycle it means anything at all. The third is **attribution**: deciding whether a new sign belongs to the illness, to a co-morbidity or to the prescription, which is the single judgement on which the management of every drug emergency in this chapter turns. The fourth is escalation: deciding what comes next when what should have worked has not, whether that is another drug, a second drug alongside the first, or a modality that is not a drug at all.

Anticipate	Measure	Attribute	Escalate
BEFORE THE PRESCRIPTION	WHEN A NUMBER BEATS A JUDGEMENT	ILLNESS OR TREATMENT	WHEN ADEQUATE TREATMENT FAILS

The operations are ordered, and the order is doing work. Anticipation is cheapest and is performed with a history and a prescription chart. Measurement is what anticipation escalates to when the variation is too large to reason about. Attribution is forced on you at the bedside, usually urgently, and is easiest for the clinician who anticipated. Escalation is the decision that follows when the first three have been done properly and the illness has still not yielded, which is precisely why a resistance judgement is only as good as the exposure and adherence work that preceded it.

1.3 The principle is taught elsewhere; the application is taught here

The first boundary this chapter keeps is with the pharmacology that precedes it. Half-life and steady state as concepts, the cytochrome system as a substrate map, the therapeutic index as a principle, and the comparison of one member of a class against another all belong to the Psychopharmacology I: principles and core drug classes notes, which teach them as properties of molecules and classes. Those notes then forward five bodies of material here by name: the target concentrations themselves, interactions that cross class boundaries, prescribing in physical illness

and across the lifespan, monitoring that spans classes, and the emergencies psychotropics produce.

The practical form of the boundary is simple. A principle is named here and moved past; an application is taught here in full. That a drug is cleared by a particular enzyme system is a principle. That adding a second agent which inhibits that system to a patient already stable on the first is an interaction with a predictable direction, a predictable time course and a defined action is an application, and applications are what this chapter is made of. The same test settles most uncertainty about where a piece of prescribing knowledge belongs: if the sentence would be true with only one drug and one healthy patient, it belongs to the class pharmacology; if it needs a second variable to be true at all, it belongs here.

TRAP **Answering a second-variable question with the class pharmacology.** Asked how to prescribe an antidepressant to a patient with established liver disease, or what to do when a mood stabiliser and a newly added analgesic meet, candidates reproduce the receptor profile and the adverse-effect signature of the class. The pharmacology may be flawless and still earn very little, because the examiner named the second variable in the stem and is marking what you did about it. State the mechanism in a clause, then spend the answer on the decision the constraint forces.

1.4 What this chapter hands over

The remaining boundaries are handovers, and each is worth rehearsing as a sentence because naming them accurately is faster and better rewarded than reconstructing a neighbouring chapter's material from memory.

- The **emergency act** is not taught here. The emergency-department presentation of a patient who is acutely unwell, the resuscitation and critical-care escalation, and the decision about where the patient is then looked after belong to the Perinatal/women's mental health and emergency psychiatry notes. This chapter owns the pharmacological lens on the same syndromes: which agents and combinations precipitate them, the mechanism by which they do, the named criteria as constructs an examiner can ask you to reproduce in your own words, the differentiation of one from another, and the drug decisions that follow.
- The **procedural act** is not taught here either. For every device-based treatment, the procedural technique is set out in the ECT and neurostimulation notes, along with the consent and legal frame and the requirements a service has to meet before it can offer the treatment at all. This chapter teaches the modality itself and its utility across disorders, at the depth a standalone answer on any single modality demands.
- Guideline-level algorithms for the treatment of a named disorder are also not this chapter's business. Where a resistance decision sits inside a disorder's own treatment sequence, the sequence belongs to the notes on that disorder, and what is taught here is the pharmacological reasoning underneath it.

Notice what the handovers have in common. In each case the neighbouring chapter owns what is done to the patient, and this chapter owns the drug reasoning that explains and follows it. That

division is not a filing convention. It is the reason an answer here should read as pharmacology rather than as emergency medicine or as a procedure list.

1.5 The map of the territory

Six territories follow, and they are arranged so that each supplies something the next assumes. The table states what each territory is for; the sections themselves supply the depth, the numbers and the attributions.

TERRITORY	THE SECOND VARIABLE IT WORKS ON	THE DECISION IT TEACHES
The drug emergencies	A syndrome the prescription itself produced	Which agents and combinations precipitate each syndrome, how to tell them apart as exam constructs, and what to stop, start and continue
Treatment resistance and augmentation	An adequate trial that has failed	What counts as resistance before the label is applied, and how switching, combining and augmenting differ as pharmacological strategies in depression and in schizophrenia
Monitoring, pharmacovigilance and pharmacogenomics	Variation you cannot see from the bedside	Which agents earn a measured concentration and when the sample is taken, how an adverse reaction becomes a recognised signal, and which inherited variation is worth testing for before prescribing
Interactions and prescribing in physical illness and across the lifespan	Another drug, another organ, another life stage	How psychotropics interact by kinetics and by pharmacodynamics, and how the choice changes in cardiac, hepatic, renal and neurological disease, in pregnancy and lactation, in the elderly and in children
Neurostimulation and device-based treatment	Illness requiring urgent definitive treatment or not responding to drugs; the entry point depends on the modality	What each modality is, how it is thought to work, which disorders it is used in and how strong the evidence is in each
Severe idiosyncratic drug reactions	An immune response nobody could predict from the dose	Which reactions are recognised, which drugs carry them, and where a pre-prescription test changes the choice of agent

Read the map in both directions. Given a patient with a complication, it says which territory holds the decision. Given a question in an examination, it says which second variable the examiner has introduced and therefore which body of reasoning is being tested. Monitoring recurs across several territories because a measured concentration, an interval on the

electrocardiogram, a blood count and a pre-prescription test are the same operation on different variables.

IN INDIA

Three of the decisions in this chapter turn on the patient rather than on the drug, and all three are worth making a routine habit at the point of prescribing rather than after a problem has appeared. Ask whether ancestry changes the pre-prescription test before certain anticonvulsants are started, and take the answer from the section on immunogenetic testing, which names the allele, the drugs and the population it applies to. Ask whether an inherited metaboliser phenotype changes the starting dose before any response has been observed, and take that from the pharmacogenomics section. And ask which agents in the prescription earn a measured concentration, and at what point relative to the dose the sample is drawn, from the therapeutic drug monitoring section. Each of the three is a question asked before the prescription is written, not a test ordered after the patient has come to harm.

1.6 Treating the prescription as a differential diagnosis

The habit this chapter is really trying to install is the habit of suspecting the treatment. A patient on psychotropic medication who develops a new physical or neurological sign has at least three candidate explanations: the psychiatric illness, an unrelated medical problem, and the prescription. Only the third is under the prescriber's direct control, and only the third can be tested by an action as simple as stopping a drug. Yet it is routinely considered last, partly because the drug has been given for weeks without trouble, partly because the patient is expected to be unwell, and partly because the medication chart is read as a record of what has been done rather than as a list of suspects.

Making the prescription a standing item on the differential changes several things at once. It brings the drug history forward from the end of the assessment to the beginning, where it is capable of altering what you do next. It makes recent changes matter more than long-standing ones, since a stable regimen is a weaker suspect than a dose increased, an agent added, or a drug stopped in the days preceding the presentation.

PITFALL

Reviewing the medication chart last. The commonest way a drug-related presentation is missed is not ignorance of the syndrome but sequence: the history, the examination and the investigations are worked through, and the prescription is checked only when nothing else has explained the picture. By then a dose has often been given again, and the account of what changed and when has been reconstructed rather than recorded. Read the chart first, note every change made in the preceding period and every agent added by another team, and ask what the combination in front of you does that neither drug does alone.

1.7 What a good answer in this territory looks like

Questions here are set as constrained problems, and they reward a recognisable shape of answer. Open by naming the second variable and saying what it changes, because that single sentence tells the examiner the question has been understood. Then give the mechanism briefly, in the

service of the decision rather than as a display. Then give the decision itself with its conditions attached, since almost nothing in this chapter is true unconditionally: a concentration means something at a stated point in the dosing interval and in a stated phase of treatment, a dose adjustment belongs to a stated degree of organ impairment, and a test belongs to a stated drug in a stated population. Finally, say what you would hand over and to whom, which demonstrates the judgement the whole chapter is built on.

GOOD TO REMEMBER

Before adding any drug to an existing psychotropic regimen, ask four questions out loud. Does the new agent share a clearing route with anything already prescribed. Does it add to an effect the existing regimen already produces, whether on the heart, the central nervous system or the same transmitter. Does the patient have an organ or a life stage that changes the exposure either drug achieves. And is there anything about this combination that should be measured rather than watched. A prescriber who answers those four before signing has performed the anticipation this chapter exists to teach, and has usually avoided the presentation the later sections are about.

1.8 A scaffold to carry into essays and vivas

Under examination pressure the method has to survive the loss of the detail. The spine that holds this chapter together is SECOND, which is a teaching scaffold rather than a validated instrument, and it will structure an answer on any topic in these notes: an emergency, a resistant illness, a measured level, an interaction, a device-based treatment or a rash.

MNEMONIC

SECOND

Second variable: name it first, whether it is another drug, an organ, a genome, a failed trial or the prescription itself. **E**xposure: ask whether the concentration in this patient is what the dose implies, and whether it can be measured. **C**ause: decide whether the new sign belongs to the illness or to the treatment before treating either. **O**ptions: when adequate treatment has failed, set out switching, combining, augmenting and the device-based modalities as alternatives with different profiles. **N**arrow margins: identify what this particular combination threatens and monitor that, rather than monitoring by habit. **D**evolve: hand the emergency act and the procedural conduct to the chapters that own them, and say so explicitly.

For a short answer, compress the scaffold to the second variable, the mechanism, the decision and the handover. For a long essay, expand each letter and draw the specifics from the section that owns them. In a viva, make the reasoning audible: say what else is on board, what that does to the exposure or to the risk, what you would therefore do differently, and at what point you would ask for help. That is the clinician the examination is looking for, and it is also the clinician who is safe with a combination no textbook has yet described.

Ask what else is present besides the drug, then say what that changes about the exposure, the interpretation, the attribution or the next step.

2 · Serotonin syndrome: precipitants, Hunter criteria, features and management

This is the emergency a prescription writes by itself. Every other syndrome in this section arrives with the illness; this one arrives with the drug chart. The drug history establishes serotonergic exposure; diagnosis then requires a compatible clinical syndrome, preferably assessed with the Hunter decision rule, and the exclusion of important mimics. The marks are correspondingly pharmacological: which agents and which combinations produce it, what the receptor account is and how firmly it may be stated, how the named criteria are constructed and what they are actually asking, and what the drug response is once the syndrome is recognised. The emergency-department presentation, the resuscitation and critical-care escalation and the disposition decision belong to the Perinatal/women's mental health and emergency psychiatry notes and are not taken up here; the comparison against neuroleptic malignant syndrome has its own section of these notes.

2.1 Why the drug chart is read first

Two properties of **serotonin toxicity** set it apart from the idiosyncratic drug reactions taught elsewhere in these notes, and both are pharmacological rather than clinical. The first is that it does not require polypharmacy. The Maudsley Prescribing Guidelines state that the syndrome can occur with a single serotonergic drug at a therapeutic dose, and more frequently with a combination of serotonergic drugs or in overdose, which means a single agent at a therapeutic dose leaves the diagnosis open. A candidate who reasons that the patient is on one antidepressant, at a licensed dose, and therefore cannot have serotonin toxicity has made the error the sentence exists to prevent.

The second is the time course. Symptoms can develop within minutes of ingestion, although most patients present within **six to 24 hours** after a medication change or overdose. That window is a useful temporal clue that must be interpreted with exposure and examination findings: it ties the presentation to a specific prescribing event rather than to the course of the illness being treated, and it tells you which page of the chart to read. An agitated, tremulous, sweating patient whose regimen changed the previous evening is a pharmacological problem until proven otherwise.

MNEMONIC

Exposure, Branch, Grade, Withdraw

The four steps in order: establish that a serotonergic agent was actually taken, find one complete qualifying criterion branch, grade the severity, and stop the offending drugs. Each step is a separate examinable construct and the sequence is not interchangeable, because the criteria set below is only licensed to run once the first step is satisfied.

2.2 The precipitants, and the routes in

The first route is additive pharmacodynamics, and one pairing dominates it. The Maudsley guidelines state that most severe cases involve an MAOI, including moclobemide, plus an SSRI. The detail that carries the mark is the parenthesis: **moclobemide** is named inside the

monoamine oxidase inhibitor group rather than outside it, so a candidate who treats it as a safer member of the class and pairs it with a reuptake inhibitor has walked into the exact combination the source singles out.

Next come selected non-psychiatric precipitants, which are not a separate mechanism at all. They are a prescriber and indication grouping, and the agents in it act through the same additive pharmacodynamics, by reuptake inhibition, monoamine oxidase inhibition or serotonin release. The American Family Physician review of serotonin syndrome tabulates the medications that may contribute, and separates an antidepressant and mood-stabiliser class from a Miscellaneous class of five entries:

- Cocaine
- Dextromethorphan
- **Linezolid**
- L-tryptophan
- 5-hydroxytryptophan

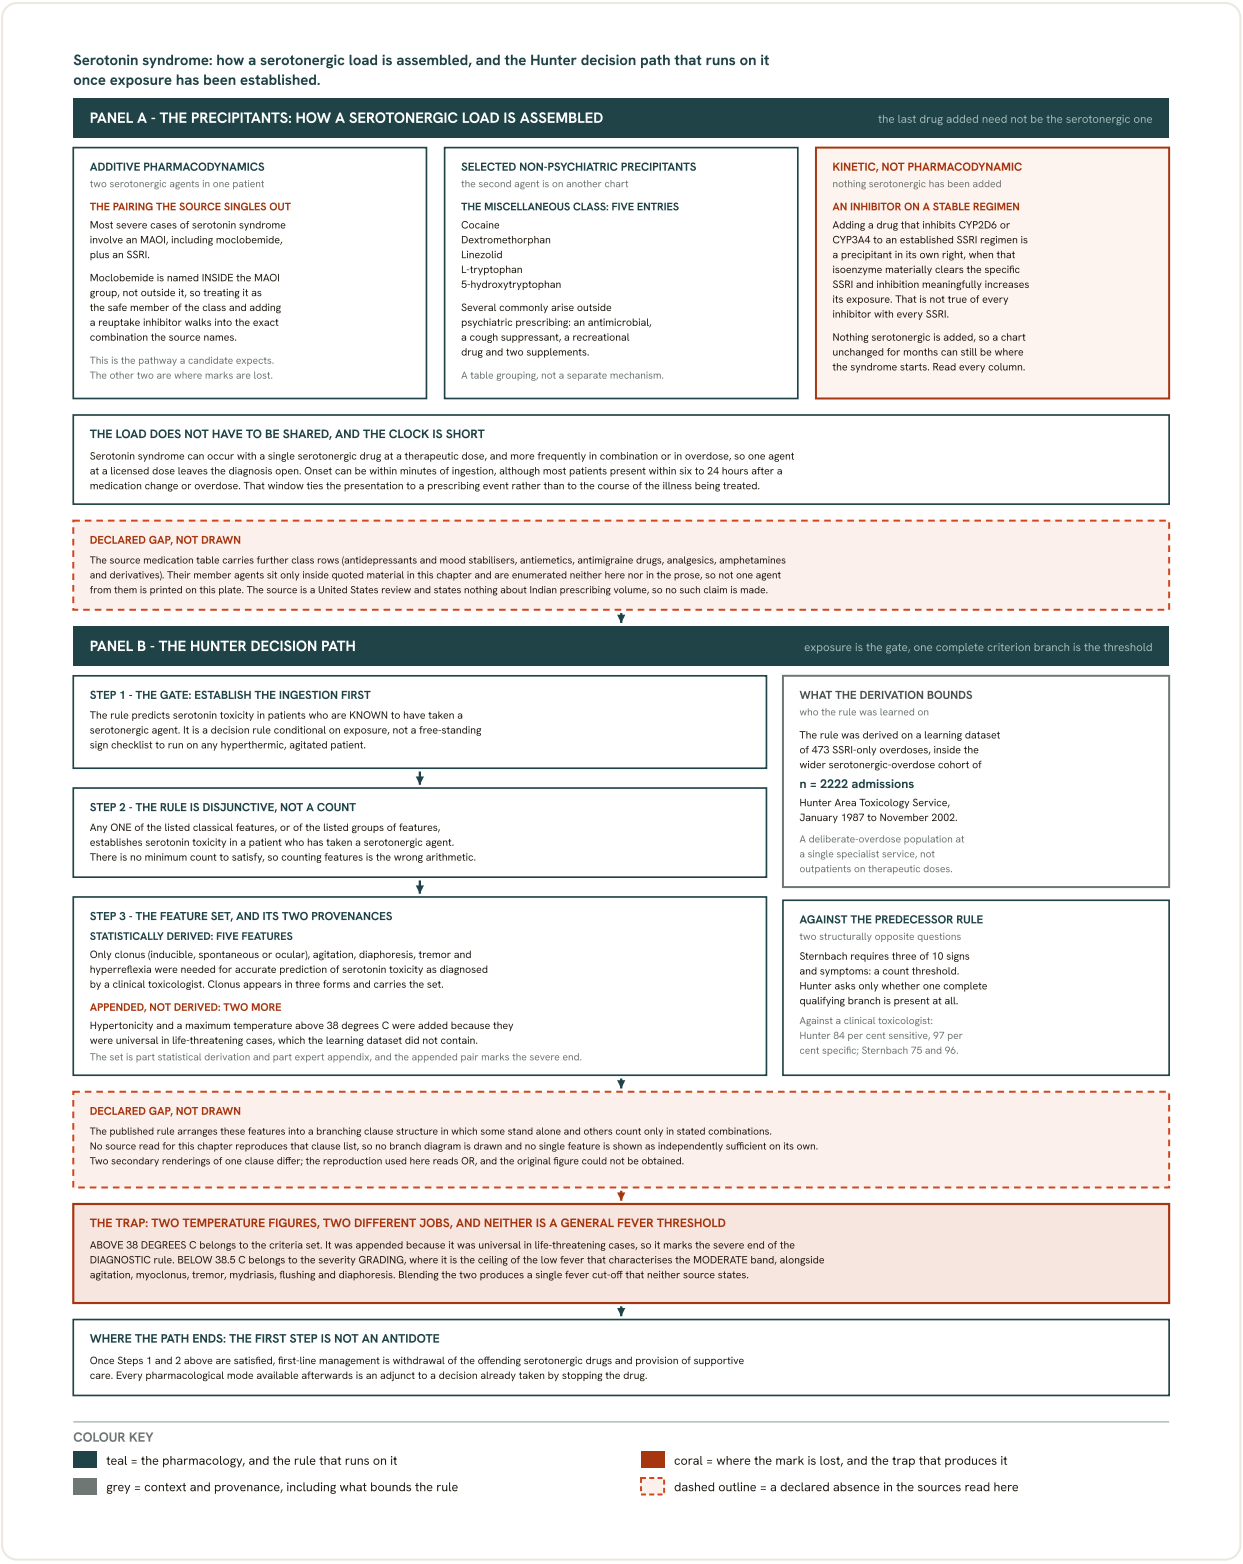

Fig 37.1 Serotonin syndrome: how a serotonergic load is assembled, and the Hunter decision path that runs on it. A single agent at a therapeutic dose leaves the diagnosis open, and most patients present within six to 24 hours of a medication change or overdose. Most severe cases involve an MAOI, including moclobemide, plus an SSRI. Selected non-psychiatric precipitants are a prescriber and indication grouping, not a separate mechanism; only the Miscellaneous class of five is enumerated. The kinetic pathway adds nothing serotonergic: a CYP2D6 or CYP3A4 inhibitor on an established SSRI regimen raises exposure to the drug already on the chart, where that isoenzyme materially clears that SSRI and inhibition meaningfully raises it. The Hunter rule runs only once ingestion is established and is disjunctive, one complete criterion branch being sufficient; it was derived on a learning dataset of 473 SSRI-only overdoses within a cohort of 2222 admissions. The branching clause list and the unenumerated class rows are declared, not drawn. (Ables and Nagubilli, American Family Physician 2010; Dunkley and colleagues, QJM 2003; the Maudsley Prescribing Guidelines in Psychiatry.)

Read that list for what it implies about where the second drug comes from. Several entries commonly arise outside psychiatric prescribing, so the complete medication and supplement history must be reviewed: an antimicrobial and a cough suppressant sit alongside a recreational drug and two over-the-counter supplements. The serotonergic contribution that completes the picture is frequently written on another team's chart, or on no chart at all.

A further route is kinetic rather than pharmacodynamic, and it is the one this chapter exists to teach. The same review names the addition of drugs that inhibit the CYP2D6 or CYP3A4 isoenzymes to an established selective serotonin reuptake inhibitor regimen as a precipitant in its own right, when that isoenzyme materially contributes to clearance of the specific SSRI and inhibition meaningfully increases its exposure. Nothing serotonergic has been added; the exposure to the existing antidepressant has simply risen. The enzyme map itself, and the systematic cross-class interaction matrix built on it, are developed in their own sections of these notes, as is the genotype that decides how much inhibition a given patient could absorb before the interaction mattered. What belongs here is the narrower point: inhibition of an isoenzyme that materially clears the antidepressant already on the chart can itself be the precipitant, so the last drug added is not necessarily the serotonergic one, and the underlying principles of enzyme kinetics and steady state belong to the Psychopharmacology I: principles and core drug classes notes.

> **GOOD TO REMEMBER**
>
> When the picture fits and the antidepressant has been unchanged for months, do not stop at the psychotropic column. Ask what was started in the last week for anything at all, including by another department, and ask specifically whether it inhibits either of the two isoenzymes named above. A drug chart read only for serotonergic agents will miss a possible pharmacokinetic route into this syndrome.

2.3 The receptor account, and how firmly to state it

An Indian case series of mild serotonin syndrome puts the mechanism in a single sentence: it is suggested that excess stimulation of brainstem and spinal cord 5-HT1A and 5-HT2A receptors causes the syndrome. Two things about that sentence are examinable. The first is its content, which is a receptor account and not an anatomical prediction: what is proposed is excess stimulation of those two receptor subtypes, and no more than that. The named locus belongs to the proposal itself; it is not a map from which the shape of the clinical presentation can be predicted.

The second is its strength. The source writes that it is suggested, not that it is established, and it offers this as a proposal rather than as a finding of its own series. An answer that hardens the suggestion into the mechanism has said more than the literature does, and in a viva the correct move is to give the account and then name it as proposed. Receptor pharmacology at the level of subtype selectivity and the adverse-effect signature it generates is the province of the Psychopharmacology I: principles and core drug classes notes; what this chapter owns is the toxic state that excess agonism produces when two prescriptions meet.

2.4 The Hunter criteria as an exam construct

The **Hunter Serotonin Toxicity Criteria** are examined more often for their structure than for their content, and the structure has two properties that a candidate must state explicitly. The first is a prerequisite: the rule runs only where recent serotonergic ingestion is already established. It is a decision rule conditional on exposure, not a free-standing sign checklist that can be applied to any hyperthermic, agitated patient. The second is that it is disjunctive. Any one of the listed classical features, or of the listed groups of features, establishes serotonin toxicity in a patient who has taken a serotonergic agent, and there is no minimum count to satisfy.

RULE **Exposure is the gate, and one complete criterion branch is the threshold.** Establish the serotonergic ingestion first, because the criteria are not licensed without it. Then a single complete qualifying branch is sufficient, and a branch may be one feature or a stated combination of features rather than a feature on its own. A candidate who counts features and reports that the patient has only two has applied the wrong arithmetic to the right rule.

The content came out of a statistical derivation. Only five clinical features were needed for accurate prediction of serotonin toxicity as diagnosed by a clinical toxicologist: **clonus** in its inducible, spontaneous and ocular forms, agitation, **diaphoresis**, tremor and **hyperreflexia**. Clonus is the load-bearing sign of the set, appearing in three separate forms, and it is a particularly important examination finding that appears in several branches of the published rule.

Two further features were appended rather than derived. **Hypertonicity** and a maximum temperature **above 38 degrees C** were added to the criteria because they were universal in life-threatening cases. Such patients lay outside the learning dataset. That provenance is worth carrying into an answer: the rule is part statistical and part expert appendix, and the appended pair is precisely the pair that marks the severe end. The published rule arranges these features into a branching structure in which some stand alone and others count only in stated combinations; the branch list is not reproduced here, and a candidate should not assume that every one of the five features is independently sufficient on its own.

2.5 Hunter against Sternbach, and what the derivation bounds

The predecessor rule is the comparison an examiner reaches for. The **Sternbach criteria** are a count threshold, requiring **three out of a possible 10** signs and symptoms, so the two rules are structurally opposite: one asks how many features are present, the other asks whether any qualifying feature is present at all. Against a clinical toxicologist's diagnosis the newer rule performed better on both axes at once, which is unusual, and Hunter is generally preferred because it was simpler and performed modestly better in the derivation study.

84%	97%	75%	96%
HUNTER SENSITIVITY	HUNTER SPECIFICITY	STERNBACH SENSITIVITY	STERNBACH SPECIFICITY

Where the rule came from bounds what it can be asked to do. It came out of a single toxicology service's serotonergic-overdose admissions, 2222 admissions to the Hunter Area Toxicology Service between January 1987 and November 2002, and the rule itself was derived on a learning

dataset of 473 SSRI-only overdoses inside that cohort rather than on the whole of it. Two limits follow. The population was one of deliberate overdose rather than of outpatients taking therapeutic doses, and the setting was a single specialist service rather than a general clinical population. Neither limit invalidates the rule, and both are the honest caveat to attach when a stem describes a patient who is not in either category, such as an outpatient on a stable regimen who has just been given an antimicrobial.

2.6 Grading the severity, and the two temperature figures

Severity is graded in three bands, and the grading matters pharmacologically because the treatment decision is taken against the band rather than against the criteria. The Maudsley guidelines place insomnia, anxiety, nausea, diarrhoea, hypertension, tachycardia and hyperreflexia in the mild band; agitation, myoclonus, tremor, mydriasis, flushing, diaphoresis and low fever below 38.5 C in the moderate band; and severe hyperthermia, confusion, rigidity, respiratory failure, coma and death in the severe band. Read down the three bands and the autonomic and neuromuscular features recur, more marked at each step: increasing severity is associated with more marked autonomic and neuromuscular abnormalities, including hyperthermia and rigidity. The bands describe what predominates at each level of severity, not one finding turning into another, and the features may coexist.

TRAP **Treating the two temperature figures as one threshold.** They come from different sources and do different jobs. The figure appended to the criteria set marks the temperature that was universal in life-threatening cases, so it belongs to the diagnostic rule at the severe end. The figure inside the severity grading is the ceiling of the low fever that characterises the moderate band. A candidate who blends them produces a single fever cut-off that neither source states, and then applies it to whichever question is asked.

2.7 Management, and why withdrawal is the whole of the first step

The treatment target by phase is straightforward to state and easy to under-weight in an answer. The American Family Physician review puts two things first and nothing before them: withdrawal of the offending serotonergic agents, together with supportive care. Every pharmacological mode available afterwards is an adjunct to a decision that has already been taken by stopping the drug, and the examinable point is that no antidote question arises until the offending agent is off the chart. Where the syndrome is severe, the setting of care, the resuscitation and the escalation decision belong to the Perinatal/women's mental health and emergency psychiatry notes, and this chapter stops at the prescription.

How long that first step takes, and whether it is enough by itself, is answered differently by the two sources. The American Family Physician review states that mild cases generally resolve within **24 to 72 hours** with conservative therapy and removal of the causative drugs, and the qualifier in that sentence is generally, not always. An Indian case series of mild serotonin syndrome found withdrawal alone insufficient in most cases: in most of its patients, withdrawal of the offending agents alone produced no or minimal response and cyproheptadine was then required. That does not contradict the broader American Family Physician formulation, which is withdrawal together with conservative therapy rather than withdrawal on its own, and the two

statements are printed here side by side without averaging. The split of that series between the patients who responded to withdrawal alone and those who did not is not available here and is deliberately not stated.

PITFALL

Reassuring a patient or a referring team that a mild case will settle on its own within a stated number of hours. The Western figure is qualified as a general expectation and the one Indian series in this material found withdrawal alone insufficient in most of its patients. Withdraw the drug, then review the patient against the clock rather than discharging against it.

2.8 Cyproheptadine: one drug, four published regimens, four populations

The specific agent is **cyproheptadine**, and the honest opening line about it is the one the American Family Physician review supplies: it is widely used, but there is no definitive evidence of its effectiveness in serotonin syndrome. That is not a reason to omit it from an answer, but it fixes the register. This is an adjunct with a plausible receptor rationale and weak evidence, given after the offending drug has been stopped, and an answer that presents it as the antidote of choice has overstated the literature.

For an Indian candidate the guideline figure comes first. The Indian Psychiatric Society clinical practice guideline gives **cyproheptadine 8 to 12 mg/day orally in severe serotonin syndrome**, and the same guideline's management instruction for the syndrome opens with stopping the offending drugs. The Western schedule is then named as the alternative rather than as the standard. Set the published figures side by side with the population each belongs to.

SOURCE	POPULATION THE FIGURE WAS PUBLISHED FOR	CYPROHEPTADINE AS PUBLISHED
Indian Psychiatric Society clinical practice guideline	Severe serotonin syndrome	8 to 12 mg/day orally in severe serotonin syndrome
Indian case series of mild serotonin syndrome	Mild serotonin syndrome, outpatients	8 mg three times daily, that is 24 mg/day, in mild serotonin syndrome, recorded as the amount these patients received and carried here as case-series evidence rather than as a dose the series recommends
American Family Physician review	Moderate to severe serotonin syndrome	In moderate to severe serotonin syndrome an initial 12 mg should be considered, then an additional 2 mg every two hours if symptoms continue; after the patient is stabilised 8 mg every six hours may be administered as the maintenance dosage
Indian product label for the marketed tablet	Licensed antihistaminic and antiserotonin use, the indication recorded on the label; the label carries no serotonin-syndrome indication of its own	For that labelled antihistaminic and antiserotonin indication, and for no other, the adult total daily dose is not to exceed 0.5 mg/kg/day, with a therapeutic range of 4 to 20 mg a day and the majority of patients requiring 12 to 16 mg a day. This is the marketed product's own labelled ceiling, not a serotonin-syndrome dose

Two features of that table are load-bearing. The first is the modals, which are permissive throughout the Western schedule: a loading dose should be considered and a maintenance dose may be administered, neither of which is an instruction. The second is that the product label is a label. It binds the dose of the marketed tablet and carries no serotonin-syndrome indication, so it is not the governing authority for an emergency regimen even though it is the only Indian document that states a weight-based ceiling.

A third feature is what these documents do not contain, and it is worth naming because a printed dose with nothing said above it reads like a complete instruction. The Indian Psychiatric Society entry gives a daily amount of cyproheptadine for severe cases and names neither a dose to begin with nor a ceiling above it. The American Family Physician cyproheptadine schedule states a loading dose, a titration step and a maintenance dose and then stops, so no maximum for the day appears anywhere in it. The cyproheptadine product label runs the other way: it states a range and a weight-based cap and no starting dose at all, which is what a document written to constrain a dose rather than to begin one looks like. Where a source is silent about an upper limit, that silence is the record, and this chapter does not fill it from elsewhere.

TRAP **Reading the four regimens as an ascending dose ladder.** Sorted by milligrams alone, the mildest illness appears to receive the most drug and the severe Indian figure appears to be an under-dose. That ordering is an artefact of crossing four populations, not a disagreement about severity. Each figure is only interpretable with its population attached, and an answer that lines them up as a titration schedule has manufactured a claim none of the four sources makes.

IN INDIA

Print the Indian Psychiatric Society figure first and treat the Western loading schedule as the named alternative. The marketed tablet's prescribing information does state a weight-based adult daily cap, but it states it for the licensed antihistaminic and antiserotonin indication and carries no serotonin-syndrome indication at all, so it is contextual product information rather than the ceiling that governs an emergency regimen, and dosing that runs up against it is a question for toxicology advice rather than for the label. The two documents disagree about the maximum a day may contain, and this chapter holds only the ceiling and the therapeutic range from the label, not the label's stated exceptional maximum, so the disagreement is named rather than quantified on both sides.

Exposure plus one complete qualifying criterion branch makes the diagnosis; stopping the offending drug is the treatment, and every agent given afterwards is an adjunct with its population attached.

3 · Neuroleptic malignant syndrome: features, pathophysiology and management

Neuroleptic malignant syndrome is a prescribing event before it is a critical-care event. The pharmacology question asks four things of you: which drug produced it, by what mechanism, which named criteria set the examiner has in mind, and what happens to the drug chart afterwards. The emergency-department presentation, the resuscitation and the disposition decision are taught in the Perinatal/women's mental health and emergency psychiatry notes and are deliberately left there. What follows is the drug's half of the problem, which is the half a psychiatrist owns on the ward round and the half the written paper asks about.

3.1 The prescription that produces it

The drug history is most of the diagnosis. DSM-5-TR records that affected individuals have generally met a **dopamine antagonist** within 72 hours of symptoms developing, and it takes care to present this as descriptive text rather than as a diagnostic criterion. That distinction is worth holding: read as a criterion it becomes a false reassurance whenever the exposure is older or less certain, and read as a description it simply tells you where to look first.

The offending agent is not always on the psychiatric chart. The AIIMS text Clinical Methods in Psychiatry states that the syndrome is seen more with high-potency antipsychotics and names metoclopramide and domperidone among the other offending agents. Central dopamine D2 antagonists can precipitate the syndrome whatever specialty prescribed them, and abrupt withdrawal or reduction of dopaminergic therapy is the other established route; in a rigid febrile patient the antiemetic chart is part of the drug history.

The Maudsley Prescribing Guidelines gather the risk factors into one undifferentiated row. Separating out its drug-related items is worth doing, because they describe the prescription rather than the patient:

- high-potency first-generation antipsychotics
- a recent or rapid dose increase
- a rapid dose reduction
- abrupt withdrawal of a co-prescribed anticholinergic agent
- **antipsychotic polypharmacy**

RULE **Dose change in either direction is a risk, not dose escalation alone.** The same list carries rapid increase and rapid reduction, which is hard to reconcile with a simple dose-toxicity model. These are associations the guideline reports rather than a mechanism it explains: a patient stable for years can present during a cross-taper, and withdrawal of an anticholinergic, a drug doing nothing dopaminergic, earns a place on the risk list without any account of why.

3.2 Two hypotheses, and the two drugs that follow from them

The central account begins where dopamine does thermoregulatory work. Tse and colleagues locate that role in the thermoregulatory centre of the hypothalamus, and particularly in the **anterior pre-optic nucleus**, which gives the hyperthermia a mechanism rather than leaving it as an association. The motor sign supplies a second clue. DSM-5-TR describes generalised rigidity, **lead-pipe** in its most severe form and usually unresponsive to antiparkinsonian agents. That unresponsiveness is the teaching point: this is not ordinary drug-induced parkinsonism scaled up, and an anticholinergic given in that belief costs time.

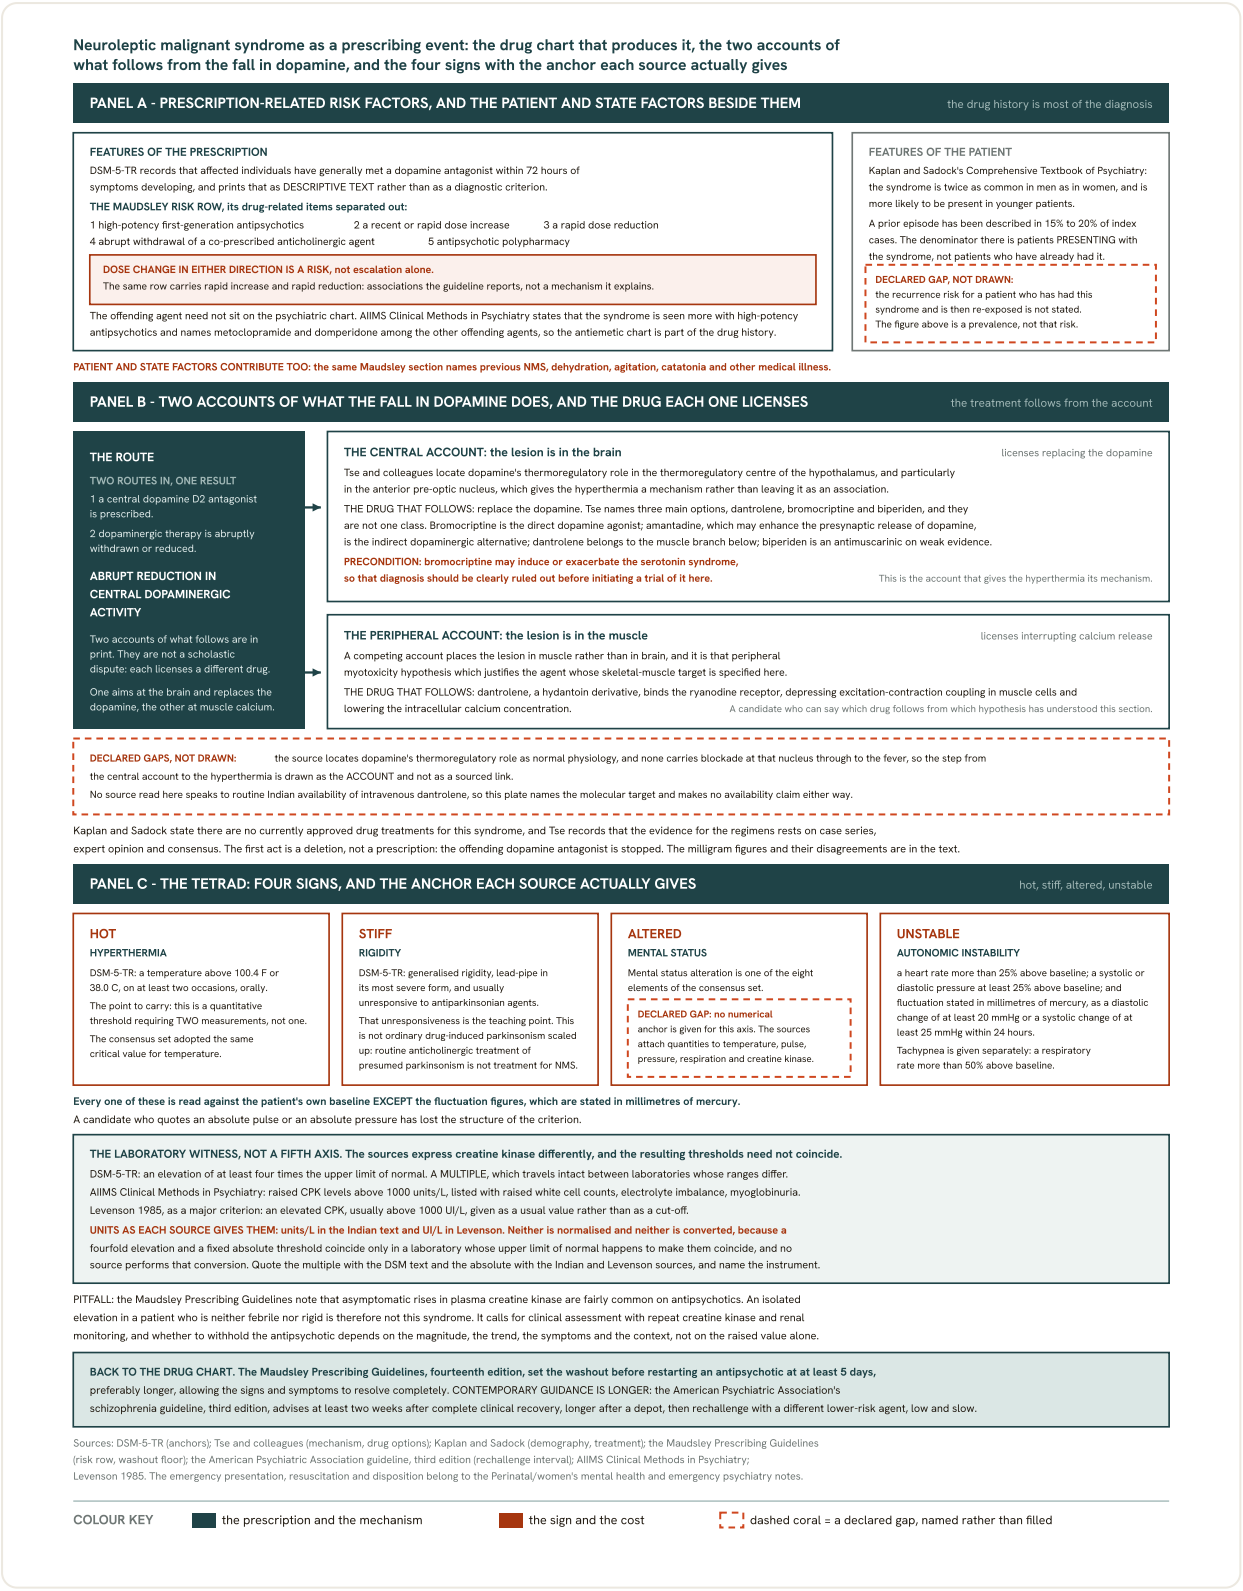

Fig 37.2 **Neuroleptic malignant syndrome: the prescription, the two accounts, and the tetrad.** Prescription-related risk factors: high-potency first-generation antipsychotics, a rapid dose change in either direction, abrupt withdrawal of a co-prescribed anticholinergic and antipsychotic polypharmacy, with patient and state factors beside them; the dopamine antagonist is generally met within 72 hours. Central dopaminergic activity falls by either route, an antagonist prescribed or dopaminergic therapy withdrawn, and each account licenses a different drug: the anterior pre-optic nucleus licenses replacing the dopamine, the myotoxicity account licenses dantrolene at the ryanodine receptor. The two creatine kinase forms need not pick out the same number: at least four times the upper limit of normal in DSM-5-TR, above 1000 units/L in the Indian text, above 1000 UI/L in Levenson. (DSM-5-TR; Tse; Kaplan and Sadock; Maudsley; AIIMS Clinical Methods; Levenson 1985.)

A competing account places the lesion in muscle rather than in brain, and it is that peripheral myotoxicity hypothesis which justifies the agent whose skeletal-muscle target is specified here. Dantrolene is a hydantoin derivative that binds the **ryanodine receptor**, depressing excitation-contraction coupling in muscle cells and lowering the intracellular calcium concentration. The two hypotheses are not a scholastic dispute, because each licenses a different drug: the central account licenses replacing dopamine, the peripheral account licenses interrupting calcium release. A candidate who can say which drug follows from which hypothesis has understood this section, and the accompanying figure carries the same route from receptor blockade to bedside sign.

3.3 Tempo: when it appears, and when it settles

Onset is early and its spread is wide. DSM-5-TR gives onset varying from hours to days after the drug is started, with some cases inside 24 hours, most in the first week and virtually all within 30 days. Recovery has a comparable shape once the drug is withdrawn: mean recovery time runs 7 to 10 days, most patients recovering within 1 week and nearly all within 30 days, the same outer bound the onset window carries.

Exposure before onset differs by drug class, though the difference is softer than the figures look. In a review of spontaneously reported cases, median exposure before onset was 23 days for cases associated with atypical antipsychotics against 6 days for typical-associated cases. Two qualifications travel with those medians and neither may be dropped. They come from a spontaneous-reporting database rather than a cohort, so they describe what was reported rather than what occurred; and the same analysis found considerable overlap between the groups, because a large share of the atypical-associated cases were taking more than one antipsychotic, frequently including a typical agent, with the reverse holding for the typical-associated cases. A clean between-class contrast is not what these data support.

3.4 How often, and in whom

Incidence depends entirely on how the cases were counted. Database studies give 0.01% to 0.02% among patients treated with antipsychotics, of the order of one case in five to ten thousand; a population-based study from Hong Kong found a higher incidence risk, and drug-safety programme data covering 1993 to 2015, reported in the Maudsley Prescribing Guidelines, give a higher figure again. These are not three competing estimates of one quantity. They are three surveillance methods, and the spread between them is the honest answer to how common the syndrome is.

0.11%	0.16%	15% to 20%	10% to 20%
HONG KONG POPULATION STUDY	DRUG-SAFETY PROGRAMME DATA	PRIOR EPISODE, INDEX CASES	FATALITY IF UNRECOGNISED

Kaplan and Sadock's Comprehensive Textbook of Psychiatry adds the demographic skew: the syndrome is twice as common in men as in women and is more likely to be present in younger patients. The mortality figure is worth little without its scope attached. DSM-5-TR puts fatality at 10% to 20% where the disorder is not recognised, which is a statement about missed diagnosis

rather than a case-fatality rate for the syndrome as a whole. Other fatality figures are in print from different eras and different case definitions; they belong to their own populations and must never be pooled into a single range.

TRAP **Reading the prior-episode figure as a recurrence risk.** A prior episode has been described in 15% to 20% of index cases, and the denominator there is patients presenting with the syndrome, not patients who have already had it. It answers how often a presenting case has a history, and says nothing about the chance that a survivor will relapse on re-exposure. That second number is the one a rechallenge conversation actually needs, and this chapter does not hold it.

3.5 The criteria sets as an exam construct

Three named sets circulate and they are built differently, which is more examinable than any single threshold. DSM-5-TR prints no counted checklist; it describes the syndrome and attaches quantitative anchors to individual features. The International Expert Consensus criteria, derived by a Delphi panel, form a counted and weighted set of **eight elements**: one drug element, recent dopamine antagonist exposure or dopamine agonist withdrawal; two cardinal signs, hyperthermia and rigidity; one cognitive element, mental status alteration; one laboratory element, creatine kinase elevation; two autonomic elements, being **sympathetic nervous system lability** and tachycardia with tachypnea counted together; and one exclusion element, a negative work-up for other causes. Levenson's 1985 criteria are older and simpler, a major-and-minor structure satisfied by all three major criteria, or two major with four minor.

CRITERIA SET	HOW DRUG EXPOSURE ENTERS	STRUCTURE	WHERE THE POSITIVE CALL IS SET
DSM-5-TR	Dopamine antagonist met within 72 hours of onset, written as descriptive text	Narrative description, with anchors attached to single features	No count and no score; judgement on the whole picture
International Expert Consensus (Delphi)	One of the eight elements, and it admits dopamine agonist withdrawal as well as antagonist exposure	Eight elements, weighted against one another by the panel	Best agreement where the total reaches 74, against modified DSM-IV-TR criteria
Levenson 1985	Absent; no drug-exposure element among either tier	Three major criteria and six minor criteria	All three major, or two major with four minor

The anchors DSM-5-TR attaches to individual features are the ones most often asked for. Hyperthermia is defined as a temperature **above 100.4 F or 38.0 C on at least two occasions, measured orally**, with profuse diaphoresis as its distinguishing companion. The autonomic criteria are partly relative and partly absolute, which is easy to garble: a heart rate more than 25% above baseline, a systolic or diastolic pressure at least 25% above baseline, but fluctuation stated in millimetres of mercury, as a diastolic change of at least 20 mmHg or a systolic change of at least 25 mmHg within 24 hours. Tachypnea is given separately, as a respiratory rate more than 50% above baseline. Every one of these is read against the patient's own baseline except the

fluctuation figures, so a candidate who quotes an absolute pulse or pressure has lost the structure of the criterion. The consensus panel's own critical values match the temperature, creatine kinase and blood-pressure-elevation anchors given here; whether it took the pulse, respiratory and fluctuation figures across as well is not verified and is not claimed.

Two further points repay attention. Levenson's set names no drug-exposure element at all, among either its major or its minor criteria, while both later sets do, so a stem offering a florid picture with no drug history is separating the sets rather than testing the syndrome. And the consensus criteria carry their own operating characteristics, sensitivity 69.6% against specificity 90.7%. Those figures must not be ranked against the decision rule taught for the serotonin syndrome in the neighbouring section: that instrument was validated in a different disease against a different reference standard, in overdose admissions rather than in archived consultations. The panel also weighted its eight elements against one another, but those per-element priority weights are not reported in the account read here and are not reconstructed from memory; the validated total is available, the weights behind it are not.

MNEMONIC

Hot, Stiff, Altered, Unstable

The four axes every set is built on: hyperthermia, rigidity, altered mental status and autonomic instability, with the creatine kinase as the laboratory witness rather than a fifth axis. They share the core clinical syndrome but differ both in the elements included and in how those elements are combined or weighted.

3.6 The creatine kinase, where the sources genuinely disagree

The sharpest disagreement in this topic is about the form of the threshold, and the two forms need not pick out the same number. DSM-5-TR sets the threshold as a multiple, an elevation of **at least four times the upper limit of normal**, which travels intact between laboratories whose reference ranges differ. The AIIMS text Clinical Methods in Psychiatry gives an absolute figure instead, raised CPK levels above 1000 units/L, listed alongside raised white cell counts, electrolyte imbalance and myoglobinuria; Levenson's major criterion is expressed the same way, an elevated CPK usually above 1000 UI/L. Both forms are in print. They are different instruments, and whether they pick out the same number depends on the laboratory's upper limit of normal; Levenson's figure is given as a usual value rather than a cut-off, and neither form is a correction of the other.

TRAP **Converting the multiple into the absolute, or the absolute into the multiple.** A fourfold elevation and a fixed absolute threshold coincide only in a laboratory whose upper limit of normal happens to make them coincide, and no source performs that conversion. Quote the multiple with the DSM text and the absolute with the Indian and Levenson sources, and say which instrument you are using. An Indian examiner is the more likely to have the absolute form in mind, which is a reason to carry both rather than a reason to substitute one.

PITFALL

Treating a raised creatine kinase as the diagnosis. The Maudsley Prescribing Guidelines note that asymptomatic rises in plasma creatine kinase are fairly common on antipsychotics. An isolated elevation in a patient who is neither febrile nor rigid is therefore not this syndrome. It requires clinical assessment with repeat creatine kinase and renal monitoring, and whether to withhold the antipsychotic depends on severity and context rather than on the raised value alone. The elevation is a supporting feature inside a clinical picture rather than a trigger standing alone.

3.7 Pharmacological management, and the rechallenge decision

Start from the honest position. Kaplan and Sadock's Comprehensive Textbook of Psychiatry states that there are no currently approved drug treatments for this syndrome, and Tse and colleagues record that the evidence supporting the different regimens rests on case series and expert opinion and consensus. Everything that follows is therefore off-label and weakly evidenced, which is precisely why the first act is a deletion rather than a prescription: the offending dopamine antagonist is stopped, and no specific agent substitutes for that. Tse names the three main drug options as **dantrolene**, **bromocriptine** and **biperiden**.

Dantrolene follows the peripheral hypothesis. For severe NMS, Kaplan and Sadock state that dantrolene may be effective, and begin with intravenous **0.8 to 2.5 mg/kg every 6 hours**, with a maximum of 10 mg/kg daily in the textbook's own words; the permissive modal is the source's own and should survive into your answer. Tse's review states the dantrolene dose in NMS differently, as intravenous 1 to 10 mg/kg body weight with no dosing interval attached, or an oral option, 50 to 600 mg once daily. These two statements do not reconcile into a single regimen and are better quoted with their sources than blended. Note also where each of them stops. The textbook's dantrolene schedule carries its own daily cap. The review's dantrolene figure states an amount and a route with no ceiling above them, so the cap printed beside the first regimen belongs to that regimen and does not travel across to the second. Neither dantrolene passage gives a separate initiation dose either: in both, the dose stated is the dose given.

Bromocriptine follows the central hypothesis, and here the same textbook contradicts itself. For NMS one chapter starts bromocriptine at 2.5 mg two or three times daily, with 45 mg as the maximum total daily dose, while another chapter of the same book carries a second, inconsistent bromocriptine regimen, added after dantrolene. That second regimen's figures are not quoted in the source behind this sentence and are not printed here; the examinable point is the contradiction itself, not the rival numbers. An independent review supports the titration form, so learn the titration and treat the disagreement as internal to the textbook rather than as a second consensus. **Amantadine**, which may enhance the presynaptic release of dopamine, is the alternative dopaminergic agent in NMS at 200 to 400 mg/day in divided doses. The passage states that range and stops there, with no initiation dose below it and no maximum above it, so the upper figure is the top of a stated range and not a stated limit.

RULE **Exclude the serotonin syndrome before giving bromocriptine.** Kaplan and Sadock state that bromocriptine may induce or exacerbate serotonin syndrome, so that diagnosis should be clearly ruled out before initiating a trial of it here. This is the clinical pay-off of the differentiation taught in the neighbouring section: the two syndromes are separated not for tidiness but because a treatment for this one worsens the other.

IN INDIA

Two decisions here are specifically Indian. First, because the AIIMS text names metoclopramide and domperidone among the offending agents and both are prescribed well outside psychiatry, the drug history in a rigid febrile patient must reach past the psychotropic chart to the antiemetics and prokinetics before any antipsychotic is exonerated or any single agent is blamed. Second, the Indian Psychiatric Society schizophrenia guideline names bromocriptine to be considered in case of NMS, inside the catatonia row of its special-conditions table, alongside intensive care admission if the clinical condition worsens and the observation that electroconvulsive therapy may be required. The table names bromocriptine for NMS but gives no NMS recommendation either for or against dantrolene, and that silence is not a recommendation against the drug. The escalation and disposition the row points at belong to the Perinatal/women's mental health and emergency psychiatry notes.

What the drug history tells you afterwards is the last piece, and it is the piece the psychopharmacology paper is most likely to ask. The fourteenth edition of the Maudsley Prescribing Guidelines sets the washout before restarting an antipsychotic at **at least 5 days, preferably longer**, allowing time for the signs and symptoms to resolve completely before **rechallenge**. Read the direction of that instruction carefully: it is a floor with an open ceiling, not a scheduled restart, and five days is not a rule that can be carried on its own. Contemporary guidance is longer. The American Psychiatric Association's schizophrenia practice guideline, third edition, advises waiting at least two weeks after complete clinical recovery, longer again where the exposure was to a depot, and then rechallenging with a different lower-risk agent at low dose and slow titration. Quote the Maudsley figure as the fourteenth edition's wording and take the two-week interval as the clinical rule.

GOOD TO REMEMBER

Two questions belong in every antipsychotic drug history and both come out of this topic. Has this patient ever had an episode of this syndrome, and how fast was the last dose change in either direction? The first is asked because a prior episode is common enough among presenting cases to be worth hunting for; the second because speed of change, up or down, sits on the risk list beside the drug itself. Neither question needs a laboratory, and both are usually answerable before the first blood sample is drawn.

Stop the dopamine antagonist first, then decide which hypothesis you are treating: dantrolene for the muscle, bromocriptine or amantadine for the dopamine, and do not give bromocriptine until the serotonin syndrome has been excluded.

4 · Serotonin syndrome versus NMS: comparative differentiation

The comparison is the question. A patient on psychotropic medication becomes febrile, altered in mental state and abnormally stiff, and two named syndromes sit on the list. Neither is excluded by how unwell the patient looks. An answer that recites the features of one syndrome and then the features of the other has not answered anything, because the examiner has not asked what each syndrome is; the examiner has asked which one this is. The marks are carried by the axes on which the two genuinely separate, by the order in which those axes are interrogated, and by an honest statement of where the separation runs out. Each syndrome is taught as an entity in its own right elsewhere in these notes. What follows is the discrimination itself, read from the pharmacology rather than from the resuscitation.

The boundary is worth fixing before anything else. The emergency-department presentation, the resuscitative and critical-care escalation and the disposition decision belong to the Perinatal/women's mental health and emergency psychiatry notes. The material here is the drug that produced the syndrome, the examination that separates the two, the criteria question as an examination construct, and what the label commits the prescriber to once it is applied.

4.1 Why this differential is not academic

The usual reason a comparison is examined is that the two entities are confusable. Here there is a second and better reason. A review of the two syndromes in Current Neuropharmacology states that there is no role for dantrolene, biperiden or bromocriptine in the therapeutic management of serotonin syndrome, and, in the same breath, no role for **cyproheptadine** in neuroleptic malignant syndrome. The syndrome-directed agents named do not cross over. Read what that does and does not say. Withdrawal of the offending drug, supportive care and the sedation of agitation are common ground, so the label does not decide the whole of management. What it decides is the syndrome-directed drug that follows, and that is enough to convert a taxonomic question into a prescribing one, because the agent chosen on the strength of the label has nothing to offer the other diagnosis if the label is wrong.

RULE **The discrimination is made from the drug chart and the neuromuscular examination, in that order.** Whatever the two presentations have in common cannot separate them, however severe it looks, so the answer is never built on how unwell the patient is. What separates them is the pharmacological class the patient was exposed to, the interval between that exposure and the illness, and the direction in which the neuromuscular system has moved. These three are the principal discriminators. Other findings may support the distinction, but none of them is individually definitive, and nothing the two presentations hold in common can do the separating at all.

Note what this rule does not claim. It does not say that the shared features are unimportant, only that a feature both syndromes produce cannot be the thing that tells them apart, and it does not promise that the three discriminating axes will always be available. In a patient brought in unaccompanied with no drug history, the class axis and the tempo axis are unreadable and only the examination remains, and the answer must say so rather than manufacture a certainty the bedside does not supply.

4.2 The prescription: the discriminator that comes first

StatPearls sets the drug-class discriminator out cleanly: serotonin syndrome is precipitated only by **agents that impact the serotonergic system**, while neuroleptic malignant syndrome is precipitated by **dopamine receptor antagonists**. The source glosses that second half as the antipsychotics, and taken as a definition the gloss is too narrow in two directions at once. The international consensus work on the syndrome, by Gurrera and colleagues, defines the lesion rather than the drug: a marked reduction in central dopaminergic activity, usually D2 antagonism but also the abrupt withdrawal or reduction of dopaminergic treatment. Read both halves as statements about a mechanism rather than as lists of drugs. Each syndrome is tied to a pharmacological action, not to a therapeutic category and not to a drug name, so the question at the bedside is never whether the patient is on an antidepressant or an antipsychotic by label. It is what the agents on the chart do to the two transmitter systems.

That distinction has consequences the examiner rewards. An agent prescribed for a non-psychiatric indication can still satisfy the serotonergic definition, and an antiemetic or a prokinetic that antagonises dopamine receptors satisfies the other one without ever having been prescribed as an antipsychotic. The withdrawal route leaves nothing on the chart to find at all: there the offending change is a dopaminergic drug that has been stopped or cut, and only the dates will show it. Candidates who scan the drug chart for a diagnostic category miss all of these. Candidates who scan it for a mechanism find them. The receptor pharmacology that underlies these two definitions, taken as a principle rather than as an application, belongs to the Psychopharmacology I: principles and core drug classes notes.

The word *only* in the serotonergic half is load-bearing and cuts in one direction. It closes the causal route in: a patient with no serotonergic exposure at all does not have serotonin toxicity, whatever the picture looks like. It does not work in reverse, because being on a serotonergic agent does not exclude the other syndrome, and a great many patients are on both kinds of drug at once. The class discriminator is therefore a strong exclusion and a weak inclusion, and it has to be used in that direction. That asymmetry is the whole of the difficulty in this item and is taken up below.

4.3 Tempo: the discriminator that costs nothing to obtain

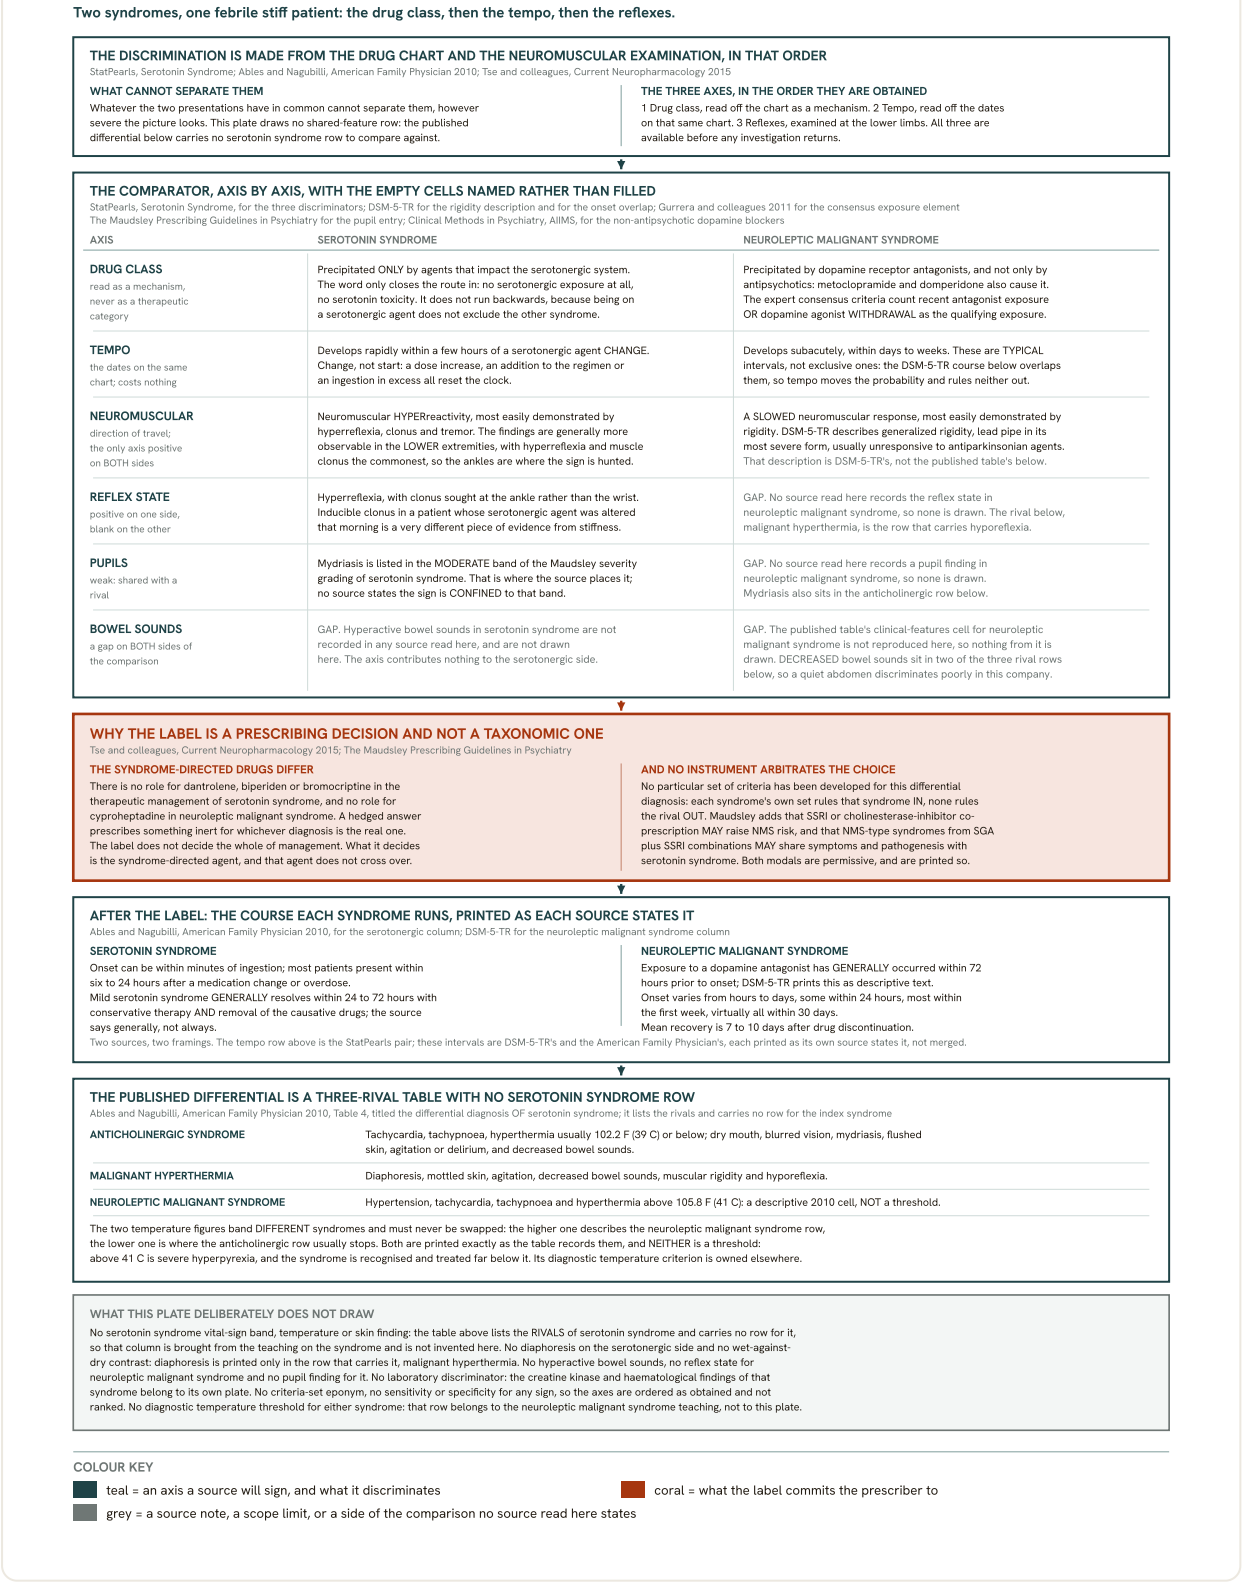

Fig 37.3 Serotonin syndrome against neuroleptic malignant syndrome: the axes that separate them, and the axes that are blank on one side. The three discriminators are obtained in order, drug class then tempo then reflexes, and only the neuromuscular axis returns a positive finding on both sides. Pupils, bowel sounds and the NMS reflex state are drawn as declared gaps rather than filled: the published differential lists the rivals OF serotonin syndrome and carries no row for the syndrome itself, and its two temperature figures band the anticholinergic and NMS rows, never the serotonergic one, and neither is a diagnostic threshold. (StatPearls, Serotonin Syndrome; Ables and Nagubilli, American Family Physician 2010, Table 4; Tse and colleagues, Current

Neuropharmacology 2015; DSM-5-TR; The Maudsley Prescribing Guidelines in Psychiatry; Clinical Methods in Psychiatry, AIIMS.)

The second discriminator is **tempo**, and it is the cheapest one available because the drug chart already carries it. StatPearls times serotonin syndrome to within a few hours of a serotonergic agent change, and neuroleptic malignant syndrome to a subacute development over days to weeks. Those are typical intervals, not exclusive ones. Neuroleptic malignant syndrome can begin far earlier than a subacute description implies, early enough to fall inside the serotonergic window, so the two overlap at their edges. Tempo therefore moves the probability and rules neither syndrome out: clonus hours after a dose change with no antipsychotic exposure is strong evidence, a slow build over a fortnight after an antipsychotic was started is strong evidence the other way, and a stiff, febrile patient on the second day of both drugs is the case tempo cannot settle. The full onset range for neuroleptic malignant syndrome is taught with that syndrome elsewhere in these notes.

Two details make it usable. The first is the word *change*: the trigger is not restricted to a newly started drug, so an increase in dose, an addition to an existing regimen, or an ingestion in excess all reset the clock. The second is that tempo can only be read from a drug chart that carries dates. A history that establishes the patient has been on both an antipsychotic and a serotonergic agent, without establishing when either was last altered, has recorded the exposure and thrown away the discriminator built on it. The accompanying figure sets the tempo axis alongside the other axes of the comparison.

Hours	Days to weeks	Zero	39 C or below
SEROTONIN SYNDROME ONSET, TYPICALLY	NMS ONSET, TYPICALLY	CRITERIA SETS FOR THIS DIFFERENTIAL	ANTICHOLINERGIC ROW, USUALLY

PITFALL

Writing "on olanzapine and escitalopram" in the admission note and nothing more. The entry looks complete and destroys the tempo discriminator, because the reviewer at midnight cannot tell whether one of those agents was changed that morning or has run unchanged for a year. Record the date of the last change to every psychotropic on the chart, not merely the fact of the prescription. The same entry is what a colleague will use to decide whether the picture that develops overnight is the illness or the treatment.

4.4 The neuromuscular examination: opposite directions of travel

The third discriminator is the one that is actually examined, and its strength is that both syndromes give a positive finding rather than one giving a finding and the other giving nothing. StatPearls records the direction of travel as opposite in the two: serotonin syndrome shows **neuromuscular hyperreactivity**, most easily demonstrated by hyperreflexia, clonus and tremor, whereas the examination in neuroleptic malignant syndrome shows a **slowed neuromuscular response**, most easily demonstrated by rigidity.

Stated that way the axis is easy to remember and easy to misapply, because rigidity and hyperreactivity are not mutually exclusive appearances at the bedside. A patient with marked

tremor and increased tone can be described by an inexperienced examiner as stiff. Reflexes and clonus are usually more discriminating than tone alone, which is why the examination has to be performed rather than inferred from the general impression of a rigid, febrile patient. They are not infallible: severe rigidity can obscure them, so an examination that returns no clonus is read alongside the exposure and the tempo rather than banked as a negative result.

Where to look is also specified. The same source records the neuromuscular findings in serotonin syndrome as generally more observable in the lower extremities, with hyperreflexia and muscle **clonus** the most common findings. That is a practical instruction: an upper-limb examination in a restless patient can be equivocal when an ankle examination is not, so the ankles are where the sign is hunted. Inducible clonus at the ankle in a patient whose serotonergic agent was altered that morning is a very different piece of evidence from generalised stiffness in a patient started on an antipsychotic a fortnight ago.

MNEMONIC

Drug class, Tempo, Reflexes

The three axes this comparison actually rests on, in the order they are obtained. The drug class comes from the chart, the tempo from the dates on that chart, and the reflexes from the lower limbs. All three are available before any investigation returns, and none of them requires the patient to be able to give a history.

4.5 The wider differential, and the shape of the published comparison

The two syndromes do not sit alone. The standard published differential of serotonin syndrome, in the American Family Physician review by Ables and Nagubilli, is a three-rival comparison, and its structure teaches something before any of its content does. AAFP Table 4 is titled as the differential diagnosis of serotonin syndrome and its rows are **anticholinergic syndrome**, **malignant hyperthermia** and neuroleptic malignant syndrome. It lists the rivals; it carries no row for the index syndrome itself. A candidate reading it as a two-column contrast will find one column missing, and the serotonin-toxicity side of every axis below has to be brought from the teaching on that syndrome rather than read off the table.

RIVAL IN THE PUBLISHED DIFFERENTIAL	WHAT THAT ROW RECORDS	WHERE THE SEPARATION IS SOUGHT
Anticholinergic syndrome	Tachycardia, tachypnoea and hyperthermia usually **102.2 F (39 C)** or below, with dry mouth, blurred vision, mydriasis, flushed skin, agitation or delirium, and decreased bowel sounds	The mucosa and the skin, which this row records as dry, and a fever band that stops lower than the others
Malignant hyperthermia	Diaphoresis, mottled skin, agitation, decreased bowel sounds, muscular rigidity and hyporeflexia	The exposure history, and reflexes that are depressed rather than brisk beside rigidity
Neuroleptic malignant syndrome	Hypertension, tachycardia, tachypnoea and hyperthermia above **105.8 F (41 C)**, which is how this 2010 table describes the row and is not a diagnostic threshold	The prescribed class and the interval since it changed, before any physical sign. The temperature is not the separator here, and the syndrome is diagnosed well below this figure

Three points earn marks off that table. Mydriasis appears in the anticholinergic row, so a dilated pupil is not by itself a serotonergic sign. Decreased bowel sounds appear in two of the three rows, so a quiet abdomen discriminates poorly in this company. And the two temperature figures band different syndromes and must not be swapped: the higher one describes the neuroleptic malignant syndrome row, the lower one is where the anticholinergic row usually stops. Neither figure is a diagnostic threshold, and the higher one is dangerous read as one. Above 41 C is severe hyperpyrexia; neuroleptic malignant syndrome is recognised and treated far below that, so a candidate who waits for the table's number before naming the syndrome has misread a descriptive cell as a criterion. The diagnostic temperature criterion is taught with that syndrome elsewhere in these notes and is deliberately not printed here. Anticholinergic toxicity, lithium toxicity and malignant catatonia are taught as entities in their own right elsewhere in these notes; what belongs here is only their role as rivals in this one comparison.

4.6 The criteria question, and what no instrument will do for you

Candidates reach for a criteria set at exactly this point, and the reach is the trap. Each syndrome has a named criteria set of its own, taught with that syndrome elsewhere in these notes, and each was constructed to identify its own syndrome in a patient suspected of having it. An instrument built to rule one condition in is not, by construction, an instrument that rules a rival out. The review in Current Neuropharmacology states the position for this pair directly: no particular set of criteria has been developed for this differential diagnosis.

TRAP **Quoting a criteria set as though satisfying it excluded the other syndrome.** A patient exposed to both drug classes can satisfy a serotonin-toxicity criteria set and still have the other diagnosis, because those criteria were validated to identify serotonin toxicity and not to exclude the rival syndrome, and a mixed exposure can produce findings that satisfy them anyway. The examiner is testing whether the candidate knows that the published instruments are diagnostic aids for one syndrome each, and that none has been validated against the specific problem of choosing between the two.

TRAP **Treating the two syndromes as points on one hyperthermic spectrum and hedging the management.** Candidates who cannot decide sometimes write that they would cover both. The published position is the opposite of a spectrum: the syndrome-directed agents used in one have no role in the other, so a hedged answer adds a drug that is inert for whichever diagnosis is real, and it tells the examiner the candidate never made the discrimination. Stopping the suspect agent and supporting the patient is not the hedge, because that is shared ground. Prescribing both syndrome-directed drugs is.

4.7 The patient who is on both drug classes

This is the case the item exists for, and it is the case the discriminators handle worst. The Maudsley Prescribing Guidelines state that co-prescription of SSRIs or cholinesterase inhibitors with antipsychotic medication may increase the risk of neuroleptic malignant syndrome, and that NMS-type syndromes induced by combinations of second-generation antipsychotic and SSRI medications may share their symptoms and pathogenesis with the serotonin syndrome. The modal in both statements is permissive and must be reproduced as such: this is a stated possibility about risk and about shared mechanism, not an established equivalence between the two syndromes.

Hold that beside the criteria position and the picture is coherent rather than merely unsatisfying. The combination that is hardest to classify is also the combination in which the two syndromes are suggested to overlap in mechanism, and it is precisely the combination for which nobody has built a discriminating instrument. The honest teaching is that in the co-prescribed patient the discrimination rests on the drug history and the physical examination, and that a confident label offered without either is a guess wearing a diagnosis.

IN INDIA

Antipsychotic and SSRI co-prescription is routine practice here, so the ambiguous case is the ordinary case rather than the examination curiosity. Two decisions follow. Date every change to both drugs in the notes, because co-prescription is what weakens the drug-class axis and tempo is one of the two discriminators left standing when a patient arrives already on both. The other is the neuromuscular examination, and both have to be recorded. And examine the ankles for reflexes and clonus in every febrile, stiff patient on a combined regimen, because that examination is free, is available in any setting, and is the one axis that gives a positive finding on both sides of the comparison. Do not wait for a criteria set to arbitrate, because none has been developed for this differential.

4.8 Writing the comparison, and what the label commits you to

A comparative-differentiation answer is marked on structure. Four elements carry it, and they are obtained in this order.

- The pharmacological class of every agent on the chart, read as a mechanism rather than as an indication, because that is the discriminator the source puts first.
- The date of the last change to each of those agents, which is what makes the tempo axis readable at all.
- The neuromuscular examination, directed at the lower limbs, looking for the direction of travel rather than for stiffness alone.
- The named diagnosis, followed by the statement that the syndrome-directed drug for one has no role in the other, which is what makes the naming consequential.

On management the boundary holds. The locus of care and the escalation belong to the Perinatal/women's mental health and emergency psychiatry notes. What the discrimination decides is the focus and the mode: the offending agent to be stopped is identified by the class definition above, and the specific agent added afterwards belongs to whichever syndrome has been named, since the review is explicit that neither syndrome's named agents have a role in the other. Each syndrome's own management, in full, is taught with that syndrome elsewhere in these notes and is not repeated here.

GOOD TO REMEMBER

When the diagnosis is genuinely undecided in a co-prescribed patient, what is not in dispute is withdrawal of the suspect agents and the supportive care around that withdrawal, because those steps are common to both syndromes while the syndrome-directed drug that follows is specific to one of them. Deciding which agent is suspect returns you to the class definitions, which is why those two definitions are worth knowing verbatim rather than approximately.

The prescription and the reflexes decide this comparison, the tempo shifts it without settling it, and the decision commits the patient to one of two syndrome-directed drugs, neither of which has a role in the other syndrome.

5 · Other psychotropic emergencies (anticholinergic toxicity, lithium toxicity, malignant catatonia)

Two of these three states are made by the prescription; the third is made by the illness and then complicated by it. Anticholinergic toxicity and lithium toxicity are drug toxicities. Malignant catatonia is not: it is a severe catatonic state usually complicating a psychiatric or medical disorder, and the prescription enters as a competing explanation rather than a cause. The three are grouped because in each of them the drug history does work that no bedside sign can do: it names or excludes a mechanism, it fixes what a measured concentration is allowed to mean, and it decides what happens to the prescription afterwards. The emergency-department presentation, the resuscitation and the disposition belong to the Perinatal/women's mental health

and emergency psychiatry notes, and the receptor logic behind each drug class belongs to the Psychopharmacology I: principles and core drug classes notes. What is examined here is the pharmacology in between: which agents and combinations produce the state, what a serum value can and cannot settle, which prescriptions carry a stable patient across the line, and what the standard sources actually say about treating each one.

5.1 The anticholinergic toxidrome, and the mnemonic that does not quite fit

Muscarinic blockade produces a picture stereotyped enough to be taught as a rhyme. StatPearls sets out the **anticholinergic toxidrome** in six phrases, and then lists the signs they stand for.

MNEMONIC

red as a beet, dry as a bone, blind as a bat, mad as a hatter, hot as a hare, full as a flask

The signs the same source pairs with them are flushing, anhydrosis, dry mucous membranes, mydriasis, altered mental status, fever and urinary retention, with decreased bowel sounds a further common finding. Count the two lists against each other before reciting them: there are seven signs against six phrases, so the one-to-one correspondence the source implies does not fully resolve, and the rhyme is a memory aid rather than a mapping.

Central involvement is what turns this from an unpleasant side-effect burden into an emergency. The same account gives delirium, hallucinations, agitation, restlessness and confusion, together with the two features it treats as characteristic of this particular delirium, **staccato speech** and picking at clothing and bedding, and notes that seizures and jerking movements are possible. The peripheral half of the syndrome tells you which receptor is blocked; the central half tells you the patient is in trouble.

The pharmacological point that organises all of it is that the offending agents are seldom labelled anticholinergics. Tricyclic antidepressants, low-potency first-generation antipsychotics, clozapine, the antiparkinsonian anticholinergics prescribed for extrapyramidal side effects, sedating antihistamines and a long tail of preparations bought without prescription all contribute, and the burden is additive across them. Toxicity may follow a single agent taken in overdose, and it may equally be an arithmetic problem across a whole prescription with no one drug on it at fault, which is why the drug history has to be taken by class of action and not by indication.

5.2 Benzodiazepine first, antidote second

The treatment sequence is examined more often than the toxidrome and it is counter-intuitive. StatPearls makes intravenous benzodiazepines the first-line therapy for agitation, potentially in large doses, in anticholinergic poisoning, and does not put the antidote first.

RULE **Treat the agitation before you treat the receptor.** The sequence is StatPearls' own, and what recommends it is that sedation stakes less on the diagnosis being right than a specific antidote does. A benzodiazepine is not thereby harmless: in the doses this picture needs it can deepen the confusion and compromise breathing. Whether the antidote follows turns on diagnostic confidence, the electrocardiogram and the contraindications, a toxicology decision this account does not make. A stem describing an agitated, flushed, dry, urinary-retaining patient is testing whether the candidate sedates first and reserves the antidote for the case that earns it.

Physostigmine is the specific antidote, a cholinesterase inhibitor whose effect is felt centrally as well as peripherally, and the source notes that it is usually only given in the case of both peripheral and central signs and symptoms of anticholinergic poisoning. That is a description of practice and not an eligibility rule, though it does encode a differential test as much as a treatment threshold. A purely peripheral picture seldom calls for a centrally acting drug, and a central picture with no peripheral signs at all is a reason to reopen the differential rather than to reach for the antidote.

The figures are worth carrying, with the caveat attached to them. StatPearls gives the recommended physostigmine dose in anticholinergic poisoning as **0.5 to 2 mg IV for adults and 0.02 mg/kg IV for paediatric patients, with a maximum paediatric dose of 0.5 mg**. Read that as a stated dose with a paediatric ceiling rather than as a full regimen: no dosing frequency and no adult maximum are stated with it, no titration schedule is carried, and no separate initiation dose sits below it, because the source prints one recommended dose rather than the first step of a schedule. It states no administration rate either, and rate is not a detail: Dawson and Buckley's review of anticholinergic delirium describes physostigmine as titrated intravenously under monitoring, because speed of administration is where the cholinergic and cardiac risk sits. No rate is carried here, and the figure above is not licence to give the dose in one push. That is an internationally recommended dose from a source that carries no Indian regulatory or formulary statement with it, so whether a given unit here can obtain the drug at all is a local question this account does not answer.

5.3 Lithium toxicity: the number, and the band it sits above

Lithium toxicity is the psychotropic emergency tied most closely to a laboratory value, but the value supports the diagnosis rather than making it: exposure pattern, renal function, clinical state and the direction of serial concentrations settle both the toxicity and what is done about it. Meyer and Stahl's Lithium Handbook records that in contemporary usage toxicity is often defined as a serum concentration of **1.5 mEq/L or above**. The Maudsley Prescribing Guidelines describe the same territory in bands: above 1.5 mmol/L toxic effects reliably occur and usually consist of gastrointestinal effects, increasing anorexia, nausea and diarrhoea, and central effects, muscle weakness, drowsiness, confusion, ataxia, coarse tremor and muscle twitching, while above 2 mmol/L increased disorientation and seizures usually occur, which can progress to coma and ultimately death. The hedge is the source's own: both bands are stated as what usually happens. The same section then limits its own figures, noting that these plasma concentrations are only a guide, and individuals vary in their susceptibility to symptoms of toxicity.

What makes the threshold examinable is how close it sits to the top of the treatment band. The Indian Psychiatric Society bipolar guideline states in its narrative that target serum concentrations for acute-phase efficacy fall between 0.6 and 1.2 meq/l. The distance between the top of that band and the concentration at which toxicity is defined is small, and that narrowness, not the absolute value of either figure, is the argument for measuring the drug at all. The published target ranges for the individual agents are taught with therapeutic drug monitoring; what belongs here is only where the band stops.

TRAP **Quoting one guideline's lithium target as though the guideline held only one.** The Indian Psychiatric Society bipolar guideline disagrees with itself. Its narrative adds that 0.4 to 0.8 meq/l may suffice for older adults, which is a permissive statement rather than a target; its own episode-specific dosing tables give a different older-adult figure again, and no erratum reconciles the two loci. A candidate who quotes either one alone is wrong against the other part of the same document, so name the disagreement instead of resolving it.

5.4 Three exposure patterns, and why the same value is not the same event

A serum concentration measures the compartment that is easy to sample, not the one that matters. The Lithium Handbook classifies toxicity by exposure pattern into acute, **acute on chronic** and chronic, and records that the latter two are the more serious in nature and account for the great majority of overdose or toxicity presentations. It gives the mechanism in the same chapter: patients chronically treated with lithium already carry brain concentrations high enough that an acute ingestion, or prolonged exposure to toxic levels, typically 2.0 mEq/L or above, is associated with poorer outcomes than comparable exposures in a lithium-naive patient.

RULE **Ask how long, not only how much.** The identical concentration in someone who swallowed a bottle yesterday and in someone who has taken lithium for a decade describes two different brain exposures, and the sources rank the chronic and acute-on-chronic patterns as the more serious ones. Duration of exposure is part of reading the value, not background to it.

Against that, the routine case has become uncommon. The Lithium Handbook records that modern monitoring schemes and serum concentration ranges have significantly lowered rates of lithium toxicity, and gives an incidence figure reported in longitudinal studies, with a Swedish cohort named alongside it. No comparable Indian incidence figure is available, so the rarity should be read as a property of well-monitored practice rather than as a property of the drug.

5.5 When the concentration is not the syndrome

The most dangerous lithium result is a normal one. The Maudsley guidelines record that neurotoxicity at normal plasma concentrations has also been described, because brain lithium concentrations may not be reflected in the plasma. That one sentence dismantles the reflex that a value inside the range excludes toxicity, and it is why this diagnosis is clinical with laboratory support rather than the reverse.

The severe end of that spectrum has a name. **SILENT**, the syndrome of irreversible lithium-effectuated neurotoxicity, denotes neurological sequelae that persist after the drug has been withdrawn, the original description setting the boundary at sequelae still present at least two

months after lithium is stopped. Persistent cerebellar dysfunction is the commonest pattern, not the whole of the definition. A review of published cases found that among the subset of 51 cases with persistent cerebellar symptoms whose peak concentrations were under 2.5 mEq/l, fever or infection was a strong predictor, with an odds ratio of 13.9 (95% CI 3.21 to 60.05), while in the 34 cases whose peak concentrations reached or exceeded that figure fever was not a significant predictor of cerebellar sequelae. Read the scope carefully. This is a review of published cases, and 2.5 mEq/l is that review's cut, not a validated line above which a patient is in danger and below which the numbers reassure. Within that selected material, fever or infection carried the association with persistent cerebellar sequelae in the subgroup under the cut, and not in the subgroup above it.

PITFALL

Sending the ataxic patient home because the level came back in range. Brain and plasma are not the same compartment and the source describes neurotoxicity at normal plasma concentrations, so new coarse tremor, ataxia or confusion in a lithium-treated patient is a neurological problem that needs an explanation whatever the assay says. Where a febrile illness sits behind it, the fever is not a side issue to the lithium question; in the reviewed cases whose peak concentrations stayed under the review's own cut, it was the variable that carried the association with persistent cerebellar sequelae.

5.6 The prescriptions, and the sample, that anticipate it

Lithium offers no receptor profile from which to predict its adverse effects. What predicts them is exposure: how much drug, for how long, and what is happening to its clearance. The interactions that matter are therefore the ones that alter renal handling of sodium and water, and they come from general medicine rather than from psychiatry. The Maudsley guidelines report that in the elderly, angiotensin-converting enzyme inhibitors increase seven-fold the risk of hospitalisation due to lithium toxicity. For thiazide diuretics the timing is predictable and the size of the effect is not: concentrations usually rise within 10 days of the diuretic being prescribed, and the magnitude of that rise varies widely between patients, which means no safe assumption can be made about how far a given patient will move.

The Indian Psychiatric Society bipolar guideline converts the same pharmacology into a monitoring instruction, naming the patients who need **more frequent monitoring**.

- Older adults.
- Those receiving diuretics.
- Those receiving non-steroidal anti-inflammatory drugs or angiotensin converting enzyme inhibitors.
- Those with renal impairment.

None of it is interpretable without the sampling rule attached to it. The same guideline requires that the lithium sample be drawn **11 to 13 hours after the last dose**, and before the next dose where the drug is given twice or three times daily. That window belongs to routine monitoring: a

concentration drawn outside it cannot be read against the monitoring bands and will not carry a dose change. It is not a reason to withhold a level from a patient who looks toxic. In suspected poisoning the sample is taken on presentation and repeated, and the interpretation rests on that trend, the time since the last dose and the clinical state.

>90%	48%	25 to 400%	0.01
CHRONIC OR ACUTE ON CHRONIC	REVIEWED SILENT CASES WITH FEVER OR INFECTION	RISE AFTER A THIAZIDE IS ADDED	TOXICITY EPISODES PER PATIENT-YEAR

IN INDIA

Two outpatient decisions follow from that footnote and that sampling rule. First, ask about analgesics by name at every review rather than asking whether the patient takes any other medicines: an anti-inflammatory bought across a counter is not experienced as a prescription and will not be volunteered, yet the guideline names that class alongside diuretics and angiotensin converting enzyme inhibitors as a reason to measure more often. Second, book the blood draw to the guideline's own post-dose window rather than to whatever hour the patient reaches the clinic, because a conveniently timed sample cannot support a dose change in either direction. The unwell patient is the exception noted above: there the blood is drawn on arrival and repeated, not deferred to the next morning's window.

5.7 Malignant catatonia, and the syndrome it may not be separable from

Malignant catatonia is the third emergency and the hardest to place, because the authorities that describe it say it may not be separable from something else. The Maudsley Prescribing Guidelines state that it may not be distinguishable from neuroleptic malignant syndrome, either clinically or by laboratory testing, and that this has prompted the view that the latter may be a variant form of the former. DSM-5-TR says the same thing from the opposite direction, in its differential diagnosis of neuroleptic malignant syndrome: malignant catatonia may be indistinguishable from it, and some investigators consider neuroleptic malignant syndrome to be a drug-induced form of malignant catatonia. Two standard sources converging on the same non-separation is not a gap in the literature to be filled in an answer; it is the finding.

That leaves the drug history as the most useful discriminator, and the sources are precise about how far it reaches. In the absence of any prior or recent administration of a **dopamine antagonist**, the Maudsley position is that neuroleptic malignant syndrome can probably be ruled out. The hedge is the source's word and is not to be upgraded, and the exclusion is about antagonist-associated disease: the fall in central dopaminergic activity that produces the syndrome also follows abrupt withdrawal of dopaminergic treatment, which no drug chart records as an exposure. The drug history shifts the probability; it does not settle the diagnosis. What the source does not state is the converse.

TRAP **Reading the exclusion rule backwards.** One inference is licensed, and only along the antagonist route: no dopamine antagonist, probably not neuroleptic malignant syndrome. The converse, that recent exposure makes the diagnosis, is not licensed, and the converse is what candidates write. A catatonic patient who has also received an antipsychotic has two candidate states and one shared laboratory picture, and naming the exposure does not choose between them.

The exposure list is also wider than the antipsychotics. The Maudsley guidelines record that neuroleptic malignant syndrome is also sometimes seen with antidepressants, valproate, phenytoin and lithium. That matters twice in this topic: it widens the prescription review that has to be done before the syndrome is excluded on drug-history grounds, and it puts lithium on both sides of the same page, as an agent that produces its own concentration-defined emergency and as an agent occasionally implicated in this one.

5.8 Pharmacological management, and the marker the two share

Malignant catatonia is not defined here by a criteria set, and that absence is part of the teaching. The standard guidelines and textbooks describe it as a clinical state and say that it may not be distinguishable from neuroleptic malignant syndrome, either clinically or by laboratory testing; none of them supplies a threshold that makes catatonia malignant. An answer that produces criteria for it has invented them. The rating instrument for catatonia and the challenge test that establishes the diagnosis belong with the catatonia teaching rather than with this emergency, and are not redrawn here.

Treatment, in the sources read for this topic, is stated for the refractory case only. The Indian Psychiatric Society schizophrenia guideline places dantrolene and dopamine agonists like bromocriptine in refractory malignant catatonia. Read the qualifier rather than the drug names: refractory. These agents are named for the case that has not responded, and the guideline does not present them as the opening pharmacological move. The emergency act itself, including escalation and the disposition decision, belongs to the Perinatal/women's mental health and emergency psychiatry notes.

EMERGENCY	WHAT PRODUCES IT	WHAT A MEASUREMENT CONTRIBUTES	THE COMMONEST WRONG INFERENCE
Anticholinergic toxicity	A single agent in overdose, or additive antimuscarinic burden across prescribed and over-the-counter agents	No defining concentration; the peripheral and central halves of the syndrome are what gate the antidote	That the specific antidote is the opening move
Lithium toxicity	Acute ingestion, or accumulation from impaired renal clearance, volume or sodium depletion, a dosing error or an interacting drug	Support, not a verdict: read against the bands only on a correctly timed sample, and in suspected toxicity it is the serial trend with the exposure pattern that counts	That a value inside the treatment range excludes neurotoxicity
Malignant catatonia	Usually a severe catatonic state arising in psychiatric or medical illness, not a drug effect; antipsychotic exposure raises the competing possibility of neuroleptic malignant syndrome and may worsen the catatonia	Nothing discriminating; the laboratory picture is shared with neuroleptic malignant syndrome	That recent dopamine antagonist exposure settles the diagnosis

GOOD TO REMEMBER

Kaplan and Sadock's Comprehensive Textbook of Psychiatry supplies the one laboratory value the two overlapping states share: serum **creatine kinase** is especially elevated in malignant catatonia and in neuroleptic malignant syndrome and can increase the risk of renal failure, and should be tracked to ensure a downtrend. The instruction is serial, not single. One raised value describes a moment; a falling series is one objective marker that the decision already taken is working, read alongside temperature, autonomic stability, rigidity and renal function rather than in place of them, and the cheapest of them in any unit.

In all three emergencies the prescription is where the reading starts and not where the diagnosis ends: read the exposure and its duration first, then the number, never the number by itself, and remember that the third of them can arrive in a patient whose drug chart had nothing to do with it.

Treatment resistance and augmentation

6 · Treatment-resistant depression: definition, staging and assessment

Resistance is a judgment on the treatment record before it is a statement about the patient. Almost every element of the definition of treatment-resistant depression is a convention that

somebody wrote down: how many failed trials, how large a fall in symptoms counts as a response, how long a trial must run before it may be called failed, and whether the failures have to be pharmacological at all. Different bodies settled those questions differently, and the better ones say so in the same paragraph as their own definition. Marks here go to an answer that states a definition and names whose it is, shows what has to be excluded before the label is applied, knows the response arithmetic sitting underneath it, and can say why the staging models built to grade resistance never entered routine practice. It is examined as a definition question and it is answered badly as one, because the definition is the least interesting part of the topic.

6.1 The definition, and the bodies that issue it

The most widely used definition of **treatment-resistant depression** is inadequate response to **a minimum of two antidepressants** given at **adequate dose and duration** with adherence confirmed, and it carries regulatory weight because both the United States Food and Drug Administration and the European Medicines Agency have adopted it. The Indian CPG 2025 sets the same bar, at least two antidepressants at adequate dose and duration, then qualifies it in the same breath: definitions vary, and they commonly overlook psychological and neurostimulation treatments and partial responses. CANMAT 2023 is blunter, recording that a universal consensus definition is lacking and that the most frequently used one is failure to respond to at least two antidepressant trials at a therapeutic dose and adequate duration. One caveat attaches to that third attribution and not to the bar itself: the CANMAT sentence quoted here could not be located in the copy of the 2023 update used for these notes, so treat the CANMAT wording as unverified and rest the two-antidepressant threshold on the regulatory and Indian statements, which are. Three bodies, one arithmetic core, and an open admission from two of them that the core is an agreement rather than a finding.

The operational detail is where they separate. The accompanying table puts the same four questions to each definition, and the blanks are as informative as the entries: a definition that fixes a trial count without fixing a non-response threshold has left the harder half of the work undone.

DEFINITION	FAILED TRIALS REQUIRED	THRESHOLD FOR NON-RESPONSE	MINIMUM TRIAL LENGTH STATED
Food and Drug Administration and European Medicines Agency, as the most used definition	A minimum of two antidepressants, with adequacy of the trial and adherence both required	Not stated in the definition	Not stated in the definition
Indian CPG 2025	At least two antidepressants at adequate dose and duration	Not attached to the definition	Not attached to the definition
CANMAT 2023	At least two trials at a therapeutic dose and adequate duration	Not stated with the definition	Not stated with the definition
Canadian expert consensus, by modified Delphi	Fixed by the consensus; figure not printed here	Fixed by the consensus; figure not printed here	Fixed by the consensus; interval not printed here
European Group for the Study of Resistant Depression	Consecutive adequate trials, characterised by named clinical predictors; the count and the predictors are not printed here	Below 50 percent symptom reduction	Not stated in the account used here

Only the Canadian consensus fixes all four, and its own report states the level of agreement each of those items reached at GRADE-high evidence. None of the four values, and none of the agreement figures, is printed in this account. The Delphi report itself could not be consulted here, and every one of those numbers is one a reader would apply to a patient's trial record, so the table says which columns the consensus filled and leaves the values to the paper. What the comparison still shows is the shape of the problem: a formal vote was needed to fix elements the other definitions leave open, which is a fair measure of how soft the ground is. The European group adds something the others leave out: it characterises its trials by the clinical features that travel with resistance rather than by the trials alone, and it operationalises response with validated rating scales instead of clinical impression. How many consecutive trials it requires, and which clinical features it names, both come from a table this account could not check against the original report either, so the requirement is described as a class and its contents are not listed.

RULE **Treatment resistance is an operational judgment, not a property of the illness alone.** It combines documented adequate treatment exposure, meaning how many agents, at what dose, for how long, and whether they were swallowed, with inadequate clinical response in a depressive illness. The exposure half is entirely a matter of record, which is why the first move on meeting an apparent non-responder is to audit the treatment record rather than escalate the regimen, and why the guidelines quoted here prescribe a reappraisal before the next prescription.

6.2 What makes a trial adequate

The trial count is arithmetic; the word carrying the weight is adequate, and it has three limbs. Duration is the limb most often assigned a number, but the published thresholds are not uniform. Across the literature the minimum antidepressant trial duration cited for adequacy is typically 4 weeks, with a reported range running from 4 to 12 weeks. The Indian material sits at the shorter end and is stable across two editions of guidance: clinical improvement with an antidepressant typically appears after **4 to 6 weeks** of adequate treatment, and the IPS CPG 2017 depression guideline states that adequate treatment for at least 4 to 6 weeks is necessary before concluding that a patient is not responsive to a particular medication. The Canadian expert consensus voted on a minimum of its own, and for the reason given above that figure is left to its paper. The Indian interval, stable across two editions of guidance and matching the shorter end of the published range, is the one to carry into the hall.

Dose adequacy resists a single number because it is agent-specific: a therapeutic dose of one antidepressant is a fraction of the daily milligram figure of another, which is why the definitions ask for a therapeutic dose of that agent and not a universal one. Which agent is chosen within a class, and the pharmacokinetic reasoning that fixes what a therapeutic dose is, belong to the Psychopharmacology I: principles and core drug classes notes. The third limb, adherence, is written into the most used definition itself, which is why it has to be confirmed rather than assumed before a trial is counted as failed.

6.3 How much improvement counts as a response

A trial can only fail against a threshold, and the conventional set is straightforward: a **partial response** is at least 25 percent but less than 50 percent improvement and **non-response** is **less than 25 percent improvement**. The 50 percent mark is where a response begins, so the three categories partition the range without overlapping. The resistance literature works from the upper of those two boundaries, not the lower. The European Group for the Study of Resistant Depression identifies resistance as below 50 percent symptom reduction, and the Canadian consensus voted a threshold of its own that this account does not print. A patient who is a partial responder on the conventional set can therefore be counted a non-responder by the resistance definitions, and the two words are not interchangeable in a written answer.

TRAP **Reading a response-monitoring rule as an adequacy criterion.** The IPS CPG 2025 depression guideline directs that where less than 50 percent improvement is observed even after 6 to 8 weeks of treatment at optimal dose with good adherence, treatment is modified by either switching or augmenting. That is a decision rule for a trial already under way, and it belongs to the guideline's material on how long an antidepressant is continued, not to its account of resistance. The section defining resistance asks only for an adequate dose and duration and attaches no number to either. A candidate who converts the monitoring interval into the adequacy threshold has printed a figure the guideline never issued as one.

6.4 Pseudo-resistance, and the work that precedes the label

The first question to put to an apparent non-responder is whether the resistance is real. A substantial proportion of apparent treatment resistance is **pseudo-resistance**, arising from

inadequate trials or non-adherence rather than true refractoriness. The distinction changes the action completely: one situation calls for finishing a trial that was never finished, the other for moving past it. Indian guidance puts the audit first, stating that the first step in caring for a patient who has not responded to medication is a thorough review and reappraisal of the psychosocial and biological information base, aimed at re-verifying the diagnosis and identifying neglected contributing factors. That places a review, not an escalation, at the head of the algorithm.

MNEMONIC

Diagnosis, Adherence, Trials, Causes, Stressors

Five checks stand between a non-responder and the label. The first three interrogate what was prescribed and whether it was taken; the last two ask what else is holding the episode open. Work them in that order, because a diagnostic revision makes the trial history irrelevant, whereas a stressor identified first tempts the clinician to stop looking.

IN INDIA

Before confirming resistance, the Indian 2025 guideline requires five assessment steps: reassess the diagnosis, with bipolar disorder and comorbidity specifically in mind; check treatment adherence; review the adequacy of past trials for dose, duration and switching strategy; identify medical causes, naming hypothyroidism and vitamin deficiencies; and evaluate psychosocial stressors. Those two are given as examples of the medical causes to look for, not as a panel to run on every non-responder: investigate thyroid dysfunction or nutritional deficiency where the clinical assessment and the local protocol indicate it. The step sits before the label in the guideline's own order, so the question is settled while resistance is being considered rather than after it has been recorded.

PITFALL

Counting a trial the patient abandoned in the second week as one of the two failures. The trial count is the easiest part of the definition to satisfy on paper and the easiest to satisfy wrongly. An agent stopped early for side effects tested tolerability, not efficacy; an agent taken intermittently tested neither. For every past drug, establish the dose reached, the time spent at it, and how much of it was actually taken, before that drug is allowed into the count.

6.5 How common resistance is, and what each figure counts

Two prevalence figures are routinely quoted against one another and they count different things. Per the Indian 2017 guideline, initial treatment with an antidepressant fails to achieve a satisfactory response in approximately 20 to 30 percent of patients with depressive disorder, which is the failure rate of the first trial. Measured against the two-trial definition, **at least 30 percent** of people with depression meet criteria for resistance. The two numbers look alike and answer different questions, so setting them side by side as an Indian figure against a Western one is an error about denominators rather than about arithmetic. No Indian prevalence estimate for

resistance itself was available for this account; the defensible answer in a viva is to give the Western figure and label it as Western.

Attrition across successive treatment steps is the more useful teaching number, because it quantifies what each further attempt is worth.

36.8%	30.6%	13.7%	13.0%
FIRST STEP	SECOND STEP	THIRD STEP	FOURTH STEP

In STAR*D, QIDS-SR remission rates fell across the four successive acute treatment steps as shown, with an overall cumulative remission rate reported at 67 percent. The collapse between the second step and the third is the single most quotable finding in this literature, because it marks where the yield of simply trying another agent falls away, and it is the empirical argument for treating two failures as a decision point rather than an arbitrary one. The cumulative figure is a different matter.

TRAP **Quoting the cumulative remission figure as a settled result.** A reanalysis of the original STAR*D data found the overall remission rate to be 35 percent, as opposed to the claimed 67 percent, and the standard prescribing texts now print the reanalysis alongside the original. The step-wise rates are not what is contested; the cumulative arithmetic is. Quote the step-wise collapse freely, and never quote the cumulative figure without its reanalysis beside it.

6.6 The staging models, and what each of them grades

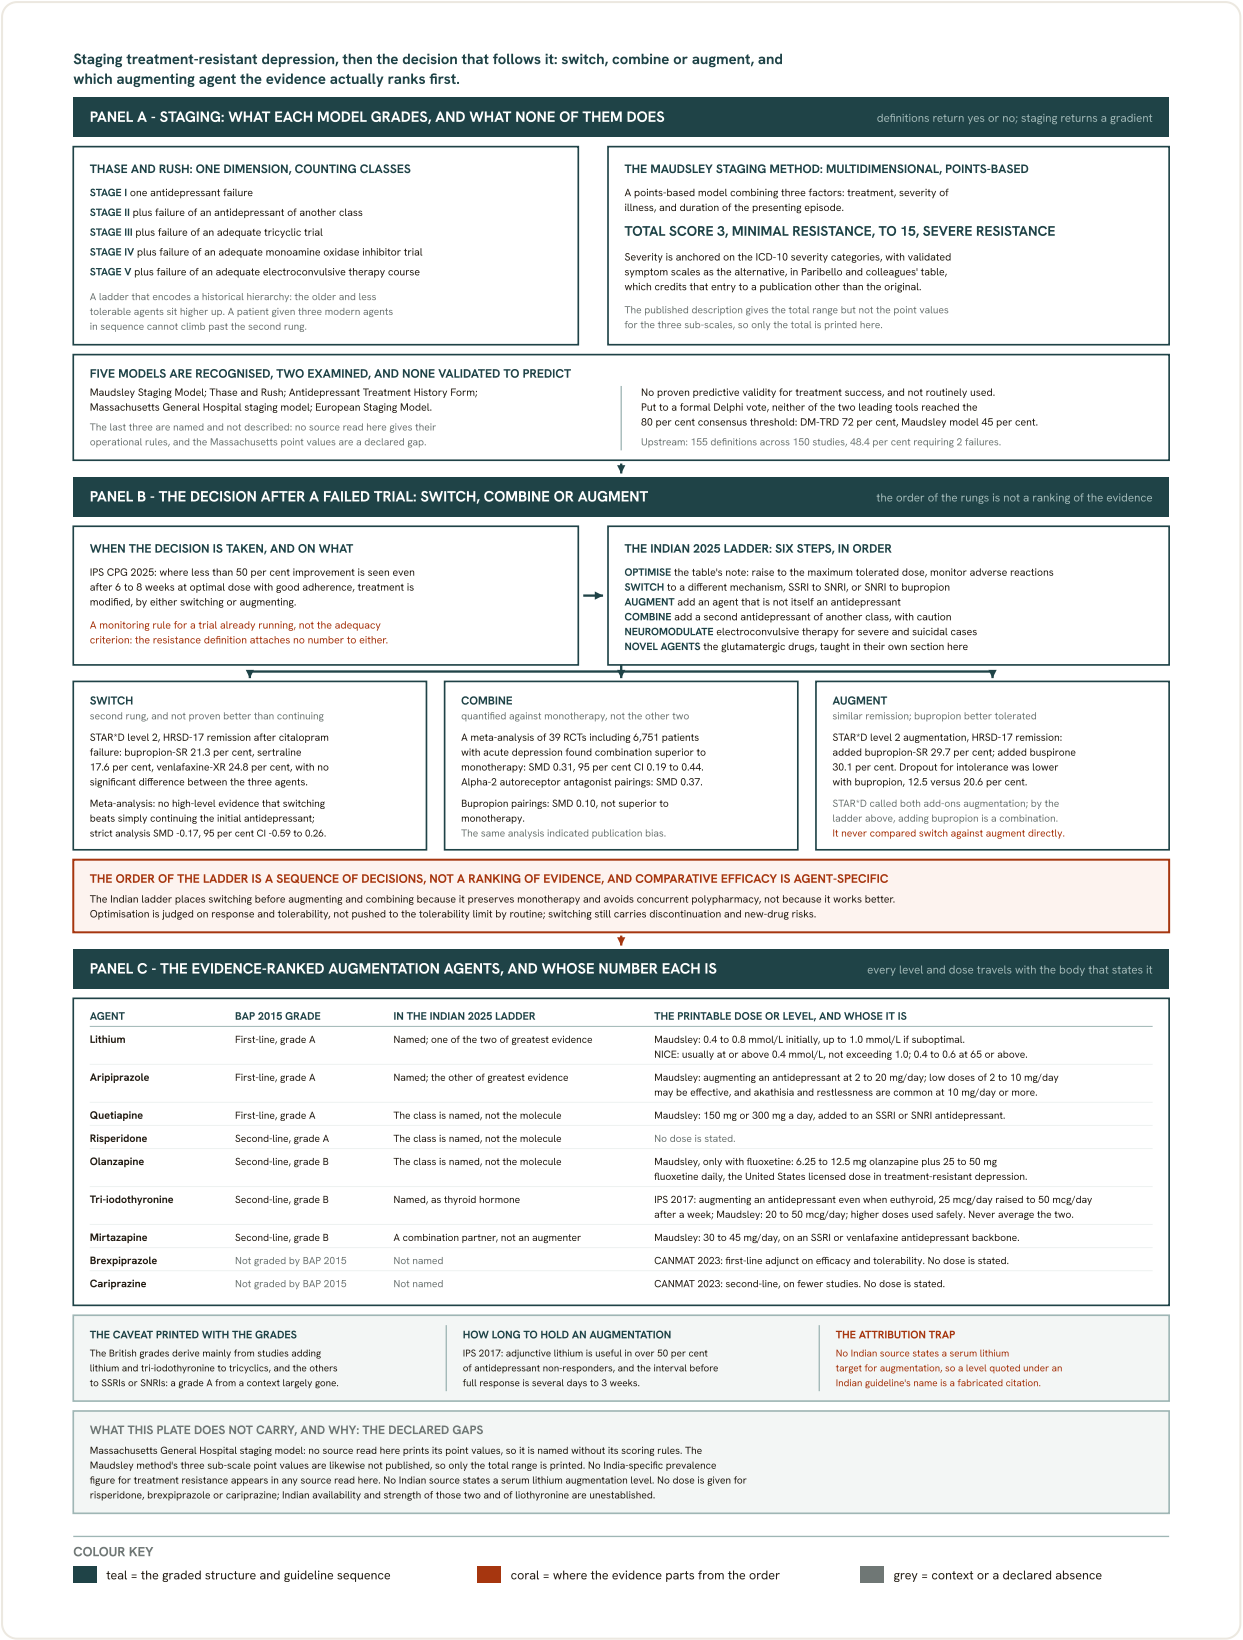

Fig 37.4 Staging treatment-resistant depression, then switching, combining or augmenting. Two of five recognised models are examined: Thase and Rush counts failed classes across five stages, the Maudsley method scores treatment, severity and duration to 3 to 15. Neither is validated to predict, and at a Delphi vote neither cleared 80 per cent. The Indian 2025 ladder runs optimise, switch, augment, combine, neuromodulate, novel agents, a decision sequence, not a ranking of evidence: switching is early because it preserves monotherapy, optimisation is the table's wording qualified in the rule box, and comparative efficacy is agent-specific. Every dose and level is attributed to the body stating it; the Indian guideline names the agents without a figure. (IPS CPG

2025 and 2017; Maudsley Prescribing Guidelines 15th edition; NICE NG222; BAP 2015; CANMAT 2023; STAR*D; Rybak and colleagues 2021; Paribello and colleagues 2026.)

Where a definition returns a yes or a no, **staging models** return a gradient. Five are recognised:

- the Maudsley Staging Model;
- the Thase and Rush model;
- the Antidepressant Treatment History Form;
- the Massachusetts General Hospital staging model;
- the European Staging Model.

Two of them are worth knowing in detail, because they grade different things and a question asking you to compare staging systems is asking for exactly that contrast. The **Thase and Rush model** is one-dimensional and counts classes: Stage I is a single antidepressant failure; Stage II adds failure of an antidepressant of another class; Stage III adds failure of an adequate tricyclic trial; Stage IV adds failure of an adequate monoamine oxidase inhibitor trial; and Stage V adds failure of a bilateral electroconvulsive therapy course. It is a ladder, and the ladder encodes a historical hierarchy in which the older and less tolerable agents sit higher up, which is both its clarity and its weakness: a patient given three modern agents in sequence cannot climb past the second rung. The procedure at the top rung is set out in the ECT and neurostimulation notes.

The **Maudsley Staging Method** is multidimensional. It is a points-based model combining three factors, treatment, severity of illness and duration of the presenting episode, scored so that the total runs from 3, marking minimal resistance, to 15, marking severe resistance. The published description gives the total range but not the point values for the three sub-scales, so only the total is printed here and the individual point allocations are to be taken from the original description. Learn the three dimensions, the direction of the scale and its two bounds. Because severity and chronicity carry points of their own, a patient with two failed trials and a severe, long-standing episode scores above a patient with two failed trials and a mild recent one, which is closer to how the difficulty is actually experienced in clinic.

How that severity dimension is anchored is stated in two places and the two must not be merged. The paper that first described the points-based model is the authority for the three factors and for the score range. The operationalised criteria attributed to the method in Paribello and colleagues' comparison table of staging systems are the ICD-10 severity categories, with validated symptom scales offered as an alternative, and that table credits its entry to a different publication on the same method rather than to the original description. Cite each to the paper that states it; a single citation covering both is wrong about one of them. The Massachusetts General Hospital model is named in the same reviews, but its scoring rules are not reproduced there, so no point values for it are given here.

6.7 Why none of this reaches the bedside

The candid position is that these staging models do not have proven predictive validity for treatment success and are not routinely used. That single sentence is worth more marks than any stage table, because it converts a list-learning answer into an appraisal. A staging system earns its

place by predicting something: which patient will respond to augmentation, which will need a procedural treatment, which will remit at all. These grade the past and have not been shown to forecast the future.

Formal consensus has said the same thing arithmetically. When the two leading staging tools were put to a Delphi vote, neither reached the 80 percent consensus threshold for recommendation: the DM-TRD scored 72 percent and the Maudsley staging model 45 percent. That same report states a different pair of figures for these two items in another passage of its own text; both cannot be the paper's figure, so only the pair given here is printed and the discrepancy is named rather than resolved.

The deeper trouble sits upstream of staging altogether. A systematic review by Brown and colleagues, published in the Canadian Journal of Psychiatry in 2019, identified 155 definitions of TRD in the published literature across 150 studies, and 48.4 percent of all definitions specified a requirement of at least 2 treatment failures. Both figures are that review's own count and are quoted on its authority. Read the second figure carefully, because it is the examinable one: a little under half of published definitions use the two-trial rule, which means that the population labelled resistant in one trial is not reliably the population labelled resistant in the next. Every efficacy figure quoted for a treatment in resistant depression inherits that imprecision, and it is the reason the switch, combination and augmentation evidence taken up later in this chapter has to be read against the definition each study used.

6.8 From resistant to difficult to treat

The terminology is moving, and the guidelines have moved ahead of the textbooks. The Maudsley Prescribing Guidelines record a move to characterise treatment-resistant depression as **difficult to treat depression**, on the basis that the former description implies that depression treatments are normally effective and that non-response is therefore somehow abnormal. That rationale is worth reproducing accurately, because it is an argument about base rates rather than about kindness of language: if a third of patients do not respond to two adequate trials, non-response is a common outcome of treatment and not a deviation from it.

Indian practice has already adopted the reframing in its own text. In the IPS CPG 2025 depression guideline, difficult-to-treat depression is used as the holistic framework, while treatment-resistant depression is retained when referring to medication options or to studies that use that definition. That sentence, rather than the two-trial rule, is the one that separates a current answer from a dated one: a candidate who offers only the failed-trial definition is answering the older guideline. The framework term governs the formulation and the narrower term governs the pharmacology, which is a division of labour rather than a change of mind, and the same logic explains why the resistant-schizophrenia material later in this chapter keeps its own vocabulary.

GOOD TO REMEMBER

The reframing changes the question asked at the review appointment. Resistance asks which agent has not yet been tried. Difficulty asks what is keeping this episode open, which returns the clinician to the five pre-label checks and to the contributors the reappraisal is meant to surface. Both questions are legitimate and only one of them can be answered by writing another prescription, so ask the second before the first.

Two failed adequate trials make the label; adequacy, adherence and a re-verified diagnosis are what make the label true.

7 · Switching, combination and augmentation strategies (lithium, atypical antipsychotics, thyroid)

A failed antidepressant trial forces a choice, not a new diagnosis. Once an adequate therapeutic dose has been given for an adequate duration, with optimisation considered against response and tolerability rather than pushed to the tolerability limit as a matter of routine, three structurally different manoeuvres are available: replace the drug, add a second antidepressant, or add something that is not an antidepressant at all. The marks sit on knowing that these are not interchangeable rungs of one ladder, that the order guidelines print them in is a sequence of decisions rather than a ranking the evidence supplies, and that almost every number attached to them belongs to one named body and is wrong under any other attribution. The definition and staging of resistance are taken up separately; what follows begins after resistance has been established.

7.1 The sequence, and what each rung actually is

The Indian 2025 guideline sets a six-step sequential ladder for **difficult-to-treat depression**, and it is the cleanest scaffold to answer from because it separates manoeuvres that an unstructured answer runs together.

- **Optimise** the current treatment: raise it to the maximum tolerated dose and monitor adverse reactions before concluding anything about response.
- **Switch** the antidepressant, choosing an agent with a different mechanism of action, such as an SSRI to an SNRI, or an SNRI to bupropion.
- **Augment**: add an agent that is not itself an antidepressant.
- **Combine**: add a second antidepressant from a different class, and the guideline attaches the words with caution to this rung specifically.
- **Neuromodulate**, with electroconvulsive therapy for severe and suicidal presentations; the modalities are taught in their own sections here.
- **Novel agents**, which is where the glutamatergic drugs sit; it has its own section here.

Two distinctions inside that list are examined more often than the list itself. **Augmentation** means adding an agent from outside the antidepressant classes, so the antidepressant continues

unchanged and the added agent works through a different mechanism. Combination means running two antidepressants together. The clinical consequence differs: an augmenting agent imports a new adverse-effect class and a new monitoring requirement, whereas a second antidepressant mostly intensifies pharmacology the patient already has, and with serotonergic pairs it raises the serotonin syndrome question taken up elsewhere here. The receptor pharmacology of each individual agent belongs to the Psychopharmacology I: principles and core drug classes notes.

MNEMONIC

Optimise, Switch, Augment, Combine, Neuromodulate, Novel

The six rungs in order. The first is the one candidates skip and the one that costs the mark: a trial at a subtherapeutic or otherwise inadequate dose has not failed, and the sequence does not begin until it has. Submaximal and subtherapeutic are not the same word. Many adequate trials run at a therapeutic dose below the maximum the patient could tolerate, so optimisation is a separate decision taken on response and tolerability, which is why the guideline gives it a rung of its own rather than folding it into the definition of failure.

7.2 Switching, and why its evidence is thinner than its position

Switching is the second rung in the Indian 2025 sequence and appears early in many algorithms, which invites the assumption that it is the best-supported second move. It is not. In STAR*D level 2, patients switched to another agent after citalopram failure reached HRSD-17 remission in similar proportions whichever agent they were given, with the difference between the three falling short of significance.

21.3%	17.6%	24.8%
SWITCH TO BUPROPION-SR	SWITCH TO SERTRALINE	SWITCH TO VENLAFAXINE-XR

The add-on arm of the same programme is examined nearly as often, and one point of nomenclature has to be settled before its numbers mean anything. STAR*D called both add-on strategies augmentation; under the taxonomy this chapter takes from the Indian guideline, adding bupropion is antidepressant combination and only adding buspirone is augmentation. Trivedi and colleagues, reporting that arm in the New England Journal of Medicine in 2006, record HRSD-17 remission of 29.7 percent with added sustained-release bupropion and 30.1 percent with added buspirone, and a lower dropout rate due to intolerance with bupropion, 12.5 percent against 20.6 percent. Both of those comparisons live inside the add-on cohort. That cohort was never randomised against the switch cohort, so no switch-versus-augmentation inference can be drawn from the two together: the numbers sit side by side because the programme ran both, not because anyone compared them, and an answer that reads the higher add-on figure as evidence that adding beats switching has overreached. The tolerability advantage is narrower still, belonging to bupropion against buspirone within the add-on comparison and saying nothing whatever about switching.

The harder counterweight comes from meta-analysis, which found no high-level evidence that switching the antidepressant is superior to simply **continuing the initial antidepressant**. That comparator is the one switching trials usually omit, and it matters because time alone produces response: a patient re-rated after a switch has had more treatment as well as a new drug, and designs that separate the two are rare.

RULE **The order of the ladder is a sequence of decisions, not a ranking of evidence.** The Indian ladder places switching early because it preserves monotherapy and avoids concurrent polypharmacy, not because it works better. That is not the same as costing nothing: switching carries its own discontinuation, interaction and new-drug adverse effects, so the trade is one adverse-effect burden for another rather than a burden avoided. Nor does the evidence supply a general ranking to put in the order's place. Comparative efficacy between switching, combining and augmenting is specific to the agents and the trial, and a candidate who can say why the order and the evidence part company, without inventing a hierarchy to replace the one they have just dismantled, has understood the topic.

7.3 Combination: which pairing earns the term

Combination carries a quantified benefit over monotherapy, and the population it was quantified in has to travel with it: the analysis is of acute depression, including but not confined to patients who had already failed a trial, so it does not establish combination as the best strategy in treatment-resistant depression specifically. A meta-analysis of 39 RCTs including 6,751 patients found combining antidepressants superior to **monotherapy**, with a standardised mean difference of 0.31. That benefit was unevenly spread across the pairings. Combinations built on a **presynaptic alpha-2 autoreceptor antagonist** were superior to other combinations, at 0.37. Bupropion combinations were not superior to monotherapy. A complementary autoreceptor mechanism is the proposed explanation for that split, and it is worth being able to state: blocking the presynaptic autoreceptor lifts the negative feedback that damps monoamine firing, which is a different lever from the one a reuptake inhibitor pulls. What the analysis actually demonstrates is an association by combination class. It does not test that mechanism, and the result is not a reason to say that bupropion merely duplicates the pharmacology of the drug it is added to. The same analysis carried an indication of publication bias, and an answer that quotes the effect size without that caveat is quoting half of it.

The Maudsley Prescribing Guidelines place the practical pairings in their tier of commonly used treatments, generally well supported by published literature. What that tier prints for treatment-resistant depression is a comparative list, not one regimen: three add-ons across two backbones, with no starting dose stated for any of them. An SSRI plus bupropion is entered as up to 400 mg/day, a ceiling and not a start, and the same evidence tier records that bupropion is not licensed for depression in the United Kingdom. Mianserin added to an SSRI or venlafaxine backbone in resistant depression is a flat figure, 30 mg/day, and the disadvantage recorded against it in the same evidence table is a risk of blood dyscrasia. Mirtazapine on those same backbones, again for resistant depression, is 30 to 45 mg/day, and one randomised trial showed no advantage for mirtazapine added to an SSRI or SNRI. Both autoreceptor pairings carry a theoretical risk of serotonin syndrome that the patient is to be informed of.

7.4 Lithium augmentation, and the number no Indian source states

Lithium is the drug primarily used as an **adjunct** in treatment-resistant depression according to the Indian 2017 guideline, which reports it useful in over 50 percent of antidepressant non-responders and usually well tolerated. Its most examinable feature is the latency: the interval before full response to adjunctive lithium is reported as **several days to 3 weeks**. That figure decides when a trial of the addition may fairly be called a failure, and it is strikingly short beside the antidepressant trial that preceded it.

No serum lithium target for antidepressant augmentation is carried by the Indian guidance these notes rest on, so the bands below belong to the bodies that state them. For lithium augmentation of an antidepressant the Maudsley target is a plasma level of **0.4 to 0.8 mmol/L** initially, increasing to up to 1.0 mmol/L if the response is suboptimal, and the same entry records plasma level monitoring as essential. NICE, for lithium used to augment antidepressant medication, states that plasma lithium levels should not exceed 1.0 mmol/L, that therapeutic levels for that purpose are usually at or above 0.4 mmol/L, and that levels of 0.4 to 0.6 mmol/L should be considered for older people aged 65 or above. The two are not the same kind of statement. The Maudsley gives a band to aim at. NICE gives a ceiling, and its lower figure is a usual practice rather than a floor: augmentation levels are usually, not invariably, at or above 0.4 mmol/L, so a level below it is not thereby declared subtherapeutic.

TRAP **Putting an Indian attribution on a lithium augmentation target.** The Indian guidance names lithium as the adjunct of first choice and states no serum level for that indication, so a level quoted under an Indian guideline's name is a fabricated citation even when the digits happen to be right. This is a different failure from quoting the wrong figure, and harder to spot: the number survives a memory check while the source does not. Quote the body that states the level, by name, in the same sentence as the level.

IN INDIA

The Indian guidance is the better scaffold and the thinner source of numbers, and the practical decision follows from that split. Take the sequence from the Indian ladder, which puts optimisation before switching and names lithium, thyroid hormone or an atypical antipsychotic as the augmenting options with the greatest evidence for lithium and aripiprazole; take the level, the dose and the monitoring interval from whichever body states them, and name that body in the same breath. Among the Indian figures in this section, the short latency reported for adjunctive lithium is the one that changes bedside behaviour most directly, because it fixes how long to hold the addition before judging it.

7.5 Thyroid hormone: one agent, two doses, two bodies

Tri-iodothyronine is the preparation used for this purpose rather than levothyroxine, and it is given to patients who are already **euthyroid**, which is what makes it counter-intuitive at the bedside and durable in vivas. The rationale is not replacement of a deficiency but potentiation of an incomplete antidepressant response, which is why thyroid function is followed as a safety measure rather than as the endpoint being treated. The Maudsley files it a tier below lithium,

aripiprazole and quetiapine, among less commonly used treatments that are nonetheless well supported by published evidence.

The two doses in circulation are genuinely different instructions from different bodies. The Indian 2017 guideline gives thyroid hormone augmentation of an antidepressant, even in euthyroid patients, at **25 micrograms/day** of tri-iodothyronine increased to 50 micrograms/day after a week. The Maudsley guidelines give tri-iodothyronine augmentation of an antidepressant at 20 to 50 micrograms/day, note that higher doses have been used safely, and require clinical and biochemical thyroid function monitoring alongside. The upper figures coincide; the starting point and the shape of the instruction do not. Neither body states a maximum for tri-iodothyronine. The Indian guideline gives a start and a step and stops there, with no ceiling named above either. The Maudsley tri-iodothyronine entry travels in the opposite direction, recording that higher doses have been used safely, which is the reverse of naming a limit, and it gives no starting dose at all, only the band inside which the prescriber chooses. So the figure the two documents share is where two instructions happen to meet, and not a ceiling either of them has set.

TRAP **Printing one tri-iodothyronine dose as the tri-iodothyronine dose.** The Indian figure is a titration with a fixed start and a fixed step at a fixed interval; the United Kingdom figure is a range within which the clinician chooses, with an explicit note that higher doses have been used safely. Writing only the range drops the Indian instruction; writing only the start and the step drops the range and that note. Write both, name the body against each, and never average them into a single band that neither source states.

7.6 Atypical antipsychotic augmentation: agent, dose and the trade it buys

This is the strategy modern guidelines lean on hardest. **Atypical antipsychotic** augmentation is named in the Indian ladder beside lithium and thyroid hormone, with the greatest evidence available for lithium and aripiprazole. The Indian text names the agent and states no dose, so the doses that follow are the Maudsley's.

Aripiprazole augmentation of an antidepressant is used at **2 to 20 mg/day**, with low doses of 2 to 10 mg/day potentially effective, and akathisia and restlessness common at standard doses of 10 mg/day or more, insomnia being the other effect that may become problematic. Quetiapine augmentation of a depressive illness is used at 150 mg or 300 mg a day added to an SSRI or SNRI, an option the Maudsley credits with a good evidence base and usual good tolerability, set against dry mouth, sedation and constipation as the problematic effects and weight gain as the longer-term risk. The olanzapine and fluoxetine combination for depression is used at 6.25 to 12.5 mg olanzapine plus 25 to 50 mg fluoxetine daily, which is the United States licensed dose; where combination formulations are not available, the Maudsley footnote says 5 mg plus 20 mg rising to 10 mg plus 40 mg seems reasonable, which is the line that matters wherever the fixed-dose product is absent.

None of those three entries is a complete prescribing instruction, and it is worth saying so beside the figures rather than leaving a reader to notice. The aripiprazole entry records the effective low

range and the dose at which akathisia becomes common, and no dose to begin at. The quetiapine entry records the two amounts used in augmentation, with no starting dose below them and no maximum above them. The olanzapine and fluoxetine entry records a licensed range and an alternative for units without the fixed-dose product, with no starting dose for the licensed range and no ceiling stated for that combination at all; the alternative does carry a start, since it is written as a titration. Its upper pair is what the licence permits, which is not the same statement as a limit the guideline has set. Read all three as the amounts these table rows record, and no further.

CANMAT 2023 sharpens the choice inside the class, listing aripiprazole and brexpiprazole as first-line adjuncts for difficult-to-treat depression on efficacy and tolerability, with cariprazine second-line because there are fewer studies of it. Whether brexpiprazole and cariprazine are approved and marketed here, and at which strengths, is not something the sources behind these notes establish, and the same is true of the marketed strength of tri-iodothyronine.

GOOD TO REMEMBER

Start aripiprazole augmentation at the bottom of its range and give it time before moving up. Akathisia and restlessness belong to the standard doses rather than the low ones, so a patient who becomes agitated and unable to settle a few days after the addition is more likely to be akathisic than more depressed. The reflex is to read the agitation as worsening illness and push the dose, which makes both problems worse.

7.7 Reading the guideline bodies against each other

Four bodies are quotable on augmentation and they do not carry the same agents at the same strength. BAP 2015 grades first-line augmentation as quetiapine, aripiprazole or lithium, each at grade A, and second-line as risperidone at grade A with olanzapine, tri-iodothyronine and mirtazapine at grade B. The caveat printed with those grades is the teaching point and is regularly dropped: the evidence derives mainly from studies in which lithium and tri-iodothyronine were added to tricyclics, and the other drugs were added to SSRIs or SNRIs. A grade A for lithium is therefore a grade A earned in a prescribing context that has largely gone.

AGENT	POSITION IN THE GRADED BRITISH LIST	NAMED IN THE INDIAN LADDER	WHERE A PRINTABLE DOSE OR LEVEL COMES FROM
Lithium	First-line, grade A	Named, and one of the two agents of greatest evidence	The Maudsley and NICE, as a plasma level rather than a dose
Aripiprazole	First-line, grade A	Named, and the other agent of greatest evidence	The Maudsley
Quetiapine	First-line, grade A	Covered by the atypical antipsychotic option, not named	The Maudsley

AGENT	POSITION IN THE GRADED BRITISH LIST	NAMED IN THE INDIAN LADDER	WHERE A PRINTABLE DOSE OR LEVEL COMES FROM
Risperidone	Second-line, grade A	Covered by the atypical antipsychotic option, not named	No dose is stated
Olanzapine	Second-line, grade B	Covered by the atypical antipsychotic option, not named	The Maudsley, only in combination with fluoxetine
Tri-iodothyronine	Second-line, grade B	Named, as thyroid hormone	The earlier Indian guideline and the Maudsley, and they differ
Mirtazapine	Second-line, grade B	Not an augmenting agent there; it is a combination partner	The Maudsley
Brexpiprazole	Not among the graded agents	Not named	The Canadian list, as a first-line adjunct, with no dose stated
Cariprazine	Not among the graded agents	Not named	The Canadian list, as a second-line adjunct, with no dose stated

Read down the third column and the Indian position becomes legible: it names a class where the other lists name molecules, a deliberate looseness written to survive a formulary that varies between institutions. The cost is that the Indian document cannot be quoted for a dose.

7.8 Monitoring what you have added

Every augmenting agent brings its own surveillance, and the schedules are the part of this topic a written answer most often omits. For lithium used to augment antidepressant medication, NICE assesses weight, renal and thyroid function and calcium levels before treatment and then monitors at least every 6 months during treatment. CANMAT 2023 states that when adjunctive agents are used, laboratory tests tailored to the specific medication should be monitored, and gives as its worked example that patients taking lithium should have lithium levels, electrolytes, calcium, creatinine, eGFR and TSH checked at baseline and every 6 to 12 months thereafter, or whenever the clinical status or the lithium dose changes. Quote that interval with a caveat attached. Neither this monitoring sentence nor the adjunct ranking taken from the same update could be located in the copy used for these notes, so the six to twelve month figure is unverified here and the NICE schedule is the one to rely on until it is confirmed.

Those are two different instructions from two bodies and neither is offered here as the resolution of the other. They also do not cover quite the same thing, and that is the part most easily mishandled. NICE sets a separate and more frequent schedule for the serum lithium levels themselves during the first year of treatment; the intervals in that schedule are not carried by these notes, and it would understate NICE to present its six-monthly panel as its instruction for

lithium levels in the first year. Say the two bodies disagree, give each figure with its body, and be explicit that the British level-monitoring schedule is tighter than the panel interval implies.

For an antipsychotic used to treat depression, NICE directs that monitoring is carried out as indicated in the summary of product characteristics for the individual medicine, and says this may include monitoring weight weekly for the first 6 weeks, then at 12 weeks, at 1 year and annually, and monitoring fasting blood glucose or HbA1c and fasting lipids at 12 weeks, at 1 year and then annually. Read the modal exactly. The schedule is offered as what product-specific monitoring may include, not as a schedule the guideline itself specifies, and an answer that presents it as a fixed requirement has silently upgraded the strength of the recommendation. Tri-iodothyronine augmentation carries its own requirement, since the Maudsley requires clinical and biochemical thyroid function monitoring for it. The wider cardiometabolic and QT surveillance that spans the psychotropics is taught in its own section here.

PITFALL

Adding quetiapine or olanzapine to an antidepressant and filing the metabolic monitoring under something that only applies to psychosis. The augmenting antipsychotic is prescribed by the clinician who has been treating a depressive illness, often in a setting that has never taken a baseline weight or a fasting glucose, and the weight gain listed as the longer-term risk accrues while nobody is measuring it. The companion instruction is to check baseline pulse and blood pressure, weight, nutritional status, diet, level of physical activity, fasting blood glucose or HbA1c and fasting lipids before the antipsychotic is started, not at the first review.

Optimise before you move: switching preserves monotherapy but brings its own discontinuation and new-drug risks and has no high-level evidence of superiority over simply continuing, the comparison between the three manoeuvres is specific to the agents and the trial rather than a general ranking, and every level, dose and monitoring interval you quote belongs to a named body and must travel with its name.

8 · Ketamine and esketamine in treatment-resistant depression (cross-reference to recent advances)

Glutamate arrived late in the antidepressant story and changed the timescale. Ketamine and its S-enantiomer esketamine are the worked example of what a resistant depressive episode does to prescribing. Here is an agent whose effect is measured in hours rather than in weeks of waiting, whose route decides which evidence applies to it, whose durability is quantified for one formulation and merely described for the other, and whose delivery needs a monitored chair rather than a prescription pad. The marks sit on route, eligibility, monitoring and durability, and candidates lose them by treating ketamine and esketamine as one drug with one dose. The receptor pharmacology of glutamatergic agents as a drug class belongs to the Psychopharmacology I: principles and core drug classes notes; what follows is the decision that has to be made once two adequate antidepressant trials have failed.

8.1 Where the glutamatergic agents enter, and who is eligible

The 2025 Indian Psychiatric Society depression guideline puts novel agents, naming ketamine and esketamine alongside dextromethorphan-bupropion, in the last row of its sequential intervention table for **difficult-to-treat depression**, qualified "wherever available" and annotated "Limited long-term data" in the notes column. The position in the table is itself the teaching. Within that Indian table these agents come after the conventional optimisation, switching, augmentation and combination strategies and after neuromodulation, each of which is a topic in its own right; and the recommendation is conditioned on supply rather than asserting that the agents can be obtained. The ordering belongs to this guideline rather than to the field: the Canadian guidance in the next paragraph puts the same agents earlier, so an answer should name the body whose sequence it is describing.

The Canadian guidance shows how quickly the position moved, and the direction of travel is examinable. CANMAT in 2016 considered ketamine an experimental treatment and recommended that its use be limited to academic depression treatment centres, its adjunctive-agent table listing ketamine as Experimental, Level 1 evidence, at 0.5 mg/kg as a single intravenous dose for acute treatment. By 2023 the same body recommended adjunctive ketamine and intranasal esketamine at second line, which is an advance on the experimental status of 2016 and not a retreat from it. CANMAT's own verb is downgraded, but what it downgrades is the placement the efficacy evidence alone would have supported, and the stated reason is worth memorising because it is not loss of efficacy: side effect potential and feasibility issues, specifically the required monitoring of blood pressure and dissociative side effects. The same update pushed the alternate routes of racemic ketamine, oral, nasal and intramuscular, down to third-line, given highly variable protocols and mixed results. That the second-line agent is the intravenous racemic route is a reading derived from the surrounding paragraph rather than a phrase the guideline itself prints.

Eligibility is defined most precisely not by a guideline but by a licence. The Summary of Product Characteristics for esketamine nasal spray indicates it, in combination with an SSRI or SNRI, for adults with treatment-resistant major depressive disorder who have not responded to at least two different antidepressant treatments in the current moderate to severe depressive episode. Read the three constraints together: the failures must be to antidepressant treatments, they must lie inside the current episode, and that episode must be moderate to severe. This is the eligibility criterion written into one product's licence, and it is not the same thing as the general definition and staging of treatment resistance, which is a separate construct.

8.2 Mechanism, and the shape of the acute effect

Ketamine is an antagonist at the NMDA glutamate receptor, and esketamine is its S-enantiomer formulated as a nasal spray. The prevailing account of the antidepressant action is not the block itself but what follows it: preferential action on inhibitory interneurons is thought to disinhibit pyramidal output, producing a brief rise in glutamate that acts at AMPA receptors and drives a rapid strengthening of synaptic connections in prefrontal circuits. That account is a hypothesis

under active revision, not a settled mechanism, and an answer that states it as established has overreached. What is not in doubt is the clinical shape of the effect.

The Maudsley Prescribing Guidelines, describing the first controlled trial, record that a single **subanaesthetic** intravenous infusion of ketamine at 0.5 mg/kg produced an antidepressant effect within hours, and that the effect increased progressively up to 3 days after administration. Two consequences follow for practice. The peak does not fall at the end of the infusion, so a patient written off as a non-responder in the recovery chair may have been judged too early; and a benefit that builds over days is a different phenomenon from the dissociative experience of the infusion hour, which is why examiners like the distinction between the psychotomimetic and the therapeutic effect.

RULE **Ketamine and esketamine are not one treatment, and the route is what decides the evidence.** Molecule, enantiomer, route, licence and monitoring requirement travel together as a single package. A statement about an intravenous racemic infusion does not transfer to a nasal spray, and the guideline bodies grade the routes separately for precisely that reason.

8.3 Route and formulation: two standard sources, one drug, different numbers

Route is where most of the examinable detail sits, and it is also where the two texts on an Indian shelf disagree without either being wrong. The rule for an answer is to print both, attributed, and never to split the difference. Note as you read the table that the Indian document supplies figures for routes it simultaneously declines to endorse, and that **racemic ketamine** and esketamine are graded separately at every step.

ROUTE	INDIAN PSYCHIATRIC SOCIETY DEPRESSION GUIDELINE, 2025	MAUDSLEY PRESCRIBING GUIDELINES, TREATMENT-RESISTANT DEPRESSION
Intravenous racemic ketamine	0.5 to 1.0 mg/kg, infused over 40 to 60 minutes, twice weekly for 2 weeks in the acute course	**0.5 mg/kg over 40 minutes**, named the gold standard for off-label ketamine administration, with the best supporting evidence for efficacy, and possibly more effective than intranasal administration
Oral ketamine	2 to 3 mg/kg, mixed with around 100 mL of purified water and sipped over 10 to 15 minutes for the first session, with the available evidence called preliminary and currently insufficient to support routine clinical use	0.5 to 1.25 mg/kg, effective but with no licensed products
Sublingual ketamine	Not established, with a suggested start at 10 mg placed under the tongue and held for 2 minutes without swallowing	Oral or sublingual doses considered between intravenous treatments
Intranasal esketamine	56 to 84 mg twice weekly for 4 weeks of induction	28 to 84 mg, licensed in most countries, where the oral evidence above has no licensed product
Intranasal racemic ketamine	50 to 150 mg twice weekly	No separate figure in the treatment-resistant depression table

Two disagreements inside that table are examinable in their own right. The first is infusion duration: the Indian range is wider at its upper end than the single British figure, and the British figure is also the duration used in the controlled trial that text describes. The range contains the point, so the two are compatible at the bedside and not interchangeable in an answer. Name the body you are quoting and give its own figure.

Something else is true of every cell in that table, and it is easy to miss because the cells look finished. No cell in it states a maximum. For ketamine, intravenous, oral or sublingual, and for esketamine by the intranasal route, the Indian guideline gives an amount and either a vehicle or an infusion time, and then stops, with no ceiling named for any of them. Nor does every row carry a frequency, and the rows differ on that point in a way the layout hides. The intravenous and intranasal rows state twice weekly. The oral row describes the first session only, with no interval between sessions and no course length. The sublingual row states neither, and its two minutes is how long the dose is held under the tongue rather than how often it is given, which is the likeliest cell here to be misread as a schedule. The Maudsley gives the intravenous ketamine figure it calls the gold standard and states no limit above it, and no interval between infusions either. Only the sublingual ketamine row is written as somewhere to start, and its own source calls that route not established while suggesting the figure; for every other ketamine and esketamine cell here there is no starting dose, because the figure recorded is the amount to give

rather than the first step of a titration. So the number a reader meets in any of these cells is what the source recorded for that route, and not the top of a permitted range.

TRAP **Averaging the two published oral ketamine doses.** For depression the Maudsley gives oral ketamine at 0.5 to 1.25 mg/kg, calling it effective on that evidence while recording that no licensed oral product exists, and the Indian guideline gives 2 to 3 mg/kg, a several-fold separation for one route in one indication. Neither is a misprint and no average exists between them: they rest on different literatures, and the Indian guideline attaches to its own figure the statement that the evidence for oral ketamine is preliminary and currently insufficient to support routine clinical use. A candidate who writes a single oral range has silently chosen a source and hidden the choice.

8.4 The esketamine schedule, and the second licensed indication

Esketamine is the one formulation with a fixed published schedule rather than a range, and it is the one most often reproduced wrongly, because the frequency steps down twice. In adults under 65 with treatment-resistant depression the label sets **56 mg on the first day, then 56 mg or 84 mg twice a week through the first four weeks**, the same dose once weekly through the fifth to eighth weeks, and from the ninth week onward the same dose either once every two weeks or once weekly. Three phases, two step-downs, one dose pair throughout: that is the whole table, and it is easier held as a shape than as a grid. The esketamine label sets no maximum above that pair. Its higher figure is a maintenance dose that recurs at every phase, so treating it as the licensed ceiling reads a schedule as a limit, which the schedule does not say.

The label attaches a durability instruction to that schedule. After depressive symptoms improve, treatment is recommended for **at least 6 months**. It is the instruction most often dropped by an answer that has carefully memorised the induction phase and stopped there.

There is a second licence, and it is not for resistance. Esketamine is also licensed for the acute short-term treatment of depressive symptoms constituting a psychiatric emergency, co-administered with oral antidepressant therapy, and for that indication the recommended dosage in adults under 65 is 84 mg, the maximum the label recommends for this indication, given twice per week for 4 weeks, with reduction to 56 mg made on tolerability. The two indications differ in more than the number. The emergency indication opens at the higher of the two doses and comes down if the patient cannot tolerate it, whereas the resistance indication opens lower and may go up; a stem that gives you the entry dose has already told you which licence it is testing. Note the shape of the emergency esketamine entry too. It records the dose for that indication and no starting dose beneath it, so the reduction it describes is a response to tolerability and not the second rung of a titration.

8.5 Durability: quantified for one formulation, described for the other

This is the discriminating section of the topic, and the asymmetry in it is uncomfortable: the strong maintenance evidence belongs to intranasal esketamine, whose Indian availability is unverified here, while the intravenous racemic infusion has no equivalent relapse-prevention trial. Which of the two a given service can actually deliver is a local question, to be established rather than assumed.

For racemic ketamine the Indian guideline describes an acute course of six to eight infusions, given twice or three times weekly, and states that continuation and maintenance ketamine may be given at an individualised frequency but that most of the evidence along those lines is anecdotal. Its own route table, printed above, describes that acute course differently, as twice weekly for 2 weeks. The two do not reconcile, and both are in the same document, so the honest answer names both rather than choosing between them. The Maudsley schedule is compatible with that and equally unquantified: an **induction phase** of once or twice a week, then a maintenance phase, according to response, of weekly, then every 2 weeks or even monthly, with oral or sublingual doses considered between the infusions.

Esketamine has the evidence the racemic infusion lacks. In SUSTAIN-1, a **randomised withdrawal** trial, continuing esketamine nasal spray with an oral antidepressant reduced relapse risk by 51 percent in patients who had achieved stable remission and by 70 percent in those who had achieved stable response. The design is the point as much as the result: patients were stabilised first and then randomised to continue or to stop, so what the trial measures is the value of not stopping.

0.49	6	0.30	4
HAZARD RATIO, STABLE REMITTERS	NUMBER NEEDED TO TREAT, REMITTERS	HAZARD RATIO, STABLE RESPONDERS	NUMBER NEEDED TO TREAT, RESPONDERS

The head-to-head comparison points the same way. In ESCAPE-TRD, esketamine nasal spray was superior to extended-release quetiapine, each added to an SSRI or SNRI, for remission at 8 weeks, reached by 27.1 percent against 17.6 percent, and for remission at that point sustained without relapse through 32 weeks, achieved by 21.7 percent against 14.1 percent. Two design features reported with the trial should travel with those figures whenever they are quoted: the comparison was open-label with the raters kept unaware of allocation, and patients who discontinued were counted as having an unfavourable outcome.

TRAP **Carrying the esketamine relapse figures across to racemic ketamine.** The hazard ratios and numbers needed to treat above belong to intranasal esketamine continued alongside an oral antidepressant in a randomised withdrawal design. No comparable maintenance trial of the intravenous racemic infusion with a relapse endpoint is available to this account, and the Indian guideline itself calls the continuation evidence anecdotal. The defensible sentence is that durability is quantified for esketamine and described only qualitatively for racemic ketamine, and a candidate who transfers a hazard ratio between them has invented a result.

8.6 What has to be in place before, during and after a session

This is where the modality stops being a prescription and becomes a service, and it is the part an answer built only from dose tables leaves out. Before administration the Maudsley recommends a physical examination including baseline blood pressure, full blood count, liver function test, thyroid function test and an electrocardiogram, with blood pressure and heart rate monitored during and after administration.

During and after the session the two standard sources set different clocks, and both are examinable. The Indian guideline describes continuous monitoring of consciousness, heart rate,

blood pressure, respiratory rate and oxygen saturation at baseline and periodically, offering every 15 minutes as its own example, throughout the session and continuing for up to **2 to 3 hours** after the session ends. The Maudsley, for racemic ketamine, has the patient observed by a trained clinician during dosing and for 1 hour after administration. For an Indian examination the Indian figure governs and the British one is quoted as the comparator; the two were set by different bodies and must not be averaged into a third period that neither recommends.

> **PITFALL**
>
> Treating the observation period as a courtesy rather than a competence requirement. Ketamine given at antidepressant doses causes significant **dissociative symptoms**, so patients must be observed by a trained clinician, and because **laryngospasm** has been reported the observing clinician should be trained in intermediate or advanced life support. Being able to obtain the drug is therefore not the same thing as being able to give it.

Esketamine carries its own haemodynamic clock. Its label records transient rises in systolic and diastolic blood pressure that peak at approximately 40 minutes after administration and last approximately 1 to 2 hours, and it times the post-dose reassessment of blood pressure to that same 40 minute point. That single figure explains the shape of the whole session: the reassessment is set against the expected peak, not against the end of the dose. For patients kept on longer-term ketamine or esketamine treatment the Canadian guidance adds periodic urinalysis to check for cystitis, a potential long-term adverse effect of ketamine use, which is the one piece of monitoring that outlives the session itself.

8.7 The Indian position: a controlled drug and a cheap route the guideline will not endorse

Ketamine is a **controlled drug** in India, so the prescribing, storage and record-keeping frame is statutory before it is clinical, and that is a fact about the drug rather than about any one hospital. Which instrument and which schedule govern it is a separate question, and the sources read here do not settle it, so this account prints no schedule number. The one Indian paper read here calls ketamine a Schedule III controlled substance under the Narcotic Drugs and Psychotropic Substances Act, 1985, but that is the schedule language of United States controlled-substances law rather than a schedule of the Indian Act; beside it sit a United Nations country listing recording ketamine's inclusion among the psychotropic substances under that Act, and secondary sources placing ketamine hydrochloride in Schedule X of the Drugs and Cosmetics Rules. The Gazette notification that would decide between them could not be consulted for this chapter. Carry the statutory obligation into an answer and leave the schedule number out of it.

Set against that is what one Indian source reports. A 2024 correspondence article in an Indian journal states that the administration of oral ketamine is prevalent in India because it is inexpensive and easy to administer in facilities with limited access to healthcare resources. The attribution has to stay visible, because that sentence is a correspondence article rather than a prevalence study, and no Indian prevalence figure or national register of ketamine use was found. The tension is still the examinable point: the cheapest and most deliverable route is precisely the

route the Indian guideline prints a dose for and then declines to endorse for routine use, and the route the Canadian guidance places third-line.

On availability the guideline is careful and an answer should be too. It lists these agents as novel agents "wherever available", which conditions the recommendation on supply rather than asserting it. In the same passage the same authors do assert Indian availability for something else, recording that **dextromethorphan-bupropion**, approved in the USA in 2022 for major depressive disorder, is now available in India. The contrast is deliberate and it is usable in an answer: these authors state availability when they mean it, and they did not state it for esketamine. No Indian regulatory or market status for intranasal esketamine is asserted by any source used here, and the correct examination answer names that absence rather than filling it.

IN INDIA

Where a unit can obtain the drug at all, the decision the sources support is to run the intravenous route in a setting that can meet the guideline's own monitoring description, and not to substitute the oral route merely because it is simpler: the Indian guideline prints an oral dose and in the same table refuses to endorse it for routine use. The pre-treatment workup the British text asks for should be in hand before the first dose wherever a service offers ketamine, and the local availability of those five investigations, along with the referral route for any the unit cannot do itself, is to be confirmed rather than assumed. And because the drug is controlled in India whichever instrument turns out to govern it, the record-keeping is part of the treatment plan rather than an afterthought to it.

8.8 Choosing between them, and what a complete answer contains

Reduced to four decisions, the topic becomes answerable in whatever form the question takes.

- Route decides the evidence: the intravenous racemic infusion carries the best efficacy data, the nasal spray the licence, the fixed schedule and the maintenance trial.
- Eligibility is drawn from a licence rather than an impression, and the licence counts failed antidepressant treatments inside the current moderate to severe episode.
- Monitoring, not the drug, is the rate-limiting step: a trained observer, a defined observation period, and for esketamine a reassessment timed to the pressure peak.
- Durability is a separate question from response, and it has a different quality of answer for each formulation.

GOOD TO REMEMBER

The commonest real-world error here is not a dosing error. It is offering the treatment in a room that cannot observe the patient afterwards. Where the post-dose observation period cannot be staffed, the honest position is that the service is not yet able to offer the treatment, rather than that the treatment is unsuitable for the patient.

MNEMONIC

Route, Evidence, Observation, Durability

The four axes on which every question about these agents separates: which route is asked about, whose evidence supports it, how long the patient is watched afterwards, and what happens to the gain once the acute course ends. A durability claim made without naming the formulation is a wrong one.

Route decides the evidence, the licence decides eligibility, and the observation period decides whether the treatment can be offered at all.

9 · Treatment-resistant schizophrenia and the role of clozapine

Treatment resistance is a verdict on the prescribing before it is a verdict on the patient. Almost all the marks in this topic sit on the entry condition rather than on what follows it: what a guideline demands before the label may be used at all, what makes a failed trial a genuine failure, and which of the ordinary explanations for apparent non-response has been left unexcluded. Once resistance is properly established the drug choice narrows sharply, and the examinable content shifts to exposure, to dose and to blood counts. The schizophrenia management algorithm itself, and the order in which agents are tried, belong to the Schizophrenia: management, antipsychotics and adverse effects notes; what follows here is the pharmacological reasoning that sits underneath that algorithm and decides whether it should ever have been entered.

9.1 What the label requires before it may be applied

The current Indian definition of **treatment-resistant schizophrenia** is a compound one, and every limb of it is doing work. The 2025 Indian Psychiatric Society schizophrenia guideline requires failure across **at least 2 adequate trials** of different antipsychotics; it requires **confirmed medication adherence**, established rather than assumed; and it requires that moderate or severe symptoms and psychosocial dysfunction both persist despite that treatment. The comparator is easy to lose in an answer. A floor of two is not a rule of two, and a candidate who writes that resistance is declared after exactly two trials has quietly converted a minimum into a maximum.

The adherence limb is the one most often skipped, and it is the one that changes what happens next. Adherence is not a historical detail collected for completeness; it is written into the definition as a precondition, so an unconfirmed adherence history means the definition has not been satisfied and the label cannot yet be applied. The third limb keeps the judgement clinical rather than symptomatic: residual symptoms do not qualify a patient whose function has recovered, because the guideline binds severity and functional cost together rather than accepting either alone.

RULE **Resistance is a conjunction, never a count.** A tally of failed trials establishes nothing by itself. The trials must have been adequate, the adherence must have been confirmed rather than presumed, and the residual illness must be both severe and functionally costly. Fail any one of those and what is in front of you is inadequately treated illness, which is a different clinical problem with a different answer.

9.2 What makes a trial adequate: dose, duration and the drug actually taken

An **adequate antipsychotic trial** has a floor written into Indian guidance rather than left to judgement. The earlier 2017 Indian Psychiatric Society schizophrenia guideline set the minimum for all antipsychotics as the highest tolerable dose sustained for **6 to 8 weeks**, and carved out one exception: for clozapine the minimum period of treatment is **at least 3 to 6 months**. Two variables are specified and both must be satisfied before a trial counts: the dose pushed to what the patient could actually tolerate, and that dose held long enough for a response to declare itself.

This is where most apparent resistance dissolves on questioning. A trial fails the definition, rather than the drug failing the patient, in four recognisable ways.

- The dose never reached the highest tolerable level, usually because a tolerable adverse effect was read as a ceiling and the titration stopped there.
- The duration fell short, the agent being switched at the point where the prescriber lost patience rather than at the point where the trial actually ended.
- The drug was not taken, in which case no trial occurred at any dose and over any interval, and the correct next step is not a new molecule.
- The drug was taken but the patient never achieved the exposure the dose implied, which looks identical to non-adherence at the bedside and separates from it only on measurement.

A failed trial belongs in the tally the definition asks for once adequate dose, adequate duration and confirmed adherence have been established. The fourth is not a precondition on every antipsychotic trial: it is what a measured level investigates, where monitoring is indicated and interpretable, chiefly clozapine. The clozapine exception is asymmetrical by design. The minimum for this one drug is several times the minimum that satisfies every other antipsychotic, and the guideline records it as an exception rather than as a preference.

TRAP **Applying the standard adequate-trial yardstick to clozapine.** A patient taken off clozapine at the point where any other antipsychotic would fairly have been abandoned has not had a clozapine trial at all and cannot be described as having failed one. The trap is attractive because the yardstick is correct for every other agent, and because notes recording the switch rarely record how long the drug ran.

9.3 Pseudoresistance, and what a measured level settles

A level converts a clinical impression into a measurement. Where a patient on clozapine fails to improve, the Indian Psychiatric Society schizophrenia guideline names **inadequate response** among the conditions under which **therapeutic drug monitoring** of clozapine is usually recommended, and it states what the measurement is for: to establish whether under-exposure

explains the failure before the patient is called clozapine-resistant. Read the modal as it is written. Usually recommended is not required, and an answer that upgrades the strength of a recommendation has misreported the guideline as surely as one that misquotes a number.

The reasoning this licenses is the pharmacological lens on this topic, and it is reasoning about exposure rather than a verdict on treatment. A concentration below the accepted band raises under-exposure, through under-dosing, rapid metabolism, enzyme induction or partial adherence, but the sampling time, the steady state, the adherence history, smoking, interacting drugs and any intercurrent inflammatory illness are checked before the dose is touched, and dose adjustment is one response among several. A concentration within the band documents exposure at the moment of sampling; adequacy still needs the duration, the adherence history and the clinical criteria before the failure can be attributed to the drug. A concentration at or near zero in a patient who is collecting prescriptions strongly raises covert non-adherence or interrupted exposure, once the timing and the validity of the assay have been checked. These readings can coexist, so the level narrows the differential and never settles it alone; it is read alongside the clinical assessment, not instead of it. The threshold itself, the sampling technique and the intervals that surround it are taught in the therapeutic drug monitoring material and are not restated here.

PITFALL

Writing "failed clozapine" into a discharge summary without recording the dose reached, the duration sustained, or whether exposure was ever measured. The next prescriber inherits a closed door and no way to test whether it was ever locked. The guideline's sequence, measurement before label, cannot be run retrospectively on a note that omits the exposure.

9.4 Where clozapine enters, and how the entry condition changed

Indian guidance has stated the clozapine entry point twice, and the difference between the two statements is examinable in its own right. The earlier guideline held that clozapine need to be considered after the failure of sequential trials with 2 antipsychotics, at least one of them a second-generation agent. The current definition of resistance drops the class requirement altogether: what it asks for is failure across adequate trials of different antipsychotics with adherence confirmed, and it names no class anywhere. Reciting the second-generation requirement as current Indian practice is therefore an error of vintage rather than of fact, and a well-read candidate is likelier to make it than a poorly read one.

The modal in the earlier wording repays attention too. Clozapine need to be considered is an instruction to consider, which is what a guideline says when the decision is still the clinician's. The current guideline is stronger: its recommendation tables direct a switch to clozapine after at least two failed adequate trials, a direction that contraindications, tolerability and the patient's own decision still qualify. The pharmacological argument for moving early rests on the alternatives rather than on the guideline strength: once two adequate trials of different agents have failed, the probability that a third agent from the same broad pharmacological space will succeed is not what drives the decision, and clozapine is the option with a distinct claim on that

ground. The evidence-ranked ladder of what may be added to or substituted for an antipsychotic, and the switch-versus-combine-versus-augment decision itself, are taught under the switching, combination and augmentation strategies.

9.5 Dose is not exposure, and the Indian patient needs less of it

The dose written on the card and the concentration the patient achieves are different quantities, and the gap between them is populated by identifiable variables rather than by noise. The Maudsley Prescribing Guidelines record that clozapine plasma levels run lower in younger patients, in males and in smokers, and higher in Asians, and they state the practical consequence directly: markedly lower clozapine doses are required in East Asians, Indians and Bangladeshis. That is a statement about the patients in front of this reader, not a footnote about somebody else's population. The kinetic principles that generate the variability, and the cytochrome map that underlies most of it, belong to the Psychopharmacology I: principles and core drug classes notes.

No Indian milligram figure follows from that observation, and none should be manufactured to fill the space; the source gives a direction of effect and nothing more. The nearest dose anchor available is regional rather than Indian. The Malaysian Ministry of Health schizophrenia guideline starts clozapine at 12.5 mg/day, gives a target dose of 300 to 900 mg/day in twice-daily divided doses, and has a serum level checked for doses above 600 mg/day. Quote that range to its own source. Attributing it to Indian guidance would be a fabrication of provenance, which the reader cannot detect and which no digit check would catch.

IN INDIA

Start lower and climb more slowly than a Western dose table implies. If markedly lower clozapine doses are required in Indian patients, then the same milligram is delivering a higher exposure here than in the populations the published dose ranges were derived in, so the titration should be driven by the response and by dose-related adverse effects rather than by arrival at a printed target dose. If you are titrating without a measured level, that is a reason to move more cautiously: response and tolerability guide the dose, but the exposure itself stays unknown until a valid level is taken, and an unmeasured patient is never a reason to move faster towards the top of a range that was not built on this population.

9.6 What the blood monitoring is actually buying

The obligation that travels with clozapine is haematological, and its size is worth knowing precisely, because candidates habitually overstate it while patients most often refuse the monitoring burden. The Maudsley Prescribing Guidelines put the risk of **agranulocytosis** during clozapine treatment at **1 in 250**, or 0.4 percent, describing that figure as lower than previously thought, and put the risk of death resulting from it, in that same treated population, at 0.05 percent. Around 3.8 percent of patients treated with clozapine develop neutropenia.

1 in 250	0.05%	3.8%
AGRANULOCYTOSIS	FATAL AGRANULOCYTOSIS	NEUTROPENIA

Three figures, three different events, and they are routinely merged into one in an answer. Neutropenia and agranulocytosis are not the same finding and do not carry the same rate; the larger is not a softer statement of the smaller. All three are risks in the treated population, and the third is the one most often misread: fatal agranulocytosis occurs in about 0.05 percent of clozapine-treated patients, and that is not the proportion of those who develop agranulocytosis who die of it. Attaching the figure to the smaller denominator changes what it says. Getting the relation right is worth more than reciting any single value; it is what one follow-up question tests.

The phrase the Maudsley attaches to the agranulocytosis figure, lower than previously thought, is itself examinable: it is a revision of an estimate, not a revision of the monitoring requirement. The requirement itself is set by the guideline bodies, and they do not agree with each other.

9.7 Two blood-monitoring schedules, and where they part

The Indian and United Kingdom schedules open identically and then diverge, which is precisely why one gets substituted for the other without the writer noticing. Indian guidance runs the full blood count and absolute neutrophil count weekly through the first 18 weeks, then monthly for 2 years, then annually, and adds C-reactive protein weekly for a further 4 weeks. United Kingdom practice, as the Maudsley Prescribing Guidelines set it out, runs weekly for the same first 18 weeks, then every 2 weeks to the end of the first year, and usually monthly thereafter.

PHASE OF TREATMENT	INDIAN PSYCHIATRIC SOCIETY SCHIZOPHRENIA GUIDELINE	UNITED KINGDOM PRACTICE, AS THE MAUDSLEY PRESCRIBING GUIDELINES GIVE IT
Before the first dose	Full blood count and absolute neutrophil count, plus C-reactive protein	Full blood count and absolute neutrophil count
Opening stretch	Weekly counts through the first 18 weeks	Weekly counts through the first 18 weeks
Immediately after that stretch	Monthly counts, sustained for the next 2 years	Counts every 2 weeks to the end of the first year
Long term	Annual counts	Usually monthly, with no annual endpoint stated
Inflammatory marker	C-reactive protein at baseline, then weekly for a further 4 weeks	Not part of this schedule

TRAP **Writing one clozapine blood-monitoring schedule as though there were only one.** The two agree for the opening stretch and then separate: Indian guidance steps straight to monthly and holds it for years before annual, while United Kingdom practice inserts a fortnightly phase to the end of the first year and states no annual endpoint. Either can be quoted, provided it is attributed to the body that issues it. Blending the two, or reciting the fortnightly phase in an Indian answer as though it were Indian, is the error, and the answer that names both and marks which is which scores above the answer that picks one and sounds certain.

9.8 When the count falls: lithium, ethnic neutropenia, and the bands this text will not print

A falling count is where the pharmacology of resistance meets the pharmacology of an adverse effect, and it is the point at which a second drug enters for a reason that has nothing to do with symptoms. The Maudsley Prescribing Guidelines list lithium as indicated in patients on clozapine with a low initial white cell count, below 4 x10^9/L, or low initial neutrophils, below 2.5 x10^9/L; and in **leucopenia**, a white cell count below 3 x10^9/L, or a neutrophil count below 1.5 x10^9/L, where the finding is thought to be linked to **benign ethnic neutropenia**.

Two qualifiers on that list carry the weight. The second indication is governed entirely by the benign ethnic neutropenia clause and must never be quoted without it, because it applies where the low count is a constitutional trait rather than a drug effect. And these are values that trigger lithium, not general definitions of leucopenia and neutropenia; the source does not define those terms in this section, and lifting the figures out as definitions misstates what was written.

GOOD TO REMEMBER

Before accepting a handover that says clozapine was stopped for a low count, ask which count, at what value, and whether the patient has a constitutionally low baseline. A low starting count and a constitutional low count are recognised situations with their own management rather than automatically the same event as a fall on treatment, and a patient wrongly closed out of clozapine has lost the option the whole definition of resistance was leading towards.

What this account deliberately does not print is the traffic-light scheme. A green, amber and red banding of the white cell and neutrophil counts, with a defined action attached to each band, is what day-to-day practice actually runs on, and its numbers belong to the product information rather than to either textbook: the marketing authorisation holder's summary of product characteristics and, in India, the approved package insert. Nothing available here carries those bands with their actions attached, and a set of thresholds recalled from memory and printed with consequences beside them is exactly the kind of error that reaches a patient rather than an examiner. Read them off the insert that governs the brand in your own pharmacy, and be suspicious of any revision text that prints them without saying which document they came from.

MNEMONIC

Dose, Duration, Delivery, Dysfunction

The four questions to answer before the word resistant is written. Was the dose pushed to the highest the patient tolerated; was it held for the minimum period the guideline sets for that particular drug; was the drug actually taken and, where it can be, was the exposure measured; and do moderate or severe symptoms still persist alongside psychosocial dysfunction. A trial that fails any of the first three does not belong in the tally, and a picture that fails the fourth is not resistance at all.

Resistance is earned by the trials, not declared by the symptoms: adequate dose, adequate duration, confirmed delivery, measured exposure where monitoring is indicated and available, and persisting symptoms with a functional cost, only then the word.

Drug monitoring, pharmacovigilance and pharmacogenomics

10 · Therapeutic drug monitoring in psychiatry: indications and target ranges (lithium, valproate, clozapine)

Most psychotropics are titrated against the patient. A short list is titrated against a number instead. The marks sit on which drugs belong on that list, when the sample is drawn, and what a printed band licenses; candidates lose them by treating every published range as one range, and by acting on a level that was never a valid measurement.

10.1 Which drugs earn a level, and why

An Indian postgraduate text gives the rationale for **therapeutic drug monitoring** in two limbs: a **narrow therapeutic index**, and confirmation of compliance. Kaplan and Sadock's Comprehensive Textbook of Psychiatry sharpens the first for lithium: it has a narrow therapeutic index, and there is large variability in the oral dose producing a given blood level, arising from differences in renal clearance. For lithium the variability limb is load-bearing, since a narrow margin alone would not compel routine measurement if the dose predicted the concentration.

RULE **A short margin and a dose that predicts the concentration badly are the rationale for measuring lithium routinely.** They are not a pair of conditions every monitored drug must satisfy: confirmation of compliance is a separate indication in the same Indian text, and others follow below. Where a drug has no accepted target range, the Maudsley Prescribing Guidelines state that a plasma level can only indicate adherence or potential toxicity, a two-branch rule that holds for agents no guideline names.

Two further indications sit outside that rationale. The Maudsley guidance on prescribing in physical illness recommends plasma-concentration-guided dosing when narrow-index drugs such as clozapine and lithium are given by enteral feeding tube, and adds, at a distinctly weaker strength, that monitoring may also help in some cases to distinguish non-response from lack of absorption. The underlying principles of half-life and therapeutic index belong to the Psychopharmacology I: principles and core drug classes notes.

10.2 Steady state, and the arithmetic that fixes the first sample

A concentration drawn before the plateau measures where the patient has reached rather than where they will end up, so **steady state** is normally required before a result is read against a target range, and a deliberately early sample has to be labelled as early rather than compared uncritically with a steady-state band. The Maudsley guidelines note that although the common adage is four to five half-lives, three half-lives are sufficient for an approximation of steady state concentrations, and print the ladder that makes this derivable rather than remembered.

75%	87.5%	94%	97%
TWO HALF-LIVES	THREE HALF-LIVES	FOUR HALF-LIVES	FIVE HALF-LIVES

An Indian text gives lithium an average half-life of 18 to 24 hours, from which three half-lives is roughly two and a half to three days and five roughly four to five days. That arithmetic sits behind every published lithium sampling interval. One corollary is examined more often than taught: **loading doses** do not hasten the achievement of steady state.

10.3 The trough, and the conventions that do not agree

A level is a measurement with a time attached. The Maudsley technique for a **trough** sample is to draw immediately before the next dose, never withholding that dose more than one or possibly two hours to obtain it, and the same chapter requires that the time of sampling and of the last dose always be recorded. The first response to a surprising level is therefore to check the timing, not the dose.

> **PITFALL**
>
> Holding the morning dose so the patient can be sampled later in clinic. The result reads low and the reflex is to increase a dose that was never inadequate. The Maudsley limit exists precisely because a longer delay produces a falsely low result.

The conventions diverge, genuinely rather than by error. Kaplan and Sadock time the lithium level as a weekly trough during titration and then every three to six months once stable, whereas the United Kingdom and Indian sources specify hours after the last dose. In twice-daily dosing the two coincide, a sample twelve hours after the last dose falling immediately before the next, and the Indian guideline requires the draw to precede the next dose in twice-daily or thrice-daily regimens. With a single nightly dose that same twelve-hour sample sits mid-interval, a standardised post-dose level and not the predose trough, and that is what a stem supplying a dosing schedule is testing.

SOURCE	WHEN THE FIRST LITHIUM LEVEL IS DRAWN AFTER STARTING OR CHANGING THE DOSE
Indian Psychiatric Society bipolar guideline	At 5 days after dose initiation, sample drawn 11 to 13 hours after the last dose
NICE	At 1 week after starting, 1 week after every dose change, weekly until levels are stable
Maudsley Prescribing Guidelines	At 7 days, then 7 days after each dose change, blood taken 12 hours after the last dose
Kaplan and Sadock	Blood levels determined after 10 days of treatment at a specific dose

Note what the Maudsley entry does not contain. It gives a starting dose and then hands the escalation to the plasma level, repeating that level after every dose change until the desired concentration is reached. No milligram maximum for lithium appears anywhere in the entry,

because the ceiling it works to is a concentration and not a dose. That is the pattern to carry into a lithium question, rather than a top milligram figure the table never issues.

The Indian guideline states its own instruction twice in two different forms: its monitoring footnote gives a window running 11 to 13 hours after the last dose, its narrative a single point at 12 hours. The two are compatible, the point sitting inside the window, but neither is the guideline figure to the exclusion of the other.

10.4 Lithium: bands by phase, by age and by source

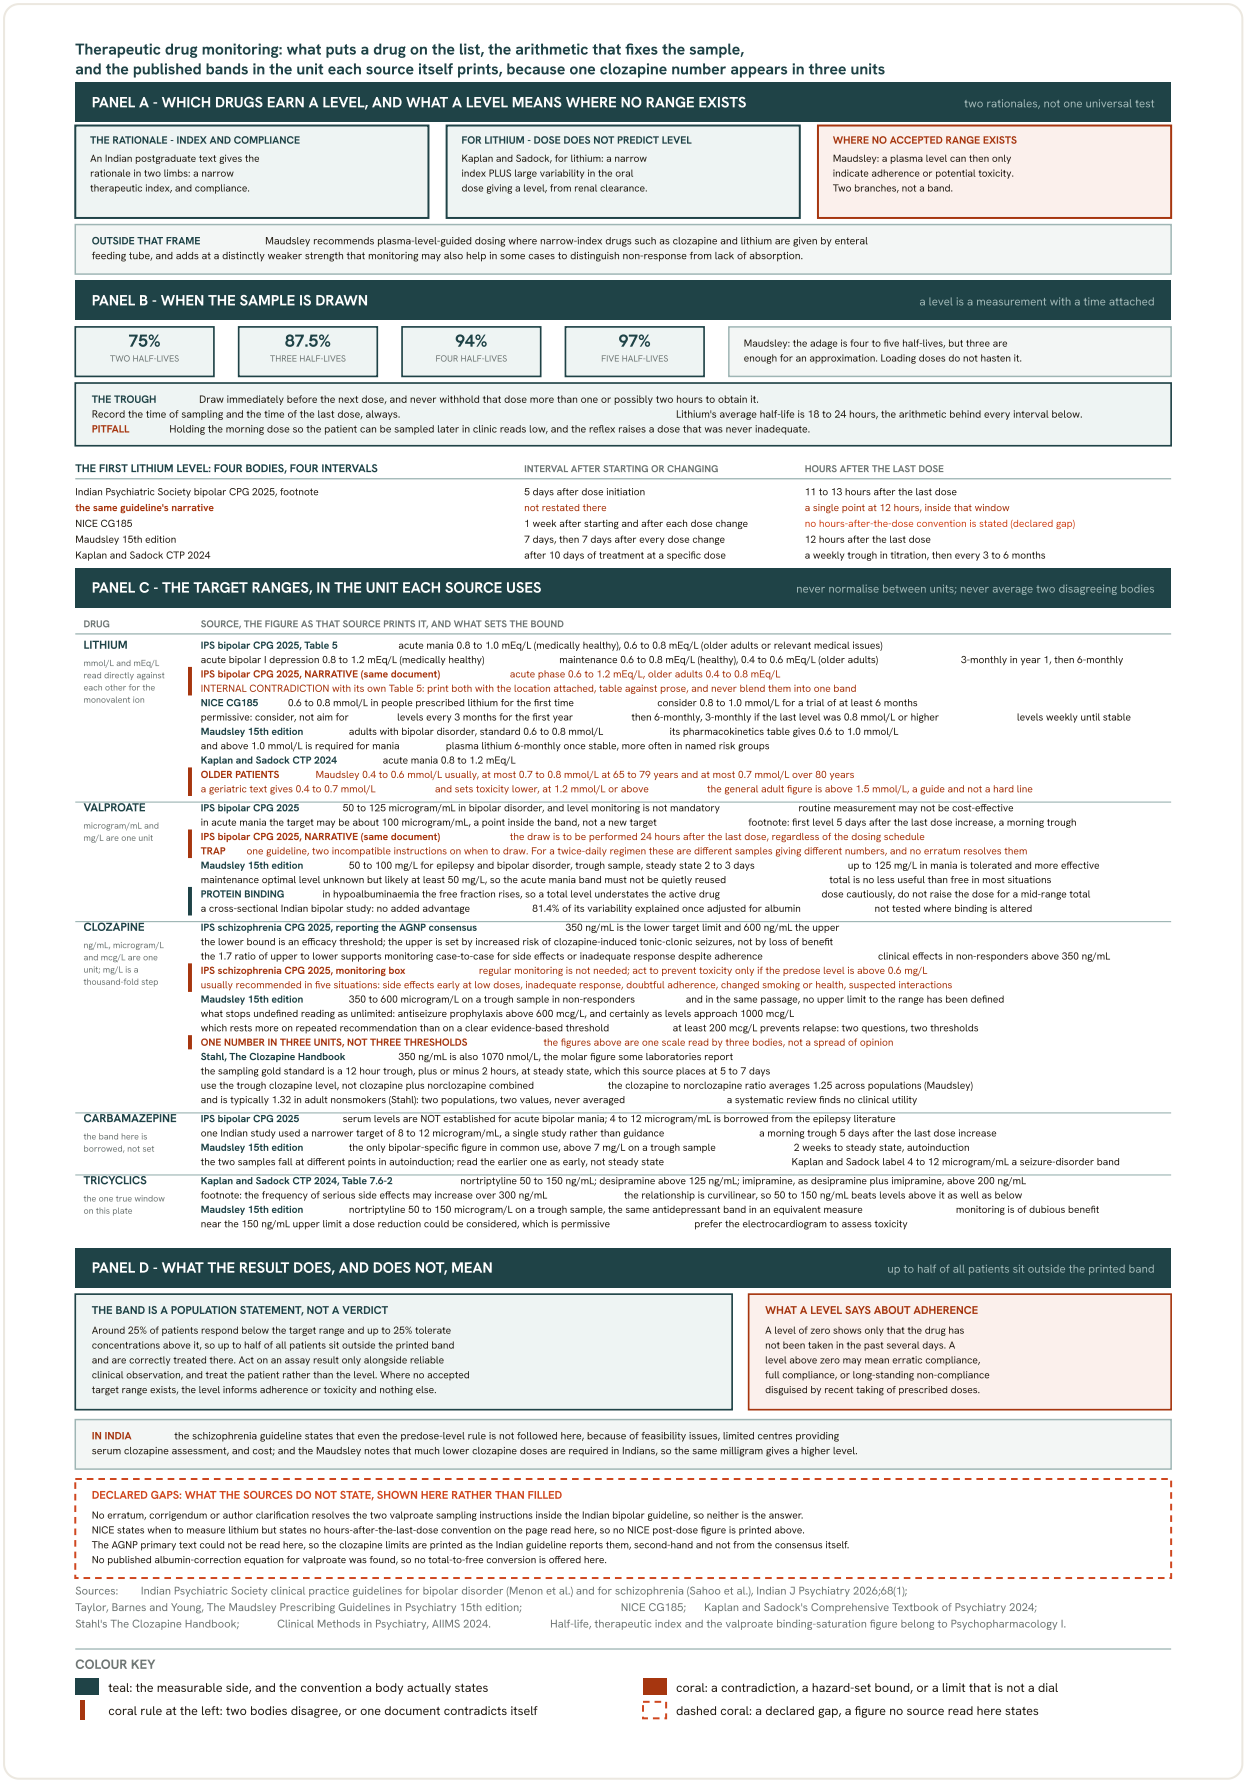

Fig 37.5 Therapeutic drug monitoring: which drugs earn a level, when the sample is drawn, and the bands as each source prints them. The lithium bands differ across four bodies, the Indian bipolar guideline contradicts

itself twice, and the clozapine target is one number printed in three units. (IPS CPG 2025; Maudsley 15th edition; NICE CG185; Kaplan and Sadock, CTP 2024; Stahl, The Clozapine Handbook.)

There is no single lithium target range, and an answer offering one is wrong against three of the four standard sources. The Indian Psychiatric Society bipolar guideline sets acute mania at 0.8 to 1.0 mEq/L in the medically healthy and 0.6 to 0.8 mEq/L in older adults or those with relevant medical issues; acute depression in bipolar type I disorder at 0.8 to 1.2 meq/L in the medically healthy; and maintenance at 0.6 to 0.8 mEq/L in the medically healthy and 0.4 to 0.6 mEq/L in older adults or those with medical comorbidity. That same document then contradicts itself: its narrative on optimising treatment gives a wider acute-phase band of 0.6 to 1.2 mEq/L and an older-adult band of 0.4 to 0.8 mEq/L, which differ from its own table figures. Quoting either alone leaves a candidate wrong against the other.

The other bodies sit near these numbers without landing on them. NICE, under its recommendation on starting lithium, directs aiming for **0.6 to 0.8 mmol/L** in people prescribed lithium for the first time, a lithium-naive rather than phase-specific target, and separately allows clinicians to consider 0.8 to 1.0 mmol/L for a trial period of at least six months after relapse on lithium; note the permissive modal. The Maudsley guidelines give adults with bipolar disorder a standard of 0.6 to 0.8 mmol/L, while their pharmacokinetics table gives 0.6 to 1.0 mmol/L and states that above 1.0 mmol/L is required for mania. Kaplan and Sadock give 0.8 to 1.2 mEq/L for acute mania. For the monovalent lithium ion the millimolar and milliequivalent figures are numerically identical, so these read directly against each other.

In older patients the sources share a floor and diverge on the ceiling. The Maudsley guidelines alone band the target by decade, giving 0.4 to 0.6 mmol/L usually and at most 0.7 to 0.8 mmol/L between sixty-five and seventy-nine years; a geriatric text gives 0.4 to 0.7 mmol/L and defines toxicity lower than the general adult texts, at 1.2 mmol/L or above. The general adult toxicity figure, above 1.5 mmol/L, marks where these ranges stop and is a guide rather than a hard line; toxicity itself belongs to the Psychopharmacology I: principles and core drug classes notes.

Monitoring frequency, once levels are stable, divides on whether the first year is treated differently.

- NICE requires levels every three months for the first year.
- The Indian guideline sets the same three-monthly first year and six-monthly thereafter in healthy individuals, once stable values are seen.
- NICE then drops to six-monthly but keeps three-monthly monitoring for six named higher-risk groups, including anyone whose last level was 0.8 mmol/L or higher.
- The Maudsley guidelines go straight to six-monthly, with more frequent monitoring for interacting drugs, the elderly and renal impairment.

10.5 Valproate: one band, one mania figure, and a contradiction about when to draw

The Indian Psychiatric Society bipolar guideline gives a target of **50 to 125 microgram/mL** in bipolar disorder and states in the same breath that level monitoring is not mandatory, adding that routine measurement may not be necessary or cost-effective in all patients, with poor

therapeutic response or doubts about compliance as examples of when it is indicated. Read the qualifier precisely: not warranted in all patients is not the same as generally unnecessary.

Within that band the guideline notes a linear dose-response relationship in acute mania and states the target may be about 100 microgram/mL, not a separate target. The Maudsley pharmacokinetics table gives a narrower headline range of 50 to 100 mg/L for epilepsy and bipolar disorder on a trough sample, with time to steady state of 2 to 3 days, yet its own comments column concedes that in mania levels up to 125 mg/L are tolerated and more effective than lower concentrations. For maintenance the Maudsley position is an honest blank: optimal levels are unknown but likely at least 50 mg/L, so the acute mania band must not be quietly reused.

TRAP **One guideline, two incompatible instructions on when to draw the valproate sample.** The monitoring footnote permits the first serum level 5 days after the last dose increase, collected in the morning before the first dose of the day. The narrative directs that the draw be performed 24 hours after the last dose, regardless of dosing schedule. For a twice-daily regimen these are different samples giving different numbers, and no erratum resolves them, so a candidate who picks one substitutes their own judgement for the guideline's.

Two further points are frequently mishandled. Valproate is highly protein-bound, so in **hypoalbuminaemia** the **free fraction** rises and a given total level produces a greater effect than expected; the instruction is to dose cautiously, not to raise the dose in response to a mid-range total. Total valproate nonetheless remains the standard analyte, and the sources qualify that rather than universalise it: the Maudsley guidelines state that total concentration is no less useful than free levels in most situations, and an Indian study found free valproate offers no added advantage, with 81.4% of its variability explained once total valproate was adjusted for albumin. The separate binding-saturation figure of 45 to 50 microgram/mL belongs to the Psychopharmacology I: principles and core drug classes notes and is not the bottom of a target band, though the Indian bipolar floor does sit at that saturation point.

10.6 Clozapine: one number in three units

The Indian Psychiatric Society schizophrenia guideline sets the clozapine target at **350 to 600 ng/mL**, reporting these figures second-hand from an international consensus rather than deriving them, and states that non-responders achieve clinical effects when serum levels are above 350 ng/mL. The two ends are set by different things, and that asymmetry is the teachable point: the lower bound is an efficacy threshold, the upper bound, 600 ng/mL, is set by increased risk of clozapine-induced tonic-clonic seizures rather than loss of benefit. With a ratio of 1.7 between its upper and lower target concentrations, clozapine has a narrow therapeutic index window, which the Indian guideline offers as support for monitoring on a case-to-case basis where side effects or inadequate response are suspected despite good adherence, not as a reason to measure every patient.

TRAP **Reading three units as three thresholds.** The Indian guideline's monitoring box triggers action, to prevent toxicity, on a predose level above 0.6 mg/L; the Maudsley pharmacokinetics table gives clozapine 350 to 600 microgram/L on a trough sample; the consensus figures reported by the Indian guideline are 350 ng/mL lower and 600 ng/mL upper. These are one number in three units, not a spread of opinion. Stahl's Clozapine Handbook adds the molar equivalent some laboratories report, giving the response threshold as 350 ng/mL or 1070 nmol/L.

The ceiling is less settled than the schizophrenia band suggests: the Maudsley text states that in non-responders the dose should be adjusted to give plasma levels in the range 350 to 600 microgram/L and, in the same passage, that an upper limit to the target range has not been defined; print it beside the consensus figure, not instead of it. What stops undefined being read as unlimited is the same page's anchor: antiseizure prophylaxis against seizures and myoclonus is prudent when clozapine plasma levels are above 600 mcg/L, and certainly as levels approach 1000 mcg/L, with the caveat that this rests more on repeated recommendation than on a clear evidence-based threshold. Separately, limited data suggest at least 200 mcg/L is required to prevent relapse, so response in schizophrenia and relapse prevention are two questions with two thresholds.

The Indian schizophrenia guideline enumerates five conditions under which clozapine monitoring is usually recommended: early in treatment with prominent side effects at lower doses, inadequate response, doubtful adherence, a change in smoking habits or health, and suspected interactions or side effects. The qualifier is usually recommended, and the box is imported from a United Kingdom practical-considerations paper rather than being guideline-original.

IN INDIA

The same guideline states that regular clozapine monitoring is not needed and is to be conducted only if predose levels are above 0.6 mg/L, especially in smokers, to prevent toxicity, and that in the Indian context even that is not done, because of feasibility issues, limited centres providing serum clozapine assessment, and cost. The Maudsley guidelines note that much lower clozapine doses are required in East Asians, Indians and Bangladeshis, so the same milligram produces a higher concentration here than in the populations the target range came from. Where the assay is unavailable, that argues for a lower starting point and slower titration.

Stahl sets the sampling gold standard as a 12 hour trough, plus or minus 2 hours at steady state, which that source places at 5 to 7 days as a practical assay margin, against the shorter interval the Maudsley table allows for comparable agents. Response correlates best with the trough clozapine level rather than the combined clozapine plus **norclozapine** concentration, which settles which figure the target applies to. The clozapine to norclozapine ratio, not the range-width ratio above, carries two sourced values for two populations and must not be averaged: the Maudsley guidelines give an average of 1.25 across populations with marked individual variation, Stahl a typical 1.32 in adult nonsmokers. A fall in the ratio suggests enzyme induction, a rise inhibition

or a non-trough sample. The counterweight: a systematic review concludes the ratio has no clinical utility.

10.7 Carbamazepine and the tricyclics: a borrowed band and a true window

The Indian guideline is explicit that therapeutic carbamazepine serum levels have not been established for acute bipolar mania, and that clinicians borrow 4 to 12 microgram/mL from the epilepsy literature; printing that as a psychiatric target misstates the guideline. Kaplan and Sadock corroborate the borrowing by labelling the same 4 to 12 microgram/mL band as belonging to seizure disorders. The guideline separately notes one Indian study using a narrower target of 8 to 12 microgram/mL, a single study rather than guidance, while the Maudsley table gives the only bipolar-specific figure in common use, a floor of above 7 mg/L on a trough sample. Timing is where this drug differs: the Maudsley table allows 2 weeks to steady state because of **autoinduction**, whereas the Indian guideline times the sample as a morning trough drawn 5 days after the last dose increase. The two samples fall at different points in that autoinduction, so an early post-increase level need not match a later one and must be read as early rather than as a steady-state result; both are printed.

The tricyclics supply the one true therapeutic window here. The nortriptyline concentration-response relationship is curvilinear, so **50 to 150 ng/mL** is more effective than concentrations above it as well as below it, unlike lithium or clozapine, where the upper bound is set by toxicity. Kaplan and Sadock print nortriptyline at 50 to 150 ng/mL, desipramine above 125 ng/mL and imipramine, measured as desipramine plus imipramine, above 200 ng/mL, with a footnote that the frequency of serious side effects may increase over 300 ng/mL; the Maudsley table gives nortriptyline 50 to 150 microgram/L, the same antidepressant band in an equivalent unit. Only nortriptyline has a ceiling of efficacy, and that is the discriminator. Where the level sits near the upper limit of 150 ng/mL, a dose reduction could be considered, which is permissive rather than mandatory. No Indian guideline addresses tricyclic monitoring, so this window is United Kingdom and United States guidance, not Indian practice.

> **GOOD TO REMEMBER**
>
> The Maudsley guidelines judge tricyclic level monitoring rarely used and of dubious benefit, preferring the electrocardiogram to assess toxicity. Where a tricyclic assay is unobtainable, the tracing is the instrument of choice.

10.8 Reading the result

The interpretive rules carry more marks than the ranges. The Maudsley position is to act on assay results only alongside reliable clinical observation, and to treat the patient rather than the level. The same chapter quantifies it: around 25% of patients respond below the target range and up to 25% tolerate concentrations above it, so up to half of all patients sit outside the printed band and are correctly treated there.

Adherence needs the same discipline. A plasma level of zero indicates only that the drug has not been taken in the past several days. A level above zero may indicate erratic compliance, full

compliance, or long-standing non-compliance disguised by recent taking of prescribed doses, and it is that third possibility a candidate loses by writing that a level confirms adherence. Doubtful adherence is a named indication in both the clozapine box and the valproate footnote, so the limitation must sit beside them.

MNEMONIC

Time, Taken, Target, Tolerance

Four questions before acting on any result: was the sample timed correctly against the last dose, has the drug been taken, does an accepted target range exist for this agent, and is this patient responding and tolerating where they sit. A level failing the first two settles nothing.

A concentration is evidence about exposure, never a verdict on treatment: check the timing, then the patient, then the band.

11 · Pharmacovigilance, adverse drug reaction reporting and signal detection

A licence is granted on a few thousand patients and then tested on a few million. Everything a psychotropic will do that is rare, delayed, or confined to a subgroup is discovered after marketing, by clinicians who notice something and write it down. The marks here are rarely on defining the word. They sit on the discriminations inside it: reaction against event, severity against seriousness, causality grade against causality instrument, and signal against demonstrated harm. Each pair is a place where two words that sound interchangeable carry different technical meanings and send the clinician down a different path.

11.1 The definitions that are examined against each other

An Indian postgraduate pharmacology text gives the wording an examiner expects. **Pharmacovigilance** is defined by the World Health Organization, in its 2002 formulation, as the science and the activities that relate to detecting, assessing, understanding and preventing adverse effects or any other drug related problems. Take those four verbs in order, because they are the architecture of the discipline: nothing can be assessed that was never detected, and nothing can be prevented that was never understood.

Two narrower terms sit inside that definition and are routinely conflated. An **adverse drug reaction**, in that same Indian text's wording, is the technically narrow one: a noxious change suspected to be due to a drug, occurring at doses normally used in man, which requires treatment or a decrease in dose or indicates caution in the future use of the same drug. Three exclusions fall out of that wording, and they are exclusions of this text's definition rather than of the term as every body uses it. On this wording it is not every side effect, because the change must be noxious and must compel a response; it is not poisoning or overdose, because the dose must be one normally used; and it is not a change merely coincident with treatment, because a drug must at least be suspected. The clause requiring that the change compel a response is the textbook's, and it should be attributed rather than carried into a definition credited to anyone else. An **adverse drug event** discards that last requirement, covering any untoward medical occurrence that may

present during treatment with a medicine but does not necessarily have a causal relationship with the treatment.

RULE **Record the event; let the system decide whether it was a reaction.** The event definition is deliberately causality-agnostic and the reaction definition is not. A clinician who waits until they are convinced the drug was responsible has applied the wrong definition at the wrong point in the pipeline, because causality is judged later, by a different body, on the submitted individual case information. Pooled information belongs to signal detection, which is a separate process further downstream.

11.2 Type, severity and seriousness: three classifications, not one

The classification that matters clinically splits reactions by whether they follow from the drug's known pharmacology. **Type B** reactions, the unpredictable or bizarre limb, are based on peculiarities of the patient rather than on the drug's known actions and include allergy and idiosyncrasy; the same text calls them less common, often non-dose related, generally more serious, and requiring withdrawal of the drug. That last property is the operative one at the bedside, because it takes dose reduction off the menu. The receptor logic behind each class's expected adverse-effect signature belongs to the Psychopharmacology I: principles and core drug classes notes; what belongs here is that a reaction outside that signature is a different kind of object.

One sentence in that passage does more work than the rest of the taxonomy: some Type B reactions can be predicted and prevented if their genetic basis is known and a suitable test to characterise the individual's phenotype is performed. That is the argument for pre-prescription testing wherever the genetic basis is known and a validated test exists, and the source confines it to some of these reactions rather than extending it to the Type B limb as a whole. Note too that the sentence asks for a test characterising the phenotype, which genotyping informs without being interchangeable with it. Stated inside a pharmacovigilance chapter rather than a genetics one, it is the hinge to the pharmacogenomics material and to allele-directed testing before the anticonvulsants.

Severity is graded on operational thresholds rather than on impression.

SEVERITY GRADE	WHAT DEFINES IT
Minor	No therapy, antidote or prolongation of hospitalisation is required
Moderate	Requires a change in drug therapy or specific treatment, or prolongs hospital stay by at least one day
Severe	Potentially life-threatening, causes permanent damage, or requires intensive medical treatment
Lethal	Directly or indirectly contributes to the death of the patient

Seriousness is a separate axis with its own outcome list, and it is the one that drives regulatory timelines. A reaction is **serious** if it results in death, a life-threatening condition, hospitalisation

or prolonged hospitalisation, disability, congenital anomaly, an intervention required to prevent permanent impairment or damage, or any other medically important condition. Note what that list does not contain: the reporter's sense of how unwell the patient looked.

TRAP **Writing severity and seriousness as synonyms.** They are independent classifications that happen to share vocabulary. A dystonic reaction settling with one injection took a specific treatment, so it grades moderate on the table above rather than minor, however brief it was; the minor grade needs a change that called for no therapy, no antidote and no added hospital day at all. An admission for observation after a first seizure is serious by the outcome list whatever the reporter thinks of it. Candidates lose the mark by grading one scale and answering on the other.

11.3 Causality: four criteria, and two competing instruments

Causality assessment rests on four named criteria, and every algorithm in use is a way of weighting them. Temporal relationship asks how the time sequence of the event relates to drug administration. Previous knowledge asks whether the drug is known to produce the event in earlier recipients with a certain degree of consistency. **Dechallenge** asks whether the event subsided on stopping the drug, and **rechallenge** asks whether it reappeared when the drug was given again after a gap, a step that is frequently not performed because deliberate rechallenge is unethical or dangerous. The fourth criterion is therefore the strongest evidence available and the least often obtainable.

MNEMONIC

Temporal, Previous knowledge, Dechallenge, Rechallenge

The four questions in the order a case is actually reconstructed: when did it start relative to the drug, is this drug known to do this, did it stop when the drug stopped, and did it return when the drug returned. An answer opening with a scoring instrument has started in the wrong place.

Applied to those criteria, the Indian textbook grades causality into four levels: definite, where causality is proven; probable, where it is not proven but the drug is the likely cause; possible, where the drug as well as other causes could be responsible; and doubtful, where the drug is unlikely to be the cause but cannot be ruled out. The scale used inside the Indian programme is a different one. The World Health Organization and Uppsala Monitoring Centre system carries six categories rather than four: certain, probable or likely, possible, unlikely, conditional or unclassified, and unassessable or unclassifiable. The last two are not degrees of confidence but dispositions for cases that cannot yet be judged, which is why the count differs.

TRAP **Naming one causality instrument as the Indian standard.** Two bodies say two different things and both are examinable. The Indian pharmacology text states that pharmacovigilance centres are expected to assess causality and severity using standard algorithms and rating scales, and offers the Naranjo algorithm for causality assessment and the modified Hartwig scale for severity grading as its examples, not as mandated instruments. The Indian Pharmacopoeia Commission's own programme paperwork states flatly that causality assessment is carried out at the monitoring centres using the World Health Organization and Uppsala Monitoring Centre scale. Print both, attributed. Averaging them, or quietly picking the one you revised, turns a correct fact into a wrong answer.

Two discriminations inside the six-category scale are worth carrying. Certain requires one assessment criterion that probable does not, the fourth: that the event be definitive pharmacologically or phenomenologically. Any other event is automatically excluded and can never qualify for certain, however convincing the time course. Probable and possible separate on a different axis: in possible there may be another equally likely explanation for the event, or there is no information or uncertainty about what happened after stopping.

GOOD TO REMEMBER

In practice few adverse reactions are certain or unlikely; most are somewhere between those extremes, possible or probable. That reflects the instrument rather than the assessor. The source is explicit about the limits: no causality system has been shown to produce a precise and reliable quantitative estimation of the likelihood of the relationship, and the system cannot prove the connection between drug and event, nor change uncertainty into certainty. A causality grade is a structured opinion, worth exactly what its criteria are worth.

11.4 The Naranjo probability scale

The Naranjo adverse drug reaction probability scale is the algorithm most often asked for by name. It is a 10-item questionnaire, and the LiverTox reference that reproduces it gives the arithmetic: total scores range from **-4 to +13**, the reaction being definite at 9 or higher, probable at 5 to 8, possible at 1 to 4, and doubtful at 0 or less. The Indian textbook names the algorithm without printing those bands, so a candidate quoting them should know where they come from.

The internal weighting tells you what the instrument believes. Two items score +2 for a yes rather than the usual one, and they are the temporal item, asking whether the event appeared after the suspected drug was administered, and the rechallenge item, asking whether it reappeared when the drug was readministered; each scores -1 for a negative answer and 0 where the answer is unknown. The weighting is therefore asymmetric rather than doubled in both directions: time and rechallenge gain two points for a yes but cost only the ordinary single point for a no. The instrument rewards a positive time course and a positive rechallenge more than it penalises their absence, which is what makes a negative rechallenge so much weaker evidence than a positive one. Note also that the scale runs to ten items, so it is not the four causality criteria rewritten as arithmetic.

The documentation is candid about the trade. Against the more elaborate organ-specific instrument it is easier to apply but has less sensitivity and specificity in assigning causality in

drug-induced liver injury, and it subtracts points for reappearance of the event on placebo, an item that does not exist outside a trial. A tool carrying an item that cannot be answered outside a trial is being used at the bedside, and that deserves a sentence in any answer that names it.

11.5 The Indian system, and where a report actually goes

The national programme has a datable history that is examined directly. A nationwide pharmacovigilance programme was initiated in **July 2010**, with the All India Institute of Medical Sciences, New Delhi as the first National Coordinating Centre. That role shifted to the Indian Pharmacopoeia Commission at Ghaziabad in April 2011, where it remains, and the commission's coordinating centre was launched as a World Health Organization Collaborating Centre for Pharmacovigilance in Public Health Programmes and Regulatory Services on 30 October 2017. The older textbook description, in which the Central Drugs Standard Control Organization coordinates the programme through peripheral, regional and zonal monitoring centres alongside a national advisory committee, describes the earlier architecture; the current structure is one national centre with a flat network of monitoring centres. Both wordings circulate in question banks.

22	895	4th	3.6%
MONITORING CENTRES AT LAUNCH	CENTRES AT LATEST REPORT	RANK BY REPORT VOLUME	SHARE OF WORLD REPORTS

Date-stamp those figures rather than memorising them loose. The network reached its present size by the end of financial year 2023-24, with 209 centres enrolling in that year alone, and the rank and share above belong to that same index period, measured against 179 member countries of the World Health Organization Programme for International Drug Monitoring. That annual rank is not the country's cumulative standing, which is a separate and lower figure, and an answer quoting one for the other is wrong in either direction.

The pathway is drawable and worth drawing. The monitoring centre reports each individual case safety report to the national coordinating centre through VigiFlow; those reports are assessed at the national centre for quality of data and, if found valid, committed onward to the global drug monitoring centre, the Uppsala Monitoring Centre in Sweden, which is the international collaborating centre. Incomplete or invalid reports go back to the originating centre. VigiBase, the global database at the far end of that pipe, held over 40 million reports from 180+ member countries as of February 2025. A single ward report is one line in that.

11.6 Who reports, on what form, and by when

Reporting duty in India is not one duty, and collapsing it into one is the commonest error in this topic.

REPORTER	INSTRUMENT	WHAT THE SOURCE STATES ABOUT THE DUTY
Patient or consumer	Medicines Side-Effect Reporting Form, available in 10 Indian languages including Kannada, Hindi, Marathi, Tamil and Telugu	The form itself states that reporting is voluntary, has no legal implication, and aims to improve patient welfare
Healthcare professional	Suspected ADR Reporting Form for Healthcare Professionals, Version 1.4, on the commission and regulator websites and in the National Formulary of India 2021	Mandatory fields are patient initials, age at onset of reaction, reaction terms, date of onset, suspected medications and reporter information; incomplete reports are still wanted
Marketing authorisation holder	Expedited individual reports, plus the periodic safety update report under Schedule Y	For a new drug, reports are to be furnished by the applicant every six months for the first two years after approval and annually for the subsequent two years, and the licensing authority may extend the total duration if it is considered necessary in the interest of public health

The asymmetry is the teaching point. All serious adverse events and reactions must be reported by the marketing authorisation holder to the regulatory authority and the national coordinating centre within **15 days** of initial receipt of the information, a hard expedited clock with a named duty-holder. Nothing comparable is stated of the consumer, whose form declares reporting voluntary in terms. Writing that adverse drug reaction reporting is mandatory in India therefore fails on at least one of the three duty-holders, whichever one the examiner had in mind. Beyond the paper form, the programme runs a toll-free helpline on 1800 180 3024, from 9:00 AM to 5:30 PM, Monday to Friday, a reporting mobile application, and an email route to the coordinating centre.

IN INDIA

What to do on the ward when a psychotropic is suspected. Use the Suspected ADR Reporting Form for Healthcare Professionals rather than a free-text note, because its mandatory fields are the minimum the national centre can act on: patient initials, age at onset, the reaction term, the date of onset, the suspected medication and your own details. Send it even when the rest is missing. Do not delay the report while you work towards certainty. The formal grade is assigned at the monitoring centre on the World Health Organization and Uppsala Monitoring Centre scale; your own working judgment about whether the drug did this is for the patient in front of you, not a precondition for sending the form. Where the patient prefers to report independently, the consumer form exists in Kannada as well as nine other Indian languages, which makes direct patient reporting an option to offer rather than a theoretical one.

PITFALL

Holding the report back until you are certain. Two features of the system are built against that instinct: the event definition asks only for an untoward occurrence during treatment and does not require a causal relationship, and the form is built around a small mandatory core with incomplete reports still wanted. The clinician owns the observation and its timing. Formal grading is completed downstream from the individual report; pooled cases are used separately, for signal detection.

11.7 Signal detection: from a database to a hypothesis

A **signal** is defined by the World Health Organization, in the wording the Indian programme itself quotes, as reported information on a possible causal relationship between an adverse event and a drug, the relationship being unknown or incompletely documented previously. The novelty clause is load-bearing, and it turns on novelty rather than on volume: repeated reports of an already-labelled reaction are not new by count alone, though they may still signal a new aspect of the known association. The broader international standard, the CIOMS VIII (2010) definition, widens this in two ways, accepting information suggesting a new potentially causal association or a new aspect of a known association, adverse or beneficial, judged sufficiently likely to justify verificatory action. A new aspect of an old association counts, and so does a beneficial one. What neither definition supplies is causation: a signal does not indicate a direct causal relationship between an adverse event and a medicine, and is essentially a hypothesis.

The statistics are a screening step, not a verdict. The Indian programme performs **disproportionality analysis** on drug-event combinations, based on the contrast between the observed and the expected number of cases, using four key parameters.

- The **Information Component**, which the programme states originated from the Bayesian Confidence Propagation Neural Network and describes as a logarithmic measure of disproportionality, the observed and expected counts being those of one drug and reaction combination against the rest of the report database. The equation itself is deliberately not reproduced. The passage quoted from the programme's report carries the criterion and the credibility interval and does not carry the formula, and the formula as it stands in the report's own text is not a well-formed expression, its numerator and denominator brackets having been lost somewhere between the printed page and the machine-readable text. Reconstructing the brackets would be an inference, and a reader cannot tell a reconstructed equation from a quoted one. Write the Information Component in words unless the primary methodological paper is in front of you. The criterion for a signal is set at **IC025 greater than 0**, IC025 being the lower end point of the 95% credibility interval for each drug and reaction combination, and that criterion is what the source states in its own words. A positive Information Component means the combination is reported more often than the rest of the database predicts, zero means no quantitative dependency, and a negative value means it is reported less often than expected.
- The Proportional Reporting Ratio, with a criterion for a signal of PRR of at least 2.

- Chi-square, with a criterion for a signal of at least 4.
- The number of drug-event combinations, of which at least 3 are required, in the programme's own wording, for the confirmation of a signal. Read the parameter as the count of reports carrying the single drug and reaction pair under test: three is the minimum case count that the disproportionality convention pairs with the ratio and chi-square thresholds, and it is not a demand for three different combinations. Meeting it screens a pair in as a potential signal rather than confirming causality.

No single parameter is decisive: fulfilment of at least three of these four parameters is required before a drug and reaction combination is considered a potential signal. Note also what is being compared. Observed and expected counts are both computed from within the report database, so the comparison sets one drug-event pair against the rest of the reporting, never against the treated population, and no incidence can be read off it.

Human review sits after the arithmetic. The programme's Signal Review Panel comprises scientists and clinical experts affiliated to government and non-government academic institutions and hospitals, and assesses the results of identified computerised signals from individual case safety reports in order to validate and confirm them. The volume surviving to regulatory action is small: in the most recently reported year the programme issued 13 drug safety alerts and recommended 7 prescribing information leaflet changes, including 3 signals, to the Central Drugs Standard Control Organization for appropriate regulatory action.

11.8 Where this touches the psychiatric prescription

The trial phase that finds what matters to psychiatry is the last one. Post-marketing surveillance, Phase IV, provides methods capable of detecting uncommon and idiosyncratic reactions, those appearing only after long-term use, and unsuspected drug interactions. Capable of, not guaranteed to, and not alone in it: the spontaneous reporting stream and the database signal work set out earlier in this section run alongside a formal Phase IV study, as do registries and observational database studies. Its own method is unglamorous: practising physicians are identified and data are collected from them on a structured proforma about the efficacy, acceptability and adverse effects of the drug in the real field situation. Because the study population is patients treated in the normal course, post-authorisation sources can cumulatively cover populations much larger and more representative than the pre-authorisation trials, and that is why they surface what the trials could not, though an individual post-marketing study may be small and an individual licensing programme large. For agents used for years in populations no trial enrolled, this is an important source of the evidence there will be rather than the whole of it.

The prevention list in the same textbook closes the loop with the rest of this chapter. Among its concrete practices is to carry out appropriate laboratory monitoring, with prothrombin time on warfarin and serum drug levels on lithium as its worked examples. A measured concentration is therefore not only a dosing tool but a pharmacovigilance instrument: an adverse reaction prevented rather than reported. Which psychotropics earn a level, when the sample is drawn and

what the printed band licenses are taught where therapeutic drug monitoring is set out, and none of those numbers belong here.

> Report the event, not your verdict on it: causality is graded downstream, and the report that never left the ward is the one the database cannot see.

12 · Pharmacogenomics in psychiatry (CYP2D6, CYP2C19, HLA-B alleles) and clinical application

A genotype changes a prescription only where someone has published what to do with it. The marks in this topic sit on the decision rather than on the molecular biology: which variant is worth knowing before which drug, in which population, and what a result licenses you to change. Two cytochrome enzymes and two HLA loci carry almost all of the examinable material, and candidates lose it in three predictable places. They read a population frequency as an individual phenotype, they carry a recommendation from one drug across to its neighbour on the same enzyme, and they treat a genotype report as a permanent property of the patient when the patient's own prescription has already moved it.

12.1 The two enzymes worth knowing, and what each one clears

KDT ranks **CYP2D6** as the next most important cytochrome isoform after CYP3A4/5, metabolising nearly 20% of drugs, a denominator that is all drugs and not psychotropics, against the nearly 50% biotransformed by the leader. Read that denominator before you quote the figure, because it is the commonest distortion in this topic, and the substrate list the same source gives ranges across tricyclic antidepressants, SSRIs, many neuroleptics, antiarrhythmics, codeine, debrisoquine and metoprolol. An enzyme handling a fifth of the pharmacopoeia is not thereby handling a fifth of your prescriptions.

The Maudsley Prescribing Guidelines print a brief summary of important interactions, and in it the psychiatric substrate cells for the two polymorphic enzymes sit side by side. Read each cell as a selection of important substrates rather than as a complete inventory of what the enzyme clears.

- CYP2D6 metabolises aripiprazole, atomoxetine, brexpiprazole, clozapine, codeine, dextromethorphan, donepezil, duloxetine, haloperidol, phenothiazines, risperidone, tamoxifen, tricyclics, tramadol, trazodone, venlafaxine and vortioxetine.
- CYP2C19 metabolises citalopram, diazepam and moclobemide.

The Maudsley summary table lists three selected CYP2C19 substrates against a much longer CYP2D6 cell, and the short cell is a selection and not the whole of what CYP2C19 clears: the CPIC rows set out below act on escitalopram, which that cell does not name. The short cell is still where the pharmacogenomic decision bites hardest, because citalopram sits on it and citalopram is a psychotropic whose phenotype carries a regulatory dose ceiling. The cytochrome substrate map as a principle, and the interaction matrix built on top of it, belong to the

Psychopharmacology I: principles and core drug classes notes. What follows here is only what a reported phenotype changes.

12.2 From genotype to phenotype: the activity score

A laboratory reports alleles; a prescriber needs a phenotype. For CYP2D6 the bridge is an **activity score**, and CPIC translates that score into a phenotype through a per-score lookup table: 0.0 is a **poor metaboliser**, 0.25 an **intermediate metaboliser**, 1.25 a normal metaboliser and 2.5 an ultrarapid metaboliser. The published table lists a phenotype against each score and does not print the edges between the bands, so the upper edge of the intermediate and of the normal band is not stated here. Two things follow that are worth fixing in memory. Any published poor-metaboliser frequency for this enzyme means the proportion of people sitting at a score of zero and nothing else, so the frequency and the cut-point are one fact rather than two. And the lowest non-zero score is already an intermediate metaboliser under the current standard, not a poor one, which is exactly the boundary a multiple-choice stem will place its distractor on.

The scheme is not shared across genes. For CYP2C19 the phenotype names CPIC uses are poor, intermediate, normal, rapid and ultrarapid metaboliser, so a report that classifies patients into a different set of categories is not reporting the same quantity, however similar the words look.

12.3 How common each phenotype is, and why the group label is half the number

The Maudsley Prescribing Guidelines record that about 20% of Asian people and 3 to 5 percent of people of European descent are CYP2C19 poor metabolisers. CPIC publishes the same quantity by **biogeographic group**, and its figures diverge from those, because the word Asian is undefined in the first source and is split into separate groups in the second.

13.0%	8.2%	4.1%	2.4%
EAST ASIAN	CENTRAL/SOUTH ASIAN	AFRICAN AMERICAN/AFRO-CARIBBEAN	EUROPEAN

Those are CPIC's CYP2C19 poor-metaboliser frequencies, and the South Asian value is roughly three times the European one, which is the single most defensible pharmacogenomic statement available about Indian patients. Within that same Central/South Asian group the rest of the distribution matters as much as its tail: intermediate metabolisers 40.8%, normal metabolisers only 29.6%, and ultrarapid metabolisers 2.9%. A fully normal CYP2C19 phenotype is the minority state in this group, which is not the intuition a table derived from European samples trains.

TRAP **Treating Asian as one population, then averaging two sources that counted different people.** One source quotes a single Asian figure without defining the group; the other splits the same phenotype into East Asian and Central/South Asian and returns two different and lower numbers. No arithmetic reconciles them, because they are not estimates of the same quantity. Print each figure with its population attached, and remember that if the stem says South Asian, the East Asian number is a wrong answer even though it is a correct number.

CYP2D6 runs in the opposite direction, and this is the part most candidates get backwards. CPIC's activity-score-zero frequency is 2.4% in the Central/South Asian group and 6.5% in Europeans, with East Asians lowest at 0.8% and the African American and Afro-Caribbean group at 2.3%. Notice that the Central/South Asian figure for this enzyme is numerically the same as the European figure for the other one in the strip above. Identical digits, different enzyme, different group, opposite clinical meaning: that coincidence is the reason every number in this topic has to travel with both its gene and its population.

TRAP **Assuming slow metabolism travels together.** Poor metabolisers of CYP2C19 are commoner in South Asians than in Europeans; poor metabolisers of CYP2D6 are less common. A stem offering "Indian patients are poor metabolisers" as a single fact is testing whether the candidate knows the statement is enzyme-specific and that its direction reverses between the two enzymes that matter most in psychiatry.

One genuine disagreement should be carried rather than resolved. CPIC's European CYP2D6 poor-metaboliser estimate sits above the figure the Maudsley Prescribing Guidelines give for people of European descent for the same enzyme. Both are published, neither is an error, and the honest answer attributes the number to the body that issued it instead of blending them. What survives both sources is the direction: for CYP2D6 the European rate exceeds the South Asian one.

GOOD TO REMEMBER

These group frequencies are model output, not counts of people. CPIC states that diplotype and phenotype frequencies are estimated from reported allele frequencies using the **Hardy-Weinberg equilibrium** equation, with the margin of error compounding across the alleles that make up a diplotype. Use them as a prior for how likely an unusual phenotype is in the patient in front of you. Do not use them as a substitute for the individual test when the decision genuinely turns on that patient's phenotype.

12.4 What Indian cohorts add, and what a single cohort cannot carry

CPIC's Central/South Asian label is a biogeographic grouping and not a synonym for Indian, so the nearest primary data are individual Indian cohorts. One Indian cohort of healthy volunteers reports a predicted CYP2C19 poor-metaboliser frequency, the phenotype inferred from genotype and not measured, and neither that frequency nor the number of volunteers behind it is printed here: the report itself could not be consulted here, and a prevalence figure is precisely the sort of number a reader carries forward unchecked. The allele frequencies reported for that same cohort are CYP2C19*2 at 0.365, CYP2C19*3 at 0.0033 and CYP2C19*17 at 0.18: one loss-of-function allele that is genuinely common, a second that is vanishingly rare, and a third present at appreciable frequency.

Two disciplines travel with those figures. The first is how to name them. This is one cohort, single-centre and drawn from healthy volunteers, so it is one Indian cohort and never the Indian prevalence, and an answer that promotes it to a national figure has overreached in a way an examiner can mark. The second is how not to combine them. The cohort's phenotypes were

predicted from genotype, while the biogeographic figures were modelled from reported allele frequencies under an equilibrium assumption, and the two were produced by different methods against different phenotype classifications. They can sit in the same discussion; they cannot sit in the same column as though one validated the other.

12.5 What a phenotype actually changes: the gene-drug pair

RULE **The unit of a pharmacogenomic decision is the gene-drug pair, not the gene.** A phenotype means nothing until a body has published an action for the specific drug in front of you, and those actions differ between drugs that share an enzyme, differ between the two ends of one enzyme's range, and are issued at different strengths. CPIC states the principle at its sharpest for the HLA locus: the comment on its carbamazepine recommendation table records that the HLA-B*15:02 test is recommended to guide the use of carbamazepine and oxcarbazepine only. That is the scope of that guideline rather than the whole current scope of the allele, because CPIC issues a separate phenytoin recommendation on the same allele, which is taught with the HLA testing and severe cutaneous reaction material.

PHENOTYPE	DRUG	PUBLISHED ACTION	STRENGTH
CYP2C19 poor metaboliser	citalopram, escitalopram	Consider an antidepressant not predominantly metabolised by CYP2C19; if citalopram or escitalopram remain clinically appropriate, consider a lower starting dose, slower titration and a 50% reduction of the standard maintenance dose	Strong
CYP2D6 poor metaboliser	paroxetine	A 50% reduction in the recommended starting dose, a slower titration schedule, and a 50% lower maintenance dose than in normal metabolisers	Moderate
CYP2D6 ultrarapid metaboliser	paroxetine	Select an alternative drug not predominantly metabolised by CYP2D6	Moderate
HLA-B*15:02 positive, carbamazepine-naive	carbamazepine	Do not use carbamazepine	Strong
HLA-A*31:01 positive, carbamazepine-naive	carbamazepine	Do not use carbamazepine if alternative agents are available	Strong

Read those as five separate instructions rather than as a pattern, because three of the differences between them are examined. The shape of the advice is drug-specific: for the pair metabolised by

CYP2C19 the recommendation leads with choosing a different antidepressant and only then offers a reduced dose, while for paroxetine at the slow end it leads with halving. The strength is drug-specific too, so a classification cannot be carried sideways from one agent to another even when the action is identical. And there is one instruction in this area that comes from outside CPIC's dose adjustments altogether: per the FDA warning quoted by CPIC, citalopram **20 mg/day** is the maximum recommended dose in CYP2C19 poor metabolisers, a ceiling set by the risk of QT prolongation rather than by any limit on antidepressant efficacy. That warning states the ceiling and no starting dose, because a restriction of this kind caps a regimen rather than opening one; where a poor metaboliser is actually being started, the instruction to work from is the CPIC row above, which asks for a lower starting dose and a slower titration without naming a figure for either. The logic underneath all of it is exposure. Less enzyme activity means more parent drug at the same milligram, which is why the published response is a smaller dose or a different drug rather than a different class.

IN INDIA

Because CYP2C19 poor metabolisers are several times commoner here than in the populations most dosing tables were built from, the CYP2C19 row of that table is the one that will alter practice most often. Where citalopram or escitalopram is the chosen antidepressant and a poor-metaboliser phenotype is known, the published instruction is a lower starting dose and a slower titration before any maintenance dose is settled, with the regulatory ceiling applying on top of it. Where the phenotype is unknown and cannot be tested, no phenotype may be read off ancestry: a higher group frequency does not make the patient in front of you a poor metaboliser, and an untested patient is started and titrated on ordinary clinical grounds rather than on a genotype-guided instruction.

12.6 Phenoconversion: when the prescription changes the phenotype

A genotype is fixed; the phenotype it predicts is not. CPIC records that paroxetine-associated **phenoconversion** of CYP2D6 normal metabolisers to intermediate or poor metabolisers, through autoinhibition of the enzyme, may occur, is dose-dependent, and is greater at steady-state concentrations. Read the modal exactly as written: may occur, not does. The clinically useful part is its shape. The drug the enzyme clears is also inhibiting that enzyme, so the phenotype printed on a report taken before treatment is not necessarily the phenotype the patient has once the drug has reached steady state, and the discrepancy grows with the dose.

Autoinhibition is only the tidiest example. The general case is any co-prescribed inhibitor of the same enzyme, which is why a genotype-guided plan has to be read against the current prescription list rather than in isolation. The full inhibitor and inducer matrix across the psychotropic classes is taught with the pharmacokinetic and pharmacodynamic drug interaction material and is not repeated here.

PITFALL

Treating a pharmacogenomic report as a permanent property of the patient. The report describes the genome; the phenotype line on it is a prediction, and that prediction can be moved by the drug being started or by a second drug already in the chart. Before explaining a non-response or an unexpected adverse effect by the genotype, read the prescription list, because a predicted normal metaboliser can behave like a poor one for reasons that have nothing to do with the report and everything to do with what else the patient is taking.

12.7 The HLA alleles: a test used to rule a drug out

The cytochrome tests adjust a dose. The HLA tests remove a drug, and that difference in what the result does is why they are examined together and answered differently. The CPIC HLA-B frequency table gives HLA-B*15:02 a Central/South Asian **allele frequency** of **2.6%**, an East Asian frequency of 4.6% and a European frequency of 0.0000655, that last figure being the table's raw proportion and not a percentage. Two things must be said with those numbers. They are allele frequencies and not carrier frequencies, which is a different quantity that these figures do not give; and the South Asian value, while below the East Asian one, is enormously above the European one, so the familiar teaching that this is an East Asian allele is only half true in an Indian clinic.

The unusual property of the test sits at its negative end. CPIC records that HLA-B*15:02 carries a **100% negative predictive value** for carbamazepine-induced SJS/TEN. That figure is stated flatly in the comment on CPIC's carbamazepine recommendation table, for that reaction with that drug, and it is what makes the allele function as a rule-out rather than a risk score: a negative result greatly reduces the risk of that reaction with that drug rather than abolishing it, and a positive result is a stop rather than a caution. Carbamazepine-associated Stevens-Johnson syndrome and toxic epidermal necrolysis are also reported with other B75 alleles that a single-allele assay does not read, so a negative assay is not a negative patient. It is also why the recommendation is issued with a restriction written into it rather than as a general test of anticonvulsant safety.

HLA-A*31:01 is a second and separate carbamazepine risk allele that does not carry the same consequences as the first, and those differences are precisely what is asked. Its risk spans SJS/TEN, DRESS and MPE, not SJS/TEN alone, so it predicts a wider reaction spectrum including a maculopapular exanthem. Its stopping rule is conditional where the other is absolute: in a carbamazepine-naive patient the instruction is not to use carbamazepine if alternative agents are available. That conditional clause is the discriminator between the two alleles and is worth reproducing in those words rather than paraphrased into a flat prohibition.

For Indian practice the association itself has been quantified. A meta-analysis of Indians from Malaysia and India demonstrated a significant and strong association between HLA-B*15:02 and carbamazepine-induced SJS/TEN, with an odds ratio of 38.54 (95% CI 6.83 to 217.34). The interval teaches as much as the point estimate. The effect is large and the sample it rests on is small, so the finding argues for testing rather than for quoting a precise risk to a patient.

IN INDIA

A low group allele frequency is a poor reason to skip this test, because the frequency describes a population and the reaction happens to an individual. The pharmacogenomic argument runs the other way: the allele is present here at a frequency that is not negligible, the association in Indian patients is strong, and the test's real yield is the negative result it returns to the great majority who are not carriers. Where carbamazepine is the drug being started and the assay is obtainable, that is the moment at which the result changes the prescription. The severe cutaneous reactions themselves, and the wider testing framework reaching phenytoin and oxcarbazepine, are taught with the HLA testing and severe cutaneous reaction material.

12.8 Ancestry, dose requirement and the honest Indian position

Some of what a genotype is invoked to explain is already visible before anyone is genotyped. The Maudsley Prescribing Guidelines record that much lower doses of clozapine are required in East Asians, Indians and Bangladeshis, and that the prevalence of clozapine poor metabolisers is also higher in East Asians. An Indian exploratory study puts a figure on the first half of that: the median clozapine **concentration to dose ratio** in its sample was 2.5 against a published weighted mean of 1.07 for Caucasians, about two and a half times higher.

Both halves of that pairing need discipline. The Indian figure is a concentration observation and not a genotype finding: no variant is named as its cause, and attributing it to a particular cytochrome polymorphism goes beyond what was reported. It is also a single exploratory sample compared against published means rather than against a concurrent control group. What it licenses is the caution that a milligram may not mean here what it meant in the population a dosing table was derived from. The plasma concentration itself, its target range and when the sample is drawn belong with the therapeutic drug monitoring material and are not restated here.

The Indian guideline position is deliberately restrained, and it is the right note to close on. The Indian Psychiatric Society schizophrenia guideline states that **psycho-pharmacogenomic studies**, focusing on cytochrome P450 enzymes, may be helpful in three situations:

- treatment-resistant positive symptoms;
- antipsychotic intolerance;
- frequent relapse despite reported fair medication adherence.

The same guideline then states that the clinical utility of psycho-pharmacogenomics is disputable, because of the lack of larger standardised trials and cost-effectiveness evaluations, and that where such testing is conducted the decisions must always be integrated with other clinical factors. Notice what that position is and is not. It is a judgement about the evidence base and about economic evaluation, and it is stated in a guideline rather than inferred. It is not a statement about which laboratories in the country run these assays, what they cost, or how long they take, and an answer that supplies those details is supplying them from somewhere other than the guideline.

MNEMONIC

Allele, Agent, Ancestry, Action

Four questions before a pharmacogenomic result changes anything: which allele or phenotype has actually been reported, which agent the published recommendation was written for, which population the frequency being quoted was measured or modelled in, and what action a named body has actually published for that pair. A result that fails any one of the four settles nothing.

A pharmacogenomic result is a gene, a drug, a population and a published action: without all four it changes no prescription.

Interactions and prescribing in physical illness

13 · Pharmacokinetic and pharmacodynamic drug-drug interactions of psychotropics

A psychotropic almost never meets a patient alone. The second drug is the commonest second variable here, and three questions are asked of every pair: by what mechanism does one agent reach the other, in which direction does the concentration or the effect move, and how long does the change take to declare itself. Marks are lost by treating every interaction as an enzyme problem, by naming an isoenzyme without committing to a direction, and by assuming a mechanism that is real must also be clinically operative. Half-life, steady state, therapeutic index and the enzymology itself belong to the Psychopharmacology I: principles and core drug classes notes; what follows is the cross-class application, on the enzymatic mechanisms and on the equally examinable mechanisms that have no enzyme in them at all.

13.1 The two axes, and why the second is not the lesser one

Kaplan and Sadock draw the line at the plasma concentration. A **pharmacokinetic** interaction is one drug changing what another drug's plasma concentration turns out to be; a **pharmacodynamic** interaction is one drug changing another's biologic activity. The second definition turns on activity, not on constancy of concentration, so a single pair can sit on both axes at once. Defining that axis as an interaction in which the level does not move imports a condition the standard text does not impose.

RULE **Name the mechanism before naming the drug.** Every interaction here resolves to one of four mechanism families: altered metabolism by a cytochrome or a conjugating enzyme, altered renal elimination, displacement from plasma protein binding, and additive or opposing action at a shared endpoint. The first three move a concentration and are pharmacokinetic; the fourth need not, and is pharmacodynamic.

13.2 Grading an inhibitor and an inducer, and which psychotropics qualify

Strong and moderate are regulatory definitions, not clinical impressions. Both are fixed by what the perturbing drug does to the area under the concentration-time curve of a sensitive **index**

substrate: an inhibitor is graded by how far it raises that exposure, an inducer by how far it lowers it. Induction is graded by loss and inhibition by gain, which keeps the two ladders apart.

5-fold or more	2 to under 5-fold	80 per cent fall or more	50 to under 80 per cent
STRONG INHIBITOR	MODERATE INHIBITOR	STRONG INDUCER	MODERATE INDUCER

The psychotropics at the top of the inhibitor ladder are ordinary drugs. Fluoxetine and paroxetine are the two clinical index strong inhibitors of CYP2D6 named by the FDA, and fluoxetine is a strong inhibitor of CYP2C19 as well, making it a two-enzyme inhibitor rather than a CYP2D6-only one. Fluvoxamine is the index strong inhibitor for both CYP1A2 and CYP2C19, and the same footnote grades it a moderate CYP3A inhibitor and a weak CYP2D6 inhibitor. Three of the commonest selective serotonin reuptake inhibitors therefore carry three different inhibition fingerprints, and knowing the class tells you none of them.

- Carbamazepine is a strong inducer of CYP3A and of CYP2B6 and a weak inducer of CYP2C9.
- The Maudsley Prescribing Guidelines additionally mark carbamazepine and phenobarbital as predominant-pathway inducers of CYP1A2, while the FDA selects no index inducer at all for that isoenzyme; since the FDA table is not exhaustive, that is silence rather than contradiction, and the direction is taught under the Maudsley name.
- No inducer of CYP2D6 is known: the Maudsley inducer column for that isoenzyme reads not known, and it is the only column left empty. Absence of an identified inducer is not a demonstration that the enzyme cannot be induced.

13.3 The substrate side, and why one enzyme reaches several classes

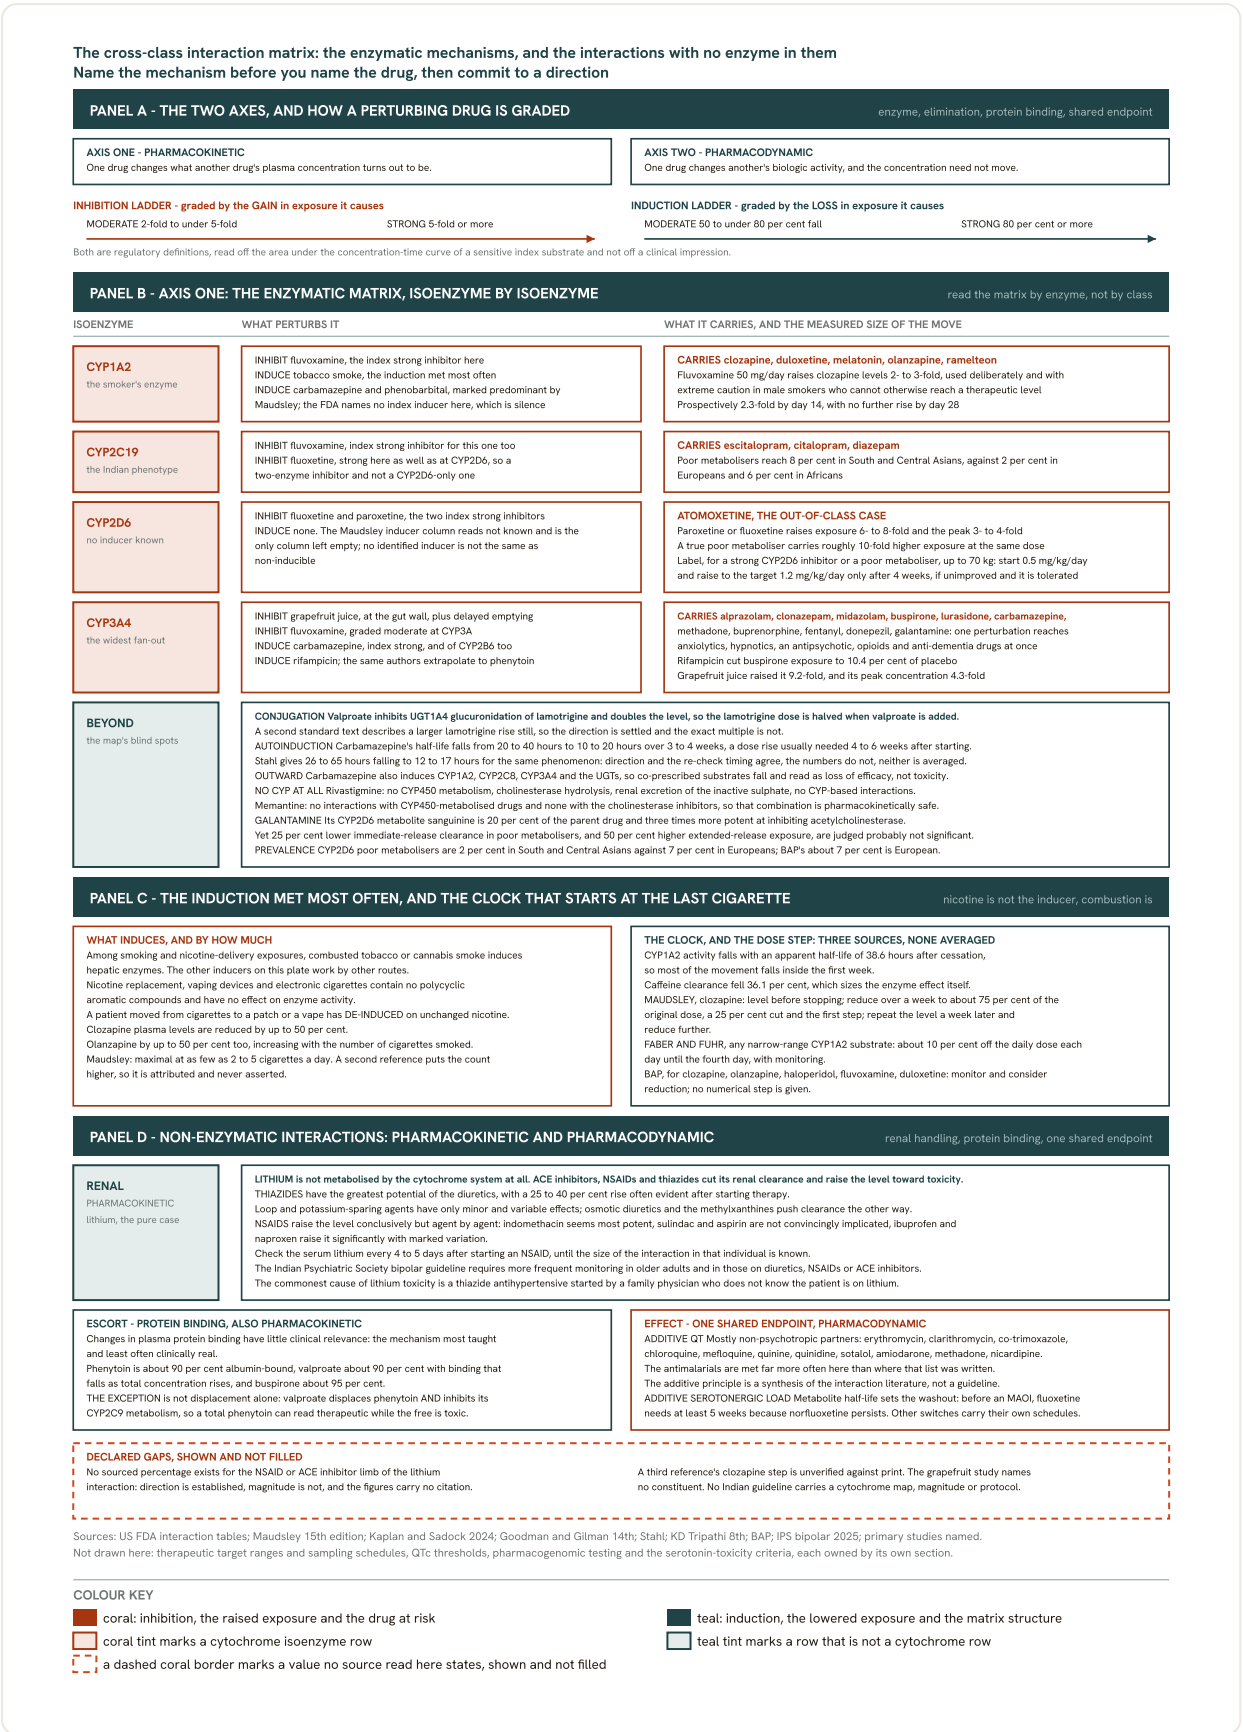

Fig 37.6 The cross-class interaction matrix, on both of its axes. The enzymatic half is read isoenzyme by isoenzyme: what inhibits it, what induces it, what it carries, and the measured size of the move, with conjugation, autoinduction, the agents that have no cytochrome involvement at all, and the population prevalences beneath it. The non-enzymatic half is the one a habit-written answer omits: renal handling with lithium and protein-binding

displacement with its one exception, both pharmacokinetic, and additive action at a shared endpoint, pharmacodynamic.

An inhibitor list is half a prediction. The other half is the substrate map, and a single perturbation fans out widely because the substrates of one isoenzyme are drawn from several therapeutic classes at once. The Maudsley guidelines mark clozapine, duloxetine, melatonin, olanzapine and ramelteon as predominant-pathway CYP1A2 substrates. Their CYP3A4 substrate cell is wider still, carrying alprazolam, clonazepam and midazolam, buspirone, lurasidone, carbamazepine itself, methadone, buprenorphine and fentanyl, and donepezil and galantamine. One CYP3A4 perturbation therefore reaches the anxiolytics, the hypnotics, an antipsychotic, the opioids and the anti-dementia drugs at once, which is the argument for reading the matrix by enzyme rather than by class. The accompanying figure sets out both of its axes together.

13.4 Tobacco smoke, and the clock that starts at the last cigarette

The induction a psychiatrist meets most often is not a drug. Among smoking and nicotine-delivery exposures, the Maudsley position is that combusted smoke induces hepatic enzymes in the manner its own table describes, that this covers cigarettes and cannabis or tobacco joints, and that nicotine replacement, vaping devices and electronic cigarettes do not reproduce that smoke-mediated induction. The footnote attributes that to their containing no **polycyclic aromatic compounds**. Smoking reduces clozapine plasma levels by **up to 50 per cent**, and olanzapine levels by up to 50 per cent as well, that effect increasing with the number of cigarettes smoked. For clozapine the same guideline records that the effect may be maximal at as few as 2 to 5 cigarettes a day; a second standard reference puts the threshold higher, and because the sources disagree the count must be attributed rather than asserted.

TRAP **Treating nicotine as the inducer.** Nicotine replacement, vaping devices and electronic cigarettes contain no polycyclic aromatic compounds and have no effect on enzyme activity, so a patient moved from cigarettes to a patch or a vape has de-induced despite unchanged nicotine intake. The same is true of the smoker admitted to a smoke-free ward. Locating the induction in nicotine predicts no change and misses the rise, which is exactly the stem built around a planned admission or a cessation attempt.

De-induction is quick without being instantaneous. Caffeine phenotyping in heavy smokers put the apparent half-life of the fall in CYP1A2 activity at **38.6 hours**, so most of the movement falls inside the first week; in the same study stopping smoking cut caffeine clearance by 36.1 per cent, which sizes the enzyme effect rather than the effect on any one drug. The participants were few and none were Indian, and that limit travels with the number. Three references address the dose step itself and none agree, so each is attributed and none averaged into the others.

SOURCE, AND THE DRUGS IT SCOPES	THE DOSE STEP ON STOPPING SMOKING	THE MEASUREMENT THAT GOES WITH IT
The Maudsley Prescribing Guidelines, for clozapine	Reduce gradually over a week until around 75 per cent of the original dose is reached, which is a 25 per cent cut and the first step rather than the destination	Take a plasma level before stopping, repeat it a week after stopping, and expect to reduce further
Faber and Fuhr, for any CYP1A2 substrate of narrow therapeutic range	A stepwise daily reduction of approximately 10 per cent until the fourth day after cessation, proposed as a rule of thumb	Accompanied throughout by therapeutic drug monitoring
BAP, for clozapine, olanzapine, haloperidol, fluvoxamine and duloxetine	Monitor and consider dose reduction of the CYP1A2-metabolised drug; no numerical step is specified	Guided by therapeutic drug monitoring
A third standard reference, for clozapine	A different step again, on a different tempo; its figures could not be verified against the printed text and are not reproduced	Not stated here

13.5 Inhibition used on purpose, met by accident, or carried in the genome

Fluvoxamine and clozapine is the case in which the inhibition is the point. The evidence in schizophrenia is that co-prescribing fluvoxamine at a dose as low as 50 mg/day raises clozapine levels 2- to 3-fold, and the combination is used deliberately, with extreme caution, in male smokers who cannot otherwise reach therapeutic levels. The magnitude is confirmed prospectively: mean plasma clozapine rose 2.3-fold at 14 days of combined treatment, with no further elevation at 28 days, so the new plateau arrives inside a fortnight. Used without a measured level, the strategy inverts its own safety logic, because the inhibition is then being relied on blind.

Buspirone demonstrates the same axis in both directions and at full amplitude. Rifampicin cut buspirone exposure to **10.4 per cent of placebo**, effectively abolishing the drug, and the same authors name carbamazepine and phenytoin as potent CYP3A4 inducers with the same consequence, which is their extrapolation rather than a measured comparison. Inhibition runs the other way just as hard: grapefruit juice raised buspirone exposure 9.2-fold and its peak concentration 4.3-fold in healthy volunteers, by inhibiting intestinal CYP3A4-mediated first-pass metabolism and delaying gastric emptying. The primary study attributes the effect to the juice as a whole and identifies no constituent, so naming one is an overreach.

Atomoxetine makes CYP2D6 concrete outside the antidepressants. Adding paroxetine or fluoxetine to a normal metaboliser raises atomoxetine exposure roughly 6- to 8-fold and its peak concentration about 3- to 4-fold, converting the patient pharmacokinetically into a poor metaboliser, and a true **poor metaboliser** carries roughly 10-fold higher exposure than a normal metaboliser at the same nominal dose. The label treats the two conditions as one. In children and adolescents up to 70 kg on a strong CYP2D6 inhibitor such as paroxetine, fluoxetine or

quinidine, or in known poor metabolisers, atomoxetine for attention deficit hyperactivity disorder is started at 0.5 mg/kg/day and increased to the usual target of 1.2 mg/kg/day only if symptoms have not improved after 4 weeks and the starting dose is well tolerated.

Genotype is the standing version of the same inhibition, and the prevalences disagree by source and ancestry. The BAP attention deficit hyperactivity disorder guideline gives CYP2D6 poor metabolisers as about 7 per cent, while the Maudsley guidelines separate the populations and give 2 per cent in South and Central Asians against 7 per cent in Europeans, so the first figure is a European one wearing no label. Allele-level testing and its interpretation are taught in the section of these notes on pharmacogenomics in psychiatry.

IN INDIA

The two polymorphisms point in opposite directions in this population. CYP2C19 poor metabolism reaches **8 per cent** in South and Central Asians, against 2 per cent in Europeans and 6 per cent in Africans, which matters for escitalopram, citalopram and diazepam. Stacking a strong CYP2C19 inhibitor, fluvoxamine or fluoxetine, on one of those agents compounds a common phenotype with a strong inhibitor, so anticipate higher exposure and follow the substrate-specific label or guideline for avoidance, dose reduction, slower titration or monitoring. CYP2D6 runs the other way: poor-metaboliser status is reported less often in South and Central Asians than in Europeans, but genotype and co-prescribed inhibitor both remain clinically relevant and may combine to raise exposure, and the inhibitor is the limb the prescriber can always see.

13.6 Autoinduction, and the drugs with no cytochrome problem at all

Carbamazepine induces its own metabolism. Its half-life falls from 20 to 40 hours down to 10 to 20 hours over 3 to 4 weeks of regular dosing, and the dose usually has to be increased about 4 to 6 weeks after starting to hold the same concentration. Stahl's guide gives different figures for the same phenomenon, an initial half-life of 26 to 65 hours falling to 12 to 17 hours with repeated dosing; direction and the timing of the re-check are agreed across the sources, the numbers are not, and printing either as the figure is an error. **Autoinduction** is also outward-facing: carbamazepine induces CYP1A2, CYP2C8, CYP3A4 and the conjugating UGT enzymes, so co-prescribed substrates of those pathways fall in concentration over the same weeks and present as loss of efficacy rather than as toxicity.

Not every drug has a cytochrome problem. Rivastigmine is the pharmacokinetic outlier of the cholinesterase inhibitors: no CYP450 metabolism, clearance by cholinesterase-mediated hydrolysis with renal excretion of the inactive sulphate metabolite, and therefore no CYP-based drug interactions. Memantine records no interactions with drugs metabolised by CYP450 enzymes and none with the cholinesterase inhibitors, which is what makes the combination pharmacokinetically safe. Galantamine is the counterexample inside the same class: it is metabolised by CYP2D6 and CYP3A4, and its CYP2D6 metabolite **sanguinine** accounts for 20 per cent of the parent drug and is three times more potent than galantamine at producing acetylcholinesterase inhibition. Even there the polymorphism is judged not to matter: Kaplan and Sadock call a 25 per cent decrease in clearance of the immediate-release form in poor

metabolisers, and 50 per cent higher exposure with the extended-release form, probably not significant given the large interpatient variability in galantamine disposition. Hold that beside atomoxetine, where the same enzyme carries the opposite verdict: a polymorphism can be real and still not actionable.

GOOD TO REMEMBER

When a patient with dementia is already established on an enzyme inducer or a strong inhibitor, choosing the cholinesterase inhibitor that is not metabolised by the cytochrome system removes the interaction instead of managing it, and memantine adds nothing to the burden either. That is a decision available at the first prescription, not a monitoring plan bolted on later.

13.7 Non-enzymatic interactions: lithium and the kidney

Lithium is the purest case on this side of the matrix, because it is not metabolised by the cytochrome system at all and its interactions are renal. Kaplan and Sadock state that angiotensin converting enzyme inhibitors, non-steroidal anti-inflammatory drugs and thiazides decrease the renal clearance of lithium and increase the likelihood of severe elevation. The diuretics do not behave alike. Thiazides have the greatest potential of the diuretics to raise lithium, with a **25 to 40 per cent** rise often evident after starting therapy, whereas loop diuretics and potassium-sparing agents have only minor and variable effects, and osmotic diuretics and methylxanthines push clearance the other way and were historically advocated as antidotes for lithium toxicity. No percentage is available for the ACE inhibitor limb: the direction is established and the magnitude is not.

The NSAID limb is agent-dependent in a way the class name hides, and the whole of the account here rests on one paper, named so that a reader can weigh it: Ragheb's review in the Journal of Clinical Psychopharmacology in 1990. Ragheb's review states there is conclusive evidence that these drugs can increase serum lithium levels, diminish renal lithium clearance and possibly induce lithium toxicity, that the effect varies greatly between agents with indomethacin seeming most potent, that sulindac and aspirin are not convincingly implicated, and that ibuprofen and naproxen can raise levels significantly but with marked interindividual variation. No percentage belongs here either: the primary review gives none and the figures in circulation disagree and carry no citation. The review does give a monitoring rule, that a patient on lithium started on one of these drugs should have the serum level checked every 4 to 5 days until the extent of the interaction in that individual is known. The Indian Psychiatric Society bipolar guideline reaches the same place from the other direction, requiring more frequent monitoring in older adults and in those on diuretics, NSAIDs or ACE inhibitors. Target concentrations and the routine sampling schedule are taught in the section of these notes on therapeutic drug monitoring, and lithium toxicity as an entity in the section on the other psychotropic emergencies.

PITFALL

Kaplan and Sadock name the commonest cause of lithium toxicity today as a thiazide antihypertensive started by a family physician who is unaware the patient is under psychiatric care with lithium. It is not created in the psychiatry clinic and cannot be intercepted there, so the warning has to travel with the patient rather than sit in the record.

13.8 Protein binding, conjugation, and the pharmacodynamic axis

Displacement is the mechanism most taught and least often clinically real. The reference position, and the title of the paper that argues it, is that changes in plasma protein binding have little clinical relevance. The figures that make the teaching concrete are unremarkable in themselves: phenytoin is about 90 per cent albumin-bound, valproate about 90 per cent with binding that falls as the total concentration rises, and buspirone about 95 per cent. High protein binding predicts a theoretical interaction, not a clinical one.

TRAP **Reading a therapeutic total phenytoin as a safe phenytoin when valproate is on board.** Valproate displaces phenytoin from albumin and inhibits its CYP2C9 metabolism, so total phenytoin can read therapeutic while free phenytoin is toxic. Displacement alone carries little clinical relevance; displacement combined with inhibition of the same drug's metabolism is the exception that proves the rule, and the Indian standard text makes the same point. Where a free assay is not obtainable, the diagnosis is made from the patient rather than from the report.

Conjugation is the other enzymatic pathway the cytochrome map does not show. Valproate inhibits the UGT1A4 **glucuronidation** of lamotrigine and doubles the lamotrigine level, so the lamotrigine dose is halved when valproate is co-prescribed; a second standard text describes a larger rise still, so the direction is settled and the exact multiple is not.

Two pharmacodynamic stacks carry most of the marks. The first is additive QT prolongation, whose commonest partners in a psychiatric patient are non-psychotropic: erythromycin and clarithromycin, co-trimoxazole, chloroquine, mefloquine and quinine, quinidine, sotalol and amiodarone, methadone and nicardipine. The antimalarials on that list are met far more often here than in the practice it was written for, which changes which partner a psychiatrist encounters. Thresholds and monitoring belong to the section of these notes on QTc prolongation and cardiometabolic monitoring; the additive principle is a synthesis of the interaction literature rather than a guideline position, and is worth stating as such. The second stack is additive serotonergic load, where the arithmetic is set by metabolite half-life rather than by parent half-life: before a monoamine oxidase inhibitor is started after fluoxetine, allow a **washout** of at least 5 weeks because norfluoxetine persists, and an interaction with a serotonergic agent remains possible over that same period after the parent drug has gone. Other serotonergic switches carry their own schedules and do not inherit this interval. Serotonin toxicity itself, with its precipitants, its named criteria and its pharmacological management, is taught in its own section of these notes.

MNEMONIC

Enzyme, Elimination, Escort, Effect

The four families, in the order worth checking them in front of a prescription. Enzyme: is either drug a substrate, inhibitor or inducer of a pathway the other uses. Elimination: does either change the renal handling of the other. Escort: is one displaced from plasma protein binding, with a second mechanism alongside. Effect: do both act on one endpoint, whether or not either concentration moves. A pair on two lines is the dangerous one.

One limitation belongs in any answer built on this material. The enzymatic axis rests on regulatory tables, United Kingdom and United States reference texts and primary pharmacokinetic studies; no Indian guideline carries a cytochrome map, an interaction magnitude or a screening protocol. Say so rather than imply otherwise.

Predict from the mechanism, not from the class: ask which enzyme, which kidney, which binding site and which endpoint the two drugs share, and only then ask which way the number moves.

14 · Psychotropic prescribing in cardiac, hepatic and renal disease

A psychotropic prescription in organ disease is two decisions, not one. The first is ordinary: which drug the disorder needs. The second is what the failing organ does to that drug, or what the drug does to that organ, and the marks are almost entirely for the second. The three organs ask three different questions. The liver principally decides how much of a dose survives to circulate and how fast it is destroyed. The kidney principally decides how much of it leaves. The heart chiefly decides what a given concentration does to conduction, contractility and rhythm, although heart failure can also alter exposure itself through reduced perfusion, hepatic congestion and impaired renal clearance. Candidates lose marks by answering all three with a single list of safe drugs, and by carrying an agent that is the right answer in one organ into the organ where it is the wrong one.

14.1 Reading the organ, not the number

The commonest error at the start is to treat the routine blood test as a measure of the organ's working capacity. The Maudsley Prescribing Guidelines in Psychiatry state plainly that liver function tests are a poor marker of **hepatic metabolising capacity** and not a measure of it: they help evaluate hepatic damage, but tell us little about hepatic function. A patient with grossly deranged transaminases may clear a drug normally, and a patient with a near-normal panel and a shrunken cirrhotic liver may not.

Three organs ask three different questions of one prescription, and a diseased brain asks a fourth: what the failing organ does to the drug, what the drug does to the organ, and which agent is therefore preferred or avoided

PANEL A - THE THREE ORGANS: WHAT CHANGES, WHICH AGENT IS PREFERRED, WHICH IS AVOIDED

the liver test reports injury, not clearance

ORGAN	WHAT CHANGES, AND WHY	PREFERRED OR PERMITTED	AVOIDED OR CONTRAINDICATED
HEPATIC IMPAIRMENT — how much of the dose survives	Most psychotropics are extensively hepatically metabolised, so lower doses may be needed across nearly the whole formulary. Liver function tests index hepatic damage and tell us little about hepatic function: the panel reports injury, not clearance. Monitor LFTs weekly, at least initially; if they deteriorate after a new drug, CONSIDER switching, which is permissive and not directed.	No or minimal hepatic metabolism: sulpiride, amisulpride, lithium, gabapentin. Lithium: no dose reduction if renal function is normal; sample more often when ascites status changes the volume of distribution. IPS tiers: aripiprazole, paliperidone and ziprasidone relatively safer, no adjustment in mild to moderate; olanzapine and clozapine greater risk, risperidone and quetiapine moderate.	Very sedative and very constipating drugs, both for the risk of precipitating hepatic encephalopathy. Hepatotoxic in their own right: MAOIs, chlorpromazine. CONTRAINDICATED: duloxetine, clearance cut even in mild impairment, with fatal hepatic failure reported. Agomelatine, with LFTs at baseline and 3, 6, 12 and 24 weeks and stopping above three times the limit. Valproate in severe or active impairment, greatest liver toxicity risk in the first 3 months.
RENAL IMPAIRMENT — how much of it leaves	The MHRA advises creatinine clearance as the estimate for narrow-therapeutic-index drugs that are mainly renally excreted, lithium among them. Assume at least mild impairment over 65 even when serum creatinine is normal: less muscle mass produces less creatinine. Long-term lithium impairs renal function in about a quarter of patients, and levels above 0.8 mmol/L carry a higher risk of renal toxicity.	IPS: most first-generation antipsychotics are CONSIDERED safe in chronic kidney disease without dose adjustment. Valproate: no routine adjustment, about 2 per cent excreted unchanged. Lamotrigine: under 10 per cent renal excretion of unchanged drug.	Nephrotoxic where renal reserve is limited: lithium, non-steroidal anti-inflammatory drugs. Caution with the extensively renally cleared: sulpiride, amisulpride, lithium. Try to avoid long-acting drugs such as depots. In established renal failure, probably best to avoid the antipsychotics with the GREATEST QTc risk. IPS: phenothiazines may raise hypotension risk, and amisulpride and paliperidone are better avoided in end-stage renal disease.
CARDIAC DISEASE — what the surviving concentration does	In heart failure, SSRIs are the first-line class and sertraline the recommended agent: few drug interactions, less propensity than citalopram to prolong the QTc, and demonstrated safety, though unproven efficacy, in SADHART-CHF. After myocardial infarction SSRIs and mirtazapine have neutral or beneficial mortality associations; the source's do-not-withhold direction is for an SSRI.	Minimal effect on the QT interval and safer at cardiac risk: cariprazine, lurasidone, brexpiprazole, lumateperone. Heart failure: sertraline. Paroxysmal or persistent atrial fibrillation: cariprazine, brexpiprazole or lurasidone may be appropriate, though all antipsychotics appear to raise bleeding risk with direct-acting oral anticoagulants in atrial fibrillation.	Tricyclic antidepressants are generally avoided in cardiac disease: effects on contractility, proarrhythmia from cardiac sodium and potassium channel blockade, and worsening ischaemic heart disease. Higher affinity for cardiac potassium channels, and higher risk of ventricular arrhythmia and sudden cardiac death: haloperidol, olanzapine, quetiapine, risperidone, sulpiride. The recommendation's explicit exclusion: avoid olanzapine.

THE CROSS-ORGAN PIVOT: THE HEPATIC EXCEPTION LIST AND THE RENAL CAUTION LIST ARE THE SAME DRUGS

Sulpiride, amisulpride and lithium are three of the four agents named as undergoing no or minimal hepatic metabolism, which is what makes them attractive in liver disease.
The same three are named as extensively renally cleared, and lithium as nephrotoxic, which is what makes them hazardous in kidney disease.

PANEL B - WHERE THE INSTRUCTION BECOMES A NUMBER

units printed exactly as each source gives them

RENAL: DOSING ACROSS THE GLOMERULAR FILTRATION RATE BANDS, mL/min

Amisulpride is banded by the antipsychotic table and the other three by the mood stabiliser table. The two tables band renal function differently, so each block is headed with its own table's bands.

AGENT	GFR 30 to 60	GFR 10 to 30	GFR under 10
Amisulpride	50 per cent of dose	33 per cent of dose	no recommendation; avoid

AGENT	GFR 10 to 50	GFR under 10
Lithium	AVOID, or 50 to 75 per cent of dose and monitor levels	AVOID IF POSSIBLE; if exceptionally used, 25 to 50 per cent of dose, levels essential
Valproate	no routine adjustment in renal impairment	free (unbound) levels may guide
Lamotrigine	start low and titrate slowly	one source suggests 100 mg every other day

HEPATIC: THE AGENT-LEVEL CEILINGS IN LIVER IMPAIRMENT

Escitalopram, mild to moderate: 5 mg daily for the first 2 weeks, maximum 10 mg daily.
Citalopram (Maudsley): maximum 20 mg/day in hepatic impairment.
IPS: citalopram is not available in India; escitalopram poses no clinically significant QTc risk.
MHRA: escitalopram still causes dose-dependent QT prolongation, so this is not QT safety.
Fluoxetine in compensated cirrhosis: reduce by at least 50 per cent or dose alternate-day.
Venlafaxine and desvenlafaxine: 50 per cent reduction in mild and moderate impairment.
Olanzapine: start 5 mg/day in moderate or severe hepatic impairment; CONSIDER plasma levels, aiming for 20 to 40 mcg/L.
Lurasidone (manufacturer): no adjustment in mild hepatic impairment; start 18.5 mg; maximum 74 mg/day in moderate and 37 mg/day in severe impairment.

ANTIPSYCHOTIC-INDUCED CARDIOMYOPATHY: THE DIRECTION IS THE TABLE'S

45 per cent is a SUGGESTED cut-off, extrapolated from cardiotoxic chemotherapy guidelines.

EF ABOVE 45% →	CONTINUE the effective antipsychotic; 3-monthly symptoms and NT-proBNP
EF BELOW 45% →	SWITCH the antipsychotic.

THE CLOZAPINE DECISIONS IN EPILEPSY

Above a plasma level of 600 mcg/L it is prudent to add antiseizure prophylaxis against seizures and myoclonus, a figure resting on repeated recommendation rather than on a clear evidence base.
After a clozapine-induced seizure: withhold for one day, restart at half the previous dose, and give an antiseizure medication.

PANEL C - THE DISEASED BRAIN: THE SAME THREE QUESTIONS, ASKED OF TWO NEUROLOGICAL ILLNESSES

in both, the first move is subtractive

EPILEPSY — a brain already seizure-prone, and the untreated illness raises the risk too	Depression 13 to 37 per cent, anxiety 20 per cent, psychosis 5 per cent, suicide threefold, and the relationship is bidirectional. Unprovoked seizures about 50 per 100,000 a year, and about 15-fold higher in the PLACEBO arms of psychotropic trials: the untreated illness is itself the seizure risk factor. IPS: ictal and post-ictal psychosis self-remit with supportive treatment and need no prophylactic antipsychotic; inter-ictal and para-ictal often do.	Antidepressants: SSRIs, mirtazapine, duloxetine. Lowest interaction risk with antiseizure drugs: citalopram or escitalopram, then sertraline, with escitalopram first, fewer seizures in overdose. Antipsychotics: amisulpride and sulpiride, aripiprazole, ziprasidone, high-potency first-generation agents, risperidone. With clozapine, lamotrigine is the antiseizure medication of choice. ECT is anticonvulsive and does not worsen epilepsy.	Proconvulsive at therapeutic doses and avoided outright: amoxapine, bupropion, maprotiline, tricyclics. Bupropion's seizure risk is dose related, greatest with the immediate-release form and less on slow release under 300 mg/day. Avoid low-potency first-generation agents, loxapine, depots and zotepine; olanzapine and quetiapine are moderate risk, clozapine higher. Chlorpromazine above 1 g/day: seizures in 9 per cent. Clozapine must not be combined with carbamazepine.
PARKINSON DISEASE — the offending drug is often already on the chart	Psychosis is often characterised by visual hallucinations; on limited data anticholinergics and dopamine agonists carry a higher risk of inducing it than levodopa or COMT inhibitors. Four moves precede the antipsychotic at step 5: exclude organic causes, delirium above all; optimise the environment; do not treat if insight is kept and hallucinations are infrequent and not troubling; and reduce or stop anticholinergics and dopamine agonists.	Only two drugs are recommended for the psychosis: clozapine and pimavanserin, a 5HT2A inverse agonist with no dopamine receptor activity. Low-dose quetiapine is best tolerated and reasonable to try before clozapine. Clozapine: start 6.25 mg, usual 25 to 35 mg/day (Maudsley Table 10.14), monitored as in schizophrenia. Depression: dopamine agonists and SSRIs rank highest for efficacy and acceptability.	Risperidone and typical antipsychotics: avoid COMPLETELY. Pramipexole augmentation MAY be considered, but dopamine agonists raise the risk of impulse control disorders and have rarely been linked to psychosis. ECT: depression and motor symptoms respond well, but delirium risk is high with pre-existing cognitive impairment. Cholinesterase inhibitors: evidence of gains in global functioning, cognition (modest), behaviour and daily activities; motor function may worsen, tremor above all.

DECLARED GAPS: WHAT THE SOURCES BEHIND THIS PLATE DO NOT STATE, SHOWN RATHER THAN FILLED

At EXACTLY 45 per cent ejection fraction the source gives an action above the cut-off and one below it and states no rule at the boundary.
No source here expresses dose adjustment for hepatic impairment as a formal severity score; no Indian availability or price for the QT-safer agents or for pimavanserin; no antidepressant renal band; no millisecond QTc threshold; no NT-proBNP concentration; and no frequency for the lurasidone start, so it prints as 18.5 mg.

Target ranges, monitoring schedules and the interaction matrix are drawn elsewhere.

teal: the organ's question and the permitted agent · coral: the hazard, the avoid list, the contraindication · coral tint: a decision, not a choice of drug

Fig 37.7 Prescribing in cardiac, hepatic and renal disease, and in epilepsy and Parkinson disease. The liver principally influences how much of a dose is destroyed, the kidney how much leaves and the heart what the surviving concentration does, though each organ works both axes and heart failure may also alter clearance and distribution. Sulpiride, amisulpride and lithium sit on the hepatic exception list and the renal caution list at once. In suspected antipsychotic-induced cardiomyopathy the source table continues above an ejection fraction of 45 per cent and switches below it, the cut-off only suggested and no rule stated at the boundary. In both neurological illnesses the first move is subtractive. (Maudsley Prescribing Guidelines in Psychiatry, 15th edition; Maudsley Prescribing Guidelines for Mental Health Conditions in Physical Illness, 1st edition; Indian Psychiatric Society clinical practice guidelines 2025.)

RULE **The liver test reports injury; it does not report clearance.** Nothing in the standard panel measures how much cytochrome capacity remains, which is why the hepatic dose adjustments below are keyed to a clinical description rather than to a laboratory value: many agent-level adjustments are expressed as mild, moderate or severe impairment, and others as compensated cirrhosis, active disease, ascites, or hepatic impairment generally. These guidelines do not express psychotropic dose adjustment in terms of a formal hepatic severity score at all, so an answer that offers dose bands by severity class is offering something they do not contain.

That matters because **most psychotropics are extensively hepatically metabolised**, so lower doses may be required across nearly the whole formulary. The Maudsley guidelines name the exceptions that undergo no or minimal hepatic metabolism: sulpiride, amisulpride, lithium and gabapentin. Commit that short list, because it is the pivot of the commonest cross-organ trap in this topic.

The renal question is answered differently. The Maudsley guidelines report that the Medicines and Healthcare products Regulatory Agency, a United Kingdom regulator and not an Indian one, advises that **creatinine clearance** be used as an estimate of renal function for direct-acting oral anticoagulants and for narrow-therapeutic-index drugs that are mainly renally excreted, lithium among them. The reasoning is portable even so: the estimate a laboratory prints by default is not necessarily the estimate a narrow-index drug should be dosed against. The underlying kinetics of half-life, clearance and therapeutic index belong to the Psychopharmacology I: principles and core drug classes notes.

14.2 Hepatic impairment: what to avoid, and the watch that follows

Three avoidance rules run across classes in hepatic impairment, and each carries its own reason. Very sedative drugs and very constipating drugs are avoided because of the risk of precipitating **hepatic encephalopathy**, and drugs known to be hepatotoxic in their own right are avoided because the liver is already the injured organ. The Maudsley guidelines give monoamine oxidase inhibitors and chlorpromazine as their examples of the third.

MNEMONIC

Sedating, Constipating, Hepatotoxic

The three properties that disqualify a psychotropic in liver disease, and the first two disqualify it for the same reason: both push an encephalopathy-prone patient towards encephalopathy, one by depressing consciousness directly and one by loading the gut with nitrogen.

The positive instruction is to choose a low-risk drug and monitor liver function tests weekly, at least initially, and it does not direct a switch if they deteriorate: after a new drug is introduced the guideline says only to *consider* switching to another drug. Read that modal exactly. It is permissive, not mandatory, and the reason is the one above: a rising transaminase is a signal about injury, not a verdict on the drug, and the alternative agent may be worse for this patient.

Some sense of how often that signal appears is essential, because an abnormal result is close to routine rather than rare.

One-third	4%	0.5 to 3%
ANY ABNORMAL LFT ON AN ANTIPSYCHOTIC	AT OVER THREE TIMES THE UPPER LIMIT	TRANSAMINASE RISE ON AN ANTIDEPRESSANT

The antipsychotic abnormalities usually appear within 1 to 6 weeks of initiation, and transaminases are most often the affected fraction. The antidepressant elevations are asymptomatic and mild, appear anywhere between several days and 6 months of initiation, and older patients are more vulnerable. Both timings matter, but they change the probability of drug-induced injury rather than settling it: a derangement found at a routine annual test in a patient stable on treatment for years is less likely to be the psychotropic's doing, and one found six weeks in is more likely to be, yet neither latency proves nor excludes the drug. Delayed and chronic presentations occur, so assess the baseline result, the competing causes, the biochemical pattern and the course after withdrawal before attributing the abnormality to the prescription.

14.3 Antidepressants and mood stabilisers in liver disease

Below the class principles sit agent-level instructions, and these are what a stem tests.

AGENT	WHAT HEPATIC IMPAIRMENT DOES TO THE PRESCRIPTION
Escitalopram	Initiate at 5 mg daily for the first 2 weeks in mild to moderate hepatic impairment, maximum **10 mg daily**.
Fluoxetine	Accumulates in compensated cirrhosis; a dose reduction of at least 50 per cent, or alternate-day dosing, is recommended in hepatic impairment, and time to steady state is delayed.
Venlafaxine and desvenlafaxine	Require a 50 per cent dose reduction in mild and moderate hepatic impairment.
Duloxetine	Contraindicated in hepatic impairment; clearance is markedly reduced even in mild impairment and fatal hepatic failure has been reported.
Agomelatine	Contraindicated in hepatic impairment; liver function tests at baseline and at 3, 6, 12 and 24 weeks during initiation and at each dose increase, stopping if transaminases rise more than three times the upper limit of normal.
Valproate	Contraindicated in severe or active hepatic impairment, or where there is a family history of severe impairment, with the greatest risk of liver toxicity falling in the first 3 months of treatment.

The valproate row is the one with the most Indian consequence, because sodium valproate and divalproex are the mood stabilisers most reachable on cost, and alcohol-related liver disease is exactly the population in which a mood stabiliser is often wanted.

TRAP **Two guideline bodies say different things about citalopram, and neither is wrong.** The Maudsley Prescribing Guidelines direct that citalopram's daily dose in hepatic impairment be restricted to a maximum of **20 mg/day**. That entry gives the figure as a restriction on the daily dose and stops; no starting dose accompanies it, so a candidate who recites the ceiling has recited the whole of what the guideline states here. The Indian Psychiatric Society depression guideline states that citalopram can prolong the QTc interval and is not available in India, whereas escitalopram does not pose a clinically significant risk of QTc prolongation. Print that second clause as the guideline's wording, not as a clean bill of health, and correct it as you print it: the United Kingdom medicines regulator's safety advice on the two drugs is that escitalopram also causes dose-dependent QT-interval prolongation. Its effect is generally smaller than citalopram's, but it is not clinically absent, and the usual contraindications and precautions still apply, particularly with cardiac disease, electrolyte disturbance, high exposure or another QT-prolonging drug. A candidate who learns only the British ceiling quotes a limit for an agent the Indian guideline says is not marketed here; one who learns only the Indian statement is caught by a question written from a British text. Attribute each position to the body that issues it and print both.

GOOD TO REMEMBER

Lithium is not hepatically metabolised, so no dose reduction is required in hepatic impairment as long as renal function is normal. The dose does not move, but the sampling discipline does: monitor levels more frequently if ascites status changes, because the **volume of distribution** changes with it. A patient tapped for ascites has not had their dose altered, but they have had their pharmacokinetics altered.

14.4 Antipsychotics in liver disease

Two agents carry usable numbers. The Maudsley guidelines note that although olanzapine is extensively hepatically metabolised, its pharmacokinetics seem to change little in severe hepatic impairment; they nonetheless advise starting at 5 mg/day in moderate or severe hepatic impairment and considering plasma levels to guide dosage, aiming for 20 to 40 mcg/L. For lurasidone, the manufacturer recommends no dose adjustment in mild hepatic impairment, a starting dose of 18.5 mg in moderate or severe hepatic impairment, and a maximum of 74 mg/day in moderate and 37 mg/day in severe hepatic impairment. Set the two rows against each other, because their shapes differ and the difference is the source's rather than an omission here. The olanzapine row fixes where to begin and then hands the rest to a concentration, and it names no milligram maximum at all, which is why the target range and not a dose is the thing to quote from it. The lurasidone row does name maxima, and separate ones for each grade of impairment.

IN INDIA

The Indian Psychiatric Society schizophrenia guideline grades antipsychotic hepatotoxicity in tiers rather than drug by drug, which makes it faster to use at the bedside. Olanzapine and clozapine pose a greater risk and risperidone and quetiapine a moderate risk, while aripiprazole, paliperidone and ziprasidone have relatively safer profiles and need no dosage adjustment in mild to moderate hepatic impairment. That last group is the practical starting point when a patient with liver disease needs an antipsychotic and the prescriber wants one decision rather than a table.

Note the difference in method between the two documents. The British source rates the individual drug and attaches a number to it; the Indian source rates the group and names a safer set. Neither contradicts the other, and an answer that supplies the agent-level ceiling and the group-level preference has covered the question from both directions.

14.5 Renal impairment: which estimate, and in whom

The renal patient is frequently the unrecognised renal patient. The Maudsley guidelines instruct that older adults over 65 be assumed to have at least mild renal impairment even when serum creatinine is normal, because a smaller muscle mass produces less creatinine and therefore a falsely reassuring value. The impairment is present; the marker has simply failed to report it.

> **PITFALL**
>
> Reading a normal serum creatinine in a frail older adult as normal renal function, and leaving a renally cleared psychotropic at the dose that suited the patient a decade ago. The prescription has not changed and the number on the report has not changed, so nothing prompts review, and the concentration climbs anyway. The same failure occurs in reverse when renal function falls acutely and the drug chart is not revisited.

Three general principles then organise the choice of agent:

- Avoid drugs that are **nephrotoxic**, lithium and non-steroidal anti-inflammatory drugs among them, where renal reserve is limited.
- Be cautious with drugs that are extensively renally cleared, such as sulpiride, amisulpride and lithium.
- Try to avoid long-acting drugs such as depot preparations, which cannot be withdrawn once administered.

A fourth principle is to try to avoid drugs known to prolong the QTc interval, and it is narrowed usefully for the sickest patients: in established renal failure, where electrolyte changes are common, it is probably best to avoid the antipsychotics with the greatest risk of QTc prolongation, not every drug that prolongs it at all. Read that as written: a prohibition on every agent with any QTc effect would exclude almost the entire class.

TRAP **The hepatic exception list and the renal caution list are the same drugs.** Sulpiride and amisulpride are named as escaping hepatic metabolism, which makes them attractive in liver disease, and they are named again as extensively renally cleared, which makes them hazardous in kidney disease. Lithium sits on both lists for the same reason. A candidate who memorises one list and reaches for it in the other organ has been set up by the pharmacology itself: a drug avoids one route of elimination precisely by depending on the other.

14.6 Dosing by glomerular filtration rate

Where the renal instruction becomes quantitative, it is banded rather than continuous.

AGENT	RENAL HANDLING	DOSING ACROSS THE BANDS
Amisulpride	Extensively renally cleared	In renal impairment, 50 per cent of the dose at a GFR of 30 to 60 mL/min and 33 per cent at 10 to 30 mL/min; no recommendation exists below 10 mL/min, so it is best avoided in established renal failure.
Lithium	Nephrotoxic; 95 per cent excreted unchanged in urine, and contraindicated by the manufacturer in severe renal impairment	At a GFR of 10 to 50 mL/min, avoid, or reduce to 50 to 75 per cent of the normal dose and monitor serum levels; below 10 mL/min, avoid if possible, and only if it is used exceptionally reduce to 25 to 50 per cent, with level monitoring essential.
Valproate	Approximately 2 per cent excreted unchanged	Dose adjustment is usually not required in renal impairment; only in severe impairment, with a GFR under 10 mL/min, may it be necessary to dose against **free (unbound) valproate levels**.
Lamotrigine	Under 10 per cent renal excretion of unchanged drug	At a GFR of 10 to 50 mL/min start low and titrate slowly in renal impairment; one source suggests 100 mg every other day where the GFR is under 10 mL/min. No lamotrigine starting dose is named at either level of function, and no maximum at the lower one.

Lithium also generates the renal problem it is dosed around. Long-term treatment may result in impaired renal function in about a quarter of patients, the phenomenon usually called **creatinine creep**, and levels above **0.8 mmol/L** are associated with a higher risk of lithium-related renal toxicity. That threshold is a prescribing constraint rather than a laboratory curiosity, because it sits inside the range some phases of illness are treated in; the published target concentrations themselves are set out elsewhere in these notes.

IN INDIA

The Indian Psychiatric Society schizophrenia guideline takes a more permissive line on the older agents than the British drug-by-drug tables do, and this matters where first-generation antipsychotics carry the public-sector caseload. Most first-generation antipsychotics are considered safe in chronic kidney disease without dose adjustment, the exception being the phenothiazines, which may increase hypotension risk. Among the second-generation agents, amisulpride and paliperidone are excreted unchanged in urine, need dose consideration, and are better avoided in end-stage renal disease. Keep the guideline's own hedges in the answer: *most* first-generation agents, and *considered* safe.

14.7 Cardiac disease: the antidepressant decision

The cardiac question is predominantly pharmacodynamic, where hepatic and renal dose adjustment is predominantly pharmacokinetic, though each of the three organs involves both axes, and the class answer is settled for one setting. In heart failure, selective serotonin reuptake inhibitors are the first-line antidepressant class and the recommended agent is sertraline: it has few drug interactions, less propensity than citalopram to prolong the QTc, and demonstrated safety, though unproven efficacy, in SADHART-CHF. Safety without proven efficacy is the honest reading and should be said aloud in an answer rather than upgraded. The recommendation behind this sentence is written for heart failure and reaches no further, so whether the same class ranking holds across cardiac disease at large is a question these notes leave open rather than answer.

Tricyclic antidepressants are generally avoided in patients with cardiac disease for three separate reasons, and separating them is what distinguishes a good answer from a list:

- their effects on cardiac contractility;
- their proarrhythmic effects, arising from blockade of cardiac sodium and potassium channels;
- their potential to worsen ischaemic heart disease.

This is the single most consequential exclusion in an Indian outpatient department, where the tricyclics remain heavily used on grounds of cost. The pharmacology that produces those three effects, and the class's membrane-stabilising action, belongs to the Psychopharmacology I: principles and core drug classes notes; what belongs here is that the cardiac history, not the depressive presentation, is what removes the class from consideration.

The converse error is equally examinable. After myocardial infarction, selective serotonin reuptake inhibitors and mirtazapine have either a neutral or a beneficial effect on mortality, and the instruction that follows from it is written for the first of those two: treatment of depression with a selective serotonin reuptake inhibitor should not be withheld post infarction. The mortality finding covers both agents; the directive not to withhold does not, so do not extend it to mirtazapine in an answer. Depression after an infarct is not a reason to defer antidepressant treatment until the heart has settled.

14.8 Cardiac disease: the antipsychotic decision

Antipsychotic choice in cardiac disease turns on two distinct liabilities: the effect on the QT interval, and the effect on the myocardium itself. On the first, cariprazine, lurasidone, brexpiprazole and lumateperone are considered safer choices in patients at risk of cardiac events, as they appear to exert minimal effects on the QT interval, and the recommendation carries an explicit exclusion: avoid olanzapine. Against them sit haloperidol, olanzapine, quetiapine, risperidone and sulpiride, which have higher affinity than other antipsychotics for cardiac potassium channels and are associated with a higher risk of ventricular arrhythmia and **sudden cardiac death**. Three of the preferred agents recur in a second setting: in paroxysmal or persistent atrial fibrillation, cariprazine, brexpiprazole or lurasidone may be appropriate choices,

and all antipsychotics appear to increase the risk of bleeding when combined with direct-acting oral anticoagulants in atrial fibrillation.

The second liability is **antipsychotic-induced cardiomyopathy**, and here the decision is not which drug but when to stop it. A left ventricular ejection fraction of **45 per cent** has been suggested as the cut-off, and the source's own table fixes the direction: while the ejection fraction stays above that figure the effective antipsychotic is continued, with 3-monthly monitoring of heart failure symptoms and NT-proBNP, and once it falls below that figure the antipsychotic is switched. Read the direction off the table rather than off the surrounding prose, because a falling ejection fraction is the signal to come off the drug and never the licence to stay on it. The word suggested is load-bearing, since the figure is extrapolated from guidelines for monitoring cardiotoxic chemotherapies and the exact level depends on the clinical scenario, so an answer that presents it as an established cut-off overstates it. The table states an action above the cut-off and an action below it and gives no rule at the cut-off itself, so the boundary case is left open here rather than answered.

> The liver principally influences how much drug is destroyed, the kidney how much leaves, and the heart what the surviving concentration does, with heart failure able to alter clearance and distribution as well; the agent that escapes one of the first two organs almost always depends on the other.

15 · Psychotropic prescribing in epilepsy, Parkinson disease and other neurological illness

The second variable here is a brain that is already diseased. Prescribing in epilepsy and in Parkinson disease inverts the ordinary logic of psychotropic choice. The agent that best fits the psychiatric syndrome may destabilise the neurological one; the drugs already on the chart for the neurological illness may be producing the psychiatric syndrome; and the option that looks safest, withholding psychiatric treatment altogether, carries a risk of its own. The marks sit on which agent, in what order, and on what is done before anything is written at all.

15.1 Epilepsy and psychiatric illness travel in both directions

People with epilepsy carry an elevated prevalence of several psychiatric disorders, and the Maudsley Prescribing Guidelines are explicit that the relationship with mental illness is **bidirectional** rather than a simple consequence of living with seizures.

13 to 37%	20%	5%	3x
DEPRESSION	ANXIETY	PSYCHOSIS	SUICIDE

Bidirectionality is what the examiner is testing, because it changes the direction of the clinical question. If the psychiatric disorder were only a reaction to the burden of a chronic illness, treating it would be a humane addition to seizure control. If the two illnesses share substrate and each raises the risk of the other, treating the psychiatric disorder becomes part of managing the epilepsy.

A second observation sharpens it. The incidence of unprovoked seizures in the general population is about 50 per 100,000 persons a year, while the incidence in the placebo arms of randomised controlled trials of antidepressants and antipsychotics is approximately 15-fold higher than that yearly figure. Nobody in a placebo arm has received an active drug, so the excess cannot be pharmacological: depression and psychosis are themselves seizure risk factors.

TRAP **Concluding that the safe course in epilepsy is to withhold the antidepressant.** Candidates reason correctly that several psychotropics lower the seizure threshold, then draw the wrong conclusion from it. The placebo-arm figure settles the argument the other way: untreated depression and psychosis carry a seizure incidence far above the population background, so leaving the psychiatric illness untreated is not the neutral option it appears to be. The decision is which agent, not whether.

15.2 Treating depression in epilepsy

The Maudsley Prescribing Guidelines sort antidepressants for people with epilepsy into low-risk good choices and a higher-risk group that should be avoided because its members are **proconvulsive** at therapeutic doses. The good choices are SSRIs, mirtazapine and duloxetine; the group to avoid is amoxapine, bupropion, maprotiline and TCAs. Read the qualifier on the second group, because it carries the whole instruction: these agents provoke seizures at ordinary treatment doses, not only in overdose, which is why they are avoided outright rather than merely capped.

MNEMONIC

In: SSRIs, Mirtazapine, Duloxetine. Out: Amoxapine, Bupropion, Maprotiline, Tricyclics

Three in, four out, and the four out share a single reason. Nothing else needs to be memorised about the antidepressant list for epilepsy; everything else is a decision about which of the three to use.

Within the SSRIs the discriminator is interaction, not seizure risk. Those with the lowest risk of interactions with antiseizure medications are generally preferred, which gives citalopram or escitalopram, followed by sertraline, and escitalopram is preferred over citalopram in people with epilepsy because of the lower risk of seizures in overdose. Overdose risk is a legitimate selection criterion in a population whose suicide rate is a multiple of the general population's. The kinetic principle that generates the interaction ranking belongs to the Psychopharmacology I: principles and core drug classes notes.

IN INDIA

Citalopram is not marketed here, so the preference order collapses without loss to escitalopram, then sertraline. For antipsychotics, the Indian Psychiatric Society schizophrenia guideline directs that where one is needed an agent of lower seizure propensity is chosen, and it groups quetiapine and olanzapine with clozapine, chlorpromazine, loxapine and zotepine as agents to avoid or use with caution. That is one tier stricter than the Maudsley position, which calls quetiapine and olanzapine moderate risk. Followed together, the two documents leave a practical Indian starting set of amisulpride or sulpiride, aripiprazole, ziprasidone, risperidone and the high-potency first-generation agents.

Bupropion is the instructive member of the avoid group, because its risk belongs as much to the preparation as to the molecule: the seizure risk is dose related and greatest with immediate-release formulations, and it is less with slow-release formulations at doses **under 300 mg/day**, which is where the seizure evidence puts the lower risk of the two preparations. That does not lift it out of the higher-risk group for a person who already has epilepsy. It explains why one drug can be rated differently in different populations, and it is the reason a formulation must be specified whenever this agent is discussed.

Where the depression is severe and the epilepsy unstable, the modality question arrives early rather than late. Electroconvulsive therapy has anticonvulsive properties, is worth considering for depression in patients with unstable epilepsy, and does not appear to cause or worsen epilepsy. That is the opposite of the intuition most candidates carry into a viva, and it is worth a sentence in any answer on this ground. The procedural technique is set out in the ECT and neurostimulation notes.

15.3 Antipsychotics in epilepsy: the tiers

The same source ranks antipsychotics on seizure propensity in four tiers. The low-risk good choices are amisulpride and sulpiride, aripiprazole, ziprasidone, high-potency first-generation antipsychotics and risperidone; olanzapine and quetiapine are moderate risk with care required; clozapine is higher risk; and the low-potency first-generation agents, loxapine, depots and zotepine should be avoided. The depots earn their place in the avoid group for a kinetic reason that generalises beyond this table: an agent that cannot be withdrawn quickly is a poor choice when the adverse effect you fear is a seizure.

One figure anchors the avoid tier. In people with epilepsy the low-potency first-generation agents are best avoided, and the incidence of seizures with chlorpromazine is **9 per cent at doses above 1 g/day**, an incidence the evidence attaches to that dose band rather than a target to prescribe into. This is not a historical curiosity in Indian practice, where high-dose chlorpromazine is still encountered on general wards, so the number is worth carrying.

15.4 Clozapine in epilepsy: three decisions

Clozapine is the most proconvulsive antipsychotic, and the same source records that it has still been used successfully in people with epilepsy who are stable on antiseizure medication. The risk is therefore managed rather than avoided, and three decisions follow, examined together.

The first is co-prescription. Clozapine should not be used with carbamazepine, because of the risk of blood dyscrasias and reduced clozapine levels, and lamotrigine is the antiseizure medication of choice alongside it. Two independent mechanisms converge on one instruction there, one haematological and one pharmacokinetic, which is why the prohibition is firmer than an ordinary interaction warning.

The second is prophylaxis. The Maudsley advises that it is prudent to use an antiseizure agent as prophylaxis against seizures and **myoclonus** when clozapine plasma levels are above **600 mcg/L**, and states in the same breath that this figure is not a clear evidence-based threshold but a level resting on repeated recommendation. Print the caveat with the figure. A reader who knows the source knows the number is a convention, and an answer that treats it as a hard biological boundary reads as second-hand.

The third is what happens after a seizure. Clozapine is withheld for one day, restarted at half the previous dose, and an antiseizure medication is given. Notice that the drug is not abandoned: the response is a brief interruption, a halved reintroduction and added cover, which is a dosing decision rather than a discontinuation. The immediate care of the patient who is fitting belongs to the Perinatal/women's mental health and emergency psychiatry notes.

> **PITFALL**
>
> Reaching for carbamazepine as the antiseizure cover. It is the reflex choice on a general ward and it is the single agent named against this combination, on two counts at once: a shared risk of blood dyscrasias, and a fall in the clozapine level that can be misread later as non-adherence. Lamotrigine is the named alternative, and the substitution should be made before the seizure, not after it.

15.5 The psychoses of epilepsy: which ones need an antipsychotic

Not every psychosis in a person with epilepsy is a psychotic illness, and the Indian Psychiatric Society schizophrenia guideline makes that discrimination the first step. Ictal and **post-ictal psychosis** are to be ruled out: they are self-remitting with supportive treatment, and preventing seizures would suffice without the need for prophylactic antipsychotic treatment. **Inter-ictal psychosis** and para-ictal psychosis would have a course similar to schizophrenia and often need antipsychotic treatment.

Read the qualifier on the first limb, because it is load-bearing: self-remitting with supportive treatment is not the same as self-remitting if left alone. The two standard sources do not say this identically. Where the Indian guideline holds that seizure control suffices without prophylactic antipsychotic treatment, the Maudsley adds a short-term symptomatic option, a benzodiazepine or an antipsychotic, tapered off carefully once symptoms resolve. They are not reconciled by picking one. The Indian wording is the citable position for an Indian answer; the Maudsley line is the comparator a strong answer names beside it.

TRAP **Treating every psychosis in epilepsy as schizophrenia and starting maintenance antipsychotic treatment.** The stem usually supplies the discriminator and candidates read past it: a psychosis tied to the seizures, which settles as the seizures are controlled, is ictal or post-ictal, and the guideline position is that preventing seizures suffices without prophylactic antipsychotic treatment. The error is not which drug was chosen. It is treating the episode as one that needs maintenance: short-term symptomatic treatment with a benzodiazepine or an antipsychotic may still be required and is tapered off carefully once symptoms resolve, and what the guideline position excludes is the prophylactic course that is started and then continued.

15.6 Psychosis in Parkinson disease: what precedes the prescription

In Parkinson disease the offending drug is usually already on the chart. Psychosis in Parkinson disease is often characterised by **visual hallucinations**, and the drug ranking that follows rests on limited data and is not a superlative about any single agent: anticholinergics and dopamine agonists seem to be associated with a higher risk of inducing psychosis than levodopa or catechol-O-methyltransferase inhibitors. It ranks one pair of drug groups against another, which makes the chart the first thing to read.

The Maudsley recommendations for the treatment of psychosis in Parkinson disease therefore place four moves ahead of any antipsychotic.

- Exclude organic causes, delirium in particular.
- Optimise the environment, to maximise orientation and minimise problems arising from poor caregiver-patient interactions.
- If the patient has insight and hallucinations are infrequent and not troubling, do not treat.
- Consider reducing or stopping anticholinergics and dopamine agonists.

Only after those does the ladder reach the step that considers an atypical antipsychotic. Three of the four are subtractive or observational, and the third is the one candidates omit: a treatment decision can be a decision not to treat, and the source states that as an instruction rather than as a permission.

RULE **In both illnesses the first move is subtractive.** In epilepsy the question is which psychotropic is provoking, or would provoke, the seizure. In Parkinson disease it is which dopaminergic or anticholinergic drug is producing the psychosis. Adding a psychotropic to a neurological illness is the second decision and never the first, and an answer that opens with the antipsychotic has skipped the half that carries the marks.

15.7 Which antipsychotic, when one is needed

Low-dose quetiapine is the best tolerated antipsychotic in Parkinson disease psychosis and it is probably reasonable to try it before clozapine, while risperidone and typical antipsychotics should be avoided completely. The word to notice is completely: this is not a caution about dose or duration but an exclusion of two whole groups, and the reason is mechanistic, since dopamine receptor blockade is the therapeutic action in schizophrenia and the pathogenic one here.

Clozapine for psychosis in Parkinson disease is started at 6.25 mg with a usual dose of **25 to 35 mg/day** in the Maudsley table of recommendations for treating psychosis in Parkinson disease. Name that table whenever the figures are printed, because the same book's guide to medication doses in older adults gives a different usual range for the same indication and adds a stated daily maximum the psychosis table does not carry. The two cells are not reconcilable, and quoting one without naming its table quotes the book against itself. Say the consequence plainly when you use the psychosis table: it gives a start and a usual range for this indication and states no ceiling above them, so the top of that range is where the usual dose ends and not where the drug is capped.

GOOD TO REMEMBER

Clozapine in Parkinson disease psychosis is monitored exactly as clozapine in schizophrenia is monitored, and older people are more prone to develop serious blood dyscrasia. A dose in the tens of milligrams does not buy a lighter haematological schedule. That, rather than the price or the supply of the drug, is what limits its use here, and it is the question to settle before the first prescription rather than after it.

Two drugs, and only two, are recommended for Parkinson disease psychosis: clozapine and pimavanserin, a 5HT2A receptor inverse agonist with no dopamine receptor activity. A network meta-analysis found only these two efficacious while having minimal effect on motor function. The mechanism explains the pairing, since an agent that suppresses psychosis without occupying the dopamine receptor has a low propensity for direct dopamine-blockade-related motor worsening. Read the meta-analysis at its stated strength: minimal effect on motor function, which is not the same as none. Quetiapine remains the reasonable first attempt on tolerability grounds while not belonging to that recommended pair, and holding both statements at once is what a good answer demonstrates. Whether pimavanserin can be obtained in India is not established by any source used here, so clozapine is the half of the pair to teach as realisable.

PSYCHOTIC SYNDROME	RELATION TO THE PRIMARY ILLNESS	FIRST MOVE	ANTIPSYCHOTIC TREATMENT
Ictal and post-ictal psychosis	Tied to the seizures; self-remitting with supportive treatment	Prevent the seizures	No prophylactic antipsychotic; the Maudsley allows a short-term symptomatic option
Inter-ictal and para-ictal psychosis	Course similar to schizophrenia	Select for lowest seizure propensity	Often needed
Psychosis in Parkinson disease	Often visual hallucinations; anticholinergics and dopamine agonists implicated	Exclude delirium, optimise environment, reduce or stop the implicated drugs	Only after those steps, and then quetiapine before clozapine

15.8 Depression and cognition in Parkinson disease

Depression in Parkinson disease has a ladder of its own, and its top step is counter-intuitive. A 2022 network meta-analysis reported in the Maudsley guidelines showed that dopamine agonists

and SSRIs have the highest efficacy and acceptability, so the class that treats the movement disorder and the class that treats depression share the top of the ranking rather than competing for it.

Augmentation with dopamine agonists such as pramipexole may be considered, but these drugs increase the risk of **impulse control disorders** and have rarely been associated with the development of psychosis. That is the same drug group implicated in inducing psychosis a moment ago, so the antidepressant strategy and the antipsychotic strategy pull against each other in one patient, and which way the prescription moves depends on which syndrome is currently dominant. The permissive modal is worth preserving in an answer: this is an option that may be considered, not a recommended step.

Electroconvulsive therapy sits further down the same ladder, and its risk signature here is not the one it had in epilepsy. Depression and motor symptoms generally respond well, but the risk of inducing delirium is high, particularly in patients with pre-existing cognitive impairment. One modality, two neurological illnesses, two opposite cautions: in unstable epilepsy its anticonvulsive property is the argument for it, and in Parkinson disease with cognitive impairment the delirium risk is the argument for care.

Cholinesterase inhibitors close the picture and are stated at a strength candidates routinely overstate. A Cochrane review and some large randomised trials concluded that there is evidence that they lead to improvements in global functioning, cognition, behavioural disturbance and activities of daily living in Parkinson disease, with the improvements in cognitive functioning described as modest, while motor function may deteriorate with a particular increase in tremor. Read it at its stated strength: a claim that evidence exists, hedged twice, with a trade of cognition against tremor that has to be discussed with the patient rather than resolved on their behalf.

> In epilepsy, treat the psychiatric illness anyway and choose the agent that does not provoke the seizure; in Parkinson disease, subtract the dopaminergic drug before adding an antipsychotic, and if one is still needed, quetiapine before clozapine.

16 · Psychopharmacology in pregnancy, lactation, the elderly and children

The drug does not change; the body around it does. Pregnancy, lactation, old age and childhood each alter clearance, distribution and vulnerability, and each adds a second person, or a failing organ, to a decision otherwise about one patient. The marks are not for reciting which agent is safe but for the decision under the changed pharmacology: which harm is traded against which, when the trade has to be made, what is measured afterwards, and which figures the standard sources dispute.

16.1 The decision is made before conception, not at the positive test

Organogenesis does not wait for a pregnancy test. The Maudsley Prescribing Guidelines place the period of maximum risk to the fetus from lithium at 2 to 6 weeks after conception, before many women know they are pregnant, and add that the risk of atrial and ventricular septal defects may

also be increased. The Indian Psychiatric Society bipolar guideline draws the operational conclusion: most pregnancies are unplanned or unrecognised in the early weeks, so contraceptive counselling is offered to all reproductive-age women with bipolar disorder on treatment. A conversation that begins when the test turns positive has missed the window it was meant to influence.

Folate sharpens the same point. The Maudsley states there is no evidence folate protects against anticonvulsant-induced **neural tube defects** if given during pregnancy, but that it may do so if given prior to conception, the neural tube being essentially formed by 8 weeks of pregnancy; folate may nonetheless benefit early neurodevelopment and so should always be offered. The Indian bipolar guideline hedges the protective claim harder while keeping the same timing. The timing rule is firm; the protective effect is not.

RULE **Relapse is an exposure too.** The Indian schizophrenia guideline states that an effective antipsychotic on which the patient has been stable should not be discontinued or changed, because relapse poses a greater risk to the mother and baby than the potential adverse effects. Every decision here compares two harms rather than choosing between a harm and safety; an answer that lists teratogenic risks without the untreated illness on the other side of the scale has answered half the question.

16.2 Comparative teratogenic risk, and what the comparison licenses

Substitution rests on the spread between agents rather than on any single figure, so the risk of **major congenital malformations** is best held as a comparison across the drugs actually chosen between.

AGENT	MALFORMATION RISK AS THE SOURCE STATES IT	WHAT THE SOURCE DOES WITH IT
Lithium	Ebstein's anomaly in **0.05 to 0.1 per cent of live births** after first-trimester exposure, about twenty times the general population rate, as the Indian guideline states it. That Ebstein-specific multiple is the historical estimate; the modern cohort figure sits below the table	Small in absolute terms, which is why lithium may still be continued after shared decision-making
Valproate and divalproex	8 to 10 per cent, including neural tube defects	Contraindicated in pregnancy, and linked to later neurodevelopmental disorders
Carbamazepine	3 to 6 per cent	Adds a **neonatal bleeding diathesis** from vitamin K deficiency
Oxcarbazepine	Comparable to the general population rate, at approximately 3 per cent	Can be used in pregnancy, although safety data are limited
Lamotrigine	Approximately 3 per cent, similar to baseline, with no definite evidence of neurobehavioural sequelae	Preferred where the course is depression-predominant; clearance rises, so the dose often has to follow
Second-generation antipsychotics	4.5 per cent in exposed against 3.5 per cent in unexposed individuals	No significant increase after adjustment, apart from a small risperidone signal a later large study did not replicate
Selective serotonin reuptake inhibitors	Small increased absolute risk of cardiac defects with paroxetine, 2 per 1000 exposed pregnancies, which is an excess and not the total incidence	Generally safe if indicated; avoid paroxetine

Two readings are examinable. First, the spread is the argument: because one agent sits several times above its nearest comparator, the regulatory response is specific to that agent rather than a class-wide caution, and a within-class alternative at baseline risk is what makes a restriction workable instead of merely punitive. Second, absolute and relative risk are different instruments pointed at one thing. The Maudsley guidance on advanced prescribing states the lithium risk as an absolute frequency: a population risk of Ebstein's anomaly of 1 in 20,000, rising with lithium exposure in pregnancy to 1 in 1000 to 2000. That is the Indian figure in another currency rather than a competing estimate, and both are the same historical Ebstein-specific estimate. Contemporary cohort evidence has moved the magnitude. Patorno and colleagues, reporting a large registry cohort in the New England Journal of Medicine in 2017, found cardiac malformations overall in 2.41 per cent of lithium-exposed pregnancies against 1.15 per cent of unexposed, an adjusted risk ratio of 1.65 that rose with dose, and did not establish a twenty-fold

Ebstein-specific excess. Quote the guideline figure as the guideline's, and know that the twenty-fold multiple is the older estimate rather than the current one.

16.3 Continuing lithium: the scan, and two monitoring cadences

Continuing lithium commits the clinician to fetal surveillance and to a level schedule, and both are specified differently by different bodies. The Indian bipolar guideline states that in all pregnancies with first-trimester lithium exposure a 20-week fetal cardiac anomaly scan is recommended. The reproductive-safety table of that same document advises fetal echocardiography over a window rather than at a single time point, and this chapter does not hold that second figure. The disagreement is internal to one guideline and should be quoted as such.

Haemodynamic change in pregnancy alters lithium handling, and the two guidelines specifying a cadence do not specify the same one. The Indian bipolar guideline gives monthly monitoring till 36 weeks, weekly from 36 to 40 weeks, and twice each week in the first 2 weeks postpartum, framed as a suggestion and not a mandate. The Maudsley reports that NICE recommends lithium levels be checked every four weeks in pregnancy and weekly after 36 weeks. Print both, attributed. The Indian schedule carries a postpartum limb the United Kingdom summary does not reproduce, and that absence is a silence in the summary rather than a statement that no postpartum monitoring is specified.

16.4 Valproate: a prohibition, and the machinery that enforces it

Valproate is the one agent here where the answer is not a trade-off: the Indian bipolar guideline records it as contraindicated in pregnancy, and the figure above is the whole of the reason. The regulatory machinery is examinable in its own right. The Maudsley compresses the United Kingdom position into one line: valproate may not be initiated in patients under 55 or continued in women of child-bearing potential unless two specialists agree and document that there is no other effective or tolerated treatment. That compression welds two different rules together and drops an exception, and the regulator separates them. Under the Medicines and Healthcare products Regulatory Agency measures of January 2024, valproate must not be started in a new patient of either sex under 55 unless two specialists independently consider and document that there is no other effective or tolerated treatment, or that there are compelling reasons the reproductive risks do not apply. Continuation in a woman of child-bearing potential is governed instead by the pregnancy prevention programme, with annual specialist review and a signed risk acknowledgement, and not by the two-specialist initiation test. The Indian bipolar guideline quotes that fuller regulatory text, second escape clause included, which the one-line summary omits. Alongside the two-specialist rule sits the programme requirement: valproate should not be offered to girls or young women of child-bearing potential unless a **pregnancy prevention programme** is in place.

That programme is a United Kingdom instrument. No Indian counterpart is established by the sources used here: the Indian guideline refers only obliquely to restrictions on divalproex in reproductively active women and men, naming no programme, no contraception requirement, no

age bar and no two-specialist rule. Name the jurisdiction and say the equivalent is not documented.

The stopping decision has a defined shape. Where a woman on valproate decides to conceive, the Australian perinatal guidance reported by the Maudsley is to stop valproate over 2 to 4 weeks while adding high-dose folic acid **5 mg/day**, continued through the first trimester, and the Indian bipolar guideline corroborates that supplementation dose for the pre-conception period. That supplementation figure is a daily amount rather than a dose to build up to: no initiation step sits below it in either document, and neither states a maximum above it for preconception use.

GOOD TO REMEMBER

Where carbamazepine is carried to term, the vitamin K limb is what gets forgotten, because it is not a psychiatric act. What is established is the neonatal limb: intramuscular vitamin K for the newborn at birth, arranged with the paediatric team. Routine antenatal vitamin K for the mother purely because she is taking an enzyme-inducing anticonvulsant is not supported by adequate evidence, and the Royal College of Obstetricians and Gynaecologists green-top guidance on epilepsy in pregnancy makes maternal treatment a response to a demonstrated coagulation abnormality or another obstetric indication rather than a routine. The malformation risk was settled months earlier; the neonatal bleeding diathesis is still preventable at delivery.

16.5 Antipsychotics and antidepressants: the dose that should not fall

The commonest prescribing error in pregnancy is a well-intentioned dose reduction. The Indian schizophrenia guideline states that the dose should not be reduced merely because a patient is pregnant, since antipsychotic metabolism may increase during pregnancy and lead to subtherapeutic levels, and names clozapine as the exception, whose levels may instead increase by the third trimester. The direction of the kinetic change decides the direction of the dose change.

PITFALL

Halving an antipsychotic at the booking visit, reasoning that less drug means less exposure. Metabolism may already be rising for the agent in question, in which case the reduction compounds a fall that was happening anyway. The rule is not that doses go up in pregnancy. The American College of Obstetricians and Gynecologists puts it as do not reduce automatically, and change a dose only where that drug's pharmacokinetics, the clinical response or a level justify the change. Where a dose was raised during pregnancy, the postpartum step is to bring it back down under close monitoring rather than leave it where the pregnancy put it.

Antidepressant decisions turn on two late-pregnancy risks rather than on malformation. The Indian guideline for obsessive-compulsive disorder states that selective serotonin reuptake inhibitors taken late in pregnancy may increase the risk of **persistent pulmonary hypertension of the newborn** by more than twofold, giving the absolute risks as 3 infants per 1000 exposed against 1.2 per 1000 unexposed. The Indian bipolar guideline describes that same association only as conflicting evidence in the third trimester, so even the strength of the claim is unsettled within one national guideline set. Separately, **neonatal adaptation difficulties** may occur in

about one-third of infants exposed late in pregnancy, which makes a paediatric handover the response rather than stopping the drug before delivery.

TRAP **One paroxetine risk, two incompatible figures inside the same national guideline set.** The bipolar guideline gives the small increased absolute risk of cardiac defects as 2 per 1000 and instructs that paroxetine be avoided. The guideline for obsessive-compulsive disorder, from the same series, states the septal-defect risk as a percentage an order of magnitude higher against a stated population rate, adding that the evidence is inconsistent. This chapter holds only the per-thousand figure. Quote what you hold, name the source, and say the other document disagrees.

16.6 Lactation: the pregnancy answer does not carry across

The reversal between the two phases is the teachable point. The Indian bipolar guideline states, in a single sentence, that breastfeeding is generally avoided with lithium because of the risk of neonatal toxicity and the need for infant serum drug level monitoring, and that divalproex is considered relatively safer in breastfeeding. Read it carefully: the comparison between the two agents is carried by a semicolon rather than asserted, and the agent contraindicated in pregnancy is the one treated more permissively at the breast. The next sentence supplies the conditional exception, that breastfeeding during lithium treatment may be considered in healthy, full-term infants with close monitoring, if only because discontinuation may pose greater risks. Emergency management of established lithium toxicity belongs to the Perinatal/women's mental health and emergency psychiatry notes.

Clozapine is where two Indian guidelines part company outright. The bipolar guideline states that clozapine should not be prescribed during breastfeeding, because of rare but serious adverse effects warranting blood monitoring. The schizophrenia guideline's corresponding table states only that antipsychotics are not contraindicated during breastfeeding and that clozapine may be present in breast milk, its potential risks to the infant needing to be considered and monitored. Both belong in an answer. For the remaining second-generation agents the bipolar guideline states that current evidence suggests quetiapine and olanzapine are safe during breastfeeding, with lactation data somewhat limited for the others.

Among antidepressants, the guideline for obsessive-compulsive disorder separates the SSRIs by how much of the drug reaches a breast-fed infant, placing sertraline, fluvoxamine and paroxetine at the low end and fluoxetine and citalopram above them, and it then surmises that they are relatively safe during breastfeeding, the hedge being the guideline's own. The two percentages that carry that separation are deliberately not printed here, because the sentence holding them describes them at once as concentrations in the plasma of breast-fed infants and as a share of the maternal dose, and those are two different quantities with two different denominators, since a plasma concentration cannot be a percentage of a dose. The source is internally inconsistent at the exact point a candidate would quote it. Reading the figures as relative infant dose, the share of the maternal dose reaching the infant through milk, is the most plausible repair, but it is an interpretation and not what the guideline says, and no source read here gives a drug-specific relative infant dose or an infant plasma ratio to substitute for it. Nothing is printed on either

reading. Milk supply is a separate axis from infant exposure, and it is where an Indian dataset displaces a Western default: **complete lactation failure** is a documented aripiprazole effect.

TRAP **Attaching a percentage to the wrong denominator.** An Indian perinatal-psychiatry chart review found that 60 of the 398 women attending the service were prescribed aripiprazole during pregnancy, with lactation data available for the 35 who continued the drug during the postpartum period; of those 35, 26 (74%) experienced complete lactation failure and 4 (11%) had insufficient milk production. The denominator of both percentages is the thirty-five with lactation data, not the sixty prescribed the drug. A national guideline compresses the study into a retrospective analysis of sixty women, attaching both percentages to the wrong number, so a candidate quoting the guideline sentence inherits an error the primary paper does not contain.

IN INDIA

Aripiprazole is the Western default for metabolic safety, and Indian perinatal data attach a lactation penalty to it that Western reproductive-safety tables do not show. A woman established on aripiprazole who intends to breastfeed therefore needs her postpartum plan settled antenatally, while there is still time to change the agent, rather than after the milk has failed. Where an antidepressant is needed alongside, the Indian bipolar guideline names sertraline as having the most substantial evidence of lactation safety.

MNEMONIC

Plan, Prefer, Persist, Postpartum

The perinatal spine. Plan before conception, because the highest-risk weeks precede the test. Prefer the agent whose documented risk is lowest for this illness course. Persist with an effective drug rather than reduce it because the physiology changed. Re-plan at delivery, when clearance, feeding and the level schedule all reverse together.

16.7 The elderly: assume the reserve has already gone

Age is a kinetic diagnosis before it is a clinical one. The Maudsley quantifies the decline that governs every renally cleared psychotropic.

35%	50%	two-thirds
RENAL FUNCTION LOST BY SIXTY-FIVE	LOST BY EIGHTY	FUNCTION TO ASSUME AT MOST

The third figure is the Maudsley's default assumption rather than a measurement, and it is a place to begin thinking rather than a dosing method. Renal function in an older adult is estimated before a renally cleared psychotropic is dosed, not assigned from age: the KDIGO chronic kidney disease guideline of 2024 makes estimated glomerular filtration rate or creatinine clearance the instrument, and adds that a creatinine-based estimate can overstate function where muscle mass is low, which is common in exactly this population, so cystatin C or a combined equation is used where creatinine is unreliable. The underlying pharmacokinetic principles belong to the Psychopharmacology I: principles and core drug classes notes. For maintenance treatment in bipolar disorder the Indian guideline's suggested serum lithium levels are 0.6 to 0.8 mEq/L in

medically healthy individuals and **0.4 to 0.6 mEq/L in older adults or those with relevant medical issues**. The acute-phase figures in that guideline do not agree between its dosing table and its running text, and neither set is printed here; target concentrations and sampling timing are taught with therapeutic drug monitoring. The standard texts also diverge on the elderly starting dose and on how soon the first level is drawn, and no figure for either is printed.

For depression in older people the Indian guideline directs start low and go slow, with monitoring especially for hyponatraemia and falls, and states that older patients usually require half the starting and target dose used in adults. The Indian schizophrenia guideline sets a different, smaller reduction for antipsychotics, and the two must not be merged into one rule. Choice of agent is then driven by two burdens rather than by efficacy: that guideline states that first-line antipsychotics in older adults will be the ones with lower **anticholinergic burden** and lower sedative property, to prevent falls, that anticholinergic co-prescription should be avoided to the possible extent, and that monitoring for metabolic adverse effects should be more frequent. The interval is nowhere quantified, and supplying one would be worse than leaving it open.

Antipsychotics in dementia carry a licence and a warning that must be quoted together. Risperidone is specifically indicated for short-term treatment, up to 6 weeks, of persistent aggression in moderate to severe Alzheimer's disease unresponsive to non-pharmacological approaches, and is licensed up to 1 mg twice daily although the optimal dose in dementia is 500 micrograms twice daily. Against that, the United States Food and Drug Administration's 2005 advisory determined an increased risk of death in older adults with dementia-related psychosis treated with atypical antipsychotic drugs of between 1.6 and 1.7 times that seen in placebo-treated patients. That estimate is pooled across placebo-controlled trials of several atypical agents, and it is the basis of a class boxed warning which risperidone carries; a standard textbook restates the same ratio as risperidone-specific, and the advisory does not support that reading. What the licence entry does not give is a dose to start at. It states the licensed upper figure and the optimal figure for dementia and nothing beneath either, so the optimal dose is where the source lands rather than a rung arrived at by titration. Prescribe, review at the stated horizon, stop.

16.8 Children and adolescents: the monitoring is the answer

Paediatric prescribing is examined through monitoring far more than through drug choice, because the choice is narrow and the surveillance specific. For depression, the Maudsley makes fluoxetine the recommended first-line medication in children and adolescents, started at 10 mg daily and increased after one week to the minimum therapeutic dose of **20 mg daily**. The entry stops there. It gives the start and the step and names no ceiling for this population, so the therapeutic minimum is a floor and must not be read backwards as the limit. Valproate reappears with a paediatric starting dose and the same prohibition attached: the Maudsley table of starting doses in children and adolescents gives valproate a weight-based starting range in divided doses, with plasma levels used to determine the maintenance dose, repeating in the same cell that valproate is not to be offered to girls or young women of child-bearing potential unless a pregnancy prevention programme is in place. The range itself is withheld here: that table row

carries no indication, and a paediatric weight-based dose quoted without the condition it treats is the shape of a wrong answer. A footnote weight-bands it, the lower end belonging to lighter children; the weight cut-off is not stated here, and the Indian adult figure for divalproex belongs to a different population. No ceiling appears in the valproate row either. It carries a starting range and a prohibition and nothing above them, the maintenance dose being fixed by plasma level rather than by any stated milligram maximum.

Stimulant monitoring is where two Indian sources diverge. The Indian Psychiatric Society guideline on attention-deficit hyperactivity disorder directs that heart rate and blood pressure be measured at every visit during titration and once every 3 months. An Indian postgraduate text gives a looser schedule: pulse, blood pressure and heart rate at each dose increase and every 6 months, with weight and height on standardized charts at 6-month intervals as a minimum, adding that routine haematological tests are unnecessary. The guideline's intervals are the ones to work to, and the textbook's looser schedule is worth knowing as the divergence rather than quoting as the standard. That guideline also contradicts itself internally, its continued-monitoring text asking for measurement at every visit with no step-down. Whether an electrocardiogram is required before a stimulant cannot be settled from these sources either: the textbook and the guideline do not agree on whether the tracing is a baseline requirement or a reactive step once a blood-pressure problem has emerged.

Two thresholds carry named consequences and both are frequently misplaced by tier. In the guideline's adverse-effect table, initial management of tachycardia and rise in blood pressure, listed for methylphenidate and atomoxetine, is triggered by sustained tachycardia of more than 120 beats per minute, or systolic or diastolic blood pressure more than the 95th percentile measured on 2 occasions, and the action is to reduce the dose and refer to a cardiologist. Separately, and only as a second-tier step once initial management has failed, persisting **growth suppression**, or growth parameters below the critical thresholds even after stopping the drug, roughly below the third percentile and growth velocity falling 2 centile lines over 1 year, prompts referral to a paediatric endocrinologist. That criterion is conjunctive: both limbs, not either alone. Initial management of growth retardation, in the order the guideline prints it, is a ladder.

- Dosage reduction.
- Weekend and longer drug holidays, to allow catch-up growth.
- Changing the class of medication.
- Stopping the drug.

The growth signal justifying all of this is real but modest. In the MTA follow-up, the group that did not receive medication was about 1 cm taller and 1 kg heavier at the 24-month follow-up than the group treated with stimulant medication for the entire two-year period. A difference of that size argues for charting growth at fixed intervals, not for withholding an effective treatment.

In every one of these populations the pharmacology of the drug is unchanged; what has changed is the body it enters, so the dose, the level and the monitoring interval must all move with it.

17 · QTc prolongation and cardiometabolic monitoring across psychotropics

Two monitoring problems share one heading for a reason. Cardiac conduction and cardiometabolic risk are the harms psychotropics produce slowly, silently and measurably, and that combination makes a schedule rather than a symptom the instrument of safety. Both are examined as decisions rather than as facts: which number obliges which action, which agent carries which liability, who gets a tracing and how often, and where an Indian guideline parts company with a British one. The receptor pharmacology behind each class's adverse-effect signature belongs to the Psychopharmacology I: principles and core drug classes notes. What follows is the monitoring that pharmacology obliges, and the decisions its results force.

17.1 The thresholds, and how firmly each is held

The **QTc** is the interval corrected for heart rate, and its published cut-offs are not held with equal confidence. The Maudsley 15th edition gives the normal limits as 440 ms for men and 470 ms for women and describes arrhythmia risk beyond those limits as exponentially related to the extent of prolongation, while labelling that limb very limited evidence with well-known exceptions. It holds the next step more firmly: values over **500 ms** carry a clearly increased risk of arrhythmia. The same passage carries a fourth limb, attaching a better-than-even chance of inducing torsades to a still longer interval, and that limb is withheld here with its figure: no QTc value has a validated patient-level probability of torsades attached to it, because the risk that a given tracing carries also depends on the drug, the correction formula used, the heart rate, the electrolytes and the structural state of the heart. Carry the strength of each statement along with its figure, because an answer that prints all three at one confidence has misreported the source it is quoting.

440 ms	470 ms	500 ms
NORMAL LIMIT, MEN	NORMAL LIMIT, WOMEN	CLEARLY RAISED RISK

A second Maudsley text puts coordinates on the same curve, and this is the point at which a printed figure has to be refused rather than quoted. The Maudsley Guidelines on Advanced Prescribing in Psychosis state that the relationship between QTc and torsade risk is exponential and attach an absolute probability to each of two named intervals. Those two percentages are withheld here. Cardiology guidance on the prevention of torsades de pointes in hospital settings describes the risk as rising continuously with the interval, substantially so above the clearly-raised-risk threshold already named, and declines to convert any single QTc value into a probability for an individual patient. So the two accounts differ in kind rather than in direction: one calls the exponential relation very limited evidence, one quantifies it, and the cardiology position is that the quantification does not survive at the level of the patient in front of you. Teach the direction and the action threshold, attribute whichever account you use to the body that states it, and do not read a percentage off a tracing.

17.2 Reading the number as an instruction

RULE **A QTc value is read as an instruction, not as a diagnosis.** Each band of the Maudsley management grid names two things at once, what happens to the prescription and how urgently cardiology is involved, and the grid carries a further row that fires on the shape of the tracing whatever the measured interval turns out to be.

Table 1.38 of the Maudsley Prescribing Guidelines sets out that ladder for patients receiving antipsychotic drugs. Read the direction of travel across it rather than the cells in isolation: the intermediate band leaves the clinician discretion over dose reduction or switching, and the top band withdraws that discretion and attaches an immediate referral to it.

QTC ON THE TRACING	WHAT HAPPENS TO THE PRESCRIPTION	CARDIOLOGY REFERRAL
Below 440 ms in men or 470 ms in women	None, unless T-wave morphology is abnormal	Consider if in doubt
Above those limits but below 500 ms	Consider reducing the dose or switching to a drug of lower effect, and repeat the electrocardiogram	Consider
Above 500 ms	Repeat the electrocardiogram, stop the suspected causative drug and switch to a drug of lower effect	Immediately
Abnormal T-wave morphology, whatever the interval	Review treatment, and consider reducing the dose or switching to a drug of lower effect	Immediately

That last row is the one candidates leave out, and it is the row that makes the grid a clinical instrument rather than an arithmetic one. **Abnormal T-wave morphology**, independent of the QTc value, triggers treatment review, consideration of dose reduction or switching, and immediate cardiologist referral. A comfortable interval on a tracing with an abnormal T wave does not discharge the clinician.

17.3 Three variables, not one: the drug, the co-prescription and the patient

The Maudsley stratification of antipsychotics by effect on the QTc runs to four bands, and the usable information sits at the two ends. The high-effect band carries pimozide and sertindole, while the no-effect band holds brexpiprazole, cariprazine, lurasidone and lumateperone. The low-effect band takes aripiprazole, asenapine, clozapine, olanzapine, paliperidone, risperidone, sulpiride and the older thioxanthenes and phenothiazines listed with them, and amisulpride, chlorpromazine, haloperidol, quetiapine and ziprasidone sit in the moderate band. The clinically useful reading is comparative rather than absolute: the choice is rarely between an agent that prolongs and one that does not, but between bands.

The co-prescription is the second variable, and it is usually written by somebody else. Table 1.37 of the same chapter groups the non-psychotropics associated with QT prolongation into four

families.

- Antibiotics: erythromycin, clarithromycin, co-trimoxazole and pentamidine, with a note that some quinolones affect the QTc. One further antibiotic printed on that row is withheld here, because the maintained database the same table points to does not carry it in any torsades-risk category and no causal source for it could be supplied.
- Antimalarials: chloroquine, mefloquine and quinine.
- Antiarrhythmics: quinidine, disopyramide, procainamide, sotalol, amiodarone and bretylium.
- Others: amantadine, cyclosporin, diphenhydramine, hydroxyzine, methadone, nicardipine and tamoxifen.

The table directs the reader to Crediblemeds.org for current information and states that it is not a complete list. That caveat teaches better than the list does: absence from a printed table is not evidence that an agent is safe, and the reference to a maintained database is the guideline conceding that a book cannot keep this current. The converse holds too, and it is why one entry was withheld above: presence on a printed row is not itself a risk category, and where the maintained database and the book disagree it is the database that the book tells you to use.

The patient is the third variable. The Maudsley Table 1.36 of physiological risk factors sorts them into cardiac factors, being **long QT syndrome**, bradycardia, ischaemic heart disease, myocarditis, myocardial infarction and left ventricular hypertrophy; metabolic factors, being **hypokalaemia**, hypomagnesaemia and hypocalcaemia; and others, being extreme physical exertion, stress or shock, anorexia nervosa, extremes of age and female gender. Of the three groups only the metabolic one is correctable by a laboratory result and a bag of fluid, which is why it is checked first.

GOOD TO REMEMBER

These additional risk factors seem almost always to be present in cases of antipsychotic-induced **torsade de pointes**. Treat that sentence as an instruction about where to look: a prolonged interval in a patient on an antipsychotic is a prompt to hunt for the second and third variables rather than a verdict on the first. Send the electrolytes, read the rest of the drug chart, and find out what the heart was like before the prescription was written.

17.4 Antidepressants, and one disagreement worth knowing

The antidepressant account is narrower than the antipsychotic one and easier to overstate. Among antidepressants, the Maudsley Prescribing Guidelines hold that QT changes are not usually seen with most SSRIs at normal clinical doses, that the class-level association is largely driven by citalopram and escitalopram and is dose-related but modest, that sertraline prolongs QT by 5 to 10 ms at 400 mg a day, a figure the same evidence sets against those normal clinical doses rather than a dose it recommends. A fourth clause, exonerating three named newer antidepressants of any effect on cardiac conduction, is withheld: the passage quoted from that chapter does not carry it, and an absolute of that width is not a thing to print on an unverified line. Treat the position on those agents as unstated here rather than as reassurance.

The Indian Psychiatric Society depression guideline declines the second of those clauses. It states that escitalopram does not pose a clinically significant risk of QTc prolongation, which is a softer position than attributing the class effect to citalopram and escitalopram jointly. Both belong in an answer: the Indian guideline exculpates escitalopram and the United Kingdom source does not, neither position is derivable from the other, and a candidate who quotes only one is wrong against the examiner who holds the other.

Citalopram, one of the antidepressants named in that class effect, is the standard pharmacovigilance illustration in this territory: the FDA restricts it to a maximum of **20 mg daily** for defined subgroups, including patients taking a CYP2C19 inhibitor and those older than 60 years, because it causes dose-dependent QT interval prolongation. That list is not closed, and reading it as closed is the error to avoid: the same 20 mg ceiling is set by the regulator's 2012 safety communication for patients with hepatic impairment and for CYP2C19 poor metabolisers. Note what kind of ceiling that is. It is not a toxicity limit and not a licensing quirk; it is a regulator converting a conduction signal, in subgroups defined by enzyme inhibition, enzyme genotype, liver function and age, into a hard dose restriction. Note also that the citalopram restriction travels in one direction only. It names a maximum for each subgroup and no starting dose at all, so it constrains where a regimen may end up and says nothing at all about where it starts.

17.5 Who gets a tracing, and when

Two bodies answer this differently and both answers are examinable. The Maudsley position is to measure QTc in all patients prescribed antipsychotics on admission and, if there is a previous abnormality or a known additional risk factor, at the annual physical health check. Its monitoring table places the electrocardiogram at baseline, at target dose, on admission to hospital, if cardiac symptoms occur, and when medication is changed; the tracing is mandatory for haloperidol, pimozide and sertindole, and for ziprasidone in some situations, and ideally all patients should be offered an electrocardiogram at least yearly.

The Indian Psychiatric Society schizophrenia guideline triggers on different criteria. For the chronic phase or multiepisode relapsing-remitting illness it states that an electrocardiogram would be needed for patients over 40 years, on injectable antipsychotics, or on antipsychotics at high risk of increasing QTc, along with nutritional status. Both documents use a drug trigger, so the contrast is narrower than it first looks. What is genuinely Indian is the age threshold, which the Maudsley triggers do not use, and the naming of the injectable route as a trigger in its own right.

Opioid substitution carries a third grid, and it is worth knowing because the same figures do different work in it. The Maudsley Prescribing Guidelines, which carry this table across successive editions with identical thresholds, grade methadone electrocardiogram monitoring by sex: borderline prolonged QTc is 470 ms or more in females and 440 ms or more in males, prolonged QTc is 500 ms or more, and very prolonged QTc is 550 ms or more, each band carrying its own action limb. The two numbers that were the upper edge of normal in the antipsychotic grid are the entry to the borderline band here, which is a reminder that a threshold belongs to the table it was printed in.

17.6 The cardiometabolic panel and the intervals that carry it

Metabolic monitoring is where the Western and Indian answers diverge furthest. The parameters are much the same in every grid; what differs is how early the first repeat falls, how the first year is treated, and which agents earn a column of their own. The accompanying figure sets the recurring intervals side by side.

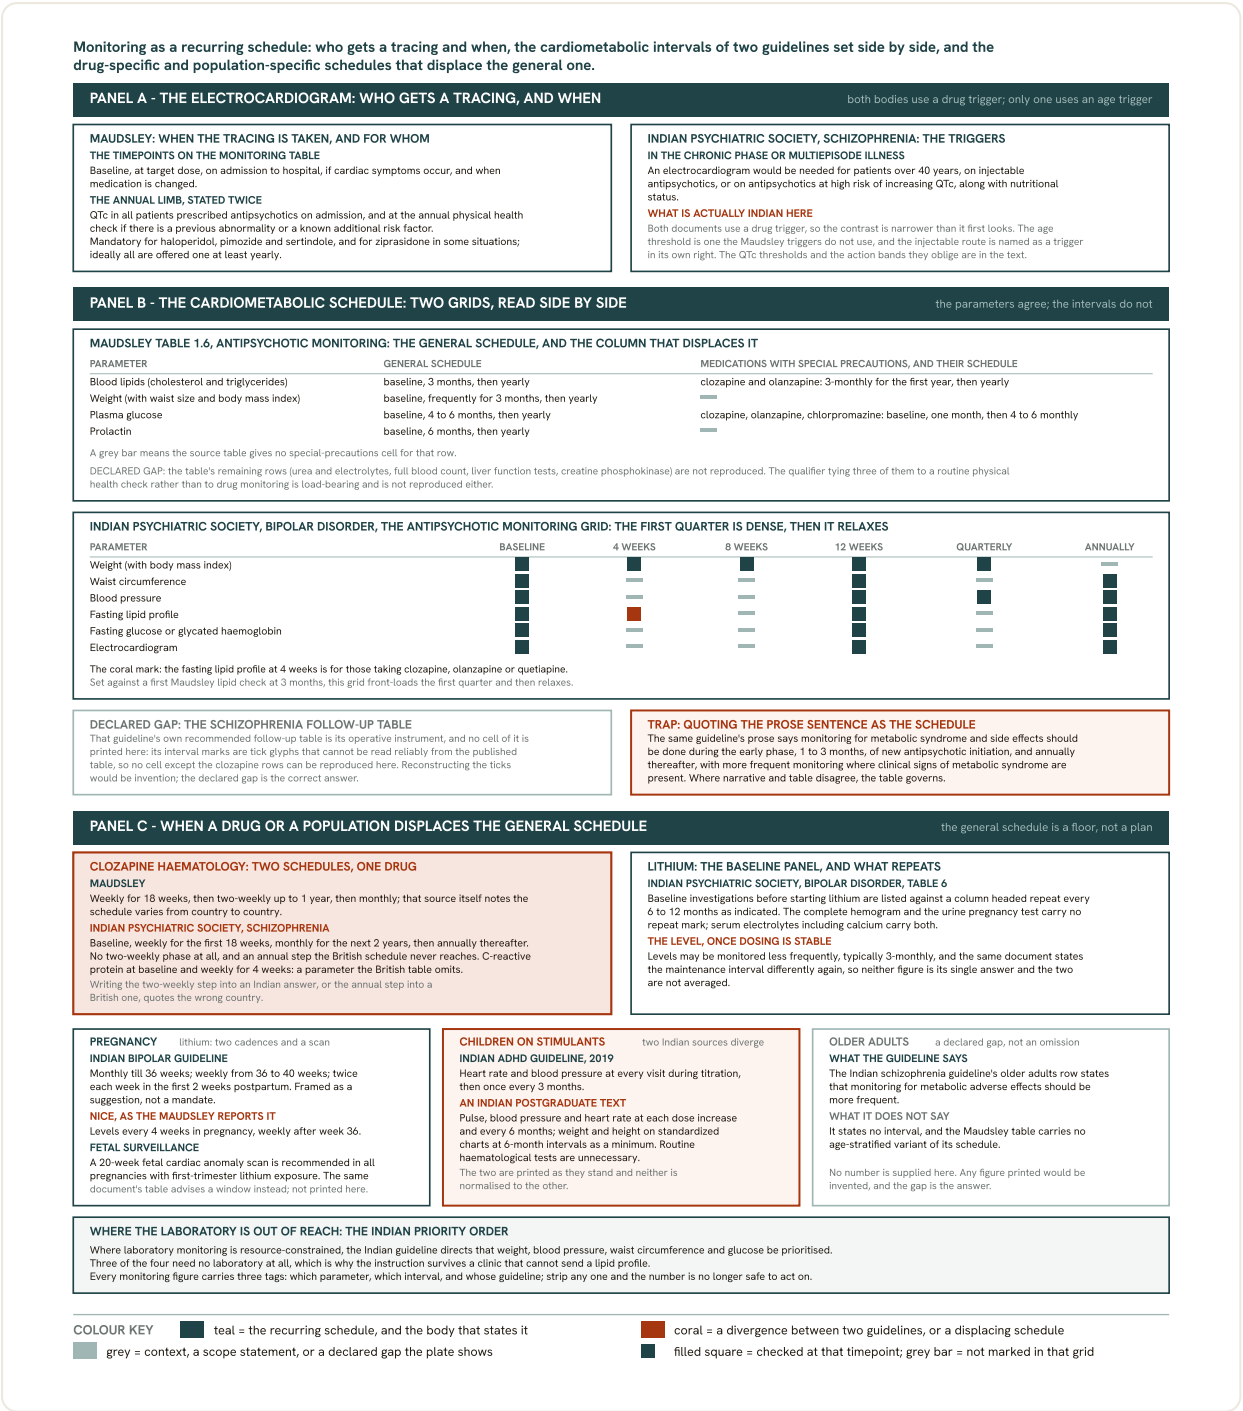

Fig 37.8 The recurring monitoring schedule: who gets a tracing and when, the cardiometabolic intervals of two guidelines set side by side, and the drug-specific and population-specific schedules that displace the general one. The Maudsley table is built around one early check and an annual rhythm, and carries a second column for clozapine, olanzapine and chlorpromazine that displaces the general one; the Indian bipolar grid front-loads the first quarter, with visits at 4, 8 and 12 weeks, and then relaxes. Clozapine haematology and lithium each carry a whole schedule of their own in place of the general one, and the two clozapine schedules part company at the second step: the British goes weekly, two-weekly, monthly, while the Indian goes weekly, then straight to monthly, and eventually to annual. Pregnancy, childhood and old age each set their own interval, and the interval for older adults is a declared gap, because the guideline says monitoring should be more frequent and states no number. The Indian schizophrenia guideline's own follow-up table is named as the operative instrument and is not reproduced, because its interval marks cannot be read reliably from the published table. Plasma target ranges are not on this plate; they are taught with therapeutic drug monitoring. (Maudsley Prescribing Guidelines in Psychiatry, 15th ed.; Indian Psychiatric Society Clinical Practice Guidelines 2025 for schizophrenia and bipolar disorder; for the stimulant row, the Indian Psychiatric Society attention-deficit hyperactivity disorder guideline of 2019, from its child and adolescent set, not the 2025 set; an Indian postgraduate child and adolescent psychiatry text; NICE as reported by the Maudsley.)

The Maudsley Table 1.6 gives blood lipids at baseline, at 3 months, then yearly; weight, including waist size and body mass index where possible, at baseline, frequently for the first 3 months, then yearly; plasma glucose at baseline, at 4 to 6 months, then yearly; and prolactin at baseline, at 6 months, then yearly. That is a schedule built around a single early check and an annual rhythm thereafter.

PITFALL

Applying the general interval to a patient who is on an agent with a column of its own. In the same Maudsley table the medications with special precautions on the blood lipids row are clozapine and olanzapine, tested 3-monthly for the first year, then yearly; on the plasma glucose row they are clozapine, olanzapine and chlorpromazine, tested at baseline, at one month, then 4 to 6 monthly. The general and the special-precautions schedules sit in adjacent columns of the same row, and reading across the wrong one is the commonest way a monitoring plan is written short for exactly the patients who needed it longest.

The Indian Psychiatric Society bipolar guideline's antipsychotic monitoring grid is denser early. Its columns are baseline, 4 weeks, 8 weeks, 12 weeks, quarterly and annually. Weight with body mass index is marked at baseline and at each of the three early visits and quarterly, but not annually; waist circumference at baseline, at 12 weeks and annually; blood pressure at baseline, at 12 weeks, quarterly and annually; the fasting lipid profile at baseline, at 12 weeks and annually, with an added check at 4 weeks for those taking clozapine, olanzapine or quetiapine; and fasting glucose or glycated haemoglobin and the electrocardiogram at baseline, at 12 weeks and annually. Set against a first Maudsley lipid check at three months, the Indian grid front-loads the first quarter and then relaxes.

TRAP **Quoting a guideline's prose sentence as though it were the guideline's schedule.** The Indian Psychiatric Society schizophrenia guideline states in its text that investigative monitoring for metabolic syndrome and side effects should be done during the early phase, 1 to 3 months of new antipsychotic initiation, and annually thereafter, with more frequent monitoring where clinical signs of metabolic syndrome are present. That sentence is not the document's operative instrument: the same guideline carries a recommended follow-up table, and where the narrative and the table do not agree the table governs. Name the prose statement, attribute it, and do not present its interval as the Indian metabolic monitoring schedule.

17.7 Clozapine haematology: two schedules, one drug

TRAP **Assuming one clozapine blood-count schedule worldwide.** The Maudsley schedule is weekly for 18 weeks, then two-weekly up to 1 year, then monthly, and that source itself notes the schedule varies from country to country. The Indian Psychiatric Society schizophrenia guideline runs baseline, weekly for the first 18 weeks, monthly for the next 2 years, then annually thereafter, with no two-weekly phase at all and an eventual annual step the British schedule never reaches. Writing the two-weekly step into an Indian answer, or the annual step into a British one, quotes the wrong country.

The action thresholds travel with whichever schedule is being used. The suspect medication is stopped if neutrophils fall below **1.5 x 10^9/L** in a patient taking clozapine, unless **benign ethnic**

neutropenia is diagnosed, and specialist medical referral is made if neutrophils fall below 0.5 x 10^9/L on clozapine. The exception is written into the rule rather than bolted onto it, so a low count is a question about the patient's baseline before it is an instruction to stop.

The Indian guideline adds a parameter the British table does not: C-reactive protein for clozapine at baseline and weekly for 4 weeks. Its own footnote is candid about the rest of the schedule, recording that an emerging expert statement suggests less stringent monthly blood monitoring after the first year of clozapine therapy because the incidence of clozapine-induced agranulocytosis is very low, but that this has yet to be reflected in any guidelines worldwide for want of robust evidence. The monthly figure therefore stands, and an answer that softens it on the strength of the footnote has read the footnote backwards.

17.8 Lithium's baseline panel, and the Indian adaptation

Lithium is monitored on two tracks and only one of them is a plasma concentration. The Indian Psychiatric Society bipolar guideline's Table 6 lists the baseline investigations to be done before starting lithium against a column headed repeat every 6 to 12 months as indicated: the complete hemogram and the urine pregnancy test carry no repeat mark, while serum electrolytes including calcium carry both. The same document also states that once lithium dosing has been stabilised the blood levels may be monitored less frequently, typically 3-monthly, and its narrative text states the lithium maintenance interval differently again, so neither figure is the guideline's single answer and the two must not be averaged into one.

What the Indian documents add beyond intervals is a definition and a priority order. The criteria for **metabolic syndrome** are population-specific, and the guideline gives its reason in the open: population-specific criteria should be followed when assessing metabolic syndrome, given the higher body fat content and risk profile in Indians.

IN INDIA

Read the list below as components, not as a checklist that must be completed. Under the harmonised definition of the metabolic syndrome, the diagnosis is made when any three of the five components are present, so a patient who meets three of them has the syndrome and a patient who meets two does not. Applied to an Indian patient, those five components are a **waist circumference** at or above **90 cm** in males and 80 cm in females, triglycerides at or above 150 mg/dL, HDL below 40 mg/dL in males and below 50 mg/dL in females, systolic blood pressure at or above 130 mmHg and/or diastolic at or above 85 mmHg, and fasting blood sugar at or above 100 mg/dL. Assess the patient in front of you against these, not against a threshold set imported from another population, because the same measurement can clear one definition and meet the other.

MNEMONIC

Weight, Pressure, Waist, Glucose

Where laboratory monitoring is resource-constrained, the Indian Psychiatric Society schizophrenia guideline directs that weight, blood pressure, waist circumference and glucose be prioritised. Three of the four need no laboratory at all, which is why the instruction survives a clinic that cannot send a lipid profile, and it answers a question the Western tables never ask: what to keep when the full panel is out of reach.

Every monitoring figure carries three tags: which parameter, which interval, and whose guideline; strip any one of them and the number is no longer safe to act on.

Neurostimulation and device-based treatments

18 · Electroconvulsive therapy: indications, mechanism, technique and adverse effects

Every other treatment in this chapter is a molecule. **Electroconvulsive therapy** is the one intervention chosen against the drugs rather than among them, and the long modality question asks the same five things each time: what it is, how it is thought to work, which disorders it earns a place in, how good the evidence is in each of them, and what it costs the patient. The procedural act itself, the technique and its parameters, is set out in the ECT and neurostimulation notes. What follows is the modality and its utility across disorders, which is where the marks are actually lost, usually by quoting one guideline body as though it spoke for all of them.

18.1 What is established about mechanism, and what is not

An Indian review of how the treatment works reaches a conclusion that is itself the examinable point: **no single mechanism of action** is established, because the cause and effect relationship between the observed biological findings and the therapeutic effect has not been settled, and a single explanatory account cannot prudently be assumed. Candidates lose marks by picking one of the competing hypotheses and defending it as the answer. The stronger answer sets them out as convergent lines of evidence and says plainly that none has been shown to carry the therapeutic effect on its own.

RULE **Seizure induction appears necessary but not sufficient for the antidepressant effect.** A generalised seizure can be induced and still fail to produce an antidepressant response, which constrains every purely seizure-based account of how the treatment works. It also explains why the modality is not interchangeable with any other way of producing a seizure, and why an answer that stops at "it induces a seizure" has answered nothing.

The integrative account now in circulation is explicitly **a proposed model** and not an established mechanism: an acute disruption of brain function, followed by a transient enhancement of neuroplasticity, with the combination of disruption and neuroplastic change rewiring the circuits implicated in depression. Write it as a model. Presenting it as settled mechanism is a correctness error, and it is the easiest one to make in this section because the model is coherent, widely

repeated and pleasant to remember. The useful discipline is to attach the evidential status to the sentence rather than to a footnote: unsettled mechanism, one plausible integrative model, one constraint that any model has to satisfy.

18.2 The indication set as the Indian guideline draws it

The Indian Psychiatric Society guideline on the use of electroconvulsive therapy sets the treatment as first-line where a rapid or definitive response is needed to avert harm to self or others, and names its exemplar situations: acute suicidal risk, agitation, **catatonia**, and deteriorating physical status secondary to a psychiatric condition. Two features of that sentence are examined. The trigger is the need for speed or certainty of response, not a diagnosis; and the guideline's own wording marks the list as open rather than closed, so it is an illustration of the trigger and not a set of four qualifying conditions.

MNEMONIC

Suicide risk, Agitation, Catatonia, Deterioration

The four situations the Indian guideline names when it places the treatment first-line. Recite the list, then immediately say that the guideline marks it non-exhaustive, because a candidate who presents four exemplars as four criteria has misread the recommendation in the direction that matters clinically.

Beyond that trigger, the same guideline enumerates indications disorder by disorder in a table, and the depression row is the spine of the Indian indication list. That row is reproduced in the comparison below rather than here. What the reader should take from the guideline as a document is its method: it was produced by consensus, with no formal systematic literature search. That is not a criticism, and it does not weaken the Indian practice position, which is what the document exists to state. It does decide where each half of an answer comes from. Effect sizes and response rates come from trials and meta-analyses; the position on when the treatment is offered in Indian practice comes from the guideline. Mixing the two, and citing the guideline for an effect size, is a sourcing error a good examiner will notice.

18.3 What each body recommends, side by side

The bodies do not say the same thing, and the divergence is not error: they are answering different questions about different populations, with different methods behind them. Reading the recommendations as one recommendation is the commonest way this material goes wrong.

ISSUING BODY AND RECOMMENDATION	POPULATION IT SPEAKS TO	POSITION, AND THE STRENGTH ATTACHED TO IT
Indian Psychiatric Society guideline on the use of electroconvulsive therapy	Any psychiatric presentation needing a rapid or definitive response to avert harm	First-line, with acute suicidal risk, agitation, catatonia and deteriorating physical status given as exemplars and the list left explicitly open
The same guideline, indication table	Major depressive disorder	Poor oral intake; high suicidal risk; high distress requiring rapid symptom remission; psychotic features; melancholic features; peripartum depression; treatment resistance; severe mixed affective features
NICE TA59 recommendation 1.1	Catatonia, and a prolonged or severe manic episode	Recommended only to achieve rapid and short-term improvement of severe symptoms, and only after an adequate trial of other treatment options has proven ineffective and/or where the condition is considered potentially life-threatening
NICE, on schizophrenia	Schizophrenia, general use	The state of the evidence does not allow general use to be recommended, which is a statement about evidence and not a safety prohibition
NICE NG222 recommendation 1.13.9	People whose depression has responded to a course	Start or continue antidepressant medication or a psychological intervention to prevent relapse; consider lithium augmentation of antidepressant medication
VA/DoD major depressive disorder guideline	Severe major depressive disorder with catatonia, psychotic depression, or need for a rapid, definitive response on medical or psychiatric grounds	Recommendation 20, a strong recommendation to offer the treatment with or without psychotherapy, on evidence the guideline itself rates very low

The last row repays a second look, because it is the cleanest available illustration of a distinction candidates blur. A strong recommendation resting on evidence the issuing body grades very low is not an inconsistency: strength encodes how confident the panel is that the benefits outweigh the harms for that population, and it can be driven by the severity of the untreated condition rather than by trial quality. The three limbs of the older NICE appraisal work the other way, and they are conjunctive rather than alternative: the aim has to be rapid and short-term improvement of severe symptoms, other options have to have failed or the condition has to be potentially life-threatening, and the patient has to have catatonia or a prolonged or severe manic episode. Rapid improvement on its own is not the threshold there.

TRAP **Citing the old technology appraisal as the current position in depression.** Its depression recommendations were superseded by the later depression guideline; only the catatonia, mania and schizophrenia limbs survive. A candidate who quotes the appraisal for depression is quoting a withdrawn recommendation, and the marks go to whoever names the right document for the right disorder rather than to whoever remembers the most recommendation numbers.

18.4 How strong the evidence is, disorder by disorder

Efficacy is not uniform across the indication list, and the evidence supporting each indication is of very different quality. The pooled analysis that remains the standard efficacy citation compared real against **simulated treatment** in depressive disorders, and separately against pharmacotherapy, in a total of eighteen head-to-head drug comparisons.

-0.91	-0.80	50%	0.55
VS SIMULATED, SES	VS DRUGS, SES	CLOZAPINE AUGMENTATION	MEMORY LOSS, SMD

The comparison against simulated treatment rests on six trials and 256 patients, with a confidence interval running from -1.27 to -0.54; the comparison against drug treatment rests on eighteen trials and 1144 participants, interval -1.29 to -0.29. Both favour the treatment significantly. Neither is a sequencing instruction. A head-to-head superiority result over pharmacotherapy is an argument against reflexively exhausting drug trials first, not an argument for reserving the modality until they are exhausted, and reading it the second way inverts what the numbers show.

In catatonia the reported figures are the highest in psychiatry and the weakest in design. Retrospective observational studies report response rates ranging from **80 percent to 100 percent**, from case series rather than randomised trials. The same review supplies the counterweight, and it has to travel with the figure: although pharmacotherapy had failed in 85 percent of the patients, the treatment improved 59 percent of the cases. Quoting the higher range alone overstates the indication.

In schizophrenia the evidence separates into two questions that are routinely conflated. For **clozapine-resistant schizophrenia**, a single-blind randomised trial found half of those given augmentation met the response criterion while none of those continuing clozapine alone did, with 47 percent responding in the crossover phase and an intention-to-treat sample numbering 39; the same report states that further research is needed on whether the improvement persists and whether maintenance treatment is required. For **treatment-resistant schizophrenia** in general, a systematic review found moderate-quality evidence of a positive effect on medium-term clinical response relative to standard care, with no clear and convincing advantage or disadvantage for other outcomes, and 14 of its 15 included studies at high risk of bias. Treating the augmentation trial as evidence for the general resistant population, or the review as evidence for the clozapine-resistant subgroup, is a correctness error in either direction.

18.5 Where it enters against the alternatives, and what has to follow it

The modality question is really a sequencing question. Each of the device-based treatments enters the pathway at a different point and for a different reason, and the accompanying figure sets all of them against the disorders they are used in and the strength of evidence behind each. What distinguishes this one is that it is the only modality in that frame with a randomised superiority result against drug treatment in depression, and the only one whose indication list is written around urgency rather than around failure.

Neurostimulation utility across disorders: all six device-based modalities in one frame, placed by what must have failed before each is offered, by the indications it has earned, and by the strength of the statement that grants each one.

SIX MODALITIES, THREE QUESTIONS: WHERE IT ENTERS, WHAT IT HAS EARNED, WHERE IT FAILS — read the last column as hard as the one before it

MODALITY and its physical logic	WHERE IT ENTERS, AND WHOSE STATEMENT SETS IT prior failure is counted in a different unit on every row	THE INDICATIONS IT HAS EARNED, AND ITS GRADE the grades are not interchangeable across disorders	NEGATIVE, NULL OR UNGRADED the rungs candidates leave out
ECT convulsive	IPS ECT guideline 2023: FIRST-LINE where a rapid or definitive response is needed to avert harm. Exemplars: acute suicidal risk, agitation, catatonia, deteriorating physical status; the list is explicitly non-exhaustive. Consensus, with no formal systematic literature search. NICE TA59 rec 1.1 binds THREE LIMBS TOGETHER: rapid and short-term improvement of severe symptoms; other options failed and/or the condition potentially life-threatening; and catatonia, or a prolonged or severe manic episode.	DEPRESSION Real against simulated ECT: SES -0.91, from 6 trials and 256 patients. Against pharmacotherapy: SES -0.80, from 18 trials and 1144 participants. VA/DoD rec 20 is strong FOR, on evidence the panel itself rated very low, in severe MDD with catatonia, psychotic depression, or a need for a rapid, definitive response. SCHIZOPHRENIA Clozapine-resistant: response 50% with ECT augmentation against 0% alone, 47% on crossover, ITT n=39. CATATONIA 80% to 100%, retrospective observational only.	Treatment-resistant schizophrenia generally: only moderate-quality evidence of medium-term response, with 14 of 15 studies at high risk of bias. The same catatonia review: pharmacotherapy had failed in 85% and ECT improved 59% of cases. NICE does not recommend general use in schizophrenia, on the state of the evidence, not on safety. TA59's depression limb was replaced by NG222.
rTMS sub-convulsive	IPS rTMS guideline 2023: an ADJUNCT to conventional treatment across the conditions reviewed, and in TRD augmentation beats stand-alone rTMS. VA/DoD rec 17: after partial or no response to two or more adequate pharmacologic trials. Weak, very low. RANZCP 2020 item 1.6: a reasonable number of adequate trials of BOTH drug AND psychological treatment, with no number fixed. Graded CBR, consensus and not evidence.	DEPRESSION graded STRONG: effect sizes 0.302 to 0.83, response odds ratios 3.26 to 3.64, remission 2.45 to 4.63. BIPOLAR DEPRESSION moderate: effect size 0.302, OR 2.72. SCHIZOPHRENIA negative symptoms SMD 0.49 to 0.64: high-frequency left DLPFC and more than 10 sessions beat sham. Resistant auditory hallucinations SMD 0.24 to 0.51, over 4 to 40 sessions given up to 8 weeks. OCD moderately positive: Y-BOCS SMDs 0.501 to 0.79, over 10 to 30 sessions across 1 to 12 weeks. GAD effect sizes are 1.45 to 1.87, with comorbid depression at SMD 1.65.	Panic disorder: not found effective. Clozapine-refractory schizophrenia: three RCTs of augmentation, no significant effect on positive or negative symptoms or on cognition. Tobacco use disorder is positive for craving and consumption; other substance use is not consistent. NOT recommended in acute suicidality. NICE: may be used with NORMAL arrangements for clinical governance and audit. MOST effect sizes above are for rTMS added to something else; verify each estimate.
tDCS subthreshold	No prior-failure count is set by any source read here. NICE puts tDCS for depression under SPECIAL arrangements for clinical governance, consent, and audit or research, one step below the position it gives rTMS. No Indian guideline sets it a place in the ladder at all.	DEPRESSION is the only disorder with a stated position, and both named trials are null on their own question. ELECT-TDCS: non-inferiority to escitalopram NOT shown over 10 weeks, with more adverse events; a single-centre trial. DepressionDC: the main trial showed no beneficial anti-depressant effect of active tDCS over sham.	No stated position in any other disorder. The mechanism is subthreshold polarisation, so the anode-excites heuristic cannot be written as a law: mechanisms vary with the current and its application.
IMPLANTED DEVICES DBS and VNS	DBS in OCD, US FDA HDE H050003, 10 February 2009: adults with chronic severe treatment-resistant OCD who failed AT LEAST THREE SSRIs, adjunct to medication. Humanitarian pathway on a probable-benefit standard, NOT effectiveness. VNS in depression, US FDA PMA P970003/S050, 15 July 2005: FOUR OR MORE adequate antidepressant treatments, at 18 or older, in a major depressive episode, chronic or recurrent. Eight guidelines: DBS only after all options have failed.	OCD carries the DBS regulatory position and DEPRESSION the VNS one, and neither rests on a positive controlled trial. DBS in depression: BROADEN found no significant difference between active and sham at six months and was halted on an interim futility analysis. VNS: acute D-02 responders 15.3% (17 of 111) active against 10.0% (11 of 110) sham, p=0.238; the 12-month uncontrolled phase gave response 29.8% and remission 17.1%.	VA/DoD recommends AGAINST DBS for depression outside research at strong strength, and suggests against VNS outside research at weak strength. NICE puts implanted VNS under special arrangements. One guideline in that same review does not recommend DBS beyond a research setting. RECOVER, the largest neuromodulation trial in psychiatry to date, did not meet its primary endpoint.
MST convulsive	Placed on no prior-failure ladder by any source read here. The comparator in both randomised trials is ECT, because the claim under test is not that seizures help but that this way of producing them costs the patient less.	CREST-MST, a confirmatory randomised non-inferiority trial, 239 randomised: remission 22.5% with MST against 27.8% with ultrabrief ECT, a 5.3% difference favouring ECT, with non-inferiority established; worsening of autobiographical memory 2.7% against 17.3%. BIPOLAR DEPRESSION CORRECT-BD pilot, n=55 randomised: remission 5/25 (20%) against 6/20 (30%), memory worsening 2/28 (7.1%) against 6/27 (22.2%). Not powered for efficacy.	Non-inferiority is not equality: the remission point estimate favoured ECT in both studies. The claim that MST seizures are less robust than ECT seizures rests on animal evidence only. No source read here states the disorder or population of the confirmatory trial, so this frame names none; only the pilot's own report names bipolar depression.
THETA-BURST AND ACCELERATED patterned rTMS	Placed on no prior-failure ladder by any source read here. VA/DoD rec 18 declines to recommend either for or against theta-burst stimulation in major depressive disorder, on insufficient evidence of very low certainty.	DEPRESSION THREE-D: iTBS non-inferior to 10 Hz rTMS in treatment-resistant depression, adjusted difference 0.103, lower 95% CI -1.16, against a pre-specified margin of 2.25. Stanford Neuromodulation Therapy: MADRS reduction 52.5% active against 11.1% sham at 4 weeks, 29 treated of 32 enrolled, at a planned interim analysis. No stated position in any other disorder.	The much-quoted SAINT remission of about 90% and the IPS guideline's 86.4% are two reported figures for the SAME OPEN-LABEL protocol, not two designs; neither is the randomised 52.5% MADRS reduction at 4 weeks. Attribute each figure to its document; never merge. A non-inferiority result licenses substitution on time, not a claim of greater efficacy.

THE TRAP: THE ENTRY COUNTS IN COLUMN TWO ARE IN DIFFERENT CURRENCIES AND DO NOT CONVERT

Three selective serotonin reuptake inhibitors is a count of ONE drug class for ONE indication. Four or more adequate antidepressant treatments counts treatments of any class, and adequate qualifies the response as well as the treatment. Two or more adequate pharmacologic trials is a third unit, and RANZCP fixes no number while also requiring a failed psychological treatment. An unattributed threshold is right only by accident, so name the body in the same breath as the number.

ACTIVE-TREATMENT NETWORK COMPARISONS, AND WHERE NO DIRECT COMPARISON EXISTS

A NETWORK analysis reviewed by the IPS rTMS guideline, which pools direct with indirect evidence and is never the result of a direct trial, found ECT in one specified form of delivery associated with higher response than high-frequency left rTMS, than continuous theta-burst stimulation and than deep TMS; that form belongs to the ECT and neurostimulation notes.
No trial read for this chapter compares tDCS directly against rTMS, so the only comparison between those two is the position NICE gave each, one step apart.
Efficacy and acceptability are separate axes, and this frame carries the efficacy one alone; an answer that reports only it is describing half the choice a patient makes.

DECLARED GAP, NOT FILLED: THE INDIAN POSITION FOR FIVE OF THE SIX MODALITIES

rTMS: no CDSCO classification entry, no Indian product or import licence for a named system, and no Indian indication-specific authorisation appears in any source read here, so a foreign clearance list must not be read across and the chapter does not assert that rTMS is approved in India for anything.
tDCS: transcranial electrical stimulation systems are classified by CDSCO at Neurological serial 127, Class B, which is classification and not approval, and no Asian country except Singapore and South Korea has approved such devices. No Indian clinical practice guideline sets indications or a place in the ladder for tDCS.
DBS: the deep brain electrical stimulation system is listed by CDSCO at Neurological serial 33, Class D, again a classification recording no approval or indication for use. Whether any Indian centre implants for a psychiatric indication, any product licence, any authorisation, and the cost in rupees, are all undocumented.
MST is not documented as available in India, and the Indian position on accelerated iTBS and imaging-targeted protocols is undocumented in the same way: no centre report, no Indian trial, no cost, and no statement on whether the imaging-targeting step is feasible in routine Indian services.

WHAT THIS PLATE DELIBERATELY DOES NOT CARRY. The procedural act for every modality named here belongs to the ECT and neurostimulation notes and is absent from this frame by design: electrode placement, stimulus dosing, motor-threshold referencing, coil specification and the peri-procedural apparatus. This frame is utility alone.

COLOUR KEY

- teal = a stated guideline or regulatory position, and the strength it carries
- grey = no position stated in the sources read here, and the boundary note
- coral = where the position is negative or null, and the trap that follows
- dashed outline = a declared absence in the sources read here

Fig 37.9 Neurostimulation utility across disorders: six modalities placed by entry point, by indication, and by the strength of the statement that grants each one. The entry column is a set of thresholds and not a sequence, because the counts are in different currencies and do not convert: no failure count at all for ECT where a rapid or definitive response is needed to avert harm, three limbs bound together in NICE TA59, two or more adequate pharmacologic trials for rTMS on a weak recommendation, three selective serotonin reuptake inhibitors for deep brain stimulation in obsessive-compulsive disorder, and four or more adequate antidepressant treatments for vagus nerve stimulation. Each modality is then graded disorder by disorder with its negative rungs printed beside its positive ones: rTMS is null in panic disorder and in clozapine-refractory schizophrenia, both named tDCS depression trials are null, and the VA/DoD guideline is against deep brain stimulation and vagus nerve stimulation outside research. ECT is the only modality in the frame with a randomised superiority result against drug treatment in depression. The Indian position is a declared absence for five of the six, and the procedural act for all six belongs to the ECT and neurostimulation notes. (IPS ECT and rTMS guidelines 2023; NICE TA59, HTG396, HTG382, HTG551; VA/DoD 2022; RANZCP 2020; UK ECT Review Group; CREST-MST; CORRECT-BD; THREE-D; Stanford Neuromodulation Therapy; US FDA HDE H050003 and PMA P970003/S050; CDSCO.)

A course is a treatment episode, not a treatment plan, and the aftercare decision is examined more often than it is taught. Where depression has responded to a course, the current NICE depression guidance directs that antidepressant medication or a psychological intervention be started or continued to prevent relapse and provide ongoing care, and that lithium augmentation of antidepressant medication be considered. Read the second limb precisely: the augmentation offered for consideration is of the antidepressant, and the modal is permissive, not directive.

GOOD TO REMEMBER

The commonest omission on a real ward is not in the decision to treat, it is in what is written on the discharge summary the week the course ends. A response achieved and then left unprotected is the predictable relapse, and the guidance names two protective options and one augmentation to consider, rather than leaving the choice to habit.

18.6 Cognitive adverse effects, and the gap in how they are measured

This is the half of the answer that separates a pass from a good mark, because the cognitive evidence is genuinely two-sided and most candidates give only one side. The Indian guideline names **retrograde amnesia** as one of the most distressing adverse effects and, in the same breath, as one that is difficult to measure using objective cognitive tests, and it places that statement in its guidance on monitoring during a course rather than in its guidance on consent.

The largest pooled analysis of objective cognitive testing found a course of treatment followed by recovery and then improvement past baseline, on twenty-four cognitive variables:

- From 0 to 3 days after treatment, a significant decrease in 72 percent of the variables, with effect sizes from -1.10 to -0.21.
- Between 4 and 15 days, all but one confidence interval included zero.
- Beyond 15 days, no negative effect sizes at all, and 57 percent of the variables significantly improved, with effect sizes from 0.35 to 0.75.

That is reassuring and it is incomplete, and the incompleteness is stated by the authors themselves: no standardised retrograde amnesia test was identified anywhere in the pooled studies. The recovery finding therefore does not cover the domain the Indian guideline calls the most distressing.

PITFALL

Answering a patient who reports lost memories of their own life by citing the objective recovery data. The measured domains recovered; the domain the patient is describing was not among the standardised measures. Offering the reassurance anyway tells a patient their experience contradicts the evidence when in fact the evidence is silent on it, and it is the fastest way to lose a person's trust in a treatment that has just worked.

What does exist for that domain is a separate meta-analysis of **autobiographical memory** measured against controls, pooling nine studies, 432 patients and 173 controls in adults with unipolar or bipolar moderate-to-severe depression, with maintenance courses excluded.

Immediately after treatment the patients had greater autobiographical memory loss than the controls, a moderate effect, with an interval from 0.35 to 0.75. From the patients' own side, a systematic review of patient perspectives found reported persistent memory loss ranging from **29 percent to 55 percent** across studies, and, unlike reported benefit, that rate did not appear to depend on whether the study was clinician-based or patient-based. The convergence matters: this is not a complaint that disappears when you ask a clinician instead.

18.7 Cardiac and systemic risk, stated at the right size

The systemic risk of the modality is small, real, and almost always misquoted in one of two directions. The largest meta-analysis, pooling 82 studies, 106,569 patients and 786,995 treatments, found the three most commonly reported **major adverse cardiac events** to be acute heart failure, arrhythmia and acute pulmonary edema. The pooled incidences were 24 per 1,000 patients for acute heart failure, **25.83 per 1,000 patients for arrhythmia** and 4.92 per 1,000 patients for acute pulmonary edema. Restated against treatments rather than patients they fall to 2.44, 4.66 and 1.50 per 1,000 ECT treatments respectively, and the difference between those two denominators is the whole point: a patient receiving a course is exposed repeatedly, so the per-patient figure is the one that answers "what is my risk", and the per-treatment figure is the one that answers "what is the risk of this session".

One further caution about that literature, and it is a correctness point rather than a nuance. The pooled mortality construct in the same review is all-cause death within 30 days of treatment, which is not the same thing as death attributed to the treatment. Writing it as a mortality rate for the modality overstates it, and an examiner who knows the source will read that as a failure to read it.

18.8 Regulation of the modality in India, and what is actually practised

Indian law regulates this modality directly, which is unusual and therefore heavily examined. **Unmodified electroconvulsive therapy** means the treatment given without muscle relaxants and anaesthesia, and Section 95(1) of the Mental Healthcare Act 2017 prohibits it for any person with mental illness, and prohibits the treatment in minors. The prohibition in minors is not absolute: Section 95(2) provides that notwithstanding sub-section (1), if the psychiatrist in charge of a minor's treatment is of the opinion that the treatment is required, it shall be done with the informed consent of the guardian and prior permission of the concerned Board. Separately, Section 94(3) of the same Act provides that nothing in its emergency-treatment section permits a medical officer or psychiatrist to use the treatment as a form of emergency treatment, while emergency treatment itself is limited to 72 hours, extendable to seven days in a declared disaster or emergency.

IN INDIA

Hold the two rules together and a real clinical decision falls out of them. The Indian guideline places the treatment first-line precisely where a rapid response is needed to avert harm, which is exactly the presentation that arrives out of hours and feels like an emergency. The statute closes the emergency-treatment route for this modality. So the lawful path to treating that patient quickly is the consent or supported-admission pathway, started at once rather than after the emergency window has been used up on something else. The clinician who plans for the consent route on the first evening treats sooner than the one who reaches for the emergency provision and discovers it is unavailable.

Regional practice diverges from the northern-hemisphere guidance in a way that is worth stating plainly in an Indian answer. Across South Asia the treatment is widely practised, most commonly delivered with brief-pulse devices in its modified form; schizophrenia, not affective illness, is the commonest indication in the region; electroencephalographic monitoring of seizures is rarely practised; and practice guidelines for the modality are available only in India.

TRAP **Quoting the British position on schizophrenia in an Indian answer without naming the divergence.** One body declines to recommend general use in schizophrenia on the state of the evidence; in this region schizophrenia is the commonest indication for which the treatment is given, and the Indian guideline's indication table is written accordingly. Both are true statements about different things, and the marks go to the candidate who states both and labels which is which, not to the one who picks the tidier of the two.

An answer on this modality is complete only when it carries the trigger, the evidence at its true strength in each disorder, the memory cost including the domain nobody has measured well, and the Indian statute that governs how it may lawfully be given.

19 · Repetitive transcranial magnetic stimulation (rTMS): mechanism, protocols and indications

A ten-mark answer on rTMS is an answer about utility, not about apparatus. Repetitive transcranial magnetic stimulation is the neuromodulation technique most likely to reach an ordinary outpatient, and the marks fall on four questions: what the magnetic field does to cortex, where the modality sits once drugs have failed, which disorders it has earned an indication in and on what strength of evidence, and what happens to the patient once the course finishes. The delivery technique itself, and the machinery of safe administration that surrounds it, are set out in the ECT and neurostimulation notes; what follows is the modality and its utility across disorders.

The commonest way to lose these marks is to answer as though rTMS were one treatment with one indication. It is a family of protocols whose evidence is graded disorder by disorder, at strengths that run from strong to frankly negative, and the bodies that recommend it do not agree on how much treatment should have failed before it is offered. Separate the disorders, attribute the guidelines, and the answer organises itself.

19.1 What the field does, and the sentence that defines the modality

In **transcranial magnetic stimulation** the stimulator is discharged to produce a strong time-varying magnetic field, briefly peaking at **1 to 2.5 Tesla** and lasting 1 ms at most. A field of that strength crosses scalp and skull with little attenuation, and that is the property that makes the technique non-invasive. Non-invasive is not the same as unfelt: scalp discomfort, scalp pain and headache are recognised effects of the stimulation itself, and they belong in the consent conversation rather than in a claim that the treatment cannot be felt. Where the field meets conducting tissue it induces an electric current, and where that induced current is large enough it depolarises cortical neurons directly rather than through a peripheral route.

A single pulse probes the motor system and is a neurophysiological measurement tool. What makes the technique therapeutic is repetition: pulses delivered repeatedly within a session, and sessions repeated over weeks, shift cortical excitability in a direction that outlasts the stimulation itself. That outlasting shift, not the individual pulse, is what the treatment is betting on, and it is the reason a course is counted in sessions rather than in minutes of stimulation. The frequency of delivery influences the direction of that shift, which is why the evidence below is reported as high-frequency or low-frequency stimulation to a named cortical target rather than as rTMS in the abstract. Frequency does not settle the direction on its own: intensity, the pattern in which the pulses are grouped, the amount of stimulation delivered, the target and the state of the cortex at the time all bear on which way the after-effect goes, and the parameters themselves belong to the procedural notes. Treat the pairing of high frequency with excitation and low frequency with inhibition as a heuristic that organises the literature, not as a law.

RULE **Therapeutic rTMS is deliberately sub-convulsive.** The seizure is the event the treatment is designed to avoid, not the event it is designed to produce. That single sentence separates rTMS cleanly from convulsive therapy and from magnetic seizure therapy, whose purpose is the opposite, and every safety statement made about rTMS follows from it.

19.2 Where the modality sits once drugs have failed

The Indian Psychiatric Society issues its own clinical practice guideline for the therapeutic use of rTMS in neuropsychiatric disorders, and its governing statement about placement is not about any single disorder. rTMS is to be used as an **adjunct** to other conventional treatments, and the guideline records that this is how it had been given in almost every meta-analysis it reviewed, across almost every condition it examined. The point is methodological before it is clinical: most of the effect sizes quoted for rTMS are effect sizes for rTMS added to something else, and reading them as the performance of rTMS given alone overstates them. Check the individual estimate before treating it as evidence for augmentation.

RULE **The evidence prices rTMS as an addition, not a substitution.** In treatment-resistant depression specifically, the same guideline finds response to rTMS better when it is added as an **augmentation** to antidepressants than when it is given stand-alone. The prescription that continues alongside the course is part of the treatment being tested.

PITFALL

Stopping or tapering the antidepressant when the rTMS course begins, on the reasoning that the patient is now getting something better. The comparison behind the guideline's own position was augmentation against stand-alone treatment, and it favoured augmentation. A patient whose drug is withdrawn at the first session is no longer receiving the treatment the evidence describes.

Where the bodies genuinely differ is on how much failure should precede the referral, and the differences are not cosmetic. Read the table below across the third column as much as the second: a threshold carries the authority of the statement that sets it, and two of these four are explicit that their statement is weak.

BODY	WHERE IT PLACES RTMS	STRENGTH OF THAT STATEMENT
Indian Psychiatric Society rTMS guideline	An adjunct to conventional treatment across the conditions reviewed, with the depression evidence graded strong	Guideline recommendation resting on graded evidence
VA/DoD major depressive disorder guideline	Suggests offering rTMS to patients showing partial or no response to **two or more adequate pharmacologic treatment trials**	Weak recommendation, very low certainty
RANZCP mood disorders guideline	Before rTMS is considered, failure to respond to a reasonable number of adequate trials of both pharmacotherapy and psychological treatment	Graded CBR, consensus-based rather than evidence-based
NICE	rTMS for depression may be used with normal arrangements for clinical governance and audit	Short-term efficacy adequate, clinical response variable

TRAP **Quoting a single line of therapy for rTMS as though the field agreed on one.** One body counts failed drug trials and fixes a number. Another requires failed drug and failed psychological treatment but deliberately fixes no number, and grades that requirement as consensus rather than evidence. The regulatory clearance that first put the device into practice was written against a different bar again from either. An unattributed threshold is therefore right only by accident: state whose threshold you are using in the same breath as the number.

19.3 Depression: the indication the modality rests on

The Indian guideline grades the evidence for rTMS in depression as strong, with pooled effect sizes for improvement in depression severity spanning **0.302 to 0.83**. It also gives the two dichotomous outcomes an examiner is most likely to ask for: pooled odds ratios for response between 3.26 and 3.64, and for remission between 2.45 and 4.63. Quote both kinds of number if the question allows it, because they answer different questions. The effect size says how far the depression score moves; the odds ratio compares the odds of crossing a response or a remission threshold under active stimulation against the odds under sham. It is not a statement of how

many times more likely this patient is to respond, because an absolute probability needs the sham event rate, and no such rate is reported here. A wide effect-size range with a consistent odds ratio is exactly what a heterogeneous but genuinely active treatment looks like.

United Kingdom guidance arrives at a compatible destination by a different route, and its wording is worth memorising rather than paraphrasing. NICE judges the evidence on short-term efficacy adequate although the clinical response is variable, and states that rTMS for depression may be used with normal arrangements for clinical governance and audit. Both halves matter. The permissive modal is not an endorsement of first-line use, and the phrase about normal arrangements is a positioning statement rather than an efficacy claim: it says the procedure needs no special oversight, not that it works better than the alternatives. Note also that the depression guideline itself sets no rTMS recommendation of its own. NICE NG222 cross-refers to the interventional-procedures guidance IPG542, so a candidate who cites the depression guideline as the source of an rTMS recommendation is in fact citing a signpost.

19.4 What the acute course actually buys

A course buys a response; it does not settle the illness. Among patients who respond to rTMS for depression at the end of the acute course, the proportion still holding that **sustained response** falls steadily across the following year.

66.5%	52.9%	46.3%
THIRD-MONTH RESPONSE HELD	SIXTH-MONTH RESPONSE HELD	TWELFTH-MONTH RESPONSE HELD

Read those three figures as one statement rather than as three facts. Roughly two thirds of initial responders are still responders a quarter of a year later, and rather under half of them at a year, with confidence intervals that widen as the follow-up lengthens because fewer studies report the later points. Two consequences follow for how the treatment is offered. First, the acute course is a planning point rather than a discharge point, and the maintenance question has to be raised before the last session rather than after the relapse. Second, these three figures measure the durability of response among patients who responded acutely, and response and remission are distinct outcomes, so no claim about durable remission can rest on them. No figure for sustained remission is reported here at all, and the honest answer says so rather than reusing these proportions for it.

> **GOOD TO REMEMBER**
>
> Book the review before the course ends, not after it. The attrition of response is steepest in the first half of the year, so a patient discharged to routine follow-up at three months is being reviewed on the shoulder of the curve rather than on its plateau. Telling the patient the shape of that curve at the outset also protects the alliance if the response fades.

19.5 The indication ladder beyond unipolar depression

The remaining indications are graded individually and the grades are not interchangeable. The examinable skill is to reproduce the ladder with each rung labelled by its own strength, including

the rungs where the evidence is negative, since an answer that lists only the positive indications is describing a marketing brochure rather than a guideline.

CONDITION	EVIDENCE POSITION	WHAT THE NUMBERS AND THE COURSE LOOK LIKE
Acute bipolar depression	Moderate and positive	Effect size 0.302, odds ratio for response 2.72
Obsessive-compulsive disorder	Moderately positive	Pooled Y-BOCS SMDs 0.501 to 0.79, across 10 to 30 sessions given over 1 to 12 weeks
Generalised anxiety disorder	Significant effect	Pooled effect sizes 1.45 to 1.87; depression accompanying the anxiety improves too, at SMD 1.65
Panic disorder	Not found effective	No effect demonstrated on the pooled analysis
Treatment-resistant auditory hallucinations	Moderate and positive	Pooled SMDs 0.24 to 0.51, across 4 to 40 sessions delivered up to 8 weeks
Negative symptoms of schizophrenia	Moderate to large and positive	SMD 0.49 to 0.64; high-frequency stimulation to the left DLPFC and more than 10 sessions superior to sham
Clozapine-refractory schizophrenia	No significant effect	Three randomised trials of rTMS augmentation, not significant for positive symptoms, negative symptoms or cognition
Tobacco use disorder	Positive	High-frequency rTMS targeted at the left DLPFC reduces both craving and the amount consumed
Other substance use disorders	Not consistent	The evidence does not converge across substances

Two rows on that ladder repay closer reading. The schizophrenia entries are not one finding: negative symptoms carry the strongest signal in the disorder, resistant hallucinations a smaller but real one, and **clozapine-refractory schizophrenia** carries no significant effect at all on any of the three outcome domains examined. That last row is the one candidates forget, and it is precisely the clinical situation in which a desperate team is most tempted to add a device. Treatment resistance in schizophrenia and the place of clozapine within it are handled as a topic of their own; what belongs here is only that adding rTMS on top of clozapine did not separate from sham.

The obsessive-compulsive row carries a disagreement that should be stated rather than resolved. The Indian guideline's own reading is that the evidence for deep TMS in obsessive-compulsive disorder is inconclusive and insufficient, while the regulatory record reproduced inside that same

document lists a **deep TMS** clearance for obsessive-compulsive disorder in 2018. These are different currencies rather than contradictory facts: a regulator asks whether a device is reasonably safe and effective for a labelled use, a guideline panel asks whether pooled trial data reach a grade. Print both, attributed to their sources, and say which question each is answering.

TRAP **Writing that rTMS works in anxiety disorders.** It has a significant effect in **generalised anxiety disorder**, with the depression that accompanies it improving as well, but it was not found effective in panic disorder. Candidates generalise across a diagnostic block because the ladder is memorised as a list of positives, and the negative rungs are where an examiner separates a memorised list from an understood one.

19.6 Where the modality stops, and how it compares with the alternatives

The Indian guideline draws one explicit boundary: it does not recommend rTMS for acutely suicidal patients. That is a positioning statement about tempo rather than about efficacy in depression, and it is the single most examinable sentence in the Indian document, because it identifies the presentation in which this modality is not the answer however strong its depression evidence is elsewhere.

In a network meta-analysis reviewed by the same guideline, in the comparisons between two active treatments, ECT was associated with higher response than high-frequency left rTMS, than continuous theta-burst stimulation, and than deep TMS. A network estimate pools direct and indirect evidence, so report it as a network comparison and never as the result of a trial that compared the two treatments directly. The analysis specified one particular form of ECT delivery, and that specification belongs to the ECT and neurostimulation notes rather than here. A separate analysis in the same reviewed set reported bilateral rTMS more acceptable than ECT, and, in treatment-resistant depression, more effective than deep brain stimulation. Efficacy and acceptability are separate axes; the two findings sit beside each other rather than against each other, and an answer that reports only the first is describing half the choice a patient is actually making.

IN INDIA

The controlling document for this modality is the Indian Psychiatric Society's own rTMS guideline, and it settles two decisions a candidate should be able to state without hesitation. First, the Indian guideline places rTMS as an adjunct to conventional treatment rather than a substitute for it, and that is this guideline's position rather than a universal restriction, since rTMS is not confined to augmentation everywhere. Keep the concomitant antidepressant or antipsychotic stable through the course where that is clinically feasible; if it has to change, the safety of continuing is reviewed rather than assumed, and the parameter side of that review belongs to the procedural notes. Second, it explicitly does not recommend rTMS in acute suicidality, so the acutely suicidal presentation is the boundary at which this modality stops and the alternatives are weighed on their own evidence rather than on an extension of this one.

19.7 Safety, stated at the right size

Safety belongs inside a utility answer rather than appended to it, because the whole clinical case for rTMS is that it delivers a moderate effect at a very low cost in risk. Seizure is the serious adverse event, and its measured rate is very low: a large safety survey reported **7 seizures per 100,000 sessions** overall, from 24 seizures in over 300,000 sessions, rising to 33 per 100,000 sessions among people carrying an identified risk factor. The consensus that reports those figures is careful about them: the survey data cannot be considered more than approximate and may carry reporting biases, so quote the order of magnitude with the caveat attached rather than the decimal with false precision.

The controlled evidence in depression separates the serious from the merely common, and that separation is the shape of the answer.

- Across 53 sham-controlled trials in depression there was no increased risk of serious adverse events.
- There was no increased risk of drop-outs attributable to an adverse event, so tolerability did not differ from sham on the measure that matters for completing a course.
- There was a significantly greater risk of mild, transient, non-serious events, which is where the real difference from sham sits and what consent should describe.
- The same guideline reports no signal of affective switch with rTMS protocols used to treat depression, which is the question a bipolar-spectrum patient's team will ask first.

19.8 The regulatory picture, and rTMS in Indian practice

United States clearance began in depression and widened by indication over the following sixteen years: 2008 for the first TMS system in major depressive disorder, 2013 for the first deep TMS system in the same indication, 2018 for deep TMS in obsessive-compulsive disorder and separately for the first theta-burst-capable system in major depressive disorder, 2020 for smoking cessation, 2021 for deep TMS in major depressive disorder with anxiety, 2022 for an accelerated protocol system in major depressive disorder, and 2024 for major depressive disorder in adolescents aged 15 to 21. Theta-burst and the accelerated protocols are substantial topics in their own right; here they matter only as the shape of the widening, which has moved from one diagnosis, to new diagnoses, to new populations.

None of that is an Indian authorisation, and the distinction has to be made explicitly rather than left to the reader. No device classification, product or import licence, or indication-specific Indian authorisation for any named rTMS system is stated in this account, and a foreign clearance list must not be read across as one. The defensible examination sentence is that rTMS is in established clinical use in India while the Indian regulatory position is not something to assert from another country's labelling.

What is documented is the service picture. TMS services began to be offered by private practitioners in India from the mid-2000s, initially concentrated in metropolitan cities, and treatment centres are now established in smaller cities as well; the concerns that persist are variability in standards of care, high treatment costs, and limited accessibility for the general

population. Training infrastructure has grown alongside the services: a one-year fellowship in **non-invasive brain stimulation** has been offered since 2016, aimed at developing clinical and research expertise in the area. For an Indian answer, that pairing is the honest one to give, because it names both the spread of the modality and the unevenness of the standards under which it has spread.

MNEMONIC

Disorder, Threshold, Adjunct, Durability

The four things a modality answer on rTMS must settle: which disorder, and therefore which grade of evidence applies; whose threshold of prior failure is being quoted; that the treatment is added to conventional care rather than substituted for it; and what proportion of responders are still responding a year later.

The closing position is best stated without inflation, and a recent Indian review, Praharaj in the Indian Journal of Psychiatry in 2025, supplies it whole rather than by halves: the exact role of TMS in the treatment of psychiatric disorders remains uncertain, although it appears to offer benefit in mild to moderate cases, particularly for the short-term treatment of depression. Print that as the review's own position, with its author and year attached, and then set the guideline evidence beside it rather than in place of it, because the two are grading different things. The review is grading severity of illness. The guidelines are grading prior treatment failure, and prior failure is not a severity band: a patient can fail two adequate trials of moderate illness, and a patient with severe illness can be drug-naive. The Indian guideline grades acute depression strong and finds augmentation superior to stand-alone rTMS in treatment-resistant depression, and the VA/DoD statement is written for patients with partial or no response to two or more adequate pharmacologic trials. None of that says anything about how severe the illness was, so none of it refutes the review's severity clause. Hold both, each attributed to the body stating it, and note that the grade everywhere else runs disorder by disorder. That is not a weak answer. It is the accurate one, and it is what lets a candidate hold the strong depression grading and the negative clozapine-refractory row in the same paragraph without contradiction.

rTMS is an adjunct with its strongest evidence in depression, a disorder-by-disorder grading everywhere else, no recommendation in acute suicidality, and a response that has to be maintained rather than assumed.

20 · Transcranial direct current stimulation (tDCS)

This is the modality that is easiest to describe and hardest to place. Transcranial direct current stimulation passes a weak, steady current between contacts on the scalp. It is simple to deliver and it has been trialled across most psychiatric diagnoses, and that combination is precisely why a full-length answer on tDCS is not an answer about promise. The marks sit in four places, and a candidate who supplies only the first loses most of them: what the technique is, in a family that has an explicit boundary; what it does to a neuron, which is not what the seizure-

based and magnetic techniques do; what the best-designed depression trials returned when they asked the question properly; and where guidance and regulators, having read those trials, have actually put it.

The procedural technique is set out in the ECT and neurostimulation notes and is not repeated here. What follows is the modality itself and the honest evidence position across disorders, which is a different examination question and is answered with different material.

20.1 What the technique is, and the family it belongs to

tDCS belongs to a defined family, **low-intensity transcranial electrical stimulation**, and the family is bounded by an explicit dose envelope rather than by an indication or a mechanism. That is an unusual way to define a treatment and it is worth pausing on: the boundary is a set of physical limits on the current delivered, so anything inside those limits belongs to the family and anything outside it is a different technique with a different safety literature. The safety and guidance paper for low-intensity transcranial electrical stimulation sets a ceiling on total current, a frequency span, and a ceiling on how long a single session may run.

4 mA or less	0 to 10,000 Hz	up to 60 minutes per session
TOTAL INTENSITY CEILING	FREQUENCY SPAN OF THE FAMILY	LONGEST SINGLE SESSION

The frequency span is the limb that explains the family's shape. Direct current sits at the zero-frequency end of it, which is what the middle word of the technique's name means: the current does not oscillate, it holds a constant direction for the whole session. The alternating-current members of the same family occupy the rest of the span, and for those the intensity ceiling is expressed peak-to-peak rather than as a steady value, because an oscillating waveform swings either side of zero and its amplitude has to be quoted across the full swing. One envelope therefore holds several techniques that look different at the bedside and are grouped within one consensus safety framework for low-intensity transcranial electrical stimulation.

Two cautions about the envelope. It is a definitional and safety boundary agreed by the field, not a legal classification that holds in every jurisdiction, and it is not a therapeutic prescription: nothing in it says what current a given patient should receive, and how a session is actually configured belongs to the procedural chapter named above. And a boundary drawn around a family is not evidence about any member of it. The envelope tells you what tDCS is; it tells you nothing at all about whether it works.

20.2 The mechanism, and why it is the answer's spine

tDCS acts by **subthreshold neuronal polarisation**, which is to say it does not itself generate action potentials. The current shifts the **membrane potential** of neurons in the field without directly bringing them to threshold, and thereby changes how likely they are to fire in response to synaptic input they are already receiving. The safety and guidance paper states this as the mechanistic contrast with rTMS and with ECT, and it is the single most examinable sentence in the topic.

RULE **tDCS does not directly trigger action potentials. It shifts membrane potential and changes how likely neurons are to fire in response to synaptic input they are already receiving.** Every other property of the modality follows from this. A technique that biases ongoing activity rather than driving it produces no directly evoked motor response to titrate against, unlike a suprathreshold technique, and its effects may be state-dependent, varying with what the cortex is already doing while the current is applied. Write this sentence first and the rest of the answer organises itself around it.

Two corollaries follow from the definition rather than from any separate finding, and stating them as derivations is safer than presenting them as results. First, the effect can be expected to be state-dependent: if the current only changes a probability of firing, then what the neuron is already doing is part of the outcome, which is why the same delivered current need not be the same intervention in two different patients or in the same patient on two different occasions. Second, the distance between this mechanism and a clinical response is very long. A membrane-potential shift is several inferential steps away from a change in mood or in a symptom score, and that gap is where the modality's evidence problem lives.

20.3 Polarity, and why the classroom rule is not a law

Every candidate has met the rule that the anode excites and the cathode inhibits. It is a useful first approximation and it is how the technique is usually introduced. It is also the single most confidently over-stated fact in this topic. The same passage that establishes the subthreshold mechanism qualifies it directly: the mechanisms of low-intensity transcranial electrical stimulation vary with the properties of the current applied and with how that current is applied, so the polarity heuristic cannot be printed as a universal rule.

TRAP **Writing "anodal stimulation is excitatory, cathodal is inhibitory" as a law of the modality.** Candidates make this error because the heuristic is how the technique is taught, because it is easy to remember, and because it has the satisfying symmetry of a real physical law. The source that establishes the mechanism explicitly qualifies the direction of effect as varying with the properties of the current and with the way it is delivered. The safe examination form is to state the heuristic as a heuristic, say what it is derived from, and then state the qualification in the same breath. An examiner who has read the current guidance is looking for the qualification, not for the rule.

20.4 Depression: the two named trials

Depression is where the modality has been tested hardest, and two trials are named here because each was designed to answer a different question and each returned a result the candidate must be able to state precisely. In **ELECT-TDCS**, a **single-centre trial**, tDCS did not show non-inferiority to escitalopram over **10 weeks** in the treatment of depression, and it was associated with more adverse events than the drug comparator. That limit belongs to the result itself and should travel with it whenever the trial is cited.

The second is DepressionDC. A published analysis from that trial records that the main trial did not show beneficial antidepressant effects of active tDCS over **sham** tDCS. The provenance of that sentence is worth stating rather than hiding: it is drawn from a subsequent peer-reviewed

report by the same investigators and not from the primary publication, so it is a faithful account of the main trial's result as its own authors describe it.

AXIS ON WHICH THE TWO DESIGNS DIFFER	ELECT-TDCS	DEPRESSIONDC
What active tDCS was compared against	An active drug comparator, escitalopram	Sham stimulation
Question the design is built to answer	Non-inferiority: is the device not meaningfully worse than the drug	Superiority: does active stimulation beat sham
What the null answer licenses	That the trial could not exclude a meaningful shortfall against the drug; not that the technique is inert	That active stimulation did not beat sham in that trial's population; not that it must fail in every population
Limit the source states alongside the result	A single-centre trial	The statement used here comes from a later report by the same investigators

20.5 What those results license, and what they do not

A failed trial and an ineffective treatment are not the same object. This is the reasoning the neuromodulation questions are actually testing, and it is where most answers go wrong in the same direction. A **non-inferiority** design asks whether the new intervention falls short of the comparator by more than a pre-specified margin. Failing to demonstrate non-inferiority means the trial could not rule that shortfall out. It does not mean the intervention did nothing, it does not mean the comparator was superior, and it certainly does not mean the modality has been refuted. A sham-controlled superiority design asks a different question, and a null there is a statement about that contrast, in that population, at the parameters that trial used.

The discipline this imposes on an answer is specific. State each trial by name with its own comparator and its own result, and stop. Do not aggregate two negative results into a verdict on the modality, and do not soften them into a vague statement that the trials have been disappointing, which sounds cautious but is an unsourced summary claim in disguise. Nothing here supports a statement about what the tDCS depression literature as a whole has shown, and an answer that offers one has left the evidence behind.

TRAP **Collapsing two named negative trials into "tDCS does not work".** This is a different error from the polarity one and it is made by the better-read candidates, who know the trials and over-read them. Two results, one against an active drug and one against sham, are two data points with their own designs, populations and stated limits. Neither was designed to answer whether the modality has utility in any other disorder, and neither can be extended to one. The correct answer names the trials, states what each showed, and says plainly what remains unsettled.

20.6 Tolerability, and the assumption a low current invites

The intensity envelope makes tDCS feel like a low-risk intervention, and the temptation is to write that it is well tolerated and move on. The one head-to-head comparison available here does

not support that shortcut. In the trial against escitalopram, tDCS was associated with more adverse events than the drug, and the events reported in that comparison were specific rather than trivial.

- Higher rates of skin redness in the tDCS group.
- Higher rates of tinnitus.
- Higher rates of nervousness.
- **New-onset mania** in the tDCS group.

> **PITFALL**
>
> Reading a low current as a low adverse-event rate. The two are separate questions and this modality separates them: the envelope is at the low end of what electrical stimulation can deliver, and the one trial read here that compared it directly against a drug still recorded more adverse events on the device arm. The clinical error that follows is describing tDCS to a patient as the option with fewer side effects, which is a comparative claim the evidence read here contradicts rather than supports.

The appearance of new-onset mania in the reported events is the item to carry away, because it is the one that changes what is asked before treatment and requires monitoring for emergent hypomanic or manic symptoms during treatment. A mood-disorder history is part of the picture for any intervention given with antidepressant intent, and the reported event list, not the current intensity, is the honest basis for that conversation.

20.7 Where guidance places the modality

Guidance positions are examinable in their own right, and this one has a distinctive shape. NICE places tDCS for depression under **special arrangements**, and the arrangements it names are clinical governance, consent, and audit or research. That is a category in its own right and it should be read as one: it is neither a prohibition nor an endorsement of routine use, but a position that permits the procedure while requiring that its use be governed, consented and either audited or conducted as research. NICE puts tDCS for depression in a lower position than it gives rTMS, and the comparison is part of the answer, because a candidate who states the tDCS position without that relative placement has given a fact without its meaning.

That relative placement is the only direct cross-modality comparison available here, and it must not be treated as the sole clinical basis for choosing when a patient could plausibly be offered either non-convulsive technique. There is no head-to-head trial here putting tDCS against rTMS, so the choice between them is not made on a direct comparison of outcomes. What this account holds is the position each has been given by the body that reviewed them, and on that basis tDCS is the one carrying the additional governance, consent and audit conditions. Other considerations that bear on the choice, including each technique's own adverse-effect profile, its contraindications and what the service can actually deliver, sit outside what the evidence read here covers. Saying so plainly is more defensible than manufacturing a comparison the evidence does not contain.

GOOD TO REMEMBER

If tDCS is being offered for depression, the consent conversation is not the same conversation as for an established treatment. The position it rests on names consent and audit or research as conditions of use, which means the patient is being told that the intervention sits in a governed category rather than in routine practice, and that the service is expected to record what happens. Building that into the conversation is not extra caution; it is the position itself.

20.8 The Indian position: classified, not approved

India has a regulatory record for this technology and it is easy to misread. Transcranial electrical stimulation systems are classified by the Central Drugs Standard Control Organisation as a **medical device**, at **Neurological serial 127**, Class B. The classification entry's own intended-use text names transcranial direct current stimulation and transcranial alternating current stimulation for psychiatric or neurological therapy, so the technology is recognised by name. Classification is not approval. It places a device in a risk class for regulatory purposes; it does not certify that the device works for a named indication. The wider position is that no Asian country other than Singapore and South Korea has approved tES devices, so India holds classification without indication approval.

IN INDIA

There is no Indian national clinical practice guideline setting indications, evidence grades or a place in the treatment ladder for tDCS in psychiatric disorders. That absence is the operative fact, not an omission from this account. The consequence for practice is concrete: the position an Indian clinician is working from is a guidance position derived from NICE plus the named trial evidence, and it should be presented to the patient and recorded in the notes as exactly that. Because classification at Class B is not approval for a psychiatric indication, the decision to offer tDCS is a governed, consented and documented one taken on the trial record, not one taken on the strength of an approved indication or of a domestic guideline that does not exist.

MNEMONIC

Envelope, Polarity, Trials, Position

The four beats of a full tDCS answer, in the order that earns marks. Envelope: the family and the physical limits that define it. Polarity: the subthreshold mechanism and the heuristic that must not be stated as a law. Trials: the named depression trials with their own comparators and their own limits. Position: what guidance permits and what Indian regulation has and has not done. An answer missing the last two beats is a description, not an answer.

Set beside the other techniques, tDCS occupies a distinctive place: a mechanism that is well characterised and modest, an evidence base in depression that is specific, named and unfavourable in the two trials read here, a guidance position that permits use only under governance, consent and audit or research, and an Indian regulatory record that recognises the device without approving an indication for it. Each of those four is a fact a candidate can state

and defend. The temptation is to replace them with a general impression of a promising low-cost treatment, and that impression is the one thing in this topic that nothing here supports.

> tDCS biases firing rather than driving it, and every honest claim about it - mechanism, evidence and regulatory position - is smaller and more specific than the enthusiasm the technique attracts.

21 · Deep brain stimulation and vagus nerve stimulation in psychiatry

Two of the neurostimulation answers require an implanted system. Deep brain stimulation and vagus nerve stimulation sit at the far end of the treatment sequence, reached only after documented pharmacological failure, and a full-mark answer on either is marked on four things: what the device is, where it acts, which disorders it has been used in, and how strong the evidence actually is. Two errors cost most of the marks. The first is promoting a regulatory status into an efficacy claim, which is easy to do because the regulatory language is written to sound like endorsement. The second is answering with the operation instead of the modality. The procedural technique, the consent and legal frame around the operation itself, and the ethics and cost-equity arguments are set out in the ECT and neurostimulation notes; what follows is the modality and its utility across disorders.

21.1 A circuit therapy, not a reversible lesion

The first conceptual correction is the one examiners look for, and it is worth opening an answer with. **Deep brain stimulation** is now better described as a **circuit therapy** and not as a reversible lesion, though it was initially conceptualised as one, a framing that made it the ablative operations' safer successor and that still shapes how referrers and families talk about it. The delivered pulses trigger action potentials in axons both orthodromically and antidromically, and the new patterns of synaptic activity this generates overwrite the pathological ones.

The distinction is not semantic, and it changes three things in an answer. It explains why the effect can be modulated or withdrawn entirely without any tissue having been removed, which is what separates this modality from the ablative procedures it descended from. It explains why the unit of treatment is a network rather than a structure, so that the clinical question is which circuit is being driven and not which nucleus is being destroyed. And it explains why the same anatomical target can support claims in more than one disorder: if the mechanism is the imposition of new activity patterns on a circuit, then any disorder in which that circuit is implicated becomes a candidate indication, which is exactly how the psychiatric target list was assembled.

RULE **A device authorisation names who may be treated, not how well the treatment works.** Both of the psychiatric authorisations discussed here are defined by a population and by a count of prior failed drug treatments. Neither is a statement about effect size, and the strength of the underlying evidence has to be read separately from the wording of the licence. Read the pathway, then read the trials, and never let the first stand in for the second.

21.2 The psychiatric targets, and why obsessive-compulsive disorder leads

Target selection is where a modality answer earns its structure, and obsessive-compulsive disorder is the psychiatric condition in which the target work has gone furthest. In deep brain stimulation for obsessive-compulsive disorder, the **ventral capsule/ventral striatum** and the nucleus accumbens have emerged as the most frequently investigated loci, with three further sites receiving substantial attention.

- Most frequently investigated: the ventral capsule/ventral striatum.
- Equally prominent: the nucleus accumbens.
- Substantial attention: the anterior limb of the internal capsule.
- Substantial attention: the bed nucleus of the stria terminalis.
- Substantial attention: the subthalamic nucleus.

Two observations make this list examinable rather than a memory exercise. First, the sites are not independent of one another: they cluster in and around the ventral striatal and capsular territory through which cortico-striato-thalamo-cortical traffic passes, which is the anatomical reason a single disorder produced several candidate targets rather than one. Second, the fact that five targets remain under investigation is itself the evidence position. A field that had settled its target would not still be studying five, and an answer that names one target as the target has misread the state of the literature. Say which are studied most, say the rest are actively studied, and resist the temptation to declare a winner.

21.3 The regulatory footing in obsessive-compulsive disorder

The United States authorisation for this indication is a **Humanitarian Device Exemption** and not a **premarket approval**, and the difference is the whole point. US FDA granted it as HDE H050003, with a decision date of 10 February 2009, for bilateral stimulation of the anterior limb of the internal capsule, as an adjunct to medications and as an alternative to anterior capsulotomy, for chronic severe treatment-resistant obsessive-compulsive disorder in adults who have failed **at least three** selective serotonin reuptake inhibitors.

Every clause in that sentence is load-bearing. The indication is bilateral. It is adjunctive, so the device is added to medication rather than replacing it. It is positioned clinically as an alternative to anterior capsulotomy; this wording does not establish that capsulotomy was a trial comparator. It is restricted to adults. And it carries the crispest prior-failure threshold anywhere in this modality group: a specific count, of a specific drug class, before the device becomes an option at all.

TRAP **Writing that deep brain stimulation is approved for obsessive-compulsive disorder.** A humanitarian device exemption is a humanitarian pathway carrying a probable-benefit standard, not a demonstration of effectiveness, and it is expressly not a premarket approval. Candidates make this error because the everyday word for any regulatory clearance is approval, and because the indication text reads exactly like a licence. Name the pathway, then the standard it applies, then the threshold it sets. That single sentence separates a candidate who has read the authorisation from one who has heard about it.

21.4 Deep brain stimulation in depression: the controlled evidence

Depression is the second psychiatric indication for which this modality has been pursued seriously, and it is the one on which the controlled evidence is clearest and least encouraging. The randomised, double-blind BROADEN trial did not show significant differences between active and sham stimulation at six months, and it was subsequently halted because of a low probability of success on an interim **futility analysis**.

Both halves of that sentence teach. A trial that fails to separate from sham has not shown that the device does nothing; it has shown that this design, in this population, at this time point, could not demonstrate that it does something, and open-label improvement in the same patients is entirely compatible with that result. But a trial stopped for futility is a stronger negative than a trial that merely misses significance, because the interim analysis has already concluded that continuing to the planned endpoint was unlikely to change the answer. An answer that reports the sham comparison without the futility stop understates the result; an answer that reports the futility stop as proof of inefficacy overstates it.

The guideline consequence follows directly. VA/DoD recommends against using deep brain stimulation for major depressive disorder outside a research setting, and does so at strong strength. Note the verb and the strength together, because both are the substance of the recommendation: this is a recommendation against, not a recommendation to consider carefully, and it is issued at the guideline's higher tier rather than its weaker one.

21.5 Vagus nerve stimulation: what the indication actually says

The second implanted modality is licensed the other way round. Where the obsessive-compulsive disorder authorisation came through a humanitarian route, **vagus nerve stimulation** in depression holds a premarket approval: US FDA P970003 supplement S050, with a decision date of 15 July 2005. The device is indicated for the adjunctive long-term treatment of chronic or recurrent depression, in patients 18 years of age or older who are in a major depressive episode and have not had an adequate response to **four or more** adequate antidepressant treatments.

Three words in that indication do most of the examinable work. Adjunctive means the device is used in addition to other treatment rather than in place of it, and the two authorisations say it with different force: the obsessive-compulsive disorder exemption reads adjunct to medications, while this one reads only adjunctive long-term treatment. Long-term is unusual in a device indication and is not decoration: it distinguishes the intended treatment horizon from an acute intervention, and it should not be relabelled as maintenance treatment, since the same indication requires that the patient be in a major depressive episode. Chronic or recurrent restricts the population by illness course, not merely by severity, so a first episode meets the illness-course limb only if it is chronic.

PITFALL

Counting prior failures loosely, or interchangeably between the two devices. The obsessive-compulsive disorder pathway counts a specific class, selective serotonin reuptake inhibitors. The depression pathway counts, in the indication's own words, four or more adequate antidepressant treatments, and adds the word adequate twice, to the treatments and to the response; that indication text does not define those treatments by class. A clinician who tallies four failed drugs of mixed classes for the obsessive-compulsive disorder pathway, or three selective serotonin reuptake inhibitors for the depression pathway, has counted the wrong thing against the wrong threshold and has not established candidacy for either.

21.6 The evidence behind the vagus nerve stimulation indication

This is the single most misremembered fact in the whole modality group, and it is worth stating plainly: the acute sham-controlled trial behind the depression indication was negative. In the D-02 acute phase, **15.3 percent (17 of 111)** of the active stimulation group were considered responders against 10.0 percent (11 of 110) of the sham group, a difference that was not statistically significant, with p equal to 0.238. Support for the indication came instead from long-term open treatment and from nonrandomised comparative evidence, with the limitations that implies; in that uncontrolled long-term phase the reported 12-month HAM-D response was 29.8 percent and remission 17.1 percent.

Set those figures side by side and the structural problem in the evidence is visible without any statistical apparatus. The controlled comparison, which is the only part of the programme in which sham stimulation is present, produced a small and non-significant separation. The larger response proportion comes from a phase with no comparator, in which the passage of time, continued pharmacological treatment, regression to the mean and expectation all remain in the estimate. A candidate who quotes only the long-term figure has quoted the uncontrolled number as though it were a treatment effect.

The most recent evidence has not resolved this. RECOVER, described as the largest neuromodulation trial in psychiatry to date, did not meet its primary endpoint on preliminary reports, although clinically meaningful improvements were reported in depressive severity, functioning and quality of life. That combination, a missed primary endpoint alongside reported secondary improvements, is the recurring shape of this literature and should be described as such rather than resolved in either direction.

TRAP **Assuming a premarket approval implies a positive pivotal sham-controlled trial.** Here it does not. The acute controlled comparison was negative and the support came instead from long-term open treatment and nonrandomised comparative evidence, and the largest trial since has not met its primary endpoint either. This is a genuinely different error from mistaking the humanitarian pathway for approval: there the pathway was misread, here the pathway is read correctly and the evidence behind it is assumed rather than checked.

21.7 How the guideline bodies read the two devices

Guideline positions are more consistent across bodies than the target literature is, and they are the safest thing to reproduce under time pressure. A systematic review of clinical practice guidelines on deep brain stimulation for obsessive-compulsive disorder found that eight guidelines recommended it be used only after all other treatment options had failed to alleviate symptoms, and that one guideline did not recommend it beyond a research setting. In depression the positions are more restrictive still: VA/DoD recommends against deep brain stimulation outside research at strong strength, and suggests against vagus nerve stimulation outside research at weak strength. NICE places implanted vagus nerve stimulation for treatment-resistant depression under **special arrangements** for clinical governance, consent, and audit or research, in guidance now numbered HTG551 and formerly IPG679, published 12 August 2020.

at least 3 SSRIS FAILED, US OCD PATHWAY	**4 or more** ANTIDEPRESSANT TRIALS, US VNS INDICATION	**8** GUIDELINES: ONLY AFTER ALL ELSE FAILS	**1** GUIDELINE: RESEARCH SETTING ONLY

Read the modal verbs against each other and a hierarchy appears. Recommends against is stronger than suggests against. Special arrangements is neither a prohibition nor an endorsement: it permits use while requiring the governance, consent and audit machinery that ordinary practice does not, which is what a body does when it is unwilling to close a door and unwilling to open it. Compared on the axes an examiner is likely to supply, the two devices separate cleanly.

AXIS	DEEP BRAIN STIMULATION	VAGUS NERVE STIMULATION
Lead psychiatric indication in the regulatory record	Chronic severe treatment-resistant obsessive-compulsive disorder in adults, adjunctive	Chronic or recurrent depression, adjunctive and long-term
Regulatory pathway	Humanitarian device exemption, not a premarket approval	Premarket approval supplement
Prior-failure threshold named in the authorisation	Failed at least three selective serotonin reuptake inhibitors	No adequate response to four or more adequate antidepressant treatments
Controlled evidence in depression	BROADEN did not separate from sham at six months and was stopped for futility	Acute sham-controlled phase negative; the largest trial to date did not meet its primary endpoint
Position in major depressive disorder	Recommends against outside research, strong	Suggests against outside research, weak

GOOD TO REMEMBER

When a patient or family raises a device after several failed trials, two answerable questions come before any discussion of the operation. How many adequate prior treatments have there actually been, counted against the threshold that belongs to that indication. And is the device being sought as a replacement for medication, which neither authorisation supports: the obsessive-compulsive disorder exemption is written as an adjunct to medications, and the depression approval as adjunctive long-term treatment.

21.8 The position in India, and the question the Act leaves open

The Indian regulatory picture is thinner than candidates expect, and the honest answer says so rather than filling the space. What is documented is a risk classification. CDSCO lists the deep brain electrical stimulation system in the Neurological category of its classification of medical devices as Class D. That is all it is. The cited document is a classification list; it records no approval and no indication for use, so it cannot be quoted as evidence that the device is authorised here for any psychiatric condition, and it says nothing at all about vagus nerve stimulation in depression.

What is not documented, and therefore not stated here, is whether any Indian centre currently implants these devices for a psychiatric indication and for how many patients, whether any product licence exists for a named system, whether any indication-specific authorisation exists, and what the treatment costs in rupees. Those are real questions and an answer is stronger for naming them as unanswered than for supplying a plausible figure. The equity and cost arguments around access to implanted neuromodulation are developed in the ECT and neurostimulation notes.

IN INDIA

Before any implanted device is offered for a psychiatric indication, establish whether the Board approval requirement applies. Under section 96 of the Mental Healthcare Act, 2017, **psychosurgery** is restricted: it requires the informed consent of the person on whom it is performed and, in addition, approval from the concerned Board. The Act does not define psychosurgery, so whether a reversible implanted system for refractory obsessive-compulsive disorder falls inside that restriction cannot be settled from the Act itself. The consequence of the ambiguity is concrete and binary. Either Board approval must be obtained before proceeding, or it need not, and no clinician should resolve that question informally. State the question, state what turns on it, and do not answer it.

MNEMONIC

Site, Stage, Sham, Stance

Four retrieval slots that fit any device answer, including one you have not revised. Site: what is stimulated and on what mechanistic account. Stage: what must have failed, and how many times, before the device is on the table. Sham: what the controlled comparison actually showed, as distinct from the open-label follow-up. Stance: what the guideline bodies recommend, in their own modal verbs and at their own strengths.

Each of these authorisations is defined by a count of prior failed drug treatments, and in depression the sham-controlled evidence for both devices did not separate.

22 · Magnetic seizure therapy and other emerging neurostimulation modalities

Every examination cycle asks for a modality nobody in the room has used. The emerging neurostimulation question is not a request for enthusiasm. It asks whether a candidate can say what a device does, which physical variable it manipulates, which disorders it has been tested in, and how strong that evidence actually is, and can do all four without inflating an investigational technique into an established treatment. Magnetic seizure therapy anchors this group because it has been tested against an active comparator in randomised trials, and because the shape of that evidence is itself examinable. The remaining modalities are best learned by what each one varies: the waveform of the current, the form of energy delivered, or the timing of stimulation. The procedural technique for every device named here, and the apparatus that surrounds it, is set out in the ECT and neurostimulation notes.

22.1 Magnetic seizure therapy, and the inversion that defines it

Magnetic seizure therapy uses the physics of transcranial magnetic stimulation. A rapidly changing magnetic field crosses scalp and skull without the attenuation an externally applied electrical current suffers, and induces a current in the cortex beneath. Repetitive transcranial magnetic stimulation, which has its own section, uses that induced current subconvulsively: the entire discipline of the technique lies in modulating cortical excitability while staying below the point at which a seizure is provoked. Magnetic seizure therapy takes the same class of hardware and reverses the intention. It is delivered so as to produce a generalised seizure, and the seizure is the therapeutic act, exactly as it is in electroconvulsive therapy.

RULE **Magnetic seizure therapy is magnetic stimulation hardware carrying convulsive intent.** One sentence, and it is the whole definition. Repetitive transcranial magnetic stimulation is delivered so as not to provoke a seizure; magnetic seizure therapy is delivered so as to provoke one. Every other feature of the modality, from where it is performed to what it is compared against, is downstream of that inversion.

Two consequences follow at once, and both are answerable without any parameter. First, magnetic seizure therapy is a convulsive treatment and therefore needs the peri-procedural support that a convulsive treatment requires, delivered in an appropriately equipped treatment

and recovery setting. That requirement places it beside electroconvulsive therapy in service terms and separates it from the subconvulsive magnetic techniques it shares hardware with, however similar the two look on a photograph. Second, for a trial testing non-inferiority and the cognitive trade-off against the established convulsive treatment, the correct comparator is electroconvulsive therapy rather than sham or a subconvulsive protocol, because the claim being tested there is not that seizures help but that this way of producing them costs the patient less. A trial asking a different question, such as whether magnetic seizure therapy has a specific effect beyond the procedure itself and expectancy, would call for a credible sham instead; the comparator follows the question. The settings that achieve the inversion, and the whole procedural apparatus around them, belong to the ECT and neurostimulation notes and are not repeated here.

22.2 Why the seizure is meant to be different, and what is actually known

The rationale is physical. An electrical current applied at the scalp must cross tissue of high resistance before it reaches the brain, and the path it takes is determined as much by that tissue as by where the operator puts it. A magnetically induced current is not attenuated in the same way, so in principle the initiating volume of cortex can be smaller and more predictable. If the seizure begins in a smaller volume, the argument runs, it may engage less of the brain, and the cognitive cost may be correspondingly lower. That hypothesis is the reason the modality exists.

What the evidence supports is narrower than the hypothesis, and the difference between the two is where marks are won. The IFCN safety consensus on transcranial magnetic stimulation records that seizures induced by magnetic seizure therapy are less robust and differ in their physiological expression from those induced by electroconvulsive therapy, and it records that on animal evidence only, not on human evidence. That is a statement about how the seizure behaves, not a statement about how far it spreads through the human brain. Human electrophysiological or imaging evidence on whether the magnetically induced seizure propagates less widely, and on how much of any observed cognitive advantage a propagation difference would explain, is not established.

TRAP **Writing focality as the established explanation for the memory difference.** It is the mechanism candidates reach for because it is tidy and because it was the design rationale. The honest position is that the animal data show the seizures differ, that the human trials show a difference on the autobiographical memory outcome they measured, and that the causal link between the two has not been demonstrated in people. An answer that states the hypothesis as hypothesis and then names the missing evidence reads as better trained than one that asserts the mechanism.

22.3 The confirmatory randomised evidence

The design is as examinable as the result. A **non-inferiority** trial sets aside the question of whether the new treatment is better. It asks whether the new treatment falls short by no more than a pre-specified margin, so that its advantages elsewhere can legitimately decide the choice. That question is the right one here, because nobody claims magnetic seizure therapy produces

more remission than electroconvulsive therapy; the claim is that it costs the patient less memory for a comparable chance of getting well.

The CREST-MST trial put that claim to a confirmatory randomised test against ultrabrief electroconvulsive therapy, on 239 randomised participants.

27.8%	22.5%	17.3%	2.7%
REMISSION, ULTRABRIEF ECT ARM	REMISSION, MST ARM	MEMORY WORSENING, ECT ARM	MEMORY WORSENING, MST ARM

Read the two pairs in opposite directions. On remission the gap was **5.3%** in favour of electroconvulsive therapy, and non-inferiority of magnetic seizure therapy was nonetheless established, with p=0.048 and a 95% CI -4.4 to 14.9. On worsening of **autobiographical memory** the difference ran the other way and was of a different order of magnitude, at p=0.0003. So the trial delivers precisely the trade the modality was designed to offer, and it delivers it with the remission point estimate favouring the older treatment.

TRAP **Reading non-inferiority as equivalence, or worse, as superiority.** Non-inferiority is a bounded conclusion: it says the true difference is unlikely to be worse than the margin the trial declared before it started. It does not say the two treatments produced the same remission rate, and in this trial they did not. A candidate who writes that magnetic seizure therapy matched electroconvulsive therapy on remission has misread the design; the defensible sentence names the direction of the difference and then says non-inferiority was established.

22.4 The bipolar pilot, and what a pilot can and cannot settle

The CORRECT-BD pilot asked the same question in bipolar depression and found the same pattern. Remission was reached by 6/20 (30%) in the electroconvulsive therapy group and 5/25 (20%) in the magnetic seizure therapy group, while clinically important worsening of autobiographical memory occurred in 6/27 (22.2%) against 2/28 (7.1%). Remission favoured the older treatment numerically; memory favoured the newer one.

Two features of those figures deserve attention because they are what an examiner is testing. The study randomised n=55. It was not powered for efficacy, so the remission comparison is descriptive and no inference about relative efficacy can be drawn from it. And the denominators are not the same across the two outcomes, because the participants contributing a remission judgement and those contributing a memory assessment are not the same set. Quoting a percentage from a pilot without saying that it came from a pilot is the commonest way this material is got wrong, and it is a failure of scientific reading rather than of memory.

22.5 Reading the two trials as one answer

An answer that lists both trials and stops has done half the work. The two are not two attempts at the same question; they occupy different rungs of the evidence ladder and they license different sentences. Setting them out on shared axes makes that explicit.

AXIS	CONFIRMATORY NON-INFERIORITY TRIAL	RANDOMISED PILOT IN BIPOLAR DEPRESSION
Question it was built to answer	Whether magnetic seizure therapy falls short of the active comparator by no more than the declared margin	Whether the same pattern appears in bipolar depression, and whether a definitive trial is feasible
Comparator	Ultrabrief electroconvulsive therapy	Ultrabrief electroconvulsive therapy
Direction on remission	Numerically favoured electroconvulsive therapy	Numerically favoured electroconvulsive therapy
Direction on autobiographical memory	Favoured magnetic seizure therapy	Favoured magnetic seizure therapy
What the result licenses	A conclusion of non-inferiority on remission, bounded by the confidence interval	Hypothesis generation and planning of a definitive trial
What it does not license	Any claim that magnetic seizure therapy produces more remission	Any conclusion about relative efficacy at all

GOOD TO REMEMBER

When a patient or a family asks about the memory-sparing alternative to electroconvulsive therapy, the honest account carries both halves of the result and not just the attractive one. CREST-MST found less worsening on its specified autobiographical memory measure, and the memory figures set out above are that result; it should not be widened into a claim about cognition as a whole. The chance of remission was numerically lower for magnetic seizure therapy in the confirmatory trial and in the pilot alike, and in the confirmatory trial the conclusion drawn was non-inferiority, not equality. Presenting the memory figure alone converts a defensible clinical discussion into a promise the evidence does not support.

22.6 Beyond the seizure: the transcranial electrical waveforms

The rest of the group varies something other than the intention. The transcranial electrical modalities are distinguished here by the waveform of the current applied at the scalp; their intensity, montage, electrode geometry and the resulting distribution of current in the head may also differ. Guidance on low intensity transcranial electric stimulation endorsed by ESBS and IFCN separates the family by waveform in this way.

- Transcranial direct current stimulation, which has its own section, applies a current of constant intensity and polarity.
- Transcranial alternating current stimulation, **tACS**, alternates between polarities at a steady sinusoidal frequency.
- Transcranial random noise stimulation, **tRNS**, alternates at a randomly changing frequency.

The distinction is not cosmetic, and the reasoning behind it is worth carrying. A constant current shifts the resting membrane potential of the underlying cortex in one direction and so biases the

likelihood of firing. An oscillating current can, in principle, interact with the brain's own rhythms, which makes the frequency chosen a hypothesis about which rhythm is disordered rather than an arbitrary setting. A randomly varying current makes no such frequency-specific claim; its rationale is the addition of stochastic input to a network. Three different theories of how to help a sick circuit therefore sit inside one apparently uniform family, and an answer that says so has understood the field.

What cannot be stated here is how well any of them works in any named disorder. No disorder-level efficacy figure for alternating current or random noise stimulation is available to this section, and the correct examination position is to describe the mechanism and the family structure, name the modality as investigational, and decline to attach an effect size to it.

22.7 Transcranial focused ultrasound

Focused ultrasound is the only technique in this group that changes the form of energy rather than the shape of a current. Acoustic energy can be steered so that it converges on a small volume at depth while passing through the tissue in front of it at much lower intensity, which is the property that makes it interesting: it offers a non-invasive route to targets that surface stimulation cannot reach, and it does so without an implanted device.

The point that must be got right is that the same physical technology spans two entirely different clinical acts, separated by intensity. **HIFU** used for ablation typically employs acoustic intensities **greater than 200 W/cm2**, whereas **low-intensity focused ultrasound** used for neuromodulation generally operates **below 100 W/cm2**. One destroys tissue at the focus and the change it produces is permanent; the other is intended to modulate the activity of tissue it leaves intact. A candidate who writes about focused ultrasound without naming that split has written about two procedures as though they were one, and the resulting answer cannot be corrected by adding detail, because the error is categorical.

22.8 Adaptive and closed-loop stimulation

The last variable available to an emerging modality is not where or how hard, but when. Conventional deep brain stimulation, which has its own section, runs open-loop: the device delivers what it was programmed to deliver, and the programme changes only when a clinician changes it. **Adaptive, closed-loop deep brain stimulation** senses a physiological signal from the patient and varies stimulation in response to it, so the device is titrating itself against the state of the circuit rather than against a clinic appointment. Conceptually this is the most significant shift in the group, because it moves the treatment from a fixed prescription to a feedback system.

Its regulatory position is precise and is the part most often stated wrongly. The US FDA granted adaptive deep brain stimulation as an optional programming feature on an existing deep brain stimulation system under PMA P960009 supplement S478, with a decision date recorded as 20 February 2025, and that authorisation is for Parkinson's disease. There is no corresponding authorisation for any psychiatric indication. The adaptive principle is being studied in psychiatry, but the approval that exists sits outside it.

PITFALL

Telling a patient with severe refractory illness, or a family that has read about it, that closed-loop brain stimulation is now approved and available for their condition. The approval is for Parkinson's disease. Describing a movement-disorder authorisation as though it extends to psychiatric indications raises an expectation that cannot be met and is a factual error in the record, not merely an optimistic phrasing.

22.9 Answering the emerging-modality question honestly

The group has no shared mechanism, so it needs a shared method of answering. For any device in it, the same three questions produce a structured reply, and they can be applied to a modality a candidate has never seen.

- Which physical variable does it change, and what does the change intend to do to the circuit?
- What has it been compared against, in whom, and how many were studied?
- What does the resulting evidence license as a sentence, and what does it not?

MNEMONIC

Intent, Waveform, Energy, Timing

The four axes on which the emerging modalities separate. Magnetic seizure therapy changes the intent of magnetic stimulation from subconvulsive to convulsive. Alternating current and random noise stimulation change the waveform. Focused ultrasound changes the form of energy. Adaptive stimulation changes the timing. Nothing in the list asserts an efficacy claim, which is exactly why it is safe to reproduce under examination conditions.

Applied to this material, that method gives an answer with different strengths in different places, and the differences are the substance. Magnetic seizure therapy carries randomised comparative evidence against an active treatment, in a confirmatory trial and a pilot that point the same way on remission and on memory. The electrical waveform variants and focused ultrasound neuromodulation are described here by mechanism and by physical parameter, and no disorder-level efficacy figure is attached to them, because none is available to this section. Adaptive stimulation has a regulatory position, and that position is outside psychiatry.

One further limit belongs in the answer rather than in a footnote. No regulatory classification, product licence or indication authorisation for a magnetic seizure therapy device in India could be established from the sources behind this section, nor any report of an Indian centre delivering it clinically or in research; the same absence holds for therapeutic alternating current and random noise stimulation and for focused ultrasound neuromodulation. The position that is defensible in an Indian examination and in an Indian clinic is therefore that magnetic seizure therapy is investigational and is not documented as available here, stated as an absence of evidence rather than as an assertion of unavailability.

Each emerging modality is defined by the single variable it changes, and its evidence is worth exactly what its comparator and its sample size make it worth.

23 · Theta-burst stimulation and accelerated TMS protocols (SAINT) as recent neurostimulation advances

Theta-burst is not a new machine, it is a new rhythm. Three separate innovations sit behind the phrase "recent advances in transcranial magnetic stimulation", and the popular account of the field runs them together: a change in how the pulses are patterned, a change in how the sessions are spaced across the calendar, and a change in how the cortical target is chosen. Theta-burst stimulation is the first. Accelerated protocols are the second. Imaging-based targeting is the third. The best-known protocol in this area is all three at once, which is why its headline result is quoted more often than it is understood. An answer that keeps the three axes apart, and attaches every published number to the design that produced it, will outscore one that recites remission rates.

The procedural side of all of this, including how the instrument is specified and how treatment intensity is referenced before a course begins, belongs to the ECT and neurostimulation notes and is not repeated here. What follows is the modality answer: what theta-burst is, where the accelerated schedules came from, what the trials actually demonstrated, where the two guideline positions currently sit, and what remains undocumented.

23.1 What theta-burst stimulation is

Theta-burst stimulation is a patterned form of repetitive transcranial magnetic stimulation rather than a modality in its own right: instead of delivering single pulses at one even frequency, the stimulator delivers short bursts of high-frequency pulses and repeats those bursts at the **theta rhythm**. The parameters the majority of the literature has used are those originally described by Huang and colleagues, 50 Hz bursts of 3 pulses repeated at 5 Hz. The rationale is borrowed rather than invented. Burst patterning at theta frequency is the arrangement that was used in animal preparations to induce lasting change in synaptic efficacy, and the argument for importing it into human cortical stimulation is that a patterned train induces plasticity more efficiently than an evenly spaced one of comparable size. That argument is a rationale, not a demonstrated human mechanism, and the clinical case for the pattern has had to be made separately in trials.

The consequence a candidate should be able to state in one line is administrative before it is biological. Because the pulses arrive in dense bursts, a treatment session runs to roughly **3 minutes**, dramatically shorter than the conventional session it substitutes for. The parent modality and the clinical setup around it are otherwise similar, but the dose structure, the session duration and the tolerability are not identical, which is precisely why the substitution had to be tested rather than assumed.

RULE **Theta-burst changes the pattern, not the modality.** The same instrument delivers the same kind of stimulation to the same patient; what changes is how the pulses are arranged in time, and with that arrangement the dose structure, the length of the session and the tolerability of it. It follows that nothing about the parent technique is superseded, and that every therapeutic claim specific to the pattern needs its own evidence. Two forms of the pattern are used, an intermittent one and a continuous one, and the depression evidence that follows is entirely about the intermittent form.

23.2 THREE-D, and what a non-inferiority result licenses

The trial that moved intermittent theta-burst out of the physiology laboratory and into routine depression practice was **THREE-D**. In patients with **treatment-resistant depression**, intermittent theta-burst was **non-inferior** to 10 Hz repetitive transcranial magnetic stimulation, with low dropout numbers and similar side-effect, safety and tolerability profiles in both arms. That sentence, and the design word inside it, is the examinable core.

The quantities matter because the argument is statistical before it is clinical. HRSD-17 scores improved from 23.5 to 13.4 in the high-frequency arm and from 23.6 to 13.4 in the theta-burst arm, an adjusted difference 0.103 with a lower 95% CI of -1.16 and p=0.0011, tested against a pre-specified non-inferiority margin set at 2.25 points. Read what that structure does: the confidence bound sits well inside the margin, so the trial excludes a loss of effect larger than the margin allows. It does not measure a gain.

Tolerability was close but not identical, and the asymmetry is worth carrying. Dropouts across the two arms were 6% and 8%, headache was the commonest adverse event in both at 64% and 65%, and pain during treatment was rated higher with theta-burst, 3.8 vs 3.4 out of a possible 10, p=0.011. A shorter session is not automatically a more comfortable one, and a patient who declines the technique on those grounds is not being unreasonable.

TRAP **Writing that this trial showed theta-burst to be better, or that it showed the two to be identical.** A non-inferiority design with a pre-specified margin can only exclude a loss larger than that margin, and the primary analysis here was per-protocol rather than intention-to-treat. The result licenses substituting the shorter protocol for the longer one on grounds of time and throughput. It does not license a claim of greater efficacy, and an absent difference is not the same finding as demonstrated equality.

23.3 The regulatory footing came before the recommendation

Theta-burst acquired a device footing before it acquired a graded guideline recommendation, and knowing the sequence explains why the technique is widely available while the formal appraisals remain unsettled. An Indian review of the evolution of transcranial magnetic stimulation services in psychiatry tabulates the regulatory record for neuropsychiatric indications, and its 2018 entry is the MagVita TMS Therapy System with TBS (Tonica Elektronik, MagVenture) for major depressive disorder, recorded as the first theta-burst entry in that table.

A regulatory entry of this kind is a statement about one named system and its labelled indication. It is not a graded appraisal of a body of evidence, and it says nothing about accelerated scheduling or about imaging-based targeting, which came later and are separately evidenced.

Candidates conflate the two because both are commonly described as approval; keeping them apart is a cheap mark.

23.4 Accelerated protocols and the Stanford protocol

"Accelerated" is a statement about the calendar, not about the pulse. An **accelerated protocol** delivers more than one session in a day so that a course which would otherwise occupy weeks is compressed into days. Three things can therefore be varied independently, and a protocol description that does not specify all three is incomplete:

- how many sessions are given in a day;
- how many days the whole course runs;
- how the cortical target is chosen for the individual patient.

The best-developed example is **Stanford Neuromodulation Therapy**, the accelerated **fMRI-targeted** intermittent theta-burst protocol previously called SAINT. Beyond the compressed schedule, its distinctive feature is the target: the region of left DLPFC most functionally anticorrelated with the **subgenual anterior cingulate cortex**, identified in the individual patient by functional imaging rather than assigned by a group rule.

In a double-blind randomised trial reported at a planned interim analysis, the protocol beat sham. The mean percent reduction in MADRS score 4 weeks after treatment was 52.5% with active treatment against 11.1% with sham, in 29 treated (14 active, 15 sham) from 32 enrolled. That denominator is the part which falls out of retelling. The report's own conclusion is that further trials are needed to determine the protocol's durability and to compare it with other treatments, so presenting it as an established treatment misstates its authors' position, not merely the evidence.

52.5% at 4 weeks	11.1% at 4 weeks	29
ACTIVE, MADRS REDUCTION	SHAM, MADRS REDUCTION	PATIENTS TREATED

GOOD TO REMEMBER

SAINT and Stanford Neuromodulation Therapy are the same protocol under two names, the newer replacing the older. A literature search or a guideline read under only one of them will miss half the record, because the trial report uses the newer name while the Indian guidance cites the older. When a referrer or a patient asks about "the Stanford protocol", they are asking about the accelerated imaging-targeted schedule, not about theta-burst patterning as such.

23.5 The remission figure, and which study produced it

The number that reaches patients and referrers is a remission rate near ninety percent, and it did not come from the randomised comparison above. The same report records a remission rate of approximately **90%** after 5 days of open-label treatment. That is a different cohort, a different design and a different outcome measure from the sham-controlled reduction in depression score, and the two quantities answer different questions.

A second figure circulates beside it. The Indian Psychiatric Society guideline on the therapeutic use of repetitive transcranial magnetic stimulation records SAINT remission at **86.4%** in treatment-resistant depression, from a high-dose accelerated protocol running 10 daily sessions for 5 days guided by resting-state functional connectivity imaging, and states in the same passage that such protocols remain to be tested in controlled studies. These are two reported figures for the same open-label protocol, appearing in two documents. Print whichever your source supports, attach the source to it, and do not average or reconcile them.

TRAP **Quoting the remission rate as though the randomised trial produced it.** The controlled result is a percentage reduction in a depression rating scale against sham; the remission rate is an open-label figure from treatment without a sham comparator. Candidates merge them because both are large percentages attached to the same protocol name, and the merged sentence reads as though a sham-controlled trial delivered remission in nine patients out of ten. It did not, and the two published open-label figures do not even agree with each other.

PITFALL

Delivering the compressed schedule without the imaging step and calling it the same protocol. Both the trial report and the Indian guidance describe the protocol as functionally imaging-guided, with the target defined in the individual patient. A compressed schedule aimed by a conventional method may be a perfectly reasonable thing to study, but it is not the protocol the published remission figures came from, and those figures should not be offered for it in a consent conversation.

23.6 Where the guideline positions stand, and why they diverge

Two guideline positions can be asked for, and they do not agree. The divergence is instructive rather than embarrassing, and an answer that names it is stronger than one that smooths it.

The VA/DoD guideline for major depressive disorder declines to recommend either for or against theta-burst stimulation, recording insufficient evidence, a strength of neither for nor against, and certainty of very low. Note the shape of that entry. It is a statement about the state of the evidence base, not a finding that the technique is ineffective, and reading it as the latter is a common error.

The Indian Psychiatric Society position on accelerated protocols is cautious for a related but separate reason: a meta-analysis restricted to accelerated protocols over the left dorsolateral prefrontal cortex was not found to be associated with significant response, and the SAINT remission figure is explicitly flagged as untested in controlled studies. The caution is attached to acceleration, not to patterning.

The tension is worth stating plainly. The non-inferiority trial showed intermittent theta-burst to be non-inferior to a high-frequency protocol that the VA/DoD guideline does recommend, and yet that guideline still declines to grade theta-burst itself. Guideline appraisals grade a body of evidence for a named intervention; inheriting a recommendation across a comparison, however sound the comparison, is not how they are constructed.

SOURCE OF THE FIGURE	DESIGN THAT PRODUCED IT	WHAT IS REPORTED	WHAT IT LICENSES
The non-inferiority trial	Randomised, per-protocol primary analysis, treatment-resistant depression	Non-inferior to 10 Hz; adjusted difference 0.103 against a margin set at 2.25 points	Substitution of the shorter protocol, on time and throughput
The Stanford protocol trial	Double-blind sham-controlled, planned interim analysis, 29 treated from 32 enrolled	MADRS reduction 52.5% active against 11.1% sham, 4 weeks after treatment	An efficacy signal in a small sample; durability left open
The same report, open-label cohort	Open-label, no sham comparator	Remission approximately 90% after 5 days of treatment	Hypothesis generation only
Indian Psychiatric Society guidance	Guideline citation of the same open-label protocol	Remission 86.4% in treatment-resistant depression	The figure met in Indian reading, flagged untested in controlled studies
VA/DoD depression guideline	Formal appraisal of theta-burst as an intervention	Insufficient evidence; neither for nor against; very low certainty	No recommendation in either direction

23.7 What predicts response, and what that finding is not

The Indian guideline's depression evidence review reports a meta-analysis restricted to theta-burst studies, which identified three features predicting higher response rates:

- at least **1800 pulses per session**;
- **subthreshold intensity**;
- a treatment duration of two weeks or less.

Three cautions travel with that list, and an answer that prints the predictors without them has overstated the source. First, these are predictors recovered from a meta-analysis and reported inside an evidence narrative; they are not issued as a recommended protocol, and the guideline does not present them as one. Second, they were derived in depression, and the same review does not establish them for obsessive-compulsive disorder, schizophrenia or addiction. Third, the direction of the first predictor is easy to invert under exam pressure: the finding is a floor, more pulses in a session rather than fewer, while the duration predictor runs the other way, a shorter course rather than a longer one. How any of these is actually implemented in the treatment room belongs to the ECT and neurostimulation notes.

The accelerated-protocol meta-analysis sits beside this list and has to be reported beside it rather than folded into it. That analysis, restricted to accelerated protocols over the left dorsolateral prefrontal cortex, found no significant association with response. The theta-burst analysis above reports three features associated with higher response rates among the studies it pooled. Neither analysis compares one schedule directly against the other, so neither licenses a statement about

what acceleration adds or removes relative to a conventionally spaced course, and no direct schedule-comparison analysis was found to settle it.

23.8 Utility beyond depression, and what is not on record

Every figure above belongs to depression, and the honest answer says so. No theta-burst efficacy figure for any other disorder is carried here, and the response predictors are explicitly not established outside depression. The disorder-by-disorder indication set for conventional repetitive transcranial magnetic stimulation is taught with that modality and should be answered from there rather than reconstructed under this heading; what can be said about theta-burst outside depression is that the evidence used here does not extend to it, which is a different statement from saying the technique does not work there.

The Indian footing for the accelerated protocols is undocumented rather than negative, and the distinction is worth making explicitly instead of filling in. Whether any Indian centre currently delivers an accelerated or imaging-targeted theta-burst course in clinical service, whether any Indian trial of accelerated intermittent theta-burst in depression has been conducted, what such a course costs a patient here, and whether the functional-imaging targeting step is feasible in routine services are all questions the sources behind this section do not answer. They would be answered by the national neuromodulation body and by the academic centres that run these services. Until they are, the defensible position in an answer is that this is an international recent advance whose Indian position is not on record.

IN INDIA

Where instrument time rather than referral volume is what limits how many patients finish a course, intermittent theta-burst is the throughput decision. The session is short enough that more patients can be treated on one machine in a working day, and the non-inferiority result means the substitution is not paid for in effectiveness that trial could detect. Note carefully what the Indian Psychiatric Society caution attaches to: it attaches to the accelerated, several-sessions-a-day protocols and to the imaging-targeted variant, and not to theta-burst patterning itself, which sits inside the same guideline's depression evidence review as a studied form of the parent technique. Choosing the pattern and declining the acceleration is a defensible position, but name each authority separately instead of summing them into a joint endorsement: the non-inferiority trial supports intermittent theta-burst as non-inferior to the high-frequency protocol, the Indian Psychiatric Society is cautious specifically about acceleration, and the VA/DoD guideline remains neutral on theta-burst itself, neither for nor against it.

MNEMONIC

Design, Denominator, Endpoint, Durability

Four questions to put to any accelerated-stimulation result before quoting it: was there a sham arm, how many patients were actually treated, which scale and which time point produced the figure, and has the effect been shown to last. The Stanford report answers the first three and leaves the fourth open in its own words.

Theta-burst changes the pattern and acceleration changes the calendar: every headline number in this field belongs to one design, and an answer is only as strong as the design it names beside the figure.

Pharmacogenetic and structural drug-reaction syndromes

24 · HLA-B*1502 and HLA-A*3101 testing and carbamazepine, oxcarbazepine and phenytoin severe cutaneous reactions (SJS and TEN)

This is the one prescription in psychiatry that a laboratory result is allowed to veto before the first tablet. Most pharmacogenetics adjusts a dose; here a single allele decides whether a drug is used at all. The marks sit on five questions, asked in this order: which allele, which drug, which population, when the test is worth doing, and how to read a test whose negative result is close to conclusive while its positive result is mostly a false alarm. A candidate who can only say that carbamazepine causes severe skin reactions in Asian patients has answered none of them.

Two alleles carry the topic: one is narrow in reaction and wide in drug, the other wide in reaction and narrow in drug. Three aromatic agents are implicated, and the classic error is that the substitute a candidate reaches for is one of the three. The wider family of idiosyncratic reactions, including drug reaction with eosinophilia and systemic symptoms, is taken up elsewhere in these notes.

24.1 The reaction the test exists to prevent

Stevens-Johnson syndrome and **toxic epidermal necrolysis** are one process separated by area. CPIC defines them by epidermal detachment as a proportion of body surface area, with a formally named overlap band between them, so a case is classified by extent rather than by morphology. The bands are exclusive at their edges, and detachment of exactly 10 per cent is overlap rather than Stevens-Johnson syndrome; the guideline's own prose writes the lower band loosely enough to assign that edge to both, so the strip below prints the boundary as the standard clinical classification sets it.

less than 10%	10 to 30%	more than 30%
BSA, SJS	BSA, OVERLAP	BSA, TEN

Mortality separates just as sharply as the area does. CPIC gives rates typically below 5% for Stevens-Johnson syndrome and above 30% for toxic epidermal necrolysis, with sepsis the most frequent cause of death, and adds that mortality is also related to age, the drug half-life and how early the drug is discontinued. Two of those three are fixed by the time the rash appears; only the third is in the prescriber's hands. Half-life as a pharmacokinetic principle belongs to the Psychopharmacology I: principles and core drug classes notes.

The population weighting is what makes this an Indian examination topic rather than a Western one. The carbamazepine boxed warning estimates these reactions at 1 to 6 per 10,000 new users

in countries with mainly Caucasian populations, with the risk in some Asian countries about 10 times higher. For oxcarbazepine the label reports that the reporting rate of toxic epidermal necrolysis and Stevens-Johnson syndrome, itself generally accepted to be an underestimate because of underreporting, exceeds background incidence rate estimates by a factor of 3- to 10-fold.

GOOD TO REMEMBER

Because mortality tracks how early the drug is stopped, the instruction that changes the outcome is given at the first prescription, not at the first rash: stop the tablet and attend the same day if any rash appears. It costs nothing and is the one part of this topic that does not depend on a genotype being available.

24.2 Two alleles doing two different jobs

The first discrimination is between allele and phenotype. **HLA-B*15:02** is tied to one reaction and, on the original Han Chinese work, to a very large effect: an odds ratio for carbamazepine-induced Stevens-Johnson syndrome and toxic epidermal necrolysis of 1357, with a 95% confidence interval of 193.4 to 8838.3. The same study showed the association is phenotype-specific rather than a general marker of drug allergy: HLA-B*15:02 is not associated with maculopapular exanthema or hypersensitivity syndrome, whereas HLA-A*31:01 is associated with maculopapular exanthema, at an odds ratio of 17.5 with a 95% confidence interval of 4.6 to 66.5. A later systematic review put the same point in clinical language: carriers of HLA-B*15:02 are at strongly increased risk of carbamazepine-induced Stevens-Johnson syndrome and toxic epidermal necrolysis in populations where the allele is common, but not of carbamazepine-induced hypersensitivity syndrome or maculopapular exanthema.

HLA-A*31:01 is the mirror image. CPIC states that, unlike the other allele, it is associated with a wider range of carbamazepine hypersensitivity reactions, including maculopapular exanthema, drug reaction with eosinophilia and systemic symptoms, and Stevens-Johnson syndrome and toxic epidermal necrolysis, in many different populations. Breadth of phenotype does not buy breadth of drug: the phenytoin guideline records that no association between HLA-A*31:01 and phenytoin-induced Stevens-Johnson syndrome and toxic epidermal necrolysis has presently been found, despite the structural similarity between the two drugs.

RULE **Each allele names a reaction and a drug list, and neither list generalises.** One allele is narrow in phenotype and wide in drug, covering three aromatic agents for a single reaction; the other is wide in phenotype and narrow in drug, covering several reactions for carbamazepine alone. An answer that treats them as two interchangeable risk markers for the same thing has lost the structure of the topic.

24.3 Four numbers, four different questions

An odds ratio in the thousands is a statement about association, not about test performance, and the two are routinely conflated. CPIC reports that **HLA-B*15:02 as a predictive test for carbamazepine-induced Stevens-Johnson syndrome and toxic epidermal necrolysis has estimated sensitivity 98% and specificity 97% in the Han Chinese population**. The

population qualifier is part of the number: no equivalent estimate exists for any Indian population. A provenance point travels with them: CPIC cites the 2006 Han Chinese study for those figures, but that study's abstract itself reports only the odds ratio, not sensitivity or specificity, so attribute them to the guideline rather than to the primary paper.

Sensitivity and specificity describe the test; predictive values describe the patient, and in a rare outcome they diverge violently. In the same population, the **positive predictive value** of the allele for carbamazepine-induced Stevens-Johnson syndrome and toxic epidermal necrolysis is **7.7%** and the **negative predictive value** 100%. The allele is therefore close to necessary and nowhere near sufficient, since the great majority of carriers would never have developed the reaction. That asymmetry justifies the strategy: a test used to exclude does not need a high positive predictive value.

The same asymmetry sharpens across the two drugs. CPIC states that the positive predictive value of HLA-B*15:02 for oxcarbazepine-induced Stevens-Johnson syndrome and toxic epidermal necrolysis is estimated at 0.73%, much lower than the 7.7% for carbamazepine-induced disease, while the negative predictive value for both nears 100% in Southeast Asian populations. Note that the guideline does not speak with one voice on that last figure: its Table 2 footnote states flatly that HLA-B*15:02 has a 100% negative predictive value for carbamazepine-induced Stevens-Johnson syndrome and toxic epidermal necrolysis, and that its use is currently recommended to guide use of carbamazepine and oxcarbazepine only, while the narrative section quoted above stops at the word "nears". Print both as the guideline's own, and read the word "only" in the footnote as governing which drugs the test guides, not as qualifying the figure.

For the second allele the arithmetic is entirely different and is often quoted out of scope. CPIC estimates that the positive predictive value and the **number needed to test** for HLA-A*31:01, to prevent one case of all carbamazepine-induced hypersensitivity reactions combined, are most favourable in European populations, at 43% and 47 respectively. Two qualifiers travel with that pair and neither is optional: it is a European estimate, and it is most influenced by maculopapular exanthema rather than by drug reaction with eosinophilia and systemic symptoms. A positive predictive value of that size buys mostly the prevention of a benign rash.

TRAP **Carrying the carbamazepine negative predictive value across to phenytoin.** It is stated for carbamazepine, and the phenytoin guideline says the opposite in terms: a negative HLA-B*15:02 test does not eliminate the risk of phenytoin-induced Stevens-Johnson syndrome and toxic epidermal necrolysis. Candidates generalise because the allele and the reaction are the same, and the drug is the variable they stop watching. Note too that 7.7% appears twice in this literature with different meanings: the carbamazepine positive predictive value, and the proportion of a Taiwanese cohort testing positive.

24.4 Which population, and the figures that do not agree

Population frequency decides whether testing is worth offering; it never decides how to read a result that has come back. Published figures for the same populations differ by source and, for the second allele, by what is counted, so they are set out below by source and by measure rather than as one consensus number.

SOURCE	ALLELE	POPULATION, AS THAT SOURCE NAMES IT	MEASURE AND FIGURE
CPIC carbamazepine and oxcarbazepine guideline	HLA-B*15:02	East Asian; Oceanian; South and Central Asian	Allele frequency 6.9%; 5.4%; 4.6%, the three highest
CPIC carbamazepine and oxcarbazepine guideline	HLA-B*15:02	Japanese; Korean	Frequency less than 1%; less than 2.5%
CPIC carbamazepine and oxcarbazepine guideline	HLA-B*15:02	African; African American, Middle Eastern, Caucasian, Hispanic and South American	Not observed; less than 1%
CPIC phenytoin guideline	HLA-B*15:02	East Asian and Central or South Asian; European	Allele frequency 1% to over 20%; 0 to 1%
Carbamazepine label	HLA-B*1502	South Asians, including Indians	Intermediate prevalence, averaging **2% to 4%, but higher in some groups**
Oxcarbazepine label	HLA-B*1502	India; Korea	Allele frequency up to about 6%; up to about 2%
CPIC carbamazepine and oxcarbazepine guideline	HLA-A*31:01	Caucasian; Hispanic and South American; Japanese; South Korean; South and Central Asian	Allele frequency 3%; 6%; 8%; 5%; 2%
Carbamazepine label	HLA-A*3101	Japanese, Native American, Southern Indian (for example, Tamil Nadu) and some Arabic ancestry	Expected carriage more than 15%

Three divergences in that table are examinable in their own right. The two regulatory labels disagree with each other about India, one giving an intermediate prevalence of 2% to 4% for South Asians including Indians and the other an allele frequency up to about 6% for India; both are current, so the honest answer names both rather than averaging them. The two CPIC documents describe the same populations with a single aggregate in one and a wide range in the other, so a figure must be attributed to the guideline it came from. Most importantly, the second allele's Indian figures are not comparable: the guideline reports an allele frequency in South and Central Asians, the label an expected carriage in Southern Indian ancestry. Different quantities over different groupings, so these are two measurements and are never converted into one. Note also that the guidelines write the colon in an allele name and the labels omit it; both spellings denote the same allele, and a stem may use either.

24.5 What the instruments instruct, and at what strength

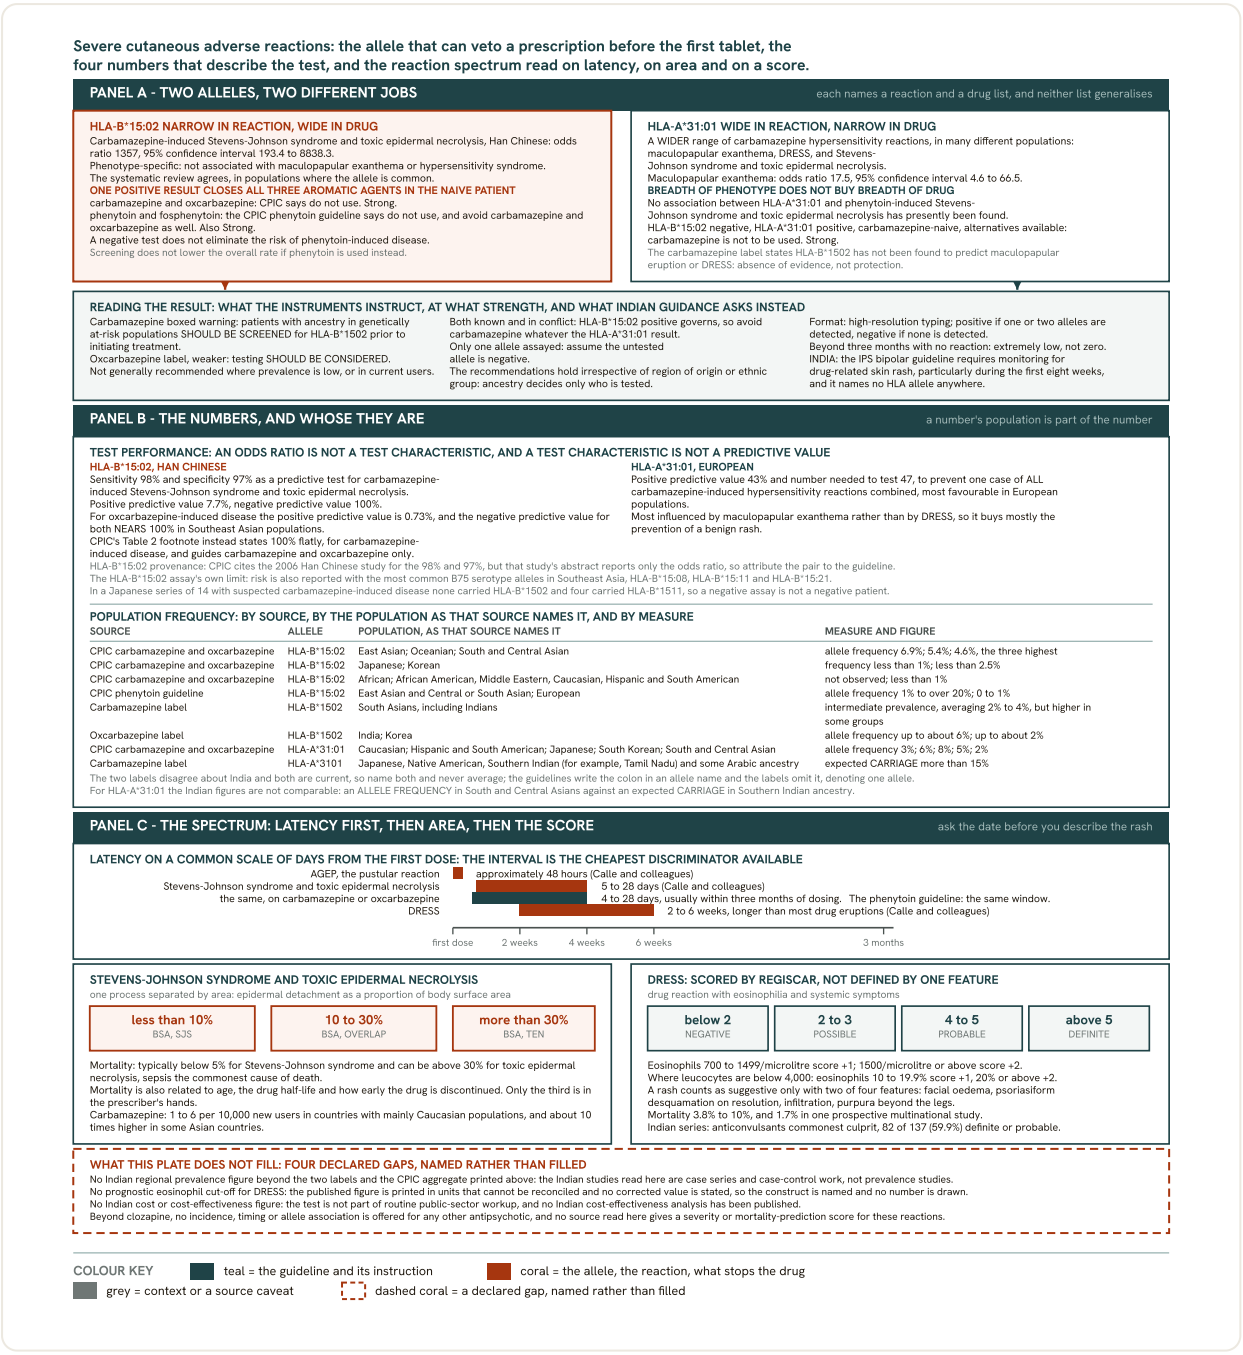

Fig 37.10 Severe cutaneous adverse reactions: allele to drug to population to test decision, then the spectrum the test exists to prevent. Two alleles do two different jobs. HLA-B*15:02 is narrow in reaction and wide in drug, carrying an odds ratio of 1357 for carbamazepine-induced Stevens-Johnson syndrome and toxic epidermal necrolysis in Han Chinese while being not associated with maculopapular exanthema or hypersensitivity syndrome, and one positive result closes carbamazepine, oxcarbazepine and phenytoin in the naive patient at Strong classification. HLA-A*31:01 is the mirror image, wide in reaction and narrow in drug, with no association with phenytoin-induced disease presently found. The four numbers answer four different questions and each carries its population: sensitivity 98% and specificity 97%, positive predictive value 7.7% against 0.73% for oxcarbazepine-induced disease, and a negative predictive value CPIC states twice and differently, 100% in its Table 2 footnote and nears 100% in its narrative, printed here as both rather than averaged. The frequency table is set out by source and by measure because the two labels disagree about India, 2% to 4% against up to about 6%, and because an allele frequency of 2% in South and Central Asians and an expected carriage above 15% in Southern Indian ancestry are two measurements and never one. The spectrum is then read on latency first, on body surface area second and on a score third, and Indian guidance asks for rash monitoring through the first eight weeks rather than a genotype. (CPIC carbamazepine and oxcarbazepine 2018 update; CPIC phenytoin 2020 update; the FDA carbamazepine and oxcarbazepine labels; Bastuji-Garin and colleagues 1993 for the body-

surface-area bands; Hung and colleagues 2006; Amstutz and colleagues 2014; Calle and colleagues 2023; Sasidharanpillai and colleagues 2022; IPS Clinical Practice Guideline, bipolar disorder, 2025.)

Strength of wording is the substance here, and flattening the instruments into one sentence about recommended testing throws away most of the marks. The carbamazepine label carries the strongest formal mandate: its boxed warning states that patients with ancestry in genetically at-risk populations should be screened for HLA-B*1502 prior to initiating treatment. The oxcarbazepine label is deliberately weaker, stating that testing for the presence of the HLA-B*1502 allele should be considered in patients with ancestry in genetically at-risk populations, prior to initiating treatment. It fences the recommendation from both ends: screening is not generally recommended in patients from populations in which prevalence is low, or in current users.

The test format is specified rather than left open. The carbamazepine label calls for **high-resolution HLA-B*1502 typing** and defines the result binarily, positive if either one or two alleles are detected and negative if none is. There is no intermediate genotype, so heterozygosity is not a partial result and does not license a partial decision.

The guideline recommendations, read against those labels, are more decisive and are graded.

- In a carbamazepine-naive or oxcarbazepine-naive patient who is positive for the allele, CPIC states that carbamazepine and oxcarbazepine should be avoided respectively, because of the greater risk of Stevens-Johnson syndrome and toxic epidermal necrolysis, classified Strong for both drugs.
- The phenytoin guideline extends the same logic across the class: in a phenytoin-naive patient positive for the allele, do not use phenytoin or fosphenytoin, and avoid carbamazepine and oxcarbazepine, also classified Strong.
- Where the second allele is positive and the first negative, CPIC's Table 2 states that for a carbamazepine-naive patient with alternative agents available, carbamazepine is not to be used, classified Strong.
- Where both results are known and conflict, the first allele governs: if the patient is carbamazepine-naive and positive for HLA-B*15:02, carbamazepine should be avoided regardless of the HLA-A*31:01 result.
- Where only one allele has been assayed, CPIC directs the clinician to assume the untested allele is negative rather than to treat the missing result as an unknown risk.

One further sentence disposes of the commonest abuse of this reasoning. CPIC records that these recommendations hold irrespective of the patient's region of origin or ethnic group. Ancestry decides who is offered the test; once a result exists it decides nothing further, and a positive result in a low-frequency population is still positive.

24.6 Timing: when the risk sits, and the patient already taking the drug

The risk is front-loaded, and every timing statement in this topic follows from that. CPIC states that the latency period for carbamazepine-induced or oxcarbazepine-induced Stevens-Johnson syndrome and toxic epidermal necrolysis is short with continuous dosing and adherence to

therapy, about 4 to 28 days, with cases usually occurring within three months of dosing; the phenytoin guideline prints the same window of 4 to 28 days for phenytoin-induced disease, again with cases usually occurring within three months of dosing. The carbamazepine label puts it as a proportion: over 90% of treated patients who will experience the reaction have it within the first few months of treatment.

That front-loading makes the treatment-experienced patient a different problem. CPIC states that patients who have been continuously taking carbamazepine or oxcarbazepine for longer than three months without developing cutaneous reactions are at extremely low risk, but not zero. Read the parenthesis: the tolerant patient is reassured, not discharged from vigilance, and an answer that writes off residual risk as nil has overstated a guideline that took care not to.

PITFALL

Treating an early rash two or three weeks into carbamazepine as a nuisance to be watched. It sits inside the stated latency window, and because mortality is related to how early the drug is discontinued, the decision to observe rather than stop is itself a determinant of outcome. The opposite error is stopping a drug taken uneventfully for years on the strength of a newly reported allele.

24.7 What a negative test does not buy

A screening programme is only as good as the drug that replaces the one it prohibits. CPIC records plainly that a HLA-B*15:02 screening policy for carbamazepine will not decrease the overall rate of Stevens-Johnson syndrome and toxic epidermal necrolysis if other anticonvulsants associated with the reaction, such as phenytoin, are used instead. The regulatory position agrees: consideration should be given to avoiding phenytoin as an alternative for carbamazepine in patients positive for HLA-B*15:02, because of the increased risk in patients of Asian ancestry.

TRAP **Substituting phenytoin for carbamazepine in a carrier.** It is the substitution a candidate reaches for first, and it is the wrong answer to write. One positive result rules out all three aromatic agents in the naive patient, and a screening policy that diverts patients from one to another prevents nothing.

Nor is the wider class clean. CPIC names **aromatic anticonvulsants** including eslicarbazepine, lamotrigine, phenytoin, fosphenytoin and phenobarbital as having very limited evidence, if any, linking them to Stevens-Johnson syndrome and toxic epidermal necrolysis through this allele, and states that caution should still be used when choosing an alternative agent. Cross-reactivity is also clinical rather than purely genetic: the carbamazepine label tells prescribers to inform patients that **about a third of those who have had hypersensitivity reactions to carbamazepine also experience hypersensitivity reactions with oxcarbazepine**.

The last limitation is in the assay itself. CPIC records that, in addition to the tested allele, risk for carbamazepine-induced Stevens-Johnson syndrome and toxic epidermal necrolysis has been reported in association with the most common B75 serotype alleles in Southeast Asia, HLA-B*15:08, HLA-B*15:11 and HLA-B*15:21. A Japanese series makes the consequence concrete:

among 14 patients with suspected carbamazepine-induced disease, none carried HLA-B*1502 and four carried HLA-B*1511. That is a case-series proportion without controls rather than a risk estimate, but it shows how a single-allele assay can return negative in a susceptible patient.

24.8 The Indian evidence base, and what Indian guidance actually says

One prospective study turned screening into policy anywhere. In the Taiwanese screening cohort, 7.7% tested positive and were advised not to take carbamazepine, being given an alternative or continuing their prestudy medication, while the 92.3% who tested negative were advised to take it; no Stevens-Johnson syndrome or toxic epidermal necrolysis developed in the screened-negative subjects receiving carbamazepine, against approximately 10 cases expected from the estimated historical incidence. The caveats should be stated: the comparison is against historical controls, and the expected cases are counted among study subjects rather than among the negatives who took the drug. There is no Indian equivalent of that trial.

What India has instead is three small studies, and their limits are the point. The foundational series found the allele in six of eight Indian patients with carbamazepine-induced Stevens-Johnson syndrome. A North Indian case-control study found the allele in 2 of 9 (22.2%) carbamazepine cases and in none of 37 carbamazepine-tolerant controls, p equal to 0.035, and in none of the 8 phenytoin cases. A South Indian study concluded that the association of the allele with phenytoin-induced Stevens-Johnson syndrome and toxic epidermal necrolysis is rare in the population studied, with small sample size acknowledged as its limitation. None is a prevalence study, and none supports a statement about how common the allele is in any Indian region. A systematic review places India inside the affected geography: allele-positive patients with carbamazepine-induced disease have been reported from Asian countries only, including China, Thailand, Malaysia and India.

IN INDIA

Indian ancestry sits inside the at-risk group the carbamazepine boxed warning names, so a genotype before the first tablet is the decision this evidence supports in a carbamazepine-naive or oxcarbazepine-naive patient. Where only one allele has been assayed, the guideline instruction is to treat the untested allele as negative and act on the result you have. A positive result closes off phenytoin as the substitute as well, which is the part most likely to be missed wherever phenytoin is the default second choice. Where no genotype can be obtained, the eight-week rash watch below is what remains, and it is not a formality.

Indian guidance has not followed the pharmacogenetic route. The Indian Psychiatric Society bipolar guideline states that patients taking carbamazepine must be monitored for drug-related skin rash, particularly during the first eight weeks of therapy, as the treatment is associated with life-threatening rashes, and it names no HLA allele anywhere. Its answer to this risk is clinical vigilance over a defined window rather than genotyping. The corresponding position in the schizophrenia guideline is equally cautious in general terms, holding that the clinical utility of psychopharmacogenomics is disputable because of the lack of larger standardised trials and cost-effectiveness evaluations. A candidate asked what Indian guidance requires should answer the

rash watch, and should not attribute a genotyping mandate to a document that does not contain one.

MNEMONIC

Allele, Agent, Ancestry, Already taken

The four questions that settle a stem: which allele is tested, which aromatic agent is being started, whether ancestry places the patient in the at-risk group the label names, and whether they are naive or have taken the drug uneventfully beyond three months. The fourth changes the answer more often than candidates expect.

A negative result narrows the risk and never abolishes it; a positive result forbids all three aromatic agents in the naive patient, whatever their ancestry.

25 · DRESS syndrome and other severe idiosyncratic reactions to anticonvulsants and antipsychotics

Most drug rashes declare themselves within a fortnight. DRESS often does not, and that single property is what makes it dangerous at the bedside and reliable in an examination. **DRESS**, drug reaction with eosinophilia and systemic symptoms, begins weeks after a drug was started, damages organs as readily as skin, and in Indian series is caused mostly by agents that sit on a psychiatric prescription. The marks are in three places: the time course that shifts the differential towards DRESS and away from the other severe cutaneous reactions, the scoring system an examiner will name and expect reproduced as reasoning rather than as a form, and the culprit drugs. Candidates lose them by quoting a diagnostic band as though it were a prognostic one, by carrying a figure out of the population it was measured in, and by waiting for a rash before believing the diagnosis.

The allele-testing framework and the severe cutaneous reaction spectrum in its own right are taught separately in these notes, and carbamazepine's own pharmacology belongs to the Psychopharmacology I: principles and core drug classes notes. What follows is the reaction itself: how it announces itself, how it is scored, which drugs produce it, and what can and cannot be said once the drug has been stopped.

25.1 The latency that names the syndrome

Calle and colleagues, in their World Allergy Organization Journal review, state that in most patients the reaction occurs **2 to 6 weeks** after the drug is started, a latency period longer than that of most drug eruptions. That property does a great deal of the diagnostic work before any morphology is described. A febrile eruption on the third afternoon of a new drug is usually something else; a febrile eruption in the second month, when the prescription has stopped feeling new and the drug chart has stopped being re-read, is the one that gets attributed to sepsis, to a viral illness, or to the psychiatric disorder itself.

The same review supplies the contrast that makes this examinable. Stevens-Johnson syndrome and toxic epidermal necrolysis run a shorter course from exposure, 5 to 28 days, and the pustular reaction **AGEP** shorter still, at approximately 48 hours. Latency shifts the differential but does not separate these three reactions by itself: the Stevens-Johnson window runs out to 28 days while the DRESS window opens at two weeks, so the two overlap for a fortnight, and morphology, mucosal involvement, systemic findings and investigations remain necessary. It is still the reason the first question in a suspected drug reaction is a date and not a description.

RULE **Establish when the drug was started before you characterise the rash.** Morphology overlaps across the severe cutaneous reactions and is read differently by different observers, whereas the interval between the first dose and the first symptom is a fixed number that the patient or the file can supply. In a syndrome whose whole difficulty is that nobody suspects a drug started six weeks ago, the interval is the cheapest discriminator available.

25.2 How common it is, and how badly it ends

Every published incidence figure for this syndrome carries a different denominator, and the three in common circulation are not interchangeable.

more than 1 per 10,000	0.9 per 100,000	2.18 to 40 per 100,000
MEDICATION EXPOSURES	INHABITANTS	INPATIENTS

Read these as estimates answering three different questions, not as one rate quoted three ways. An exposure denominator asks how risky a prescription is; a population denominator asks how much of this a health system will see; an inpatient denominator is enriched for polypharmacy, for severity and for the surveillance that produces a diagnosis at all, which is why its upper end sits far above the population figure. A syndrome that is under-recognised is also under-counted, so each estimate may be shifted by how reliably the diagnosis is made and recorded in the setting it was measured in, and none of the three is a clean measurement of risk.

Mortality is reported by the same group as 3.8% to 10% despite treatment, with 1.7% in one prospective multinational study. A single figure is therefore hard to defend: the prospective cohort and the pooled literature are not measuring the same population, and an answer that quotes only the low end understates a syndrome that kills, while one that quotes only the high end inflates it. Give the spread and attribute each end.

What cannot be offered here is a prognostic laboratory threshold. The eosinophil count said to mark a poor outcome is printed in the source literature in units that cannot be reconciled with the quantity they describe, and no corrected value is stated anywhere in that paper. Reconstructing the intended number would be an invention. Substituting the diagnostic eosinophil band described below would be worse, because a cut-off built to classify a case was never validated to predict its outcome.

RULE **A diagnostic threshold is not a prognostic threshold.** The two are derived from different questions on different samples. Where a prognostic cut-off is genuinely unavailable, the correct answer names the construct and says the number is not established, and prognosis is then discussed through mortality and through the pattern of organ involvement rather than through a laboratory line that does not exist.

25.3 The phenotype, and the warning that precedes the rash

The FDA-approved label for carbamazepine describes the reaction as presenting, typically though not exclusively, with fever, rash, lymphadenopathy and/or facial swelling in association with involvement of other organ systems, with eosinophilia often present. Four points in that sentence repay attention: fever is part of the syndrome and not an incidental infection; facial swelling is a positive feature rather than a variant of urticaria; the organ involvement is the reason the syndrome is severe; and the phrase "not exclusively" is the label refusing to make any single feature necessary.

The same label carries the warning that changes practice, which is that the early manifestations of hypersensitivity can be present before any rash is evident. A patient on a recently started anticonvulsant with unexplained fever and lymphadenopathy is already inside the differential. Waiting for skin before considering the drug converts a recognisable prodrome into a multiorgan presentation.

One negative statement from the same label needs teaching exactly as written. It states that the HLA-B*1502 allele has not been found to predict the risk of less severe cutaneous reactions such as maculopapular eruption, nor to predict DRESS. That is an absence of demonstrated predictive value, not a demonstration that carriers are protected: it means the allele cannot be used to anticipate this syndrome, and equally that a negative result cannot be used to dismiss it. Allele testing in its own right, with its indications and its operating characteristics, is taught elsewhere in these notes.

25.4 Scoring it: RegiSCAR as an examination construct

The **Bocquet criteria** came first and were simple enough to memorise: a drug rash, a haematological abnormality in the form of eosinophilia or atypical lymphocytes, either of which satisfies that element, and systemic manifestations. They define the syndrome but stop short of grading confidence in it. **RegiSCAR** was built to fill that gap. RegiSCAR sorts a suspected case by total score into four bands: **below 2 negative, 2 to 3 possible, 4 to 5 probable, and above 5 definite**. The examination point is that the instrument returns a level of certainty rather than a yes or a no, so a case can be reported as probable and treated as real.

Three of its parameters are worth knowing in detail because each is defined more tightly than candidates assume. Eosinophilia is scored in two bands, the higher scoring double: eosinophils 700 to 1499/microlitre earns one point and **1500/microlitre or above** earns two. Because a septic or marrow-suppressed patient may have a low total count, there is a percentage route as well: where leucocytes are below 4,000, eosinophils of 10 to 19.9% earn one point and 20% or above earn two. Lymphadenopathy is scored only when it clears a size and a site threshold,

namely nodes of more than 1 cm affecting two anatomical regions, which is why a single palpable cervical node adds nothing.

The rash parameter is the one most often misquoted. A rash counts as suggestive of the syndrome only when it carries at least two of four specified features: facial oedema, resolution with psoriasiform desquamation, infiltrated skin lesions, and purpuric lesions involving areas other than the legs.

MNEMONIC

FIPP: Facial oedema, Infiltrated lesions, Purpura beyond the legs, Psoriasiform desquamation on resolution

Two of these four are what turns a nonspecific exanthem into a rash the scoring system will accept as suggestive. The last is retrospective, which is a useful reminder that some of the score can only be completed as the patient recovers.

A further point is available for the exclusion of alternative causes. The footnote to the Indian scoring table adds one point if at least three of four listed tests were performed and found negative, the four being:

- antinuclear antibody
- hepatitis A, B and C
- infection due to Mycoplasma or Chlamydia
- blood culture

TRAP **Quoting the exclusion-of-alternatives item as though one agreed list existed.** The Indian paper's footnote enumerates the four investigations above. The World Allergy Organization Journal review states the same item differently and does not enumerate the same set. Neither wording is an error and they must not be blended into a single averaged list. Name the source you are quoting, and if the stem does not specify one, say that published versions of the item differ.

25.5 RegiSCAR against the Japanese criteria

The competing construct is **DiHS**, drug-induced hypersensitivity syndrome, for which the Japanese consensus group laid down seven mandatory features, one of them reactivation of HHV-6. Because that assay is unavailable in many centres, the same group proposed a modification with five essential features for atypical DiHS. The two systems are not two names for one thing, and the difference is examined through the parameters they treat as mandatory.

PARAMETER	REGISCAR	JAPANESE DIHS CRITERIA
Fever	No positive points; its absence instead scores one negative point	Mandatory for typical and atypical disease
Maculopapular rash	No positive points as one of the three features mandatory for DiHS	Mandatory for typical and atypical disease
Persistence of symptoms after the drug is stopped	No positive points	Mandatory for typical and atypical disease
Early resolution	No positive points, and resolution before 15 days scores one negative point	Not specified in the sources drawn on here
Viral reactivation	Not among the parameters described here	Reactivation of HHV-6 is one of the seven mandatory features; a five-feature version exists where testing is unavailable
Yield in an Indian tertiary centre, severe reactions	57 of 58 (98.3%) classified as definite or probable	32 of 58 (55.2%) classified as atypical DiHS

Two readings of that comparison are needed. First, Sasidharanpillai and colleagues make the statement about the three DiHS-mandatory parameters narrowly, and it should be read narrowly: it says those three earn no positive points as the mandatory triad, not that RegiSCAR never scores a rash at all. Second, the difference in yield in that Indian series was statistically significant at P less than 0.001, so the choice of instrument changes how many severe reactions are captured as cases, which matters for pharmacovigilance reporting as much as for the individual patient.

TRAP **Treating fever as a scoring point in RegiSCAR.** Fever is mandatory in the Japanese criteria and earns nothing positive in RegiSCAR, where its absence subtracts instead. A candidate who has memorised one system and answers a question set on the other will score the same patient two different ways and defend the wrong one. Say which instrument you are using in the first line of the answer.

25.6 The culprit drugs a psychiatrist actually prescribes

In the Indian tertiary-centre series, anticonvulsants were the commonest culprit class by a wide margin, accounting for 82 of 137 (59.9%) cases of definite or probable disease and 36 of 53 (67.9%) of the definite cases. That profile lands squarely on the mood-stabiliser prescription.

IN INDIA

In a patient presenting with fever, an eruption and deranged organ function, work the anticonvulsant column of the drug chart first rather than last, and interrogate everything started in the preceding weeks rather than only the most recent addition. In the Indian series above, the anticonvulsants supplied the majority of definite and probable cases, and the latency reported by Calle and colleagues means the offending drug will often have been started several weeks earlier, commonly within the preceding 2 to 6 weeks, at a point where both patient and clinician have stopped regarding it as new.

Lamotrigine is the agent whose risk a psychiatrist is most often asked to quantify. Its label reports serious rashes, including Stevens-Johnson syndrome, at approximately 0.3% to 0.8% in paediatric patients aged 2 to 17 years and 0.08% to 0.3% in adults. The timing follows the pattern of this whole section: nearly all life-threatening rashes have occurred within 2 to 8 weeks of treatment initiation, with isolated cases after prolonged treatment, for example at 6 months. Note that this window is drawn from a different source and a different endpoint than the general latency quoted earlier, so the two figures should be attributed rather than merged.

The interaction that matters most in bipolar practice is with valproate. In paediatric epilepsy trials, serious rash affected 1.2% (6 of 482) of children taking concomitant valproate against 0.6% (6 of 952) not taking it. The label also lists the presence of the HLA-B*1502 allele among the rash risk factors in its boxed warning, and reports that retrospective case-control studies in patients of certain Asian ancestry suggest an approximately 2 to 3 times higher risk of Stevens-Johnson syndrome and toxic epidermal necrolysis in carriers using lamotrigine. Lamotrigine is therefore not a self-evidently safe substitute in a carrier, and an answer that offers it as one should say which source it is following.

PITFALL

Quoting the valproate figures above when counselling an adult with bipolar disorder about a lamotrigine and valproate combination. Both come from paediatric epilepsy trials in children on multidrug regimens. No bipolar-population figure for that combination is offered here, and the honest counselling position is that the risk is real and quantified only in a different population.

25.7 Beyond DRESS: the other severe idiosyncratic reactions

Carbamazepine carries a second idiosyncratic reaction of boxed-warning severity that is haematological rather than cutaneous. Its label puts the risk of aplastic anaemia and **agranulocytosis** at **5 to 8 times** that of the general population, while noting that the untreated general-population risk is low, at approximately 6 patients per million population per year for agranulocytosis and 2 patients per million population per year for aplastic anaemia. Both halves of that warning must be taught together. A multiplier of that size applied to a base of that size still produces a rare event, which is why the reaction is not a reason to withhold the drug, and why the monitoring that accompanies it is justified by severity rather than by frequency.

The same label also describes a cutaneous pattern that is neither DRESS nor Stevens-Johnson syndrome. A fixed drug eruption presents as single or multiple circumscribed patches recurring at the same site with each exposure, and with repeated exposure the lesions may progress to a **generalised bullous fixed drug eruption**, a serious reaction that may resemble Stevens-Johnson syndrome or toxic epidermal necrolysis. The teaching value is the recurrence at a fixed site, a feature no other reaction in this group shares and one that is available from the history alone.

25.8 Clozapine, and the limits of the antipsychotic evidence

The antipsychotic side of this topic is smaller than it looks. A screen of the European pharmacovigilance database identified 51 probable or definite cases among 75,190 clozapine-treated patients with reports, with a median of 25 days between clozapine initiation and symptom onset and 3.9% ending fatally. A separate systematic review of the published literature found 26 reports covering 27 patients meeting RegiSCAR criteria, which is a collection of published cases and not an incidence cohort.

Those denominators must not be converted into a rate. A pharmacovigilance database counts reports, not patients at risk, and its denominator is the population for whom some report exists rather than the population exposed. Dividing the case count by that denominator produces a number that looks like an incidence and is not one, and because both the cases counted and the population reported on are shaped by who files a report, there is no defensible direction in which to correct it. Read the two studies for what they do establish: the reaction occurs on clozapine, the median interval from initiation to symptom onset in that pharmacovigilance series was 25 days, and a small proportion of reported cases die.

Beyond clozapine, the evidence assembled here stops. No incidence, timing or genetic-association data are offered for the other antipsychotics, and no allele association is stated for clozapine-induced blood dyscrasias or for clozapine-related DRESS. That is a limit of the sources and not a statement that the risk is absent, so the class-level generalisation is precisely what a careful answer refuses to make. The clozapine plasma level, its target range and the haematological monitoring schedule are taught separately under therapeutic drug monitoring, and the resistance decision that put the patient on clozapine is a separate question again.

25.9 After the reaction: confirming the culprit

Where several drugs were started together, the suspected culprit is identified at the bedside during the illness, and testing after recovery refines that attribution rather than making it for the first time. What follows the suspicion acutely is one step, and only one, that this chapter can source: the same authors who set the patch-testing interval, reviewing the French treatment algorithm, place interruption of the suspected drug inside the treatment of even the least severe scenario, alongside topical corticosteroids, emollients and antihistamines, and they describe the rash and the organ damage as resolving gradually after the involved drug is stopped. Withdrawal is therefore an acute treatment step and not something deferred until attribution is confirmed. Everything else about treatment stays untaught here: no corticosteroid indication, dose, route or taper, no second-line immunosuppressant, and no rule for what to do when several drugs remain

equally plausible. Calle and colleagues also state that **patch testing** should be performed 4 to 6 weeks after the reaction, with the patient off immunosuppressive therapy or systemic corticosteroids for at least 4 weeks, in order to reduce false negative results. The washout requirement is itself informative: it is a reminder that many of these patients will have been treated with systemic corticosteroids, and that testing them too early answers a question about their immunosuppression rather than about their drug.

GOOD TO REMEMBER

Do not send the patient for culprit testing at the discharge visit. Testing performed inside the washout period reads negative for the wrong reason, and a false negative here is more harmful than no test at all, because it returns the patient to a drug that nearly killed them with a piece of paper saying it did not. Book the test after the interval and after the steroids have stopped, and record the suspected drug in the chart in the meantime.

One Indian contribution is worth knowing as depth rather than as standard practice. A prospective Indian validation study of the **CET score** as a bedside screen reported that, at a cut-off above 2.12, it achieved sensitivity 94.3%, specificity 60%, positive predictive value 80.5% and negative predictive value 85.7%, against a median diagnostic delay using RegiSCAR of around 14.5 hours. Read those operating characteristics correctly: high sensitivity with modest specificity is the signature of a screening instrument, so it is a tool for deciding whom to work up quickly, not a replacement for the scoring system that classifies the case.

Fever with eosinophilia and deranged organ function weeks after a new anticonvulsant is DRESS until another cause is proven, and the rash may not have arrived yet.

Consolidate and apply

26 · Worked vignettes

A vignette in this territory is never really about the drug; it is about what changed around the drug. Stems that carry marks here rarely open with an undiagnosed patient. They open with someone already on treatment, then introduce one further fact: a second prescription, a failing organ, a pregnancy, an inherited metabolic capacity, a concentration somebody has measured, a trial that did not work, or a syndrome the treatment itself produced. That further fact is the **second variable**, and the examination value of the stem lies entirely in whether the candidate reasons from it or reads past it. This closing section introduces no new agent and no new class; it rehearses the reasoning assembled across this chapter as a reading skill, working each stem from the second variable inwards.

The discipline that earns marks is refusing to answer with a treatment algorithm. A patient who destabilised after a physician added something is not asking which antidepressant treats depression; it is asking which clearance pathway two drugs share. A patient whose measured concentration comes back low is not asking whether the drug works; it is asking whether it was

taken, whether the sample means anything, and what a low value does to the claim that the illness is resistant. Where a stem genuinely turns on class pharmacology itself, the receptor logic behind an adverse-effect signature or a choice within a single class, that reasoning belongs to the Psychopharmacology I: principles and core drug classes notes. What this chapter supplies is the layer sitting above those decisions.

26.1 Four questions locate the second variable

Before deciding what a stem is asking, run the same four questions across it. Between them they cover almost every way an examiner can complicate an ordinary prescription inside one paragraph, and each opens onto a different section of this chapter.

Company	Organ	Genome	Sequence
WHAT ELSE IS ON BOARD	WHAT IS CLEARING IT	WHAT THE PATIENT BROUGHT	WHAT HAS ALREADY HAPPENED

Company asks what else the patient is taking, including everything no psychiatrist prescribed: the physician's additions, the over-the-counter purchase, the traditional remedy, tobacco. Organ asks which tissue transforms and excretes this agent, and whether it is currently doing that work. Genome asks what metabolic capacity and what risk alleles the patient brought into the room. Sequence asks what has already been given, at what exposure, for how long, with what adherence, and what it produced. The fact a stem plants to make one of the four decisive is its discriminator, and a well-built stem carries exactly one.

RULE **The prescription is the setting; the second variable is the question.** If your answer can be written without naming the interaction, the organ, the allele, the measured concentration or the failed sequence, you have answered a question about the diagnosis rather than the one the stem asked. The diagnosis here is usually scenery: it tells you which class the patient is on and nothing more. The marks sit in naming the second variable, stating the mechanism by which it acts on this prescription, and choosing the move that addresses that mechanism.

26.2 The vignette that resolves on another drug

The commonest stem describes a patient stable for a long time who is not stable now, while the psychiatric prescription is unchanged. Somebody else changed something. The reading move is to date the deterioration against the whole medication list rather than the psychiatric part of it, then ask by what route the new agent could reach the old one. The routes behave differently. A **pharmacokinetic interaction** changes how much drug is present, by altering absorption, protein binding, metabolism or renal handling, and the picture is that of too much or too little of an agent whose dose nobody touched. A **pharmacodynamic interaction** changes what a drug does rather than how much of it is there, most often by two agents acting additively on one physiological endpoint; the concentration need not move for the interaction to be real, and one pair of drugs can sit on both axes at once.

Candidates instinctively look for the enzyme, and enzymes do account for many of these stems, but the interaction matrix this chapter develops is deliberately not closed at the cytochrome axis. Drugs also compete for renal excretion, alter the sodium handling that decides how much of a

renally cleared agent is retained, displace one another from plasma protein, and add their effects at a shared receptor or a shared electrophysiological target with no enzyme involved. A stem placing a diuretic, an anti-inflammatory or an antihypertensive beside a psychotropic is usually testing that non-enzymatic axis, and a candidate hunting for a cytochrome substrate will not find one. The agent-by-agent matrix is set out in this chapter's interaction section; what the vignette wants first is the route, named correctly.

GOOD TO REMEMBER

Ask the question a psychiatric review rarely asks: what did somebody else start or stop, and when. Take the physician's list, the surgical discharge summary, the over-the-counter purchases and the herbal preparations, and lay the onset of the new problem against them. Ask about tobacco too, because moving a patient onto a smoke-free ward alters an inducing exposure without a single prescription being rewritten. Anything lining up in time with a change outside the psychiatric list is an interaction until it has been reasoned away.

26.3 The vignette that resolves on an organ

A second family holds the drug list constant and changes the patient. The physiology has moved: renal function has fallen with age or with intercurrent illness, the liver is cirrhotic, cardiac output is poor, or a neurological disorder has altered the tissue the drug acts on. The reading move is to ask which organ this agent depends on, then whether the stem has quietly told you that organ is compromised. **Renal elimination** and **hepatic biotransformation** are not interchangeable answers: an agent excreted essentially unchanged behaves quite differently in kidney disease from one extensively metabolised first, and the two failures call for different adjustments.

The recurring organ stems are cardiac, hepatic and neurological. The cardiac stem asks not only whether an agent is tolerated in heart disease but what it does to conduction and to the metabolic profile that helped produce the disease, and this chapter's monitoring section carries both halves. The hepatic stem asks about reduced clearance, and about sedation a compromised liver tolerates poorly. The neurological stem is subtlest: whether the psychotropic makes convulsions more likely, whether it worsens the movement disorder already being treated, or whether the antiparkinsonian medicine and the antipsychotic are pulling in opposite directions at one transmitter system. The vignette's job is to make the candidate notice that the organ, not the diagnosis, decides the answer.

26.4 The vignette that resolves on a measured concentration

A number in a stem is an invitation to interrogate it, not to recite a range against it. When a stem supplies a plasma concentration, the testable content is what that value means, and its meaning depends on when the sample was taken relative to the dose and to steady state, on which assay produced it, and on the patient's adherence beforehand. A value drawn before the concentration has plateaued is a point on a rising curve, not the patient's exposure. A value drawn at the wrong point in the dosing interval is not comparable with a range derived from a standard sampling time. The ranges, the sampling times and the monitoring schedules are taught in this

chapter's therapeutic drug monitoring section, and a vignette answer reasons against them rather than reproducing them.

The payoff arrives when the value is low. A low concentration in a patient who is not improving has competing explanations: the dose is genuinely too small, the drug is being cleared faster than expected because of an interaction or an inherited phenotype, or the patient is not taking it. Helping to investigate **covert non-adherence** against true pharmacological failure is one of the things a concentration does better than clinical judgement alone, which is why a level belongs in the assessment of apparent resistance before the sequence is escalated. It does not settle the question by itself. A value of zero establishes only that the drug has not been taken recently, and a value above zero is compatible with erratic taking, with full adherence, and with long-standing non-adherence disguised by a few recent doses. What turns a level into an answer is the timing of the last dose against the draw, the dose history, the interacting agents and, where doubt persists, a repeated sample. A high value in a patient who looks well matters too: the margin has narrowed, and the next intercurrent illness will be less forgiving of it.

PITFALL

Acting on a concentration without recording when the previous dose was swallowed. The result travels through the notes as a bare number, and by the time somebody decides, nobody can say whether the sample sat near the peak or near the trough, or whether the patient had been taking the drug at all beforehand. The dose then moves on a value that never described the patient's exposure. Write the time of the last dose and the time of the draw on the request form, and treat a result carrying neither as uninterpretable rather than reassuring.

26.5 The vignette that resolves on the genome

A third family plants an inherited fact. Sometimes it is explicit, a reported metaboliser status or an ancestry; more often implicit, in a patient with marked adverse effects at an ordinary dose, or no effect at a dose that suits most people, or a severe rash soon after an anticonvulsant was started. The reading move is to separate two quite different genetic questions that examinations like to set side by side. A **metaboliser phenotype** is a quantitative statement about clearance: it predicts the exposure a standard dose will produce, and the answer it drives is an adjustment of dose or a move to an agent independent of that pathway. A **risk allele** for a severe cutaneous or systemic reaction is not quantitative at all: it predicts a categorical hazard no dose adjustment addresses, so the decision it drives is whether to prescribe that drug at all.

The discrimination follows from that difference. Testing a metaboliser phenotype is informative mostly after an unexpected response, or before an agent with a narrow margin whose clearance that pathway dominates. Testing a risk allele is informative before the first exposure, in populations where the allele is common enough for the result to change practice, and its worth depends on the balance between how many affected patients it catches and how many unaffected patients it labels. This chapter's pharmacogenomics section teaches the enzymes and their application; the allele testing framework, the drugs it covers and the severe reaction spectrum sit in their own section beside it.

26.6 The vignette that resolves on a failed sequence

The resistance stem gives a history rather than a moment: a list of agents tried, with doses and durations, and a patient still unwell. Candidates rush to the next drug. The mark is in auditing the sequence first. Before an illness is called resistant, each previous trial has to be examined for whether the dose reached an adequate exposure, whether it ran long enough for a response to be judged, whether the patient actually took it, and whether the diagnosis and any maintaining physical or substance-related factor were right. A sequence failing those tests is **pseudoresistance**, and treating it as true resistance escalates a patient who has not yet had one adequate trial. This is where the measured concentration and the resistance assessment meet: a subtherapeutic level inside a supposedly failed trial reclassifies that trial instead of confirming it.

Once the sequence is genuinely adequate, the options are structurally distinct rather than a menu of equals. Switching replaces the agent; combination runs a second agent of the same class alongside the first; augmentation adds an agent from outside that class, which works through a different mechanism while the original treatment continues unchanged. The distinction turns on the class the added agent comes from, not on whether that agent has a therapeutic role of its own in the disorder being treated, because several of the standard augmenting agents do. The definitions of resistance, the staging models, how many failed trials each requires and the comparative evidence for each strategy are developed in this chapter's resistance and augmentation sections. For most of the modalities positioned against resistance, the decision moves to the device-based treatments once the drug sequence has been exhausted, and their indications and utility across disorders are taught in full in this chapter; the procedural technique for each is set out in the ECT and neurostimulation notes. Electroconvulsive therapy may enter earlier, because it is not positioned behind an exhausted drug list where a rapid or definitive response is required, and a candidate who makes it wait for one has misread the indication; the indication itself, with the body that states it, sits in this chapter's ECT section.

TRAP **Calling an illness resistant on the strength of a drug list.** Candidates read a stem containing several agent names and answer with the resistance pathway, because a long list looks like evidence. It is not evidence until every entry has been audited for adequacy of dose, adequacy of duration, adherence and diagnostic accuracy. Examiners write those failures into the stem deliberately, most often as a dose that never rose, a trial abandoned early, or a patient who quietly stopped.

26.7 The vignette that resolves on a syndrome the prescription produced

The next family reverses the direction of reasoning. The stem describes a syndrome and expects the candidate to read it backwards to the prescription that produced it. A febrile, rigid, confused patient on psychotropic medication is an urgent diagnostic and pharmacological problem at once: review the prescription immediately, asking which agents on this list act on which transmitter system, what was added or increased recently, and which of the drug-induced syndromes that combination makes possible, while the competing medical causes are evaluated alongside. The drug chart narrows the field faster than anything else available at the bedside, but it does not license deferring the search for sepsis, for central nervous system disease or for a

severe catatonic state, and this chapter's syndrome sections treat the exclusion of those competing causes as part of making the diagnosis rather than as an afterthought to it. The **iatrogenic phenocopy** is the trap in both directions, because a drug-induced syndrome can be mistaken for deterioration of the illness and deterioration of the illness for toxicity, and the discriminating information comes from the drug history, the tempo of onset and a directed neuromuscular examination taken together, with no single axis decisive on its own. What cannot separate them is whatever the two pictures hold in common, however unwell the patient looks.

The decisions that follow are pharmacological. The first is what to stop. Where the syndrome is severe, where several agents are acting additively, or where the diagnosis is still unresolved between two drug-induced syndromes, every plausible causative agent is withheld rather than one culprit chosen and the rest left running; the list is narrowed afterwards, and only where narrowing it is clinically safe. Naming the agent that most plausibly drove the syndrome still earns the mark, but it is an account of the mechanism, not a licence to continue the others. The second is the **rechallenge decision**: whether the same agent can be reintroduced, whether another member of the class is a safer destination, and what is monitored afterwards. Those judgements, with the precipitant combinations, the mechanism, the named criteria sets as examination constructs and the pharmacological management, are taught in this chapter's sections on the individual syndromes and on their comparative differentiation. The emergency-department presentation, the resuscitation and critical-care escalation and the disposition decision belong to the Perinatal/women's mental health and emergency psychiatry notes, and an answer here stops cleanly at that boundary.

26.8 The vignette that resolves on a physiological state

Pregnancy, lactation, advanced age and childhood are second variables of the same species as an organ, except that they move several things at once and often carry a second patient or a developing one. The stem usually presents a woman established on treatment who is now pregnant, an older patient on several medicines who has become confused or unsteady, or a child in whom an adult regimen has been scaled by weight and something has gone wrong. Distribution and clearance are altered, target sensitivity changes, and the risk being balanced is no longer only the patient's own.

The reading move is to name what has changed and for whom, before naming any drug. In the older patient the variables are cumulative: reduced clearance, altered target sensitivity, more co-prescriptions and poorer tolerance of anticholinergic and sedative burden, which is why the answer there often lies in subtraction rather than substitution. In pregnancy and lactation the balance sits between exposure of the fetus or infant and the risk carried by an untreated maternal illness, so a decision to stop is itself a decision with risk on both sides. The agent-level detail across all four groups is developed in this chapter's lifespan section.

26.9 Look-alike stems and the answering spine

Consolidation is easiest in pairs. The table sets out the stems most often confused in this territory, against the second variable that separates them and the axis the reasoning lands on.

TWO STEMS THAT LOOK ALIKE	THE SECOND VARIABLE THAT SEPARATES THEM	THE AXIS IT LANDS ON
Deterioration in a patient whose psychiatric prescription never changed, against deterioration of the illness	Whether a non-psychiatric medicine was started or stopped, and when	Company
Toxicity on unchanged dosing, against toxicity after a dose increase	Whether renal or hepatic function has fallen since the dose was set	Organ
Marked adverse effects at an ordinary dose, against adverse effects from a co-prescribed inhibitor	Whether the reduced clearance was inherited or acquired	Genome against Company
A severe reaction to an anticonvulsant, against a benign drug eruption	Whether a categorical risk allele rather than an exposure level is what is being tested	Genome
A low measured concentration from too small a dose, against one from covert nonadherence	Whether exposure was ever achieved at any point in that trial	Sequence
A genuinely resistant illness, against a run of inadequate trials	Whether each earlier trial reached adequate dose, duration and adherence	Sequence
A drug-induced syndrome, against a deterioration of the disorder being treated	Whether the tempo, the drug history and the neuromuscular findings fit the prescription or the illness	Sequence

MNEMONIC

Company, Organ, Genome, Sequence

The four second variables spell COGS, and the prescription is only one cog: the vignette asks what the others are doing. **C**ompany, what else is on board, prescribed or not. **O**rgan, which tissue clears the agent and whether it is failing. **G**enome, what capacity and what risk alleles the patient brought. **S**equence, what has been tried, whether it was adequate, and what it produced. Each opens a different section of this chapter, and a stem is usually built on exactly one.

With the second variable identified, an answer that earns marks follows four moves in order.

- Name the second variable in pharmacological language, not as a description of the patient.
- State the mechanism by which it acts on this particular prescription.
- Choose the move that addresses that mechanism: a dose adjustment, a switch off the shared pathway, a measured concentration, a test before prescribing, or an audit of the sequence.
- Say what you would not do, and why the obvious algorithmic answer leaves the second variable untouched.

That last move is where the pharmacology becomes visible to an examiner. A candidate who answers that the drug should be stopped has answered a question about a patient. One who answers that it need not be stopped, because the problem is an added inhibitor that will clear, a level drawn at the wrong moment, or a trial that was never adequate, has answered a question about pharmacology. Every vignette in this territory rewards the second answer.

> Find the second variable - company, organ, genome or sequence - and answer with the mechanism by which it acts on this prescription, never with the next drug in the algorithm.

27 · Consolidation and quick review

Nothing in this chapter is about a drug on its own. Every section here starts where a psychotropic meets something else: another agent competing for the same clearing enzyme, an organ that no longer clears what it used to, an inherited difference in handling or in immune recognition, a life stage in which the exposure is shared, a treatment course in which adequate trials have already failed, or a syndrome the prescription itself produced. The pharmacology of the agent as an object was settled in the chapter before this one. What is settled here is what happens to that pharmacology once it stops being the only thing in the room.

Call that something else the **second variable**. This closing section teaches no new agent and no new syndrome, because each has been taught in the section that owns it. What remains is to state the argument those sections were arranged to make, and to convert it into something that can be produced from a blank page with the book shut. The argument is that safe psychopharmacology is the management of second variables, and that the reasoning is the same every time: work out what the second variable does to exposure or to effect, measure the thing that has changed where a measurement will inform the decision, and act on the established risk or the observed change rather than on the label the patient arrived with.

27.1 One argument, tested against six second variables

Read as a list of territories, this chapter is long and disconnected: emergencies, resistance, monitoring, interactions, prescribing in physical illness and across the lifespan, pharmacogenetics and the device-based treatments. Read as one argument it is a single claim tested six times. The claim is that a psychotropic's behaviour is predictable once you have named what else is acting on it, and that the things that can act on it are few and recurring.

The six recur because they are the routes this chapter's material keeps arriving by: something competing with the drug pharmacologically, a fall in the capacity to clear or tolerate it, a constitutional difference in how the molecule is handled or recognised, a life stage the standard dose was not derived in, a treatment history of adequate courses that already failed, and the drug having produced the presentation itself. Every item in this chapter is one of those six wearing a clinical name, which is why the same three moves answer all of them.

RULE **A psychotropic prescription is safe or unsafe only in the presence of its second variable, never on its own.** The agent's own pharmacology sets what it can do; the second variable sets what it will do in this patient. An answer that describes the drug and stops has described only what the molecule brings, and left out everything else acting on it.

27.2 Exposure or effect: the question that opens every answer

Before anything can be monitored or adjusted, the second variable has to be sorted into one of two kinds, because the two are managed differently and confused constantly. An **exposure change** means the same prescribed dose now produces a different concentration at the site of action: the drug is cleared faster or slower, absorbed or distributed differently, or displaced from the protein carrying it. An **effect change** means altered biological activity at a shared endpoint: two agents push that endpoint in the same direction, a receptor population has changed, or the tissue is more vulnerable than it was. Concentrations may be entirely unchanged in a purely pharmacodynamic interaction, but constancy of concentration is not part of the definition, and the two mechanisms coexist in the same pair often enough that neither excludes the other.

The distinction decides the response. An exposure problem is answered by changing exposure: the dose, the interval, the route, the co-prescribed inhibitor or inducer, or the agent itself if its elimination route is the compromised one. An effect problem is answered by reducing or removing one of the converging contributors, with direct monitoring of the shared endpoint, or by accepting the combination under closer observation; a level inside the reference range does not exclude benefit from dose reduction, because a concentration-dependent effect can still be lessened by lowering exposure. Candidates who cannot separate the two reduce a correct dose and leave an additive combination untouched.

It also decides whether a measurement will help at all. A concentration informs the exposure question but cannot by itself rule an effect problem in or out, so a level requested in a purely pharmacodynamic problem returns normal and is then misread as reassurance; the effect endpoint itself, clinical, electrocardiographic or laboratory, has to be watched directly.

27.3 The three moves, and why they run in that order

Once the second variable is named and sorted, the same sequence organises the answer whichever of the six it is. It is a revision scaffold rather than a prescribing algorithm, and it yields in two situations: act immediately where delay is unsafe, as in a suspected drug-produced emergency, and act on what is already established where a contraindication or a positive pretreatment test is known before the prescription. Measure first only where the result is needed to choose the action. Outside those, the order matters, because each step is meaningful only if the one before it has been done.

- Anticipate. Before the prescription is issued or changed, state what this second variable does to exposure or to effect. This is a prediction from pharmacology, and needs no measurement.
- Measure. Monitor the thing the prediction says will move, alongside the routine monitoring the drug and the patient already require, and expect more than one endpoint to need watching at once. Monitoring chosen this way is **anticipatory monitoring**: the test is selected

because a specific mechanism predicts a specific change, not because it belongs to a routine panel.

- Act. Change the prescription on the strength of either a sufficiently established prospective risk or an observed change, according to the urgency and the evidence, and not on the diagnostic label, the drug's reputation, or the fact that the patient has tolerated the agent before. A contraindicated interaction, organ impairment, a pregnancy hazard, a positive pretreatment test and a suspected toxic syndrome are all acted on before any injury has been observed.

Reversing any two produces a recognisable clinical error. Measuring without anticipating gives a number nobody knows how to read; acting without measuring leaves the prediction untested, which is defensible only where waiting would be unsafe or where the risk was already established; and anticipating and measuring without acting is the commonest of the three, which is how an abnormal result sits in a chart while the prescription that produced it continues unchanged. A fourth step closes the loop outward: reporting what happened, so that a hazard invisible to any single prescriber reaches the surveillance system that can see it.

Anticipate	Measure	Act	Report
WHAT THE VARIABLE CHANGES	THE THING PREDICTED TO MOVE	ON THE RISK OR THE CHANGE	SO THE NEXT PATIENT BENEFITS

27.4 A frame that names all six

Because the six recur and the three moves do not change, one retrieval frame serves the whole chapter. Hold it as six prompts rather than as six topics: under pressure the failure is almost never that a candidate does not know a second variable exists, but that they answer on the one the stem made obvious and never scan for the others.

MNEMONIC

Second drug, End-organ capacity, Constitution, Ontogeny, Non-response, Drug-produced syndrome

The six second variables spell the thing they are: **S**econd drug, meaning another agent competing for the same clearing enzyme, displacing the drug from protein binding, altering its renal handling, or pushing the same physiological endpoint in the same direction; **E**nd-organ capacity, meaning cardiac, hepatic, renal or neurological function below what the standard dose assumed; **C**onstitution, meaning the inherited metabolising phenotype and the immune risk alleles that predict a severe reaction to a specific agent; **O**ntogeny, meaning pregnancy, lactation, childhood and old age as physiological states rather than as diagnoses; **N**on-response, meaning adequate trials that have already failed; and **D**rug-produced syndrome, meaning the acute psychotropic emergencies and the severe idiosyncratic reactions. Scanning all six before answering is the habit this chapter exists to build.

Each of the six is taught in full in the section that owns it, with its own agents, mechanisms and figures. The frame below is a retrieval index rather than a teaching table, and it deliberately gives

the same four columns to all six, because the point of the chapter is that the columns do not change.

THE SECOND VARIABLE	WHAT IT CHIEFLY CHANGES	WHAT IS WATCHED	WHAT THE CHANGE MEANS FOR THE PRESCRIPTION
A second drug taken alongside	Exposure where the agents meet at an enzyme, transporter or binding protein; effect where they converge on one endpoint	The drug concentration for the exposure route where a validated and clinically useful assay exists, otherwise an appropriate clinical or laboratory exposure marker; the shared endpoint for the effect route	Separate the agents, change one, or adjust exposure. Not every interaction is enzymatic: some are renal, some purely additive
End-organ capacity that has fallen	Mostly exposure, through reduced clearance; for some agents the tolerable effect narrows as well	Organ function and organ injury markers, interpreted alongside a drug level only where a validated level exists	Prefer the agent whose elimination route is intact, and set the starting exposure to the organ rather than to the diagnosis
Constitution: the inherited handling and the risk alleles	Exposure for the metabolising variants; the probability of a specific severe reaction for the immune risk alleles	The phenotype where testing is available, ideally before the first prescription rather than after a reaction	An unexpected dose response is a signal to assess phenotype alongside adherence, interacting drugs, organ function and sampling validity, none of which excludes the others. Where the owning section indicates a pretreatment test, testing precedes prescribing
Ontogeny: pregnancy, lactation, the very young, the old	Exposure through altered physiology, and the number of people exposed to it	Both parties where the exposure is shared, and the endpoints the age group is vulnerable on	The dose derived in a healthy adult is a hypothesis, not a prescription, and the risk of leaving the illness untreated belongs in the same calculation
Non-response after adequate trials	Neither exposure nor effect, but the meaning of every subsequent prescription	Whether each trial was adequate in exposure and in duration, and whether the drug was actually taken	Establish adequacy before declaring resistance. A course never absorbed or never swallowed is not a failed trial of the drug
A syndrome the drug itself produced	The whole question, from what to add to what to withdraw	The temporal relation between the prescription change and the onset, read together with the syndrome-specific examination findings	Withdraw or withhold the responsible agent first. The rechallenge and substitution decision is a later and separate judgement

27.5 The monitoring layer, and what each measurement is really for

Monitoring is the chapter's connective tissue, and it is badly taught as a schedule to memorise. Monitoring detects drug exposure, the drug's own effects and the patient-specific modifiers acting on either, and much of what it detects is clinically silent, so each test is best held as a **monitoring proxy**: a visible quantity standing in for an invisible one. What a test proxies for tells you when it is worth taking, what a normal result fails to exclude, and which second variable an abnormal one points at.

WHAT IS MEASURED	WHAT IT IS ACTUALLY A PROXY FOR	THE SECOND VARIABLE IT EXPOSES FIRST
The drug's plasma concentration	Exposure achieved, as distinct from the dose written on the chart	A changed clearance, a competing agent, or a prescription that was never taken
The corrected QT interval on the electrocardiogram	A shared cardiac effect that several unrelated agents can each contribute to	Additive pharmacodynamic interaction, and patient-specific susceptibility to delayed repolarisation and torsades
Weight, glycaemia and the lipid profile	Cumulative metabolic effect, which accrues without any symptom announcing it	A slow effect burden that no acute presentation will reveal
The blood count	An emerging haematological adverse effect tied to particular agents, which the patient cannot feel and cannot report	A drug-produced reaction caught as it develops, rather than a constitutional susceptibility the count could have identified in advance
Renal function	The remaining capacity to eliminate what the kidney clears	An end-organ change that happened after the dose was set
The liver function tests	Hepatocellular injury. They detect damage and do not quantify metabolising capacity, so a normal set does not establish that clearance is intact	An end-organ change that happened after the dose was set, and sometimes a hazard the drug itself produced
The reported adverse reaction	A population signal that no individual clinic can generate alone	A hazard that is real in aggregate and invisible at any single bedside

Held this way, the monitoring sections stop being a timetable and become the second half of a prediction. It also supports **reverse retrieval**, the drill worth doing: instead of asking what to monitor for a given drug, take an abnormal result and produce the second variables that could have generated it. That is the direction an examiner's stem runs, and the direction a referral arrives in.

27.6 When the drug itself is the second variable

Two of the six deserve separating out, because in both the prescription has stopped being the intervention and become part of the problem. The first is non-response. Once adequate trials have failed, the question is no longer which agent is theoretically best but what the failure has

established, and the answer is to check exposure before accepting effect: a course that never reached an adequate concentration, or was never taken, teaches nothing about the drug. Only once adequacy is verified does the switch, combine and augment decision become real, and the same verification is what positions the resistance-indicated device treatments taught here as modalities in their own right. That positioning is not universal: electroconvulsive therapy may be used first line where a rapid or definitive response is required, and is not conditional on failed adequate drug trials.

The second is the drug-produced syndrome, where the discipline is the **iatrogenic differential**: asking of any new presentation in a patient on psychotropics whether the prescription could have caused it, before asking what else the patient has developed. Rigidity, fever, confusion, a rash, a fall in the blood count and a disturbance of consciousness are all things a psychiatric patient can acquire independently and all things a psychotropic can produce. Timing against the last prescription change, the exposure history and the syndrome-specific examination findings have to be integrated, and none of them is universally sufficient on its own, which is what makes the drug history part of the investigation rather than its background. What this chapter owns is the pharmacology: which agents and combinations precipitate each syndrome, the mechanism, the monitoring that anticipates it and the pharmacological management. The emergency-department presentation, the resuscitation and critical-care escalation and the disposition decision are set out in the Perinatal/women's mental health and emergency psychiatry notes.

27.7 The two ways candidates lose these marks

Two failures account for most of the marks lost here. The first is **label-driven prescribing**: answering from the diagnosis and the drug class when the stem's real content is the second variable it quietly supplied, whether that is a physical illness, a co-prescription, an ancestry, a pregnancy or a previous failed course. The second is treating monitoring as a ritual, reciting what is checked without saying what it is checked for, which reads as memorised and does not survive a supplementary question.

TRAP **Answering the drug question the stem appears to ask instead of the second-variable question it actually asks.** Vignettes here are built by taking an ordinary prescribing decision and adding one complication, so the marks sit almost entirely in that complication. Candidates who begin by classifying the drug and end by naming an agent write a fluent answer to the wrong question; an answer that opens by naming the second variable and saying whether it changes exposure or effect has already earned most of what is available.

PITFALL

Continuing an unchanged prescription through a changed patient. The dose was correct for the renal function, co-prescriptions, weight and physiological state that existed when it was written, and none of those is fixed. Dehydration, a medicine started elsewhere, a pregnancy, an intercurrent illness and simple ageing all move the second variable while the chart stays still. Reviewing the prescription against the patient's current state, rather than reissuing what was tolerated before, is the most transferable habit here.

27.8 Where this chapter stops, and what to carry in

A disciplined answer is defined as much by what it hands over as by what it teaches.

Consolidating this material includes consolidating its edges, because several neighbouring chapters treat the same drugs and the same syndromes from a different angle. Each of the following is worth rehearsing as a **boundary handover**: named where it touches the question, passed to its owner in one sentence, and left there.

- The principles this chapter applies, meaning half-life and steady state, the cytochrome substrate map, the therapeutic index and choice between agents within a single class, belong to the Psychopharmacology I: principles and core drug classes notes. This chapter uses them as instruments rather than deriving them.
- The emergency act for the drug-produced syndromes, meaning the presentation to the emergency department, the resuscitation and critical-care escalation and the disposition decision, belongs to the Perinatal/women's mental health and emergency psychiatry notes.
- The procedural technique of the device-based treatments, meaning how each is administered and the service arrangements it needs, is set out in the ECT and neurostimulation notes. This chapter keeps the modality and its utility across disorders.

IN INDIA

Two of the six second variables carry a decision that is made differently on Indian ground, and both are worth retrieving as decisions rather than as facts. Where the section that owns the testing framework indicates a pretreatment genetic test before a specific anticonvulsant in people of the ancestries at raised risk, the decision is to test before prescribing rather than to react after a severe cutaneous reaction has occurred. Where the patient's own slow-metaboliser phenotype has been determined, the decision is to follow the gene-drug recommendation that result carries. Where only the population frequency of the variant is known, the decision is ordinary cautious prescribing, opening at the lower end of the range and titrating against response, without labelling this patient a slow metaboliser: a frequency in a population is a prior probability and not a result in the person in front of you. In the first of these the second variable is known before the first prescription, and that is where anticipation is at its most complete.

GOOD TO REMEMBER

Finish every prescribing decision in a complicated patient with a spoken sentence: this agent, at this exposure, in the presence of this second variable, watched with this measurement. Said aloud on a ward round it exposes the limb nobody thought through, and it is the sentence that earns marks in a viva. A decision that cannot be completed in that form has not been made pharmacologically.

Carried into the examination, the whole chapter collapses to a sequence that survives when detail fails. Name the second variable the stem introduced. Say whether it changes exposure or effect. State what you would measure because of that, what you would do with the answer, and what you are handing to somebody else. Consolidation buys not more facts but faster access to the ones

already learned, so that under pressure the reasoning arrives as a method rather than as half-remembered warnings about individual drugs.

> Safe psychopharmacology is the management of second variables: name what else is acting on the prescription, decide whether it changes exposure or effect, measure the thing that moves where a measurement will inform the decision, and act on the established risk or the observed change rather than on the label.

References

Every specific in this chapter was taken from a named source, and the figure against each entry below is the number of specifics that came from that work. This section lists the 138 works those 662 specifics rest on. It is a list of works, not of page references: for each specific, the chapter's source record keeps the exact page, table row, source file and date of retrieval, 605 separate entries in all, and that detail is kept there rather than reprinted here. To check where one specific came from, look it up there; to find a work, read this list. Doses were read at current regulatory labelling, and each is filed with the regulator, the product, the label version and the date the label was read. 3 specifics are recorded at partial confidence. This list records where each specific came from. It does not assert that the chapter's prose uses each source correctly, which is checked separately.

PART IX

IX

Recent Advances and Landmark Studies

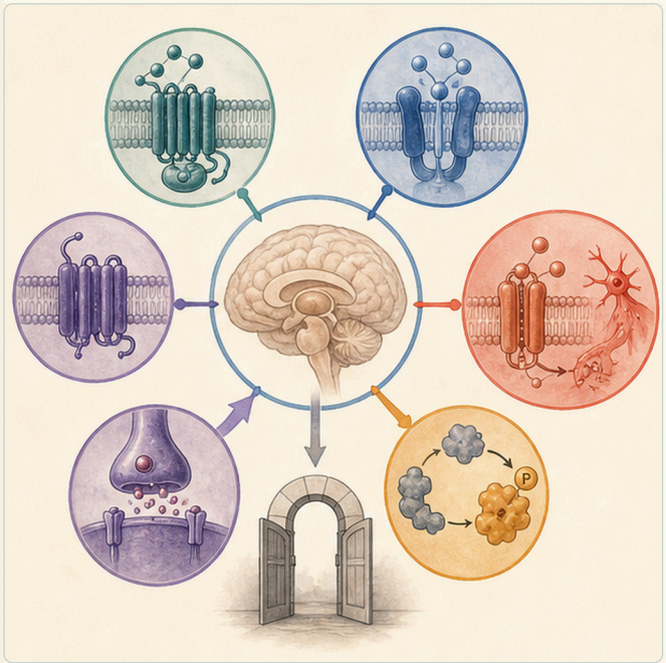
What changed recently and which studies changed it, read as evidence rather than as news.

01 Recent advances and landmark studies

02 Individual newer agents

03 Consolidate and apply

VISUAL 9.1



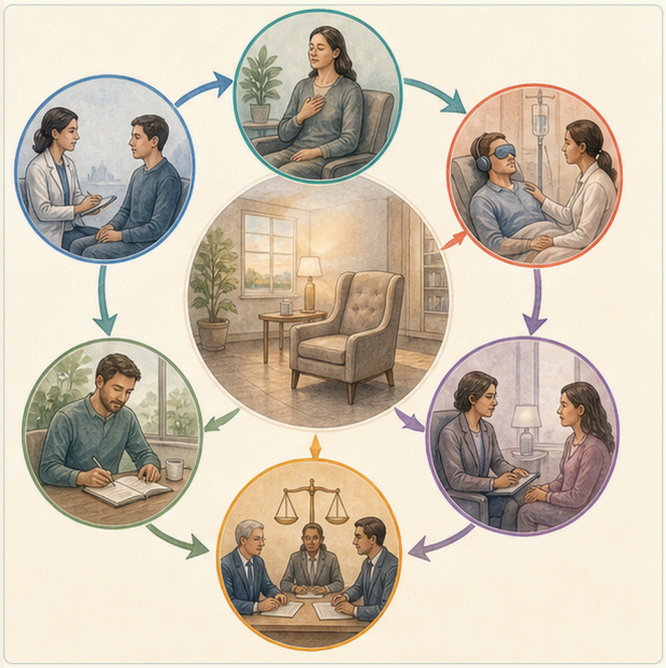
Rapid antidepressants use different treatment containers

- Glutamatergic
- Neurosteroid
- Monoamine
- Setting and monitoring
- Continuation plan

Rapid-acting antidepressant classes differ in mechanism, indication, delivery setting and continuation plan; speed alone does not make them interchangeable.

Source lock: day-38.final.html#sec-t04

VISUAL 9.2



New mechanisms widen psychiatry beyond monoamines

- Muscarinic
- Orexin
- Sigma and NMDA
- Dopamine partial agonism
- PKC targeting
- Approval and indication

Recent agents expand mechanism classes, but each claim remains bounded by the medicine, indication, regulator and evidence base.

Source lock: day-38.final.html#sec-t13

VISUAL 9.3

Psychedelic treatment is more than a molecule

- Screening
- Preparation
- Supervised dosing
- Psychological support
- Integration
- Regulatory status

Psychedelic-assisted therapy is a structured intervention whose screening, support, setting, follow-up and regulatory status are part of the treatment.

Source lock: day-38.final.html#sec-t10

VISUAL 9.4

Computational psychiatry needs an evidence ladder

- Data
- Model
- External validation
- Bias and privacy
- Clinical integration
- Regulatory evidence

AI and computational tools require valid data, external testing, bias and privacy safeguards, and clinical integration before they can improve care.

Source lock: day-38.final.html#sec-t12

PAPER IV

Recent advances and landmark studies

Two bands . one complete notes document

Recent advances and landmark studies

1 · Recent advances and landmark studies for the psychiatrist: what this chapter owns, and what it points to

A drug is never simply approved: it is approved somewhere, for something, on a named authority, as of a date. This chapter gathers the agents, arguments and technologies that arrived in psychiatry most recently. The obvious risk in such a chapter is overlap, since most of these molecules are taught at depth elsewhere in these papers, and the boundaries later on this page handle it. The risk that actually costs marks is different, and installing it is this page's purpose: many of the questions this chapter can ask are about a status rather than a mechanism, and a status is not a property of a molecule.

That is a claim about most of the chapter and not about all of it, and the limit tells you where the discipline applies. Thirteen of the eighteen sections ahead have a regulatory record behind them, at the grain of one agent in one jurisdiction. Five do not, and not through oversight: an argument about a body of evidence, three technologies that are not medicines, and one landmark whose status is left deliberately to the chapter that owns it. In those five the examinable content is mechanism, appraisal and readiness, and a candidate looking for an approval to quote will find none and must not supply one. So the first move on any stem is to decide which of the two kinds of question you have.

1.1 The lens: a status claim is a four-field claim

A statement that an agent may be given, to whom and for what, is a claim about a regulator's document rather than about pharmacology, and this chapter treats it as a **four-field status claim**. The **four fields** are the jurisdiction, the exact indication or trial purpose in the source's own words, the authoritative source that carries it, and the date on which the status was true, which these notes record as **status true as of**. A sentence missing any one of the four is unmarkable, for a clinical reason rather than a stylistic one.

Jurisdiction	Indication	Source	Date
WHICH REGULATOR	IN THE SOURCE'S OWN WORDS	THE DOCUMENT, NAMED	WHEN IT WAS TRUE

Each field fails in a characteristic way. Drop the jurisdiction and the sentence is true somewhere and false where the patient is. Paraphrase the indication and the population quietly widens, because a licence is written for a defined group and the defining words are the ones that were reviewed. Leave the source unnamed and the claim rests on the speaker, which under examination means on memory. Leave the date off and a regulatory record is offered as a

permanent fact, when the reason this chapter exists is that these records moved recently and will move again.

RULE **An approval verb never travels alone.** Before writing that an agent is approved, indicated, authorised or licensed, put all four fields beside it: the jurisdiction, the indication in the source's own words, the document, and the date it was read. If any of the four is unavailable the sentence is not written shorter; it is written as a declared gap.

1.2 Jurisdiction is the hazard, and it does not run as a ladder

The organising fact of this chapter is that its agents are carried in up to **three jurisdictions** and that the cell, not the agent, is the unit of truth. Nothing about the three is ordered. The ledger behind these notes carries a grounded Indian row for lemborexant while its European cell is a declared gap on the centralised register, and a grounded Indian row for endoxifen while its United States cell is a declared gap after multi-route probing of the federal application database. Reading the United States first, the European Union next and India last as a ladder of maturity produces two confident wrong answers in this chapter alone.

The intuition behind the ladder is not stupid, which is why it survives. Volume does run that way: across the sixteen agents the ledger holds, the United States column carries the most grounded cells, the European Union fewer, India fewest. But a column total says nothing about any particular cell, and **regulatory recency** is the hazard this chapter names because a recent record is distributed unevenly, for reasons with little to do with maturity. An agent may reach one regulator first because that is where its sponsor filed, or reach India by a route that never went to a large market. Reasoning from column to cell is arithmetic where the question asked for a document.

TRAP **Filling an empty cell from a full one.** Asked about Indian availability, candidates answer from the American label, because the American record is the one they have read. The two cells are independently sourced, and this chapter holds pairs that point in opposite directions, so an inference from one to the other is not a cautious estimate. It is a fabricated citation wearing a real document's name. Say what the Indian record shows, or say what was searched and on whose authority a claim would rest.

1.3 Three states a cell can be in

Every cell reads in one of three ways, and knowing which one you have settles what may be written from it. A **declared gap** is the state most often misread, because it is a statement about an instrument and never about the world. Where the search ran on several routes, each positive-controlled in the same run, these notes call the result a **measured absence** rather than a probe silence, and even then one gap in this chapter turned out to be a probe miss once the record was retrieved another way. The third state is the one a candidate never expects: a **supportive source** that recites an approval without being one.

THE CELL READS	WHAT IT LICENSES	WHAT IT NEVER LICENSES
Grounded	The indication in the source's own words, for that jurisdiction alone, with its document and its date beside it	A sentence about any other jurisdiction, or the same sentence later without a fresh reading
Declared gap	What was searched, on which instrument, how sensitively, and whose authority a claim would ultimately rest on	Any categorical negative. Silence on an instrument is a fact about the instrument
Supportive source only	That a named body recited an approval, and the document in which it recited it	That the regulator granted it, or the recited date reused as an approval date

The middle state carries most of the weight, because this chapter has already had one gap turn out to be wrong: a cell that read as an absence was re-probed by another route and the record came back. So a declared gap is written as a description of a search rather than a verdict, on the terms the table above sets. A gap written that way can be closed by the next reader of the primary document. A gap written as a negative has to be retracted.

1.4 The instrument, and the five sections it cannot see

The shape of the apparatus behind these notes decides which questions it can answer. The record holds one row per agent per jurisdiction, sixteen agents across three regulators, every row carrying the same four fields. Those rows attach to thirteen of the chapter's eighteen sections. The five without them are the sections whose subject is not a licensed medicine: the serotonin hypothesis debate, an argument about a body of evidence rather than about any agent's licence; the artificial intelligence, biomarker and digital therapeutics sections, which are not what a drug-approval register records; and the anti-amyloid antibodies, where no row is written deliberately, so that none can be quoted from here.

The instruments behind this chapter are drug-approval instruments. When one returns nothing about a technology that is not a medicine, the silence is a fact about the instrument and not about the product, and a sentence converting it into a status is an invented claim wearing a real register's name. In those five sections the honest move is to say what the instruments cover and what they cannot see, then teach what is genuinely examinable: what the object is, what evidence would establish it, and what a service would have to know before using it.

IN INDIA

The Indian cell is the one most often filled in from memory, and the published CDSCO approval lists behind these notes carry a measured limit worth knowing before any silence in them is trusted: their positive controls all sit in documents dated well before the era this chapter covers, and one component substance of an agent taught here appears nowhere in that corpus under any spelling. So an Indian cell is either written from a document that was read, or declared as a gap naming what was searched and how sensitively. A brand on a pharmacy shelf, a CTRI trial registration, a no-objection certificate for a clinical trial and a committee minute recommending approval are none of them a marketing authorisation, and one agent here sits in exactly that state: a national committee's minutes recite an approval, and the row recording them licenses only the fact that they recite it.

1.5 A map of the chapter

With the lens in place the architecture becomes legible. The chapter runs in two declared halves: the recent advances of the last two years, then six individual newer agents held as whole-agent profiles. The map groups the eighteen sections into seven bands. It is not a list to memorise; it tells you which question a later section answers and which neighbour it borders.

BAND OF THE CHAPTER	THE SECTIONS IN IT	WHAT THE BAND IS FOR
The rapid-acting antidepressants	Esketamine and intranasal therapy; zuranolone and the neurosteroid antidepressants; rapid-acting antidepressants as a class	A comparative class map, so the category is not learned as a third ketamine monograph
Sleep-wake pharmacology	Dual orexin receptor antagonists and sodium oxybate	The sharpest regulatory contrast here: one class, four agents, three patterns across three jurisdictions
Mechanisms outside the established algorithms	Xanomeline-trospium and the muscarinic antipsychotics; endoxifen and the protein-kinase-C-targeted agents	Two mechanisms beside the established algorithms rather than inside them, and the most Indian section here
A landmark named and handed on	Anti-amyloid monoclonal antibodies	Why the class matters to psychiatry and not only to neurology, with its status delegated explicitly
Two arguments about evidence	The serotonin hypothesis debate; psychedelic-assisted therapy	What a body of evidence does and does not license, and how to appraise an intervention that is a package, not a molecule
Research to clinic	Artificial intelligence and machine learning; biomarker-driven and computational psychiatry; digital therapeutics and prescription apps	One readiness ladder read three times: analytical validity, clinical validity, clinical utility, regulatory authorisation, routine deployment
The individual newer agents	Asenapine; lurasidone; brexpiprazole; cariprazine; lumateperone; zuranolone as an agent profile	Whole-agent profiles read cell by cell, with the class primer given once instead of six times

Read the map both ways. Given a question, it says which band holds the answer and what kind of answer is wanted. Given a section, it says what its neighbours already cover, which stops an answer drifting into material being marked elsewhere.

1.6 What this chapter owns, and what it hands over

Naming the owning chapter is faster and better rewarded than rebuilding its material from memory. For the drug handovers below, that chapter holds the clinical pharmacology and this chapter holds only what changed, where, and on whose record. For the last two the neighbour holds the neurobiology and the service question instead, and this chapter holds no regulatory record for either, as the second paragraph above says. The handovers are not the whole picture, and treating them as though they were is its own error: this chapter owns seven of its eighteen sections in full, being the neurosteroid material and its agent profile, the muscarinic, endoxifen and lumateperone sections, and the artificial intelligence and biomarker sections. The research-to-clinic readiness ladder those last two build with the digital therapeutics section is this

chapter's as well. Where a section is owned in full there is no neighbour to point at, and an answer that gestures at another chapter has left the marks on the table.

- Ketamine and esketamine in treatment-resistant depression are taught in full in the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes, and the antidepressants and antipsychotics themselves in the Mood disorders: pharmacotherapy notes.
- The hypnotics and the oxybates belong to the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes and the Eating and sleep-wake disorders notes; the psychedelics as substances belong to the Substance use disorders notes.
- Anti-amyloid monoclonal antibodies are named here and taught in the Dementias and neurocognitive disorders notes, which own their status entirely; this chapter states none.
- Service-level deployment of anything digital belongs to the Community psychiatry and public health notes, and the serotonin hypothesis as neurobiology to the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes and the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes.

PITFALL

Quoting a status you learned once as though it were still true. Every row behind this chapter carries the date its status was true, because this is the most recently changed material in the syllabus: an indication is widened, a second regulator authorises the same agent for something narrower, a product is discontinued while its approval stands. A candidate who memorised a status and reproduces it much later has not made a small error of currency: the sentence carries no date, so it offers a stale reading as a permanent fact. Learn the four fields and the shape of each record rather than the record itself, and say when you last read it. In the clinic it means checking the document before prescribing a recently licensed agent, not after a query is raised.

1.7 What the examination rewards

A small number of moves earn most of the marks here, and they recur across every band in different clothing. Naming them before the detail arrives is worth more than any single fact, because the detail in this chapter is unusually perishable and the moves are not.

- Answering at the cell rather than at the agent, so a question about one jurisdiction is never answered out of another's record.
- Producing the four fields as a sentence, instead of a verdict with the qualification left to be assumed.
- Reading a silence as a statement about an instrument, and saying what was searched, how sensitively, and on whose authority a claim would rest.
- Giving an ordering with its basis named wherever no quantity is available, rather than a figure that would have to be invented to be given.
- Deciding whether the stem wants a status or a construct, then handing over what a neighbour owns in one sentence rather than rebuilding it.

Those five are also, in the same order, the five ways an answer here goes wrong, which is why they are habits rather than advice. A candidate who runs them will sometimes have to say that a record was searched and not found, or that an ordering is all the evidence supports. Both are complete answers here, because the alternative is a confident sentence nobody can source.

GOOD TO REMEMBER

Before recommending, prescribing or teaching any agent from this chapter, ask four questions in order. Which regulator's document supports this use in the country where this patient is being treated. What does that document say the indication is, in its own words rather than in yours. When did you last read it. And is the thing you are about to say a status claim, needing all four fields, or a mechanism claim, needing none of them and needing a stated limit instead. A clinician who answers those four before speaking will not be the person who tells a family a treatment is available on the strength of a label written for another country.

1.8 Holding it together

Under examination pressure the detail goes first, because a date and a verbatim indication are harder to hold than a mechanism. What has to survive is a routing sequence. The scaffold below is a teaching device for that sequence rather than a validated instrument, and it will structure an answer on any of the eighteen sections.

MNEMONIC

Kind, Currency, Grain, Owner

Kind: which of the chapter's three kinds of section the stem sits in, an agent with a regulatory record, an argument about a body of evidence, or a technology on a readiness ladder. **Currency**: what the answer is paid in, a status with its four fields, or a construct with its mechanism, its evidence and its limit. **Grain**: if it is a status, answer at one agent in one jurisdiction, and say which of the three states that cell is in. **Owner**: who holds the clinical pharmacology, which for most sections is a neighbouring chapter named in a sentence, and for seven of the eighteen is this chapter, where a full account is owed and a cross-reference earns nothing.

For a short answer, run the four and stop. For a long essay, expand each into a paragraph and take the specifics from the section that owns them. In a viva, make the sequence audible: name the jurisdiction, say what the document says and when it was true, and say what you would have to read to answer for anywhere else. That last sentence separates a candidate who has understood this chapter from one who has memorised it, because it concedes a limit without conceding the question.

Every status sentence carries its jurisdiction, its exact indication, its authoritative source and the date it was true, and no status is ever carried across a border.

2 · Esketamine and intranasal therapy, including monotherapy indication updates

An approval is not a property of a molecule; it is a sentence a named regulator wrote in a named country on a named date. Intranasal esketamine is where that discipline is examined, and the marks are lost in one move: a status carried across a border, almost always from the United States inward, into a sentence true somewhere and false where the patient is. Delivery, dissociation and blood-pressure monitoring, the observation period and the access problem belong to the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes and are not repeated here.

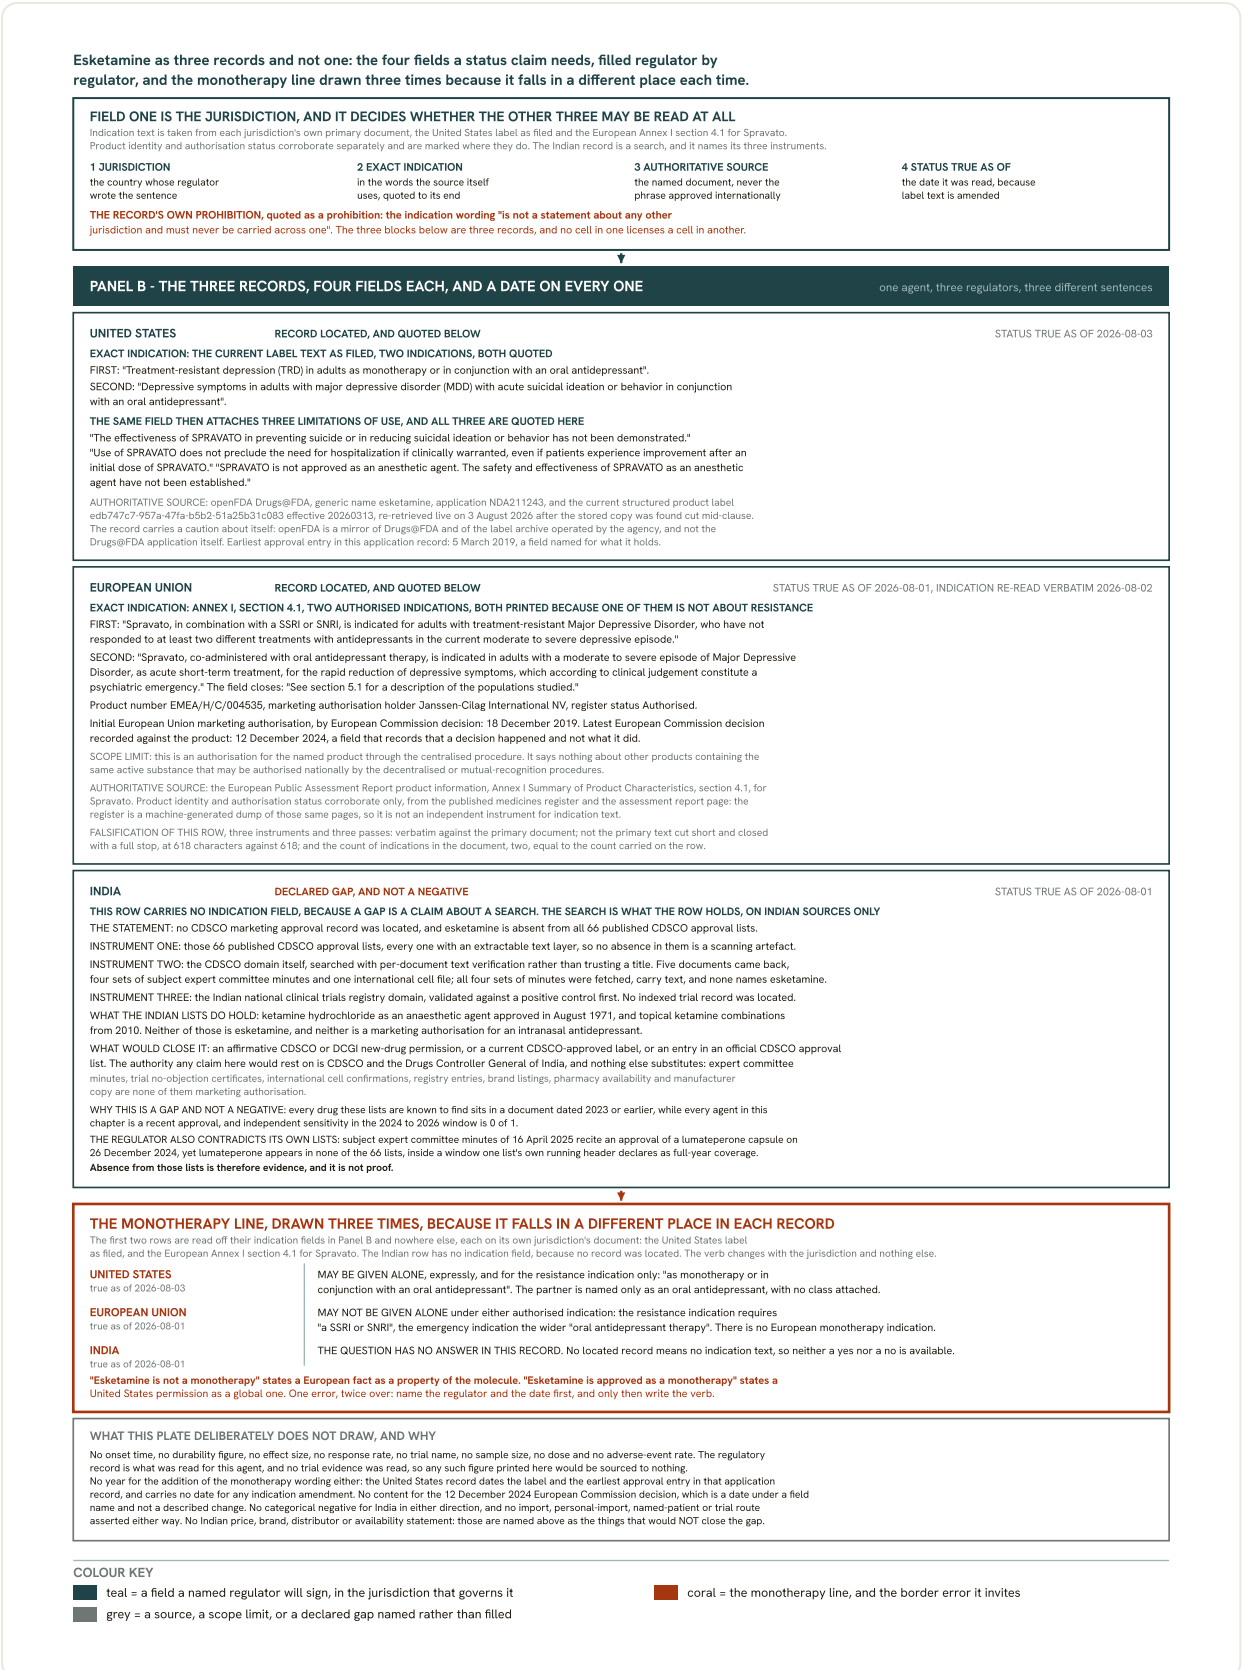


Fig 38.1 **The four-field status ledger applied to esketamine, one record per regulator.** The United States record, read 3 August 2026, permits the spray alone for its resistance indication, as monotherapy or in conjunction with an oral antidepressant. The European record, read 1 August 2026, carries two authorised indications, one requiring a SSRI or SNRI and the other oral antidepressant therapy, so neither authorises it alone. The Indian record is a declared gap: no CDSCO marketing approval record located, across 66 published approval lists, with the document that would close it named. The monotherapy question therefore has three answers and no single one. (openFDA Drugs@FDA NDA211243; the European Annex I section 4.1 for Spravato; the CDSCO approval lists and the Indian trials registry.)

2.1 Four fields, and the sentence that fails without them

A regulatory status is usable only when it carries four fields together: the jurisdiction, the exact indication in the words the source itself uses, the authoritative source, and the date on which the status was true. "Esketamine is approved for depression" fails on all four, and last on the date, in a domain where label text is amended and last year's correct answer can already be wrong.

Every statement below was read from its primary source on 1 August 2026, with the European indication text re-read verbatim on 2 August 2026 and the United States label text re-retrieved on 3 August 2026, and each is offered as true as of that reading and nothing more.

A status never travels, and the source record says so: the label wording is not a statement about any other jurisdiction and must never be carried across one. And "approved internationally" is not an answer: name the regulator, or say that no record was located and what was searched.

RULE **A status sentence is written in one jurisdiction and stays there.** An American indication does not imply a European one, and neither implies anything about a country whose regulator was never asked. Where the record for a jurisdiction is empty, say the record is empty, in that jurisdiction, on that date.

Marketing authorisation is a permission granted by a national regulator, and it is not availability. Expert committee minutes, trial no-objection certificates, registry entries, brand listings and pharmacy availability are none of them marketing authorisation.

2.2 The United States: the indication that carries monotherapy

Two indications sit on the current United States label. The first is for the treatment of treatment-resistant depression (TRD) in adults as monotherapy or in conjunction with an oral antidepressant. The second is for depressive symptoms in adults with major depressive disorder (MDD) with acute suicidal ideation or behavior in conjunction with an oral antidepressant. The resistance indication offers a choice, **monotherapy** or combination; the suicidality indication offers none, the oral antidepressant being part of it rather than an option inside it.

The label then attaches three Limitations of Use. The first: the effectiveness of SPRAVATO in preventing suicide or in reducing suicidal ideation or behavior has not been demonstrated. So the licence is for depressive symptoms in a patient who has **acute suicidal ideation or behavior**, and it is not a licence for treating the suicidality; sliding from the first formulation to the second claims an effect the label explicitly declines. The second: use of SPRAVATO does not preclude the need for hospitalization if clinically warranted, even if patients experience improvement after an initial dose of SPRAVATO. A rapid response is not a disposition decision. The third: SPRAVATO is not approved as an anesthetic agent. The safety and effectiveness of SPRAVATO as an anesthetic agent have not been established.

The status was read from the openFDA Drugs@FDA interface, application NDA211243, with the current structured product label effective 13 March 2026, on 3 August 2026. The record carries a caution about itself: openFDA is a mirror of Drugs@FDA and of the label archive operated by the agency, and not the Drugs@FDA application itself.

The earliest approval entry in that application record is dated **5 March 2019**, and the field is named for what it holds, the earliest approval-status date in the record, not for what a reader would like it to mean. The record carries no date for the monotherapy wording: the label in force at the reading contains it, and nothing in the source read here says when it entered. So the defensible sentence is that the United States indication included monotherapy on the label effective 13 March 2026, read on 3 August 2026; the indefensible one names the year monotherapy was added.

GOOD TO REMEMBER

An indication that permits monotherapy permits it; it does not recommend it, and it does not make the evidence for the drug alone equal to the evidence for the drug alongside an antidepressant. The maintenance trial and the head-to-head comparison taught in the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes are both add-on designs there, so a durability or comparator figure from either carries the design it came from and does not attach to a monotherapy sentence it was never generated under.

2.3 The European Union: two authorised indications, and neither is a monotherapy

The European authorisation covers the same product and is not the same licence. Annex I of the **Summary of Product Characteristics**, section 4.1, carries two therapeutic indications, and both must be reproduced before the licence has been described. The first: Spravato, in combination with a SSRI or SNRI, is indicated for adults with treatment-resistant Major Depressive Disorder, who have not responded to at least two different treatments with antidepressants in the current moderate to severe depressive episode. The second: Spravato, co-administered with oral antidepressant therapy, is indicated in adults with a moderate to severe episode of Major Depressive Disorder, as acute short-term treatment, for the rapid reduction of depressive symptoms, which according to clinical judgement constitute a psychiatric emergency.

Neither indication authorises the spray by itself: the first requires an SSRI or SNRI, the second requires oral antidepressant therapy, so there is no European monotherapy indication of any kind. And the sentence that European esketamine is indicated only for treatment-resistant depression is false, because the second indication is not about resistance. It is an acute, short-term indication for what clinical judgement calls a **psychiatric emergency** inside a moderate to severe episode, and a patient can meet it at first presentation, having failed nothing.

That the second indication is really there was tested. The European row was checked against the primary document on three instruments: whether its text is verbatim in the product information, whether it is the primary text cut short and closed with a full stop so that nothing signals the loss, and whether the count of indications carried matches the count in the document. Two indications are in the document and two are on the row. A one-indication summary of a two-indication licence reads as complete, which is why the third instrument counts.

Spravato holds product number EMEA/H/C/004535, its marketing authorisation holder is Janssen-Cilag International NV, and its status on the European Medicines Agency register is Authorised. The initial European Union marketing authorisation, by European Commission

decision, is dated **18 December 2019**. The most recent European Commission decision recorded against the product is dated **12 December 2024**, and that date needs a warning: the field records the latest decision and does not state what it did. Nothing read here says it touched the indication, and converting a decision date into an indication change manufactures the change out of a timestamp.

One limit belongs on every European sentence here. This is an authorisation for the named product through the **centralised procedure**, and it says nothing about other products containing the same active substance that may be authorised nationally by the decentralised or mutual-recognition procedures, which the central register does not cover by construction. "Authorised in the European Union" therefore means authorised centrally, for this product, and an answer should say so.

2.4 The monotherapy line, drawn regulator by regulator

The line falls differently in each jurisdiction.

JURISDICTION	THE RESISTANCE INDICATION, IN THE SOURCE'S OWN TERMS	MAY THE SPRAY BE GIVEN ALONE?	NAMED PARTNER DRUG
United States	Treatment-resistant depression in adults, as monotherapy or in conjunction with an oral antidepressant	Yes, expressly, for this indication	An oral antidepressant, no class named
European Union	Treatment-resistant major depressive disorder in adults who have not responded to at least two different treatments with antidepressants in the current moderate to severe depressive episode	No	A SSRI or SNRI, named and restricted
India	No CDSCO marketing approval record located as of 1 August 2026	The question has no answer in the record	The question has no answer in the record

One difference is not in the table. Only the European indication writes its own entry criterion, counting failed antidepressant treatments within the current episode; the American resistance indication names the condition and leaves the counting elsewhere.

Both second indications require an oral antidepressant alongside, and there the agreement stops: the American is anchored to a symptom on which the label then declines to claim an effect, the European to a clinical judgement about the situation as a whole.

1 of 2	2	66	0
US INDICATIONS PERMITTING MONOTHERAPY	AUTHORISED EU INDICATIONS, BOTH COMBINATION	CDSCO APPROVAL LISTS SEARCHED	INDIAN APPROVAL RECORDS LOCATED

TRAP **Writing "esketamine is not a monotherapy" as a fact about the drug.** It is a fact about a jurisdiction. The add-on-only sentence matches the European wording, where both authorised indications require a partner antidepressant, and it does not match the current United States label, where the resistance indication reads as monotherapy or in conjunction with an oral antidepressant. It is also the sentence carried in the Mood disorders: pharmacotherapy notes, and that adjunctive position holds on the European wording; the American half of it is what this dated update revises. The mirror-image error is just as costly: writing that esketamine is approved as a monotherapy, full stop, states an American permission as though it were a global one.

TRAP **Writing that the European licence requires an SSRI or SNRI.** True of the resistance indication and untrue of the other one. The SSRI or SNRI restriction is printed in the treatment-resistant indication; the psychiatric-emergency indication says co-administered with oral antidepressant therapy, the wider phrase. A candidate who has learned only the resistance indication will state the narrow partner rule for a patient it was never written for. Quote the indication you mean, and quote it whole.

2.5 India: what was searched, what was not found, and what would close it

The Indian position is the one an Indian examination cares about most and the one most often invented. Stated exactly: no CDSCO marketing approval record was located, and esketamine is absent from all 66 published CDSCO approval lists, as of 1 August 2026. That is a statement about a search, which has to be described before it means anything.

Three instruments were run. The first was the corpus of 66 published CDSCO approval lists, every one of which yielded an extractable text layer, so no absence in it is an artefact of an unreadable scan. The second was a search of the regulator's own domain with each returned document downloaded and its text verified rather than its title trusted. The third was a search of the national clinical trials registry domain, validated against a positive control before any zero result was believed. The design point: a search never shown to find what it should find cannot prove that something is missing.

Five documents came back: four sets of subject expert committee minutes for neurology and psychiatry, and one international cell file. All four sets of minutes were fetched, all carry an extractable text layer, and none of them names esketamine. Those **subject expert committee minutes** were search-index false positives, not evidence. No indexed trial record was located on the national registry either.

The corpus is not empty of the parent molecule, which is where a careless reader manufactures an approval. It contains ketamine hydrochloride as an anaesthetic agent approved in August 1971, and topical ketamine combinations from 2010. Neither of those is esketamine. Neither a racemic anaesthetic licensed for another purpose nor a topical combination licensed for another route is a marketing authorisation for an intranasal antidepressant; and the American label states in terms that SPRAVATO is not approved as an anesthetic agent.

What would close the gap is nameable, which is the test of an honest one. The missing document is an affirmative CDSCO or DCGI new-drug permission, or a current CDSCO-approved label, or

an entry in an official CDSCO approval list. Nothing else substitutes. Expert committee minutes are supportive at best and are not themselves marketing authorisation; a clinical-trial no-objection certificate, a written confirmation from the international cell, a CTRI registration, a brand listing, pharmacy availability and manufacturer copy are none of them marketing authorisation either. Name the document that would settle it, and say whether you have it.

IN INDIA

The sentence to write, in an examination and in a clinical note, is that no CDSCO approval record for intranasal esketamine was located as of August 2026, followed by what was searched: the published approval lists, the regulator's own domain, and the trial registry. Do not write that esketamine is unapproved in India, which is stronger than the evidence supports, and do not write that it is approved, because nothing retrieved says so. A brand name, a price or a distributor's letter is not that document. For a patient or a family: this treatment has a licence elsewhere and no located Indian licence, and what a service can actually offer today is the question to answer first.

2.6 Why the Indian finding is a declared gap and not a negative

A **declared gap** states that a search of named instruments did not retrieve a document, and names the document it wanted. A negative states that the thing does not exist. The first is defensible on the evidence in hand; the second needs an instrument whose silence means something, and that sensitivity has to be measured, not assumed.

Here it was measured, and it is poor in exactly this chapter's window. Every drug the corpus is known to find sits in a document dated 2023 or earlier, while every agent in this chapter is a recent approval, and independent sensitivity in the 2024 to 2026 window is 0 of 1. The corpus is therefore no warrant for a gap on a recently approved agent: it has never been shown to find one.

The stronger leg is that the regulator's own documents contradict its own lists. CDSCO subject expert committee minutes of 16 April 2025 state that a lumateperone capsule had already been approved in the country on 26 December 2024, yet lumateperone appears in none of the 66 lists, and the list that declares full-year 2024 coverage in its own running header carries entries dated 17 and 30 December 2024, so it is not truncated before the approval those minutes recite. A list that misses an approval its own committee recites, inside its own declared coverage window, is a list whose silence cannot be read as absence.

Write the conclusion narrowly. Absence from this corpus is evidence and not proof, and the claim being made is that no CDSCO approval record was located, not that the drug is unapproved in India. Note what was deliberately not done: the absence was established from Indian sources only, and no American or European value was consulted to produce any part of it. A jurisdiction's emptiness is established in that jurisdiction, never inferred from another's fullness.

PITFALL

Counting search hits instead of reading them. The regulator-domain search returned five documents and none names esketamine; a count would have recorded five findings where the correct number is zero. The error runs the other way in the trial registry, where a zero was believable only because a **positive control** had returned a known record first. Open what the search returns, and prove the instrument can see before reporting that it saw nothing.

2.7 Reading a regulatory record without being fooled by it

Three failure modes turned up while this position was assembled, each producing a confident, well-cited, wrong sentence.

- **Corroboration that is circular.** The European indication was first taken from the agency's published medicines register and checked against the public assessment report page. The register is a machine-generated dump of those same pages, so the corroboration was circular and blind to precisely the failure that had occurred, a stale summary layer. Annex I section 4.1 of the Summary of Product Characteristics is the genuinely independent instrument and is the authority for the indication text; the register and the report page corroborate product identity and authorisation status only.
- **Truncation that closes with a full stop.** A summary reproducing the first part of an indication and stopping at a sentence boundary reads as complete, because nothing signals the loss. The European row was tested for it from the start; the American row was not, and the stored copy of this very label stopped mid-clause at "does not preclude the need ", hiding a whole third limitation until an author refused to complete it from memory. The instrument was then pointed at the American column too, and the repaired row passed at 1649 characters against 1649. Quote an indication to its end, and where the copy in hand is cut off, say so and quote only the part that is whole.
- **A date wearing the wrong field name.** The register's decision-date column carries the latest European Commission decision, not the first; the build proved it on another product in the same workbook, where the column showed a 2026 date against an authorisation granted in 2014. Label a date for what it is: initial marketing authorisation, latest decision, earliest approval entry in an application record. A true date of one thing published under the field name of another is factually sourced and substantively false.

All three share one shape: the instrument returned something, the reader accepted it, and nobody asked what it was incapable of showing. The discipline is not what did the source say, but what could it not have told me.

2.8 What a complete answer contains

Reduced to four sentences:

- United States, on the label effective 13 March 2026, read 3 August 2026: treatment-resistant depression in adults, as monotherapy or in conjunction with an oral antidepressant; and depressive symptoms in major depressive disorder with acute suicidal ideation or behavior, in

conjunction with an oral antidepressant, under the three Limitations of Use quoted whole above.

- European Union, on the Summary of Product Characteristics read 1 August 2026 and re-read verbatim the next day: two authorised indications, treatment-resistant major depressive disorder in combination with an SSRI or SNRI, and the acute short-term reduction of depressive symptoms constituting a psychiatric emergency, co-administered with oral antidepressant therapy. Neither is a monotherapy indication.
- India, as of 1 August 2026: no CDSCO marketing approval record located, across 66 published approval lists, a verified regulator-domain search and a positive-controlled trial-registry search. A declared gap, not a statement that the drug is unapproved.
- The monotherapy question therefore has three answers and no single one.

MNEMONIC

Where, What, Who says so, When

The four fields of a status claim, in the order an examiner checks them. Where is the jurisdiction; What is the indication in the source's own words, whole and to its end; Who says so is the named regulator and the named document, never "approved internationally"; When is the date the status was read. An answer missing the fourth is an undated assertion in a domain that changes.

Esketamine permits monotherapy in one jurisdiction, forbids it in another, and has no located record in a third: the monotherapy question has no answer until a regulator and a date are named.

3 · Zuranolone and neurosteroid antidepressants for postpartum and major depression

This is the class that turned an endogenous hormone into a fourteen-day prescription, and then discovered how narrow the licence for it would be. Neuroactive steroids are the first antidepressants reasoned backwards from obstetric physiology rather than forwards from a monoamine, and two reached a regulator: brexanolone, an infusion now marketing status Discontinued in the United States, and zuranolone, the oral successor. The marks sit in three places: the subunit, the clock and the border.

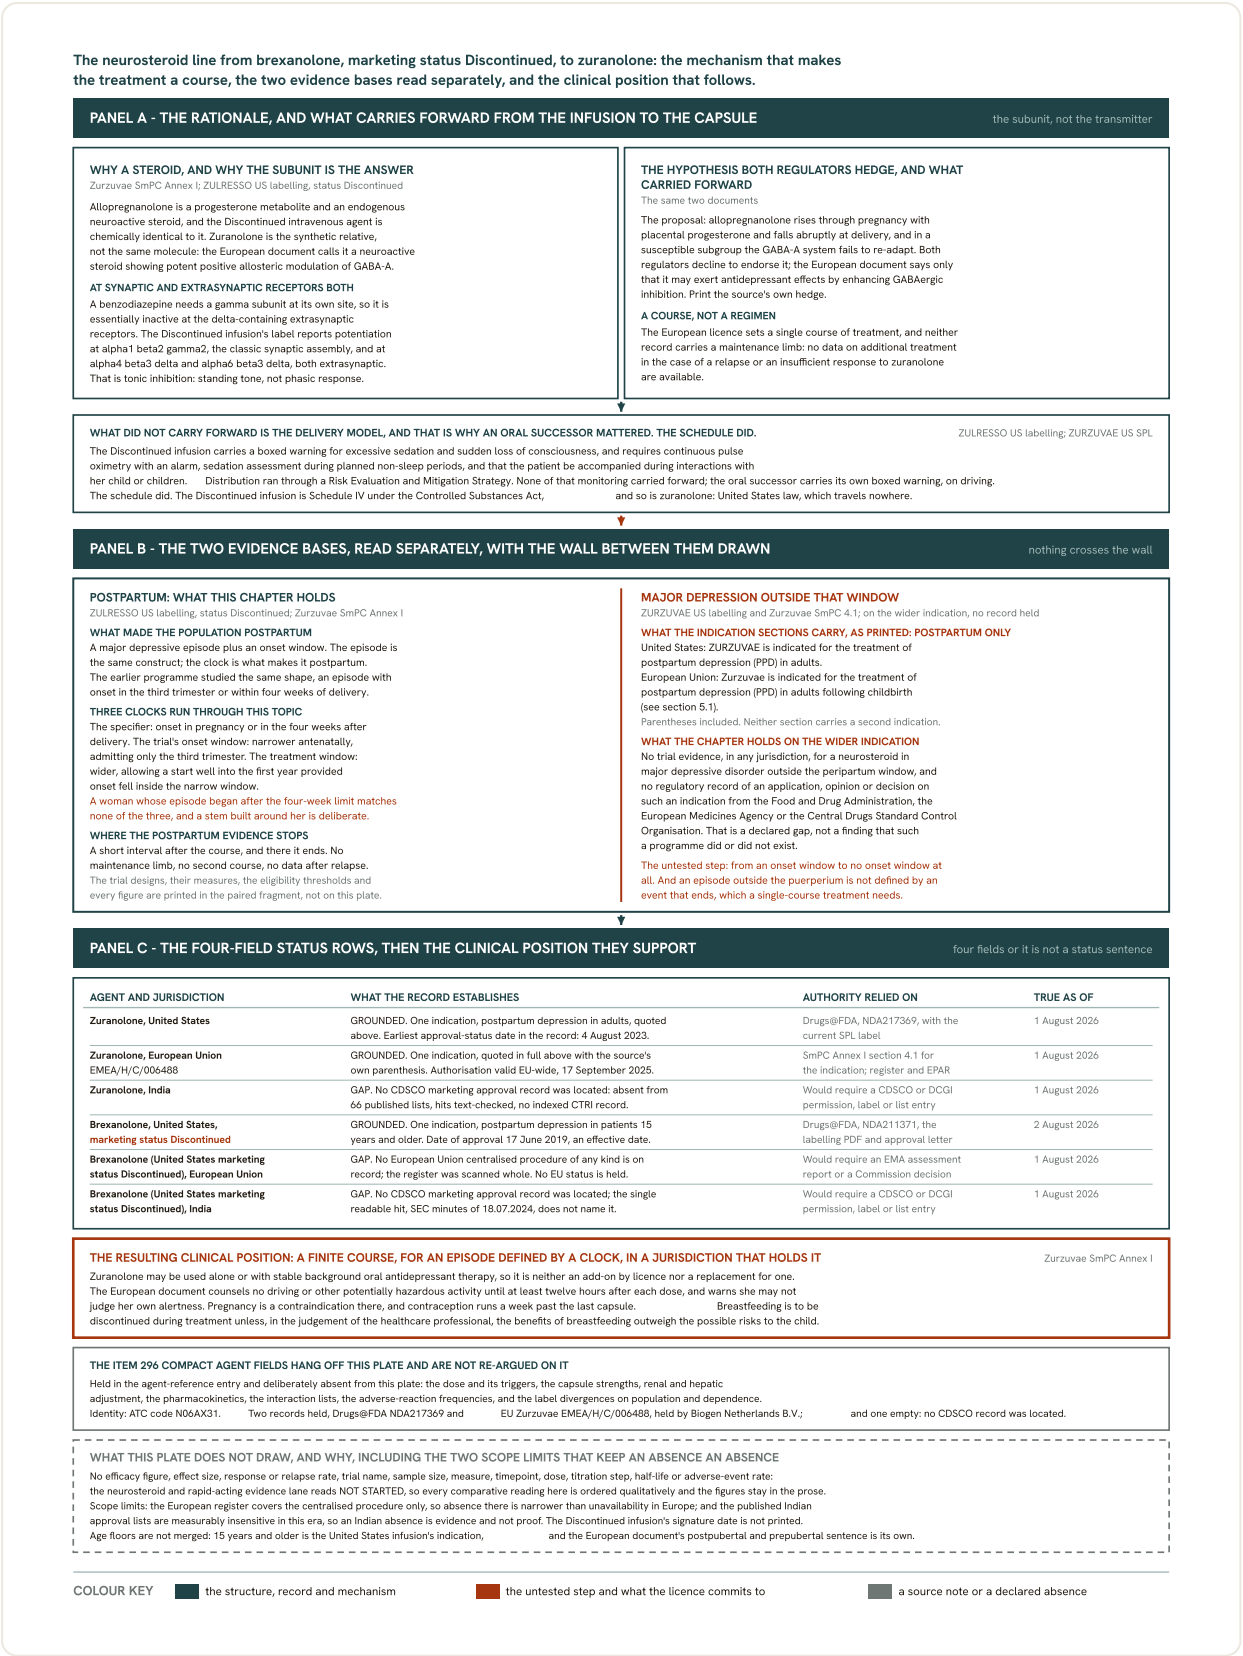

Fig 38.2 Zuranolone and the neurosteroid line from brexanolone, marketing status Discontinued: the mechanism, the two evidence bases read separately, and the position that follows. What carried forward from the Discontinued infusion is a single course of treatment with no maintenance limb, and the United States schedule; what did not is the monitoring service it required. Each indications section names one indication: postpartum depression (PPD) in adults in the United States, and postpartum depression (PPD) in adults following childbirth (see section 5.1) in the European Union. (Zurzuvae EMA EPAR Annex I SmPC; ZURZUVAE and ZULRESSO United States labelling, the latter marketing status Discontinued; the EU medicines register; the published CDSCO approval lists.)

3.1 Why a steroid, and why after delivery

Allopregnanolone is a progesterone metabolite and an endogenous neuroactive steroid modulating inhibitory transmission. The United States label for the intravenous agent: brexanolone is a neuroactive steroid GABA-A receptor positive modulator chemically identical to endogenous allopregnanolone, marketing status Discontinued. Zuranolone is the synthetic relative, not the identical molecule. Its European Summary of Product Characteristics calls it a **neuroactive steroid** showing potent **positive allosteric modulation** of the GABA-A receptor, enhancing GABAergic activity at **synaptic and extrasynaptic GABA-A receptors** and increasing their cell surface expression in vitro.

That last clause is the examinable difference. The benzodiazepine site needs a gamma subunit, so benzodiazepines act at synaptic receptors and are essentially inactive at the delta-containing extrasynaptic receptors carrying the persistent background current. Neuroactive steroids bind elsewhere and modulate both. The United States brexanolone label, marketing status Discontinued, shows it: the drug potentiated GABA-mediated currents from recombinant human receptors expressing alpha1 beta2 gamma2 subunits, the classic synaptic assembly, and alpha4 beta3 delta and alpha6 beta3 delta subunits, which are extrasynaptic. Modulating the extrasynaptic population modulates **tonic inhibition**, the standing tone rather than the phasic response. An answer saying only "it works on GABA" has given away the subunit, the part being tested.

The physiology that pointed the class at the puerperium is a hypothesis. Allopregnanolone rises through pregnancy with placental progesterone and falls abruptly at delivery; the proposal is that in a susceptible subgroup the GABA-A system fails to re-adapt. Both regulators decline to endorse it. The Discontinued intravenous agent's label says the mechanism of brexanolone in postpartum depression is not fully understood but is thought to relate to positive allosteric modulation of GABA-A receptors, and the European zuranolone document says only that it may exert antidepressant effects by enhancing GABAergic inhibition. Print the source's own hedge.

RULE **The mechanism is why this is a course and not a regimen.** The United States licence for brexanolone, Drugs@FDA NDA211371, approved for postpartum depression on 17 June 2019 and now marketing status Discontinued, administers one 60 hour infusion. The European licence for zuranolone, Zurzuvae, EMEA/H/C/006488, authorised for postpartum depression on 17 September 2025, sets a single 14 day course. Neither document carries a maintenance schedule, which is why every question about continuation, relapse and a second course meets an absence of evidence, not a dosing table.

3.2 Brexanolone, the Discontinued first-in-class, and its delivery model

Brexanolone, marketing status Discontinued, proved the class could work. Its United States labelling indicates it for postpartum depression in patients 15 years and older. Administration is a **continuous intravenous infusion over 60 hours**: 30 micrograms per kilogram per hour for the first 4 hours, 60 for the next 20 hours, 90 for the following 28 hours, then 60 for 4 hours and 30 for the last 4 hours, holding at 60 through the middle block if 90 is not tolerated. The shape: open low, hold high, taper, never stopped abruptly.

The monitoring turned it into a service. This Discontinued product's label carries a boxed warning for excessive sedation and sudden loss of consciousness, and requires continuous pulse oximetry with an alarm, sedation assessment every 2 hours during planned non-sleep periods, and that patients be accompanied during interactions with their child or children while the infusion runs. Distribution ran through a **Risk Evaluation and Mitigation Strategy**, and the product is Schedule IV under the Controlled Substances Act. In the trials behind this Discontinued agent's licence, sedation or somnolence forced dose interruption or reduction in 5 per cent of treated patients against none on placebo, loss or altered state of consciousness occurred in 4 per cent against none on placebo, and recovery took 15 to 60 minutes. Most services cannot deliver that whatever the effect size, which is the case for an oral successor.

TRAP **A true date wearing the wrong field name.** The United States date of approval for brexanolone, marketing status Discontinued, is **17 June 2019**, while the regulator's submission-status field for the original application holds 19 March 2019. Both are real, and the approval letter explains the gap: because controlled-substance scheduling was incomplete, it states the date of approval shall be the date the Drug Enforcement Administration publishes a Federal Register notice announcing interim final scheduling. A date is not a fact until you know which event it timestamps.

3.3 Zuranolone: the shape of a fourteen-day treatment

The European posology sets **50 mg once daily for 14 days** as a **single course of treatment**, reducible to 40 mg once daily for 14 days if not tolerated, and states dosing may be stopped without down-titration. There is no maintenance limb and no second course: the same document records that no data on additional treatment in the case of a relapse or an insufficient response to zuranolone are available.

The capsules are taken in the evening with fat-containing food, as either a meal or a snack, an exposure requirement, since absorption is food-dependent. A missed dose is not made up. Zuranolone may be used alone or with stable background oral antidepressant therapy, unlike agents licensed only as add-ons.

Zuranolone is metabolised primarily by CYP3A. Strong inhibition raises exposure, so the dose drops to 30 mg once daily through the 14 day treatment period when a strong CYP3A inhibitor is co-prescribed, and grapefruit is avoided for the same reason. Induction does the opposite: exposure is reduced by 85 per cent in the presence of rifampicin, which is why inducers are avoided outright rather than dose-adjusted. In an Indian setting that list is not hypothetical: carbamazepine, phenytoin, phenobarbital and rifampicin. Renal and hepatic adjustment and the full adverse-reaction table sit in the agent-reference entry.

3.4 The postpartum evidence, read the way an examiner reads it

Two development programmes, one population, and no licence to mix their numbers.

PROGRAMME	WHO WAS STUDIED	PRIMARY ENDPOINT	WHAT IT SHOWED
Brexanolone, status Discontinued: two placebo-controlled studies, Studies 1 and 2	Women aged 18 to 45 meeting DSM-IV criteria for a major depressive episode, onset in the third trimester or within 4 weeks of delivery; Study 1 severe, HAM-D total at or above 26, Study 2 moderate, HAM-D total between 20 and 25	Change from baseline in HAM-D total at the end of infusion, the sixtieth hour; the thirtieth day pre-specified as secondary	Severe illness: the 90 microgram per kilogram per hour target beat placebo by 3.7 points and the 60 microgram target by 5.5; moderate illness: the 90 microgram target by 2.5
Zuranolone: one randomised, double-blind, placebo-controlled multicentre study, 217-PPD-301, NCT04442503, SKYLARK	Women aged 18 to 45 meeting DSM-5 criteria for a major depressive episode, baseline HAMD-17 at or above 26, onset limited to the third trimester or within 4 weeks of delivery, treatment started up to 12 months after childbirth, followed 4 weeks after the 14 day course	Change from baseline in HAMD-17 at the fifteenth day, the day after the course ends	Least-squares mean change minus 15.6 against minus 11.6, a treatment difference, 4.0 points, 95 per cent confidence interval 1.7 to 6.3, p equals 0.0007

Speed: separation is present by the third day, at 3.4 points, the property separating this class from a conventional antidepressant. Durability inside the trial: the difference is still measurable at the forty-fifth day, at 3.5 points, a month after the last capsule, where follow-up stops. The placebo arm improved by nearly 12 points, so the drug effect is a modest increment on a large non-specific recovery, as a naturally remitting condition with intensive trial contact produces.

4.0	57.0%	38.9%	14
TREATMENT DIFFERENCE IN HAMD-17 POINTS	RESPONDERS ON ZURANOLONE	RESPONDERS ON PLACEBO	DAYS, THE WHOLE COURSE

Response, at least a halving of the baseline total, was reached by 57.0 per cent against 38.9 per cent on placebo, a relative risk 1.409 and an absolute difference, 16.4 percentage points. Among those responders, three subjects, 5.7 per cent, relapsed by the trial's definition of two consecutive totals at or above 20 after the fifteenth day, and none met the definition of rebound. Two cautions: the denominator is small, so the confidence around 5.7 per cent is wide, and the window closes four weeks after the course.

3.5 What happened to the major depressive disorder claim

Most answers go wrong here by writing a sentence that is nearly true. Both regulatory records held for zuranolone name one indication, and it is not major depressive disorder. The United States labelling reads that ZURZUVAE is indicated for the treatment of postpartum depression (PPD) in adults, carried twice in that record. The European therapeutic-indications section, Annex I section 4.1, reads that Zurzuvae is indicated for the treatment of postpartum depression

(PPD) in adults following childbirth (see section 5.1). Both are quoted as printed, parentheses included. Neither indications section carries a second indication.

Set that against the trial population. Every patient in the pivotal study met criteria for a **major depressive episode**; what made the study postpartum was the clock, onset restricted to the third trimester or the 4 weeks after delivery. The untested step is from that onset window to no onset window at all.

Three clocks run through this topic; merging them produces a wrong sentence. The DSM-5 peripartum-onset specifier covers onset during pregnancy or in the 4 weeks after delivery. The trial's onset window is narrower antenatally, admitting only the third trimester. The treatment window is wider, since subjects could start treatment up to 12 months after childbirth provided symptoms began inside the narrow window. A woman presenting at nine months with an episode that began at eight matches none of the three, and a stem built around her is deliberate.

TRAP **Reading the postpartum evidence as depression evidence.** This chapter holds no trial evidence, in any jurisdiction, for a neurosteroid in major depressive disorder outside the peripartum window, and no regulatory record of an application, opinion or decision on such an indication from the United States Food and Drug Administration, the European Medicines Agency or the Central Drugs Standard Control Organisation. That is a declared gap in this chapter's evidence, not a finding that such a programme did or did not exist. Writing "zuranolone is a new rapid-acting oral antidepressant for depression" crosses the indication boundary and the evidence boundary at once.

One further argument comes from the shape of the licence, not from a decision this chapter lacks: the whole authorised European exposure is a single fourteen-day course, with no data on treatment after relapse. Major depression outside the puerperium is not defined by an event that ends, so a treatment with no second course and no maintenance limb has a structural problem in that indication whatever its acute effect.

3.6 Sedation, the driving rule, and the abuse question

Every frequency here is from the European Summary of Product Characteristics. The most frequent adverse reactions were somnolence at 27.6 per cent, dizziness at 13.3 per cent and sedation at 11.2 per cent; the reaction classed as serious was confusional state, at 1.3 per cent. Only 2 per cent discontinued for an adverse reaction, while 14.3 per cent had a dose reduction or interruption. Among those on the higher dose, 69.7 per cent of somnolence events and 58.3 per cent of sedation events occurred within the first 2 days of treatment. Warn her that the first two evenings are the heaviest.

The same European document counsels patients not to drive or engage in other potentially hazardous activities until **at least 12 hours after taking each dose**, and advises they may not be able to judge their own ability; the United States labelling carries the same restriction in a boxed warning. Two driving-simulation studies found dose-dependent impairment nine hours after dosing, and modelling of the lateral-position data put median placebo-corrected impairment

below the threshold for a 0.05 per cent blood alcohol concentration only by the twelve-hour mark.

PITFALL

Treating the sedation as a side effect to be tolerated rather than as the thing structuring the prescription. The patient is by definition caring for an infant, and the two documents handle that differently. The United States label of the Discontinued intravenous product requires a companion during interactions with the children. The European zuranolone document names driving and hazardous activities and does not name infant care among them, so an answer must not attribute to zuranolone a chaperone requirement the European document does not name. The counselling point: she may not judge her own alertness reliably, and night-time infant care over the first evenings is a conversation to have before the first capsule.

Abuse potential is assessed in that same European document. In a human abuse potential study in 60 recreational users of central nervous system depressants, zuranolone at 30, 60 and 90 mg showed dose-dependent abuse potential against alprazolam at 1.5 mg and 3 mg on positive subjective measures including drug liking and good drug effects, while clinical-trial data indicate low physical dependence potential. Liking is not dependence. Caution is advised where there is a history of abuse of or addiction to alcohol or other substances.

3.7 Pregnancy, contraception and breastfeeding

In the European document zuranolone is contraindicated during pregnancy, on animal reproductive toxicity and an absence of human data, and women of childbearing potential must use effective contraception during treatment and for 7 days following discontinuation. Contraception is part of the prescription, and cover runs a week past the last capsule.

The numbers and the instruction pull against each other; print both. A lactation study measured the **relative infant dose** under 1 per cent: the mean was 0.357 per cent at a 30 mg maternal dose, and simulation put the expected mean at 0.738 per cent and 0.984 per cent for a 50 mg maternal dose at two assumed milk intakes. Despite figures that low, the European document instructs that breastfeeding should be discontinued during treatment unless, in the judgement of the healthcare professional, the benefits of breastfeeding outweigh the possible risks to the child, because the effect on a breastfed infant is unknown and milk-production data are limited. The United States label for the Discontinued intravenous agent records a higher relative infant dose, 1 to 2 per cent of the maternal weight-adjusted dosage, with oral bioavailability under 5 per cent keeping infant exposure low. Quantified low exposure and a precautionary instruction are not a contradiction.

The age boundaries differ and must not be merged. The European document records that for zuranolone, safety and efficacy in postpubertal females under 18 years old have not been established, and there is no relevant use in prepubertal females. For the Discontinued intravenous agent the United States indication runs to patients 15 years and older.

GOOD TO REMEMBER

Two questions decide relevance, and neither is pharmacological: when the episode began, and whether she is breastfeeding. The first decides whether any evidence held here applies to her; the second, whether the licensed instruction can be followed without imposing a loss she may not accept.

3.8 Status by jurisdiction: what each regulator's record actually says

Every regulatory sentence here carries four fields, and one missing a field is not a status sentence: the jurisdiction, the exact indication or purpose, the authority the claim rests on, and the date the status was true. The interesting rows are the empty ones.

AGENT AND JURISDICTION	WHAT THE RECORD SAYS	AUTHORITY RELIED ON	STATUS TRUE AS OF
Zuranolone, United States	Indicated for the treatment of postpartum depression (PPD) in adults. Earliest approval-status date in the record, 4 August 2023	Drugs@FDA, NDA217369	1 August 2026
Zuranolone, European Union	Indicated for the treatment of postpartum depression (PPD) in adults following childbirth (see section 5.1); authorised as Zurzuvae, product number EMEA/H/C/006488, holder Biogen Netherlands B.V.; **marketing authorisation** valid throughout the European Union from **17 September 2025**	Indication from Annex I section 4.1 of the Summary of Product Characteristics; identity and status from the medicines register and assessment-report page	1 August 2026
Zuranolone, India	No CDSCO marketing approval record was located. Absent from all 66 published approval lists; the three documents a CDSCO-domain search returned were text-checked and none names the drug; no indexed CTRI record	Would require a CDSCO or DCGI new-drug permission, an approved label or an official list entry	1 August 2026
Brexanolone, United States, marketing status Discontinued	Indicated for the treatment of postpartum depression (PPD) in patients 15 years and older [see Clinical Studies (14)]; date of approval 17 June 2019; marketing status Discontinued	Drugs@FDA, NDA211371; indication from the single-column prescribing information, date from the approval letter	2 August 2026
Brexanolone (United States marketing status Discontinued), European Union	No European Union centralised procedure of any kind is on record for this active substance; the register was scanned whole and returns no row under any name. No European marketing status is on record	Would require an EMA assessment report or a Commission decision	1 August 2026

AGENT AND JURISDICTION	WHAT THE RECORD SAYS	AUTHORITY RELIED ON	STATUS TRUE AS OF
Brexanolone (United States marketing status Discontinued), India	No CDSCO marketing approval record was located. Absent from all 66 published approval lists; the single CDSCO-domain hit, expert-committee minutes dated 18 July 2024, is readable and does not name the substance; no indexed CTRI record. No Indian marketing status is on record	Would require a CDSCO or DCGI new-drug permission, an approved label or an official list entry	1 August 2026

Two properties must be stated in words or a reader will over-read the table. The register covers the European Union centralised procedure only, so a medicine authorised nationally through the decentralised or mutual-recognition route would not appear in it. What the empty row establishes is that no central application was ever concluded, by authorisation, refusal, withdrawal, lapse, revocation or suspension, since the register carries all those outcomes. That is narrower than "not available anywhere in Europe". For this substance the scope limit bites hard, and the confirming second instrument never ran on any gap row.

India second. The published CDSCO approval-list corpus is demonstrably incomplete, and no positive control establishes its sensitivity in the period these agents belong to: the one drug in this chapter whose Indian approval is known from outside the corpus, through expert-committee minutes, appears nowhere in the 66 documents, and the list declaring full-year coverage for that year carries entries dated after the approval it omits. A corpus that misses a drug the same regulator says it approved cannot prove another drug was not approved. So the sentence a candidate may write is not that these agents are unapproved in India, but that **no CDSCO approval record was located** as of August 2026, naming what was searched, on the authority of the Central Drugs Standard Control Organisation and the Drugs Controller General of India.

IN INDIA

Four things are mistaken for an Indian approval record. A CTRI registration records that a trial was registered, not that a drug was approved. Expert-committee minutes are advisory proceedings. A brand in a pharmacy list or a distributor catalogue is a commercial artefact. And an approval in Washington or Amsterdam is a fact about Washington or Amsterdam. The record statement: as of August 2026 no CDSCO approval record was located for either agent. This chapter holds no instrument that measured Indian availability either way.

- Mechanism: a neuroactive steroid modulates synaptic and extrasynaptic GABA-A receptors, reaching a tonic inhibition a benzodiazepine does not.

- A course, not a regimen: fourteen days orally, sixty hours by infusion, no second course described for either.
- A major depressive episode with an obstetric onset window, which is why the licence reads postpartum depression and the evidence goes no further.
- A status sentence names a jurisdiction, an exact indication, an authority and a date, or it is not written.

MNEMONIC

Subunit, Course, Clock, Border

Subunit separates this class from the benzodiazepines. Course is the finite exposure that follows. Clock is the onset window making a major depressive episode a postpartum one. Border is the rule that a regulator's record speaks only for its own territory.

The mechanism explains why the treatment is short, the onset window explains why the licence is narrow, and the jurisdiction explains why a true sentence about this drug can still be the wrong answer.

4 · Rapid-acting antidepressants: mechanism class and clinical positioning

A rapid-acting antidepressant is defined by a claim about time and licensed by a sentence about an indication. The class lives between those two objects. Its members share a response measured in hours to days rather than weeks, produced outside monoamine reuptake, and nothing else: not the receptor, the setting, the population each licence names, how long the treatment runs, or whether any regulator has concluded anything. Marks go in three places. Candidates write **rapid-acting antidepressant** as though a regulator had licensed the category; they collapse five members and three jurisdictions into one verdict; and they read the silence of one search as a fact about five products. The clinical accounts belong elsewhere: ketamine and esketamine in treatment-resistant depression to the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes, their mood-disorder positioning to the Mood disorders: pharmacotherapy notes.

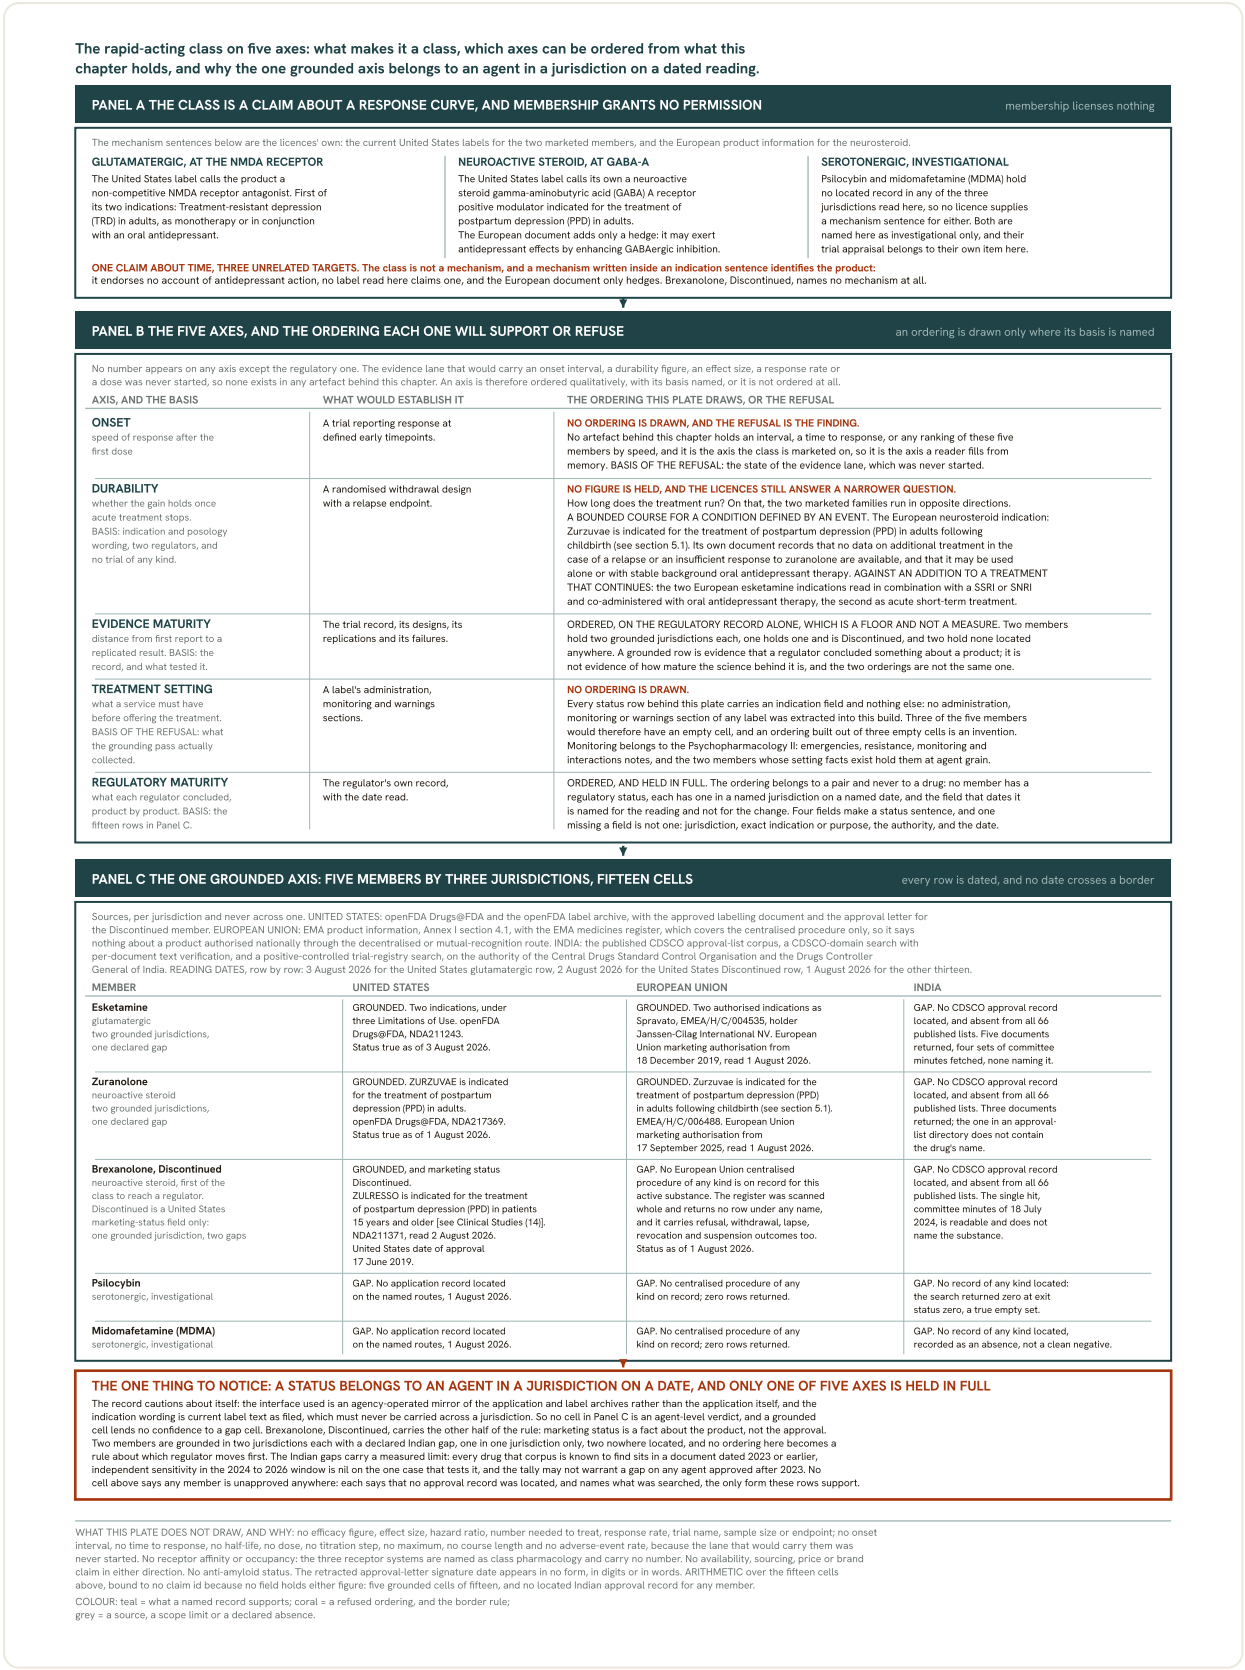

Fig 38.3 The rapid-acting class on five axes: only regulatory maturity is held in full, three of five not at all. Onset and treatment setting are refused orderings, each basis named. Durability is licence wording alone: a bounded course for a condition defined by an event, in adults following childbirth (see section 5.1), against an addition to continuing treatment, in combination with a SSRI or SNRI. Regulatory maturity belongs to an agent in a jurisdiction on a dated reading: five grounded cells of fifteen, with 17 June 2019 the United States date of approval for brexanolone, marketing status Discontinued. (openFDA Drugs@FDA, label archive and approval letter; EMA Annex I section 4.1, centralised procedure only; CDSCO approval lists and domain search, on CDSCO and DCGI authority.)

4.1 What makes this a class, and what the class promises

No regulator in these records authorises a rapid-acting antidepressant. Every authorisation names a product, an indication and a population, so the class is a construct built for a clinical purpose and carries no permissions. A sentence travelling from "this agent is rapid-acting" to where it may be used, in whom, or on whose authority has become a permission without passing through a document.

The promise sets the two questions the class is judged on. Conventional practice tolerates a latency of weeks and builds the service around that wait. Shorten it and two questions open: what happens to the gain when acute treatment ends, and what was the shortened wait supposed to buy?

One regulator has answered the second in writing. Among the **Limitations of Use** on the current United States label for esketamine stands the statement that The effectiveness of SPRAVATO in preventing suicide or in reducing suicidal ideation or behavior has not been demonstrated. The same label indicates the product for Depressive symptoms in adults with major depressive disorder (MDD) with acute suicidal ideation or behavior in conjunction with an oral antidepressant. The licence covers a population defined by suicidal ideation while declining any effect on the event that population is at risk of. Symptom change and prevention of an outcome are separate endpoints, and the regulator separated them. An answer arguing from speed of response to a suicide-prevention benefit makes the leap the licence refuses.

Notice what kind of negative that is, because a candidate trained to distrust categorical negatives may mistake it for one. It states what a trial programme demonstrated, printed inside a licence by the authority that granted it, so it is a positive fact about an evidence base; a claim that a drug is unapproved somewhere needs a regulator's affirmative statement and appears nowhere here without one. The same label's SPRAVATO is not approved as an anesthetic agent is again a licence describing its own boundary.

RULE **Rapid-acting describes a response curve and never grants a permission.** Every sentence about what may be given, to whom, where and on whose authority must be sourced to one named regulator's record for one named product, with the date read. The class name cannot stand in for a document.

4.2 Three mechanistic families, and the mechanism sentence a licence gives you

Three receptor systems sit under one heading: the glutamatergic agents at the NMDA receptor complex, the neuroactive steroids as positive modulators at the GABA-A receptor, and the serotonergic psychedelics, investigational throughout, at serotonin 2A receptors. One claim about time, three unrelated targets: this class is not a mechanism, and an answer offering one has answered another question.

Two of the three have a mechanism written into the licence. Esketamine's United States label calls the product **a non-competitive NMDA receptor antagonist**, spelling the receptor name out in full, indicated for Treatment-resistant depression (TRD) in adults, as monotherapy or in conjunction with an oral antidepressant. Zuranolone's United States label calls its own **a**

neuroactive steroid gamma-aminobutyric acid (GABA) A receptor positive modulator indicated for the treatment of postpartum depression (PPD) in adults. A mechanism inside an indication sentence identifies the product; it endorses no account of antidepressant action, and no label read here claims one.

The third teaches it from the other side. Brexanolone, whose United States **marketing status** is Discontinued, carries an indication naming no mechanism: ZULRESSO is indicated for the treatment of postpartum depression (PPD) in patients 15 years and older. The neuroactive-steroid account of it comes from the literature, not the licence. Asked what a licence says, answer only that.

No receptor affinity, occupancy figure, onset interval, half-life or comparison of potency or speed between these families is held by any artefact behind this chapter, because the evidence lane that would carry them was never completed. Writing one from memory would be a fabricated citation, the one defect no later pass repairs.

4.3 The five axes, and which of them anything here fills

A class map is useful only if it is honest about its columns, and here one of five axes is held in full, one narrowly, and three not at all. A table hiding that invites a reader to fill the empty columns from memory and quote the result as though the map supplied it.

AXIS	WHAT IT WOULD MEASURE	WHAT WOULD ESTABLISH IT	WHAT THESE NOTES HOLD
Onset	Speed of response after the first dose	A trial reporting response at defined early timepoints	Nothing: no interval, no time to response, no ranking by speed
Durability	Whether the gain holds once acute treatment stops	A randomised withdrawal design with a relapse endpoint	No figure. Only licence wording, separating a bounded course from a continuing treatment
Evidence maturity	Distance from first report to replicated result	The trial record, its designs, replications and failures	Only the regulatory record and the instruments that tested it: a floor, not a measure
Treatment setting	What a service must have before offering the treatment	A label's administration, monitoring and warnings sections	Nothing directly; never extracted. Monitoring belongs to the chapters named above
Regulatory maturity	What each regulator concluded, product by product	The regulator's own record, with the date read	Held in full, at the grain of one agent in one jurisdiction

The columns a candidate most wants to fill are the two the class is marketed on, so the defensible answer runs the map backwards: from what each regulator concluded, to what the licence implies about treatment length, then naming the rest unestablished.

4.4 Durability: the axis two licences answer in opposite ways

Nothing here quantifies durability, and the licences still answer the question. They answer the narrower version a service plans around: not how long a response lasts, but how long the treatment runs. On that the two marketed families run in opposite directions in the indication text.

The neurosteroid licences are built around a bounded situation. The European authorisation reads Zurzuvae is indicated for the treatment of postpartum depression (PPD) in adults following childbirth (see section 5.1). The United States indication for the same molecule reads ZURZUVAE is indicated for the treatment of postpartum depression (PPD) in adults. A condition defined by its relation to an event implies a treatment with an end, and the European text names the event where the American does not.

The glutamatergic member's European licence runs the other way, indicating esketamine in combination with a SSRI or SNRI for treatment-resistant major depressive disorder, and in its second authorised indication co-administered with oral antidepressant therapy for a moderate to severe episode as acute short-term treatment, for the rapid reduction of depressive symptoms, which according to clinical judgement constitute a psychiatric emergency. Two facts sit there: both European indications license the agent inside a continuing antidepressant treatment rather than instead of one, and the second carries its own durability limit in the words acute short-term treatment.

The class therefore splits along a line unrelated to receptor: a bounded course for a bounded condition, against an addition to a treatment that continues. Both say how long a prescription runs, not how long a response lasts, which decides staffing and review intervals. The United States monotherapy line belongs to esketamine's own section here.

One demographic comparison is available. Brexanolone, marketing status Discontinued, is licensed, in the United States, in patients 15 years and older, while the indications quoted above for both marketed members name adults. The class's only reach below adulthood sits on the member that is Discontinued, a fact about a licence rather than an option to offer anyone.

> **GOOD TO REMEMBER**
>
> Two questions answer the planning problem from the licence alone, without a trial: is this agent licensed as an addition to something that continues, and is the condition it names defined by an event that ends? Different clinical commitments, and the patient should be told which is starting.

4.5 Regulatory maturity belongs to a pair, not a drug

Four fields make a status sentence and one missing a field is not one: the jurisdiction, the exact indication or purpose in the source's words, the authority the claim rests on, and the date it was true. That last field's name is worth using, **status true as of**, because it dates the reading and not the change. The United States rows here were read on 3 August 2026 for esketamine, 1 August for zuranolone and 2 August for brexanolone, marketing status Discontinued, and every European and Indian row on 1 August 2026.

Five members and three jurisdictions make fifteen cells, and they disagree inside one agent: no member has a regulatory status, each has one in a named jurisdiction on a named date. The record says so of itself: the interface used is an agency-operated mirror of the application and label archives rather than the application itself, and the indication wording is current label text as filed, which must never be carried across a jurisdiction.

MEMBER	GROUNDED RECORDS	DECLARED GAPS	WHAT MAY NOT BE WRITTEN
Esketamine, glutamatergic	United States, two indications under three Limitations of Use, NDA211243, read 3 August 2026. European Union, two indications as Spravato, EMEA/H/C/004535, holder Janssen-Cilag International NV, from **18 December 2019**	India: no CDSCO approval record located	Either indication carried across, and any Indian status either way
Zuranolone, neurosteroid	United States, postpartum depression in adults, NDA217369. European Union, the same with following childbirth added, as Zurzuvae, EMEA/H/C/006488, holder Biogen Netherlands B.V., from **17 September 2025**	India: no CDSCO approval record located	The European wording quoted as the American indication, and the register's decision column read as an authorisation date
Brexanolone, neurosteroid, marketing status Discontinued	United States only, postpartum depression in patients 15 years and older, NDA211371, date of approval **17 June 2019**, read 2 August 2026	European Union: no centralised procedure on record; India: no CDSCO record located	That its approval has lapsed, and any inference from Discontinued about the gap rows
Psilocybin, investigational	None located	United States, European Union and India, all three declared	Any categorical negative, and any upgrade of investigational status to an authorisation
Midomafetamine (MDMA), investigational	None located	United States, European Union and India, all three declared	The same two, plus transfer from the other investigational member

The investigational pair belongs to the psychedelic-assisted therapy item in this chapter, which owns their trial appraisal. They appear only because a class comparison that drops its immature members flatters the class.

TRAP **Collapsing the map to one verdict per agent.** Two members hold two grounded jurisdictions each with a declared Indian gap, one holds one grounded jurisdiction and two gaps, two hold none anywhere. "Esketamine is approved" is true of two records, unsupported for a third, and unmarkable because it names no regulator. Never write an approval verb without the jurisdiction, source and date beside it, and never let a grounded row lend confidence to a gap row.

4.6 Brexanolone, Discontinued: a probe miss, a date set by scheduling, and an empty key

One row has been wrong in every interesting way and repaired each time. It also carries the rule for every sentence about it: teach this agent and carry its marketing status in the same breath, since marketing status is a fact about the product and not about the approval, and this product is Discontinued while its approval stands.

The row read GAP, on a verdict of no record found, until multi-route probing retrieved it. The verdict was a probe miss and not an absence: the record carries no agency-standardised name block, so queries through generic name, substance name and brand name returned not-found while the query reading the product's active-ingredient field returned it. The record's own sentence transfers: a decided action is not a licence to ignore a record that turns up.

Then the date, a controlled-substance lesson in clerical dress. The United States date of approval for brexanolone, marketing status Discontinued, is 17 June 2019, and the approval letter did not set it by its own signing. The letter states that the date of approval shall be the date on which the Drug Enforcement Administration publishes a notice in the Federal Register announcing the interim final scheduling of brexanolone, marketing status Discontinued. The original submission carries an earlier status date, that signature and not the approval; no number for it is printed here.

The third repair is worth the most and looks like housekeeping. This row's canonical earliest-approval key is deliberately absent, because writing the submission's signature date under a field name meaning first approval would put a retracted number back into the field every consumer reads. Rarer than getting that right, it writes down the cost. The carry check reads only the European, Indian and canonical earliest-approval keys, so it cannot see where this row's approval date now lives; the row sits outside that check until it learns the key, and the pass's claim to compare every date field is no longer true of this file. A correct repair left a control blind, and the record says so.

It is also the one indication here no instrument could test. All three text instruments returned unresolved extraction rather than a pass, for a documented reason: with no name block the label archive cannot be queried by application number, so the indication came from the approved labelling document instead; the pass's own discipline is that a failed extraction is unresolved extraction and never a pass. How it was read matters too. The indication was taken from the single-column prescribing information, not the two-column highlights block, whose extract interleaves the columns. Interleaved columns produce fluent sentences no document contains.

5 of 15	0 of 5	3 of 3	2 of 2
GROUNDED CELLS, FIVE MEMBERS BY THREE JURISDICTIONS	INDIAN APPROVAL RECORDS LOCATED FOR THESE MEMBERS	BREXANOLONE, DISCONTINUED, US TEXT CELLS UNTESTED, NOT PASSED	EU ESKETAMINE INDICATIONS CARRIED AGAINST SOURCE

The fourth figure counterweights the third: The completeness instrument found two indications in the European source document and two on the row, and the instrument set was validated by planting the real historical defect on that row, a dropped second indication, and confirming the guard fired. A pass from an instrument tested against the failure it exists to catch is worth something.

TRAP **Reading an untested cell as a clean one.** Three cells here were never tested, because the source text could not be retrieved by the route the instrument uses, and are recorded as unresolved rather than as passes. A reader who scans a matrix for the word fail, finds none and calls the column sound has learned nothing. The mirror error costs as much: an unresolved text check does not undermine a status resting on the labelling document and the approval letter.

4.7 The Indian column, and what nine search hits established

Every member has the same Indian entry: no located CDSCO marketing approval record. At class level that is one instrument's result five times over, so all five cells carry that one search's sensitivity, which the record measures rather than assumes.

What was opened is the lesson. For esketamine, a domain search returned five documents, four sets of subject expert committee minutes for neurology and psychiatry and one international cell file; all four were fetched, all carry an extractable text layer, and none names the drug, so all were search-index false positives and not evidence. For zuranolone, three came back, and the one in an approval-list directory was downloaded and its text does not contain the drug's name, as with both sets of minutes. For brexanolone, marketing status Discontinued, the single hit, committee minutes dated 18 July 2024, was fetched, is readable, and does not name the substance. Nine hits, eight documents opened, nine false positives, the fifth esketamine document scored one without being fetched: a search hit is not a document naming your drug.

The two investigational members returned nothing, and even that is graded. The domain search returned zero results at exit status zero, a genuine empty result set rather than a failed query, and the finding is still recorded as the absence of any located record rather than a clean negative, which would overstate what an instrument with a measured miss rate and three failed positive controls delivers.

Two sensitivity facts belong in any Indian sentence about a recent agent, and the first has a name, **era mismatch**. Every drug this corpus is known to find sits in a document dated 2023 or earlier, and independent sensitivity in the 2024 to 2026 window is nil on the one case testing it; the positive-control tally may not warrant a gap on any agent approved after 2023.

The authority is named, and its substitutes with it. The claim would rest on the Central Drugs Standard Control Organisation and the Drugs Controller General of India, and committee minutes, trial no-objection certificates, international cell confirmations, CTRI registration, brand

listings, pharmacy availability and manufacturer copy are none of them marketing authorisation. A CTRI entry records that a trial exists, not permission to market. The rule closing the column sits in each of these rows: no India row here asserts that a drug is not approved in India; each asserts that no CDSCO approval record was located, and names what was searched.

IN INDIA

Write the Indian column in this order. No CDSCO marketing approval record was located for any member as of 1 August 2026, on the three instruments named above, and the corpus has never been shown to find an approval from 2024 onward. Do not write that any is not approved in India, which is stronger than the evidence supports, and do not write that any is approved, because nothing retrieved says so. For a family: there is no located approval record to point to, and licensing is a question for the regulator's record, not a brand listing.

4.8 Choosing across the class, and what a complete answer contains

Five statements answer it in whatever form it is asked.

- The class is a claim about a response curve, not a licensed category, so membership licenses nothing.
- Three unrelated receptor systems share one heading, and a licence naming a mechanism identifies a product rather than endorsing an account of action.
- Of five axes a class map needs, only regulatory maturity is held in full, durability only in the narrow form licence wording settles.
- Regulatory maturity belongs to an agent and a jurisdiction on a stated date; a grounded row never lends confidence to a gap row.
- The Indian column is five copies of one search result with a measured sensitivity: a statement about a search, never about a product.

MNEMONIC

Curve, Country, Course, Corroboration

Curve is what the class name describes. Country is the jurisdiction every status sentence must name and never leave. Course is durability in the form a licence answers, how long the treatment runs. Corroboration is the last question before quoting a cell: was it tested, tested against the failure it exists to catch, or merely unmarked?

The class name describes a curve and grants nothing; status belongs to an agent and a jurisdiction on a dated reading; and an untested cell is not a clean one.

5 · Dual orexin receptor antagonists (DORAs) and sodium oxybate in sleep psychiatry

Four agents that one sleep service may use in the same week hold, between them, no single shared pattern of national approval. Three **dual orexin receptor antagonists** and one oxybate show that regulatory status belongs to an agent inside a jurisdiction and never to a class. The

pharmacology is not rebuilt here: the orexin mechanism, the agents, dosing, adverse effects and insomnia prescribing belong to the Dissociative, conversion and anxiolytic/hypnotic pharmacology notes, and narcolepsy, cataplexy, orexin biology and the disease-specific use of sodium oxybate belong to the Eating and sleep-wake disorders notes. What is dated and new is the regulatory record. Three errors cost most: one class verdict for four agents, an approval carried across a border, and a sentence read as complete because it ends in a full stop.

5.1 Four fields, and why this group needs them most

A status sentence is checkable only if it carries the jurisdiction, the indication in the regulator's own words, the named source, and the date the reading was true. The rule that follows governs the chapter: a row may be written only in the jurisdiction it was grounded in, and none crosses a boundary. A declared absence is written as an absence, naming what was searched and whose authority a claim would rest on; an inferred figure is not written at all.

At the grain of one agent in one country these four generate twelve records that disagree. Seven carry an affirmative located record and five are declared absences, and which is which follows neither the agent, the class, the year nor the indication; the tally is computed across these rows. The three orexin antagonists are licensed, where they are, for insomnia, and the oxybate for narcolepsy with cataplexy or the excessive daytime sleepiness of narcolepsy.

RULE **An insomnia approval is never transferred to narcolepsy or cataplexy, and a narcolepsy approval is never transferred to insomnia.** Both families act on the same sleep-wake machinery and are prescribed by the same clinician, which is why the licences get swapped in an answer. Quote the indication belonging to that product in that country.

5.2 The United States: four records, four dates, one reading date that is not the others

All four carry an affirmative American record, read from the openFDA Drugs@FDA interface with a **structured product label** named by identifier and effective date, current for three rows and not for the oxybate. Three resolve to one application; the fourth does not, which is 5.3.

AGENT	APPLICATION AND LABEL	INDICATION AS FILED, QUOTED	EARLIEST APPROVAL-STATUS DATE IN THE RECORD
Suvorexant	NDA204569, label 21306af5 effective 10 March 2025	BELSOMRA (suvorexant) is indicated for the treatment of insomnia characterized by difficulties with sleep onset and/or sleep maintenance.	13 August 2014
Lemborexant	NDA212028, label c82838dc effective 24 February 2025	DAYVIGO is indicated for the treatment of adult patients with insomnia, characterized by difficulties with sleep onset and/or sleep maintenance	20 December 2019
Daridorexant	NDA214985, label 10e24e38 effective 26 February 2026	QUVIVIQ is indicated for the treatment of adult patients with insomnia, characterized by difficulties with sleep onset and/or sleep maintenance	7 January 2022
Sodium oxybate	Four applications, two original; text re-read from label 3839d447 effective 1 July 2025, whose own application number is NDA021196, not the row's current label	Xyrem is indicated for the treatment of cataplexy or excessive daytime sleepiness (EDS) in patients 7 years of age and older with narcolepsy.	**17 July 2002**

Three differences are examinable. The three insomnia texts differ: two name adult patients and the earliest names no population, a difference between three documents rather than an inference about who may be treated. The oxybate row does not call itself an **orexin receptor antagonist** as the other three do; its label calls it a central nervous system depressant. And the last column is named for the field it came from: whether any is a first marketing approval these records do not say.

The record cautions about itself: openFDA is an agency-operated mirror of Drugs@FDA and of the label archive rather than the application itself, and the indication wording is current label text as filed, which is not a statement about any other jurisdiction and must never be carried across one. The reading dates differ: the three orexin rows carry a status true as of 1 August 2026 while the oxybate row carries 3 August 2026, because it was repaired in between. Harmonising the newer date onto the others asserts readings nobody made.

5.3 Right citation, right date, wrong product

The oxybate row is the most instructive failure here, because nothing about it looked wrong. The cited application and the date were both correct and both belonged to Xyrem. The indication text was not: it was the text of LUMRYZ, a different application by a different sponsor, approved in 2023, whose label reads almost identically in structure at 349 characters against 351 and differs mainly in the product name. Comparing lengths would have passed it; checking the retrieved document's own application number against the one cited caught it.

The vulnerability is structural: three of these four return one application, so there is nothing to blend; sodium oxybate returns four. Adjudication had already established that Xyrem, Xywav and Lumryz are three separate applications and that Xywav is not even a single-entity sodium oxybate product; that finding could not reach the ledger because its regeneration was parked, so the defect stood for a day after being solved elsewhere. The row is checkable now because it records an identity test anyone can repeat.

5.4 The European Union: two authorised, two absences, and a cut that closed with a full stop

Two agents carry a European centralised authorisation and two do not. For the two that do, indication text comes from Annex I of the **Summary of Product Characteristics**, section 4.1 Therapeutic indications, read from the cached product-information document; the register and assessment-report page corroborate identity and status only. Daridorexant: QUVIVIQ is indicated for the treatment of adult patients with insomnia characterised by symptoms present for at least 3 months and considerable impact on daytime functioning. The oxybate: Treatment of narcolepsy with cataplexy in adult patients, adolescents and children from the age of 7 years. Both are Authorised, daridorexant under EMEA/H/C/005634 and the oxybate under EMEA/H/C/000593, each with a **marketing authorisation holder** the register names by company and not by country: Idorsia Pharmaceuticals Deutschland GmbH and UCB Pharma Ltd. Both dates are of a declared kind, the initial European marketing authorisation as a Commission decision: **29 April 2022** and 13 October 2005, each file carrying a later Commission decision in 2026 and 2025.

> **GOOD TO REMEMBER**
>
> Whether a patient must have cataplexy to fall inside the licence depends on which regulator you are reading: one text reaches excessive daytime sleepiness in narcolepsy without requiring cataplexy, the other names narcolepsy with cataplexy. When a colleague quotes an oxybate indication, the question is not what it says but which country's document it came from.

That row carries this section's instrument lesson. Until it was corrected that row read "Treatment of narcolepsy with cataplexy in adult patients." The words "adolescents and children from the age of 7 years" had been dropped and the surviving prefix closed with a full stop the source does not have. The same correction fixed a second defect: the indication had come from the published register while the assessment-report page was cited as an independent second instrument, though the register is generated from those pages, so the corroboration was circular and blind to the stale summary layer that had failed.

TRAP **Treating a sentence that ends in a full stop as one that ends where the source ends.** A truncation landing mid-word announces itself; one landing at a clause boundary and closing with valid punctuation is undetectable by eye, and it removed a paediatric population from an authorised indication in this ledger. The instrument that catches it asks one question: is the stored text a prefix of the primary text? Learn the question, not the incident.

For the two with no European record the absence is written as an absence, its strength stated. The agency's own medicines register, generated on 1 August 2026, was scanned whole across all 39 columns of all 2730 medicine rows, and each substance returns zero rows under any of its names. The register carries Authorised, Refused, Application withdrawn, Withdrawn, Lapsed, Expired, Revoked, Suspended and Opinion outcomes, so absence means no central application of any kind was ever concluded, including a refused or abandoned one; what would close the row is an agency assessment report or a Commission implementing decision. The authority a claim would rest on is named, and "approved internationally" is not a permitted substitute for a named regulator.

Then the limit: the register covers the European **centralised procedure** only, and a product authorised nationally through the decentralised or mutual-recognition route would never appear in it. That limit is printed identically on every European absence here but does not bite equally, and on both these agents it is graded as biting weakly, because a small molecule outside the mandatory centralised scope could hold a national authorisation this instrument cannot see. Two weaknesses travel with the finding: the confirming second instrument ran on all eight grounded rows and none of the eight absences, so no European absence here has independent corroboration, and the assessment-report page would anyway be a second rendering of the register's own source.

5.5 The ladder that does not exist

Lemborexant carries a located Indian approval record and a declared European absence. That defeats the assumption almost every candidate brings to a recent-advances question: that maturity runs America, then Europe, then India. Here the middle rung is the empty one, and these four agents run three patterns across three jurisdictions.

The Indian record is affirmative. The approval-list cell reads, whole, Treatment for insomnia. Lemborexant tablets 5mg/10mg. It sits at serial number 12 of a 2021 approval list, one document in a corpus of 66 distinct published approval documents, deduplicated by content hash, discovered by four mapping passes and downloaded directly, all 66 yielding an extractable text layer, so no absence in this corpus is an artefact of an unreadable file. The strengths there are a formulation fact from the regulator's own name column, quoted because the discipline is to carry a cell whole; they are not a dosing recommendation, and no dose or maximum appears here.

The date needs the same care. The value is **1 July 2021**, and the field says what is printed: the figure in the column headed **Date of issue**. An earlier version claimed to quote a label the document does not carry, and was narrowed. Corroboration is thinner than it looks: two documents are cited, but they are one running list in two renderings rather than two independent documents, and the second lies outside the 66-document corpus, found by a drug-specific search

and appearing in no mapping pass, so the corpus discovery step was incomplete though the fetching step was not.

TRAP **Answering at the grain of the agent instead of the agent and the country together.** "Lemborexant is approved" is not a shorter version of a true sentence but a different and unverifiable one. Treat each of these twelve records as its own row, and answer any availability question with the jurisdiction, the record and the date. The mirror-image error costs as much: inferring a European or American absence from an Indian gap, when here the Indian record is the affirmative one.

5.6 The three Indian absences, and the one built on documents that exist

The other three carry no located Indian marketing approval, and the absences are not equal. Suvorexant's is strongest, resting on documents that exist rather than on documents that do not. The row records the file at pre-approval stage: CDSCO subject expert committee minutes for neurology and psychiatry of 24 September 2025 record a named manufacturer proposing permission to manufacture and market suvorexant tablets, the committee recommending permission to conduct a bioequivalence study, and minutes of 26 November 2025 record a second manufacturer with the same proposal, the committee recommending a Phase III clinical trial. Both are applications, and an application is not an approval.

That row's lead sentence once read that the agent was not approved in India at retrieval, and it was withdrawn: pre-approval activity by two named firms is evidence that those two firms had not yet been granted permission, not proof that no other holder exists, in a corpus this build itself shows to be incomplete. The evidence did not change; only the claim it was asked to carry was narrowed, and the row remains a declared absence.

The other two rest on searches that returned nothing usable, each naming what it searched. For daridorexant the substance is absent from all 66 published lists; four committee minutes returned by a domain search were all fetched, are all readable and none names the drug, and a fifth hit in an approval-list directory does not contain the string either, so all five were search-index false positives; no indexed CTRI trial record was located. For the oxybate the five domain hits are all International Cell written confirmation files naming Indian manufacturers, export-related documents that are not Indian marketing authorisation; no committee minute, no clinical-trial approval and no indexed CTRI record was located. A **written confirmation** is likeliest to be mistaken for an approval, being a real regulatory document about a real manufacturer that says nothing about the Indian market.

The authority that would settle any of these is the Central Drugs Standard Control Organisation and the Drugs Controller General of India, and committee minutes, clinical-trial no-objection certificates, International Cell written confirmations, CTRI registration, brand listings, pharmacy availability and manufacturer copy are none of them marketing authorisation. A **CTRI registration** records that a trial exists, not permission to market. Two sensitivity facts then bind any Indian sentence here. Every one of the seventeen positive controls this corpus finds sits in a document dated 2023 or earlier, and measured independent sensitivity in the 2024 to 2026 window is 0 of 1, so the corpus has never been shown to find a recent approval; and the positive-

control tally of 17 of 20 may not be cited as warrant for an absence on any agent approved after 2023. Absence from this corpus is evidence and not proof, and no Indian row in this build asserts that a drug is not approved in India: each asserts that no CDSCO approval record was located, and names what was searched.

IN INDIA

Write it one agent at a time. Lemborexant: a CDSCO approval-list entry for insomnia at serial number 12 of a 2021 list, date of issue 1 July 2021. Suvorexant: no CDSCO marketing approval located, the file documented at pre-approval stage on 2025 committee minutes; an application is not an approval. Daridorexant and sodium oxybate: no CDSCO approval record located, and what was searched is named. Do not write that any of them is not approved in India, and do not write that any is approved without naming the located record.

5.7 What certified these rows, and what a null cell is worth

These twelve records were tested rather than trusted, on three instruments: is the stored text verbatim against the primary document, is it that text cut short, does the count of indications carried match the document's? That is 36 cells, of which 21 are applicable and all 21 pass, with no failures and nothing unresolved.

1 of 2730	21 of 21	349 of 349	1 of 66
EU REGISTER MEDICINES NAMING OXYBATE	APPLICABLE FALSIFICATION CELLS PASSING	CHARACTERS, US OXYBATE ROW VERSUS LABEL	CDSCO LISTS WITH A LOCATED ENTRY

The fifteen inapplicable cells matter as much, and the reason for skipping them defines a declared gap: a row that is a declared absence carries no indication text, so an instrument comparing text against a primary document has nothing to test, because a gap is not a claim about a product but a claim about a search. An absence can be certified only as honest about its own reach.

Two instruments were proved on defects taken from this group, not invented ones. The prefix instrument was tested by replanting the real European oxybate truncation and returned a failure; the verbatim instrument by replanting the real Indian misattribution, in which a flattened text extraction attached the obesity indication belonging to the next serial number, cetilistat, to the lemborexant row, and it also returned a failure. That defect was repaired by reading the raw column layout of the source table instead of the flattened text line. An instrument never shown to fire on a known defect is not evidence.

The Indian cell is certified on a geometric reader's agreement with the drawn rules, its locator recorded to document, page, serial number and column coordinates, while the second document that row cites is absent from the cached corpus altogether. Certification concerns the reading, corroboration the sources.

5.8 The four records side by side, and what a complete answer contains

Reproduce this grid and the item is answerable in any form.

AGENT	UNITED STATES	EUROPEAN UNION	INDIA
Suvorexant	Located label indication for insomnia, NDA204569	No centralised procedure of any kind on record; scope limit weak	No approval located; file at pre-approval stage on 2025 minutes
Lemborexant	Located label indication for adult insomnia, NDA212028	No centralised procedure of any kind on record; scope limit weak	Approval-list entry for insomnia, serial 12, date of issue 1 July 2021
Daridorexant	Located label indication for adult insomnia, NDA214985	Authorised, EMEA/H/C/005634; indication carries a duration and a functioning criterion	No approval located; four minutes read, none names the drug
Sodium oxybate	Located indication: cataplexy or excessive daytime sleepiness in narcolepsy from age seven	Authorised, EMEA/H/C/000593; indication is narcolepsy with cataplexy including children from age seven	No approval located; the five documents found are export written confirmations

Reduced to four sentences:

- Status belongs to an agent inside a jurisdiction on a date, so twelve records is the right number and one class verdict is wrong.
- The two families carry different diseases in their licences, and their indications are never substituted for one another.
- The commonest silent defect is a regulator's sentence cut at a clause boundary and closed with a full stop.
- A declared absence is a statement about a search, naming the instrument, its reach, and whose authority would make it a negative.

MNEMONIC

Agent, Border, Cell, Cut

Agent: one drug in one country, never a class. Border: no indication, date or verdict crosses a jurisdiction. Cell: quote the regulator's cell whole, including the population at its end. Cut: ask whether a quoted indication is the primary text closed off tidily.

The licence belongs to a drug in a country on a date, and a sentence that ends in a full stop has not thereby ended where its source did.

6 · Xanomeline-trospium and muscarinic agonist antipsychotics

One capsule holds a muscarinic agonist and a muscarinic antagonist, and that pairing is the design rather than an accident of formulation. Two disciplines are examined at once. The

pharmacological question is how a treatment for psychosis that gives up dopamine blockade is supposed to work, and why the second molecule is there to be kept out of the brain rather than let into it. The regulatory question is why three national records of the same drug read so differently. Marks are lost in three predictable places: candidates treat the antagonist as a central anticholinergic; they carry an American indication across a border; and they read the silence of an instrument never shown able to speak. Receptor principles for the muscarinic system belong to the Psychopharmacology I: principles and core drug classes notes and are not rebuilt here.

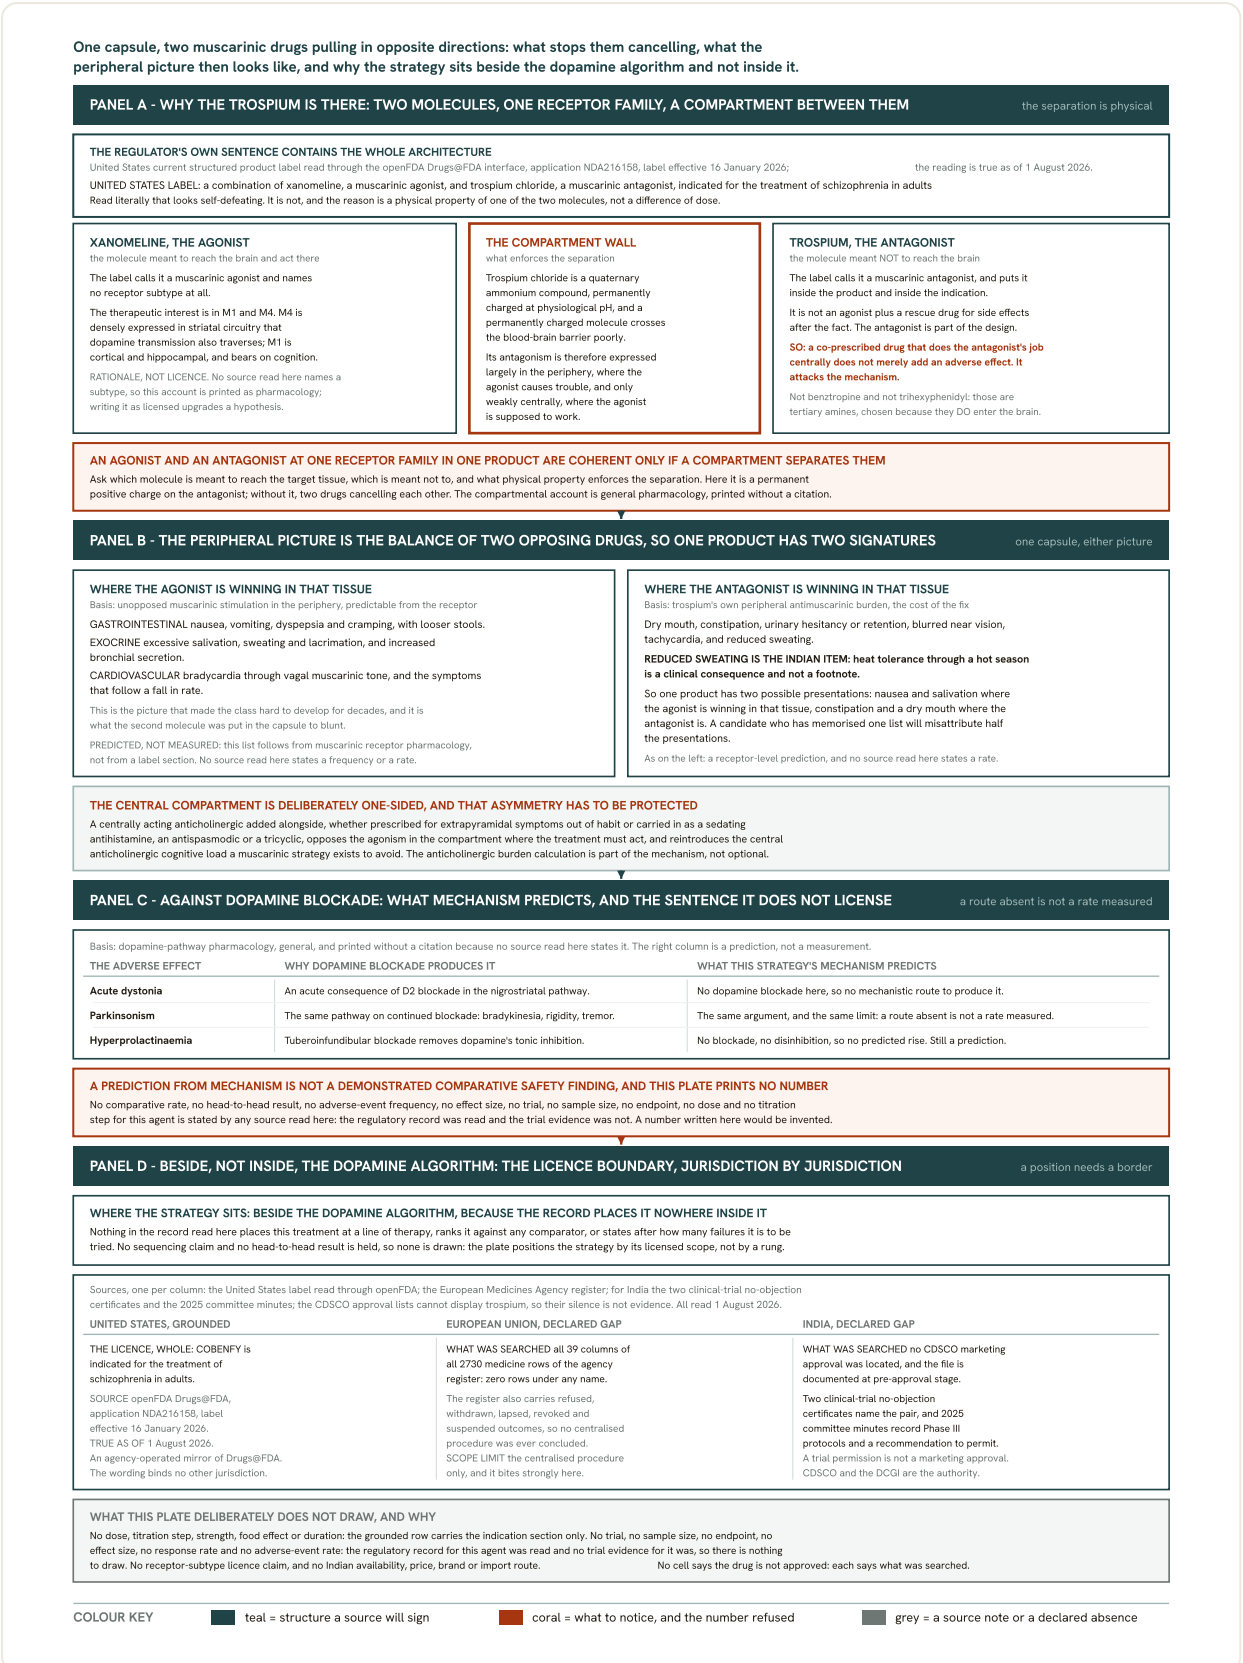

Fig 38.4 Muscarinic agonism with a peripherally restricted antagonist: why the trospium is in the capsule, and where the strategy sits. The label describes a combination of a muscarinic agonist and a muscarinic antagonist, and the pairing is coherent because trospium is permanently charged and stays peripheral, so one product can present with either signature, both predicted from the receptor and neither with a rate. The licence is the treatment of schizophrenia in adults in one jurisdiction; the European Union and India are drawn as declared gaps naming what was searched. (United States label via openFDA, NDA216158, effective 16 January 2026; European Medicines Agency medicines register; for India two trial no-objection certificates and 2025 committee minutes; read 1 August 2026.)

6.1 An agonist and an antagonist in one capsule, and why that is not a contradiction

Start with the sentence the regulator wrote; it contains the whole architecture. The product is described on its current United States label as a combination of xanomeline, a muscarinic agonist, and trospium chloride, a muscarinic antagonist, indicated for the treatment of schizophrenia in adults. Read literally that looks self-defeating; a candidate who says so has noticed the right thing and drawn the wrong conclusion.

The pairing is coherent because the two molecules are separated by a compartment and not by a dose. Xanomeline, the **muscarinic agonist**, is intended to reach the brain and act there. Trospium, the **muscarinic antagonist**, is a quaternary ammonium compound, permanently charged at physiological pH, and a permanently charged molecule crosses the blood-brain barrier poorly. Its antagonism is therefore expressed largely in the periphery, where the agonist causes trouble, and only weakly centrally, where the agonist is supposed to work.

Two things follow. The combination is not an agonist plus a rescue drug for side effects after the fact; the antagonist is inside the product and inside the indication. And a co-prescribed drug that does the antagonist's job centrally does not merely add an adverse effect. It attacks the mechanism.

RULE **An agonist and an antagonist at the same receptor family in one product are only coherent if a compartment separates them.** Ask which molecule is meant to reach the target tissue, which is meant not to, and what physical property enforces the separation. Here it is a permanent positive charge on the antagonist; without it, two drugs cancelling each other.

6.2 What the muscarinic strategy replaces, and where it sits

Every antipsychotic algorithm a postgraduate has learned is built on occupancy of the dopamine D2 receptor. This strategy is not on that axis; it engages the cholinergic muscarinic system instead, and the therapeutic interest sits with the M1 and M4 subtypes, M4 because it is densely expressed in striatal circuitry dopamine transmission also traverses, M1 because of its cortical and hippocampal distribution and its relationship to cognition. Xanomeline came out of a development programme aimed at Alzheimer's disease, where the antipsychotic signal was noticed before it was pursued in schizophrenia; the cholinergic tolerability problem that limited it then is what the second molecule was added to solve.

Be exact about what is licensed and what is merely explanatory. The label text held here calls xanomeline a muscarinic agonist and names no receptor subtype at all. The M1 and M4 account is pharmacology and belongs to the rationale, not the licence. Teach it as the rationale; writing it as though the regulator had endorsed a subtype-selective claim upgrades a hypothesis into a licence.

The strategy sits beside the dopamine-blockade algorithm rather than inside it, because nothing in the record read here places it at a line of therapy, ranks it against any comparator, or states after how many failures it is to be tried: no comparative efficacy claim, no sequencing claim and no head-to-head result is held for this agent in this build, and inventing one is more costly than admitting the absence.

GOOD TO REMEMBER

Acute dystonia, parkinsonism and hyperprolactinaemia are consequences of dopamine blockade, so a treatment that does not block dopamine has no mechanistic route to produce them. That is a prediction from mechanism rather than a demonstrated comparative safety finding, and what cannot be said without a trial is any figure comparing rates. Write the mechanism and stop; do not smuggle in a number.

6.3 The peripheral antagonist: what it buys and what it costs

An unopposed muscarinic agonist in the periphery produces a recognisable picture, the reason this class was hard to develop for decades. Predictable from the receptor alone:

- Gastrointestinal stimulation: nausea, vomiting, dyspepsia and cramping, with looser stools.
- Exocrine stimulation: excessive salivation, sweating and lacrimation, and increased bronchial secretion.
- Cardiovascular slowing through vagal muscarinic tone: bradycardia and the symptoms that follow a fall in rate.

Trospium is in the capsule to blunt exactly that list. The cost is that it brings its own peripheral antimuscarinic burden: dry mouth, constipation, urinary hesitancy or retention, blurred near vision, tachycardia, and reduced sweating with its implications in Indian summer heat. The net peripheral picture is therefore a balance of two opposing drugs given together, and the same product can present with either signature: nausea and salivation where the agonist is winning in that tissue, constipation and a dry mouth where the antagonist is. A candidate who has memorised one list will misattribute half the presentations.

The central compartment is deliberately left one-sided, and that asymmetry must be protected. A centrally acting anticholinergic added alongside, whether prescribed for extrapyramidal symptoms out of habit or carried in as a sedating antihistamine, an antispasmodic or a tricyclic, opposes the agonism in the compartment where the treatment must act, and reintroduces the central anticholinergic cognitive load a muscarinic strategy exists to avoid. The anticholinergic burden calculation is not optional here; it is part of the mechanism.

PITFALL

Describing trospium as though it were benztropine or trihexyphenidyl. Those are tertiary amines chosen because they enter the brain, to oppose central cholinergic tone. Trospium is chosen for the opposite property. Calling it an anticholinergic without saying peripherally restricted loses the point of the combination, and is the single sentence most likely to lose the mechanism mark here. The related error is prescribing a central anticholinergic alongside the product.

6.4 The United States: the one grounded record, read field by field

Of the three jurisdictions, exactly one carries a grounded status row, a model of a status claim written properly. The indication, verbatim: COBENFY is indicated for the treatment of schizophrenia in adults. The source is named and narrow: the status was read from the openFDA

Drugs@FDA interface, application NDA216158, with the current structured product label effective 16 January 2026, and the reading was true as of 1 August 2026. Jurisdiction, indication in the source's words, named source, date: the sentence becomes checkable by someone who does not trust you.

Then the field easiest to misreport. The earliest approval-status date in that application record is **26 September 2024**, and the field is named for what it holds, not for what a reader would like it to mean. Whether that date is a first marketing approval, a supplement or something else is a question the record read here does not answer, and this ledger has already published one drug's generic approval date under a first-approval field name and had to retract it. Label a date with the name of the field it came from, every time.

The record carries a caution about itself, which a careful answer respects: openFDA is an agency-operated mirror of Drugs@FDA and of the label archive rather than the Drugs@FDA application itself, and the indication wording is current label text as filed, which is not a statement about any other jurisdiction and must never be carried across one.

This row was tested rather than trusted. The query returned exactly one application, NDA216158, so the row does not blend several applications into one agent-level claim; and three text instruments were run against the primary document, checking that the row text is verbatim, that it is not the primary text cut short and closed with a full stop so that nothing signals the loss, and that the count of indications carried matches the count in the document. All three passed: 262 characters on the row against 262 in the primary, and one indication in the document against one on the row.

1 of 1	0 of 2730	0 of 66	0 of 121
INDICATIONS CARRIED, US ROW VERSUS LABEL	EU REGISTER MEDICINE ROWS MATCHING	CDSCO APPROVAL LISTS WITH AN ENTRY	EXTRACTED TEXTS NAMING TROSPIUM

TRAP **Widening the indication because the mechanism sounds as though it should be wider.** The licensed wording read here is **the treatment of schizophrenia in adults** and nothing else. It is not an indication for negative symptoms as a separately licensed target, for cognitive impairment, for psychosis in dementia, for adolescents, or for use as an add-on to another antipsychotic. The M1 cognitive rationale in 6.2 is what tempts a candidate to widen the sentence, and the widening is unlicensed. Quote the indication whole and let the mechanism stay a mechanism.

6.5 The European Union: an absence in a register that records refusals too

The European position is a declared gap, and a gap's strength depends entirely on the instrument that produced it. The instrument: the European Medicines Agency's own medicines register, generated by the agency on 1 August 2026, downloaded whole and scanned across all 39 columns of all 2730 medicine rows; this substance returns zero rows under any of its names.

What makes that more than a shrug is the range of outcomes the register carries. It records Authorised, Refused, Application withdrawn, Withdrawn, Lapsed, Expired, Revoked, Suspended and Opinion outcomes, so the absence means no central application of any kind was ever

concluded, including one refused or abandoned. The missing document is an agency public assessment report for the substance, or a European Commission implementing decision. Nothing else closes it, and the phrase approved internationally is not a permitted substitute for a named regulator.

Now the limit, where an honest answer separates itself. This register covers the European Union **centralised procedure** only. A product authorised nationally in one or more member states through the decentralised or mutual-recognition procedure would never appear in it. That limit is stated on every European gap row in this build, but it does not bite equally on all of them, and on this agent it is graded as biting strongly: this is a small molecule outside the mandatory centralised scope, so a national authorisation somewhere in the Union is genuinely possible and is wholly unmeasured here. Two further weaknesses are recorded and travel with the finding: the confirming second instrument was run on the grounded rows and on none of the gap rows, so no European gap in this build has independent corroboration, and the assessment-report page would in any case be a second rendering of the same source rather than an independent one, since the register is generated from those pages.

The defensible European sentence is therefore narrow, and worth writing in full: no European Union centralised procedure of any kind is on record for this active substance as of 1 August 2026, which does not exclude a national authorisation that this instrument cannot see.

6.6 India: the affirmative documents, and the sentence that was corrected away

The Indian entry is the one an Indian examination cares about, and it is the one where a confident wrong sentence is easiest to write. The row states that no CDSCO marketing approval was located and that the file is documented at pre-approval stage. That second clause is worth learning, because unlike most gaps in this chapter it is built on documents that exist rather than on documents that do not.

What was found is specific and dated. Two CDSCO **clinical-trial no-objection certificates** name Trospium Chloride plus Xanomeline, one against an IQVIA file numbered 44439 and one against a Bristol-Myers Squibb file numbered 52364. Minutes of the **subject expert committee** for neurology and psychiatry dated 30 May 2025, 10 December 2025 and 22 December 2025 record Bristol-Myers Squibb India Private Limited presenting the Phase III protocols CN0120051 and CN0120025, with the committee recommending permission to conduct the trial.

That footprint licenses one sentence and forbids another. A trial permission is not a **marketing approval**. The authority that would settle the question is the Central Drugs Standard Control Organisation and the Drugs Controller General of India, and expert committee minutes, clinical-trial no-objection certificates, International Cell written confirmations, CTRI registration, brand listings, pharmacy availability and manufacturer copy are none of them marketing authorisation. A **CTRI registration** deserves separate mention because it is the substitution an Indian candidate is likeliest to make: it records that a trial exists, not permission to market. What would

close the row is an affirmative CDSCO or DCGI new-drug permission, a current CDSCO-approved label, or an entry in an official CDSCO approval list.

Note what the row does not say, because it was deliberately taken out. The lead sentence of this row once read that the agent was not approved in India at retrieval, and that was corrected: pre-approval activity by two named firms is evidence that those firms had not yet been granted permission, and it is not proof that no other holder exists, in a corpus this build itself demonstrates to be incomplete. The evidence did not change; only the claim it was being made to carry was narrowed, and the row remains a declared gap either way. No India row in this build asserts that a drug is not approved in India. Each asserts that no CDSCO approval record was located, and names what was searched.

IN INDIA

Write it in this order. No CDSCO marketing approval record for xanomeline with trospium was located as of 1 August 2026; the Indian file is documented at clinical-trial stage, with two trial no-objection certificates and subject expert committee minutes of 2025 recording Phase III protocols and a recommendation to permit the trial; a trial permission is not a marketing approval. Do not write that the drug is not approved in India, which is stronger than this evidence supports. Do not write that it is approved, because nothing retrieved says so. For a patient or a family: the treatment is not something an Indian service can offer today outside a trial, and a sponsor's trial permission is not an availability promise to a patient.

6.7 The instrument that cannot see half of this drug

The India row carries one clause that looks like evidence and is worth nothing, and why is the most transferable thing on this item: the agent is absent from all 66 published CDSCO approval lists.

Trospium is absent from all 66 of those documents and from all 121 extracted text files under every spelling tried, including variants tolerant of the rn and m ligature confusion, of 0 against o and 1 against l, and of letter-spaced layout, and under the brand and programme names. It is one of three drugs that failed as **positive controls** for this corpus, alongside agomelatine and molnupiravir: drugs taken to be approved and marketed in India that the corpus nonetheless cannot display. The corpus has been shown incapable of displaying trospium at all, so its silence is a property of the instrument and not a fact about the drug.

The row records this explicitly: the absent-from-66-lists clause is worth nothing for trospium specifically and must not be read as a negative finding about it, and the verdict does not depend on that clause, because the verdict rests on the affirmative documents, the two trial no-objection certificates and the dated committee minutes, which are unaffected. The template: a null reading from an instrument shown blind to the target contributes nothing, and the same page can still carry a sound conclusion resting on something else.

Two sensitivity facts belong to any Indian gap sentence on a recent agent. Every drug this corpus is known to find sits in a document dated 2023 or earlier, and independent sensitivity in the 2024 to 2026 window is 0 of 1, so the corpus has never been shown to find a recent approval;

and the positive-control tally of 17 of 20 may not be cited as warrant for a gap on any agent approved after 2023. The corollary is that a gap is a statement about a search and not about a product, which is also why the three text-comparison instruments were recorded as not applicable to both gap rows on this agent: a declared gap carries no indication text, so an instrument that compares text against a primary document has nothing to test.

TRAP **Quoting a null result from an instrument that was never shown able to detect the thing.** Placed beside two genuine documents, the sentence that trospium appears in none of 66 approval lists reads as a third piece of evidence, and is not evidence at all. The test before quoting any absence: was this instrument ever demonstrated to return a known positive? Here the answer is no, recorded as one of three control failures. The mirror-image error is to conclude the whole row collapses because one clause is empty; the verdict was built on the affirmative documents and never on the absence.

6.8 The three records side by side, and what a complete answer contains

The same drug, the same date, three records of entirely different kinds. Reproduce the differences and the question is answered in any form.

JURISDICTION	WHAT THE RECORD HOLDS	THE SENTENCE THAT MAY BE WRITTEN	THE SENTENCE THAT MAY NOT
United States	A current label indication for the treatment of schizophrenia in adults, application NDA216158, read 1 August 2026	The indication quoted whole, with the application, label date and reading date	Any wider indication, and any date labelled as a first approval
European Union	Zero rows in the agency medicines register of 2730 medicines, which also records refusals and withdrawals	No centralised procedure of any kind is on record, as of the reading date	Not authorised in Europe, which the centralised-only instrument cannot support
India	Trial no-objection certificates and 2025 committee minutes recording Phase III protocols and a recommendation to permit, and no located approval	No CDSCO approval record located; the file is documented at trial stage	Not approved in India, and any negative inference from the approval-list corpus about trospium

Reduced to four sentences, the item is this.

- The mechanism is muscarinic, not dopaminergic; the combination works because a permanently charged antagonist stays peripheral while the agonist acts centrally.
- The adverse-effect picture balances two opposing peripheral actions, so either a cholinergic or an antimuscarinic presentation is possible from one product, and a centrally acting anticholinergic added alongside attacks the mechanism.
- The regulatory position has three answers and no single one, each carrying its jurisdiction, its indication in the source's words, its named source and the date it was read.

- The Indian file is a declared gap standing on affirmative documents, and its one clause reporting an absence is void because the instrument is blind to trospium.

MNEMONIC

Charge, Compartment, Country, Control

Charge is why trospium stays out of the brain. Compartment is where each molecule is meant to act, and why the pairing is not self-cancelling. Country is the jurisdiction every status sentence must name and never leave. Control: before quoting any absence, ask whether the instrument was ever shown able to find what it was looking for.

The antagonist is in the capsule to be kept out of the brain, the approval is in one country and must stay there, and an absence reported by a blind instrument is not a finding.

7 · Endoxifen and protein-kinase-C-targeted agents in mania

This is the one agent in the chapter with an affirmative Indian record and a measured American absence, and the examinable content of the item is that both sentences are true at once. The marks sit on the regulatory question: writing about one molecule in three jurisdictions without letting any of them leak into another. It goes four ways. Writing "approved" with no country attached. Converting an American search that found nothing into a statement that nothing exists. Reading a tablet strength printed inside a product-name cell as a dose. And quoting the Indian indication with its qualifier quietly missing, the defect this build planted on this entry to prove its instruments could catch it. The acute-mania treatment algorithm is not rebuilt here.

7.1 A metabolite promoted to a drug, and what that changes

Endoxifen is an **active metabolite** of tamoxifen, and tamoxifen is named here only as the parent compound. When a parent owes its activity to a metabolite, response depends on a conversion step, and that step is where people differ: genotype, competing inhibitors and adherence all act on it before any target is reached. Give the metabolite itself and the step leaves the chain, taking its variability with it.

That is an argument about pharmacological architecture and not about magnitude. It says where variability enters, not how much of it there is, and no exposure figure, potency ratio, conversion proportion or genotype frequency is held anywhere in the material behind this chapter. It is also a different drug from its parent for regulatory purposes, with separate applications, indications and approval records, so nothing true of tamoxifen may be carried onto endoxifen in either direction.

GOOD TO REMEMBER

Giving a metabolite removes a source of variation between patients. It does not remove the need to show that the metabolite works. Removing a conversion step is a pharmacokinetic argument and the prescriber's question is a pharmacodynamic one, so answering the second with the first answers the wrong question.

7.2 The protein kinase C rationale, and what kind of claim a rationale is

Protein kinase C is not a receptor. It is a family of intracellular signalling enzymes downstream of receptor activation, acting on the machinery that changes what a cell does over hours and days rather than milliseconds. The intervention is aimed at a node inside the cell, several steps from the synapse, and the phenotype it must move is a whole manic episode.

The shape of that proposal is what an examiner can test. It is target-first: start from a mechanistic node, find a compound with activity there, and predict a clinical effect in a syndrome the node is thought to join. Most older agents arrived the other way round, from a clinical observation worked backwards. So its strength and its weakness are one feature: it is derived rather than observed.

A rationale licenses a hypothesis and a trial. It does not license a statement about efficacy, about how quickly an effect appears, about how large it is, or about how the agent stands against any existing treatment. No artefact behind this chapter holds trial evidence for this agent: no trial name, no sample size, no endpoint, no effect size, no response rate, no dose, no titration step, no adverse-event rate. This account names none of them, and offers no comparison against any existing mood stabiliser, because none is held.

RULE **A mechanistic rationale is a reason to run a trial and never a substitute for one.** Could your sentence be false even if the mechanism is right? "Protein kinase C is implicated in mania" and "inhibiting protein kinase C treats mania" are separated by the whole of clinical trial evidence.

7.3 India: the affirmative record, read field by field

The Indian record is the strongest of the three here, which reverses the order candidates expect. Its source is the published new-drug approval lists of the Central Drugs Standard Control Organisation, CDSCO: 66 distinct documents deduplicated by content hash, downloaded direct over verified transport on 1 August 2026, every one yielding an extractable text layer so that no absence in the corpus is an unreadable-file artefact; the entry is serial number 20 in the list file ndedec13appro.pdf.

The indication, quoted whole because a paraphrase is where the qualifier goes missing: For the acute treatment of manic episodes with or without mixed features of Bipolar I disorder. Endoxifen citrate bulk and Endoxifen tablets 8 mg. The first leg is an indication bounded three ways: acute treatment, manic episodes, bipolar I. The words **mixed features** are the part most often dropped, and dropping them changes who the indication covers. The second is a product-name leg naming a **bulk drug** entry and a tablet strength. That strength is a formulation fact

printed inside a name cell: not a dose, not a starting dose, not a maximum, and no dosing information for this agent exists in any artefact behind this chapter.

Then the date, the field this build has already had to correct once. The entry carries **10 December 2019**, and the row now describes that as the quantity printed in the column headed **Date of issue** rather than as an approval date, the earlier wording having claimed to quote a label the document does not print. The reading is dated too: the status true as of date on this row is 1 August 2026.

Corroboration is thinner than the verbatim quotation looks. It rests on one CDSCO document. Date and indication were confirmed against the raw column layout of the source table rather than its flattened text, and the neighbouring date of 20 November 2019 was checked and belongs to serial number 19 and to an entirely different substance. In a printed table a date can be read off the row above with nothing looking wrong.

An older record of the same search read this jurisdiction as a gap and named what would close it: a CDSCO or DCGI permission, an approved label, or an official approval-list entry with its date and indication verbatim; and what would not: a CTRI registration, a brand listing, pharmacy availability or manufacturer copy. What closed it was the third permitted item and nothing weaker. The question is never whether a document exists, but whether it can settle the question.

IN INDIA

Write it in this order. An entry for endoxifen appears in a CDSCO published new-drug approval list at serial number 20, carrying the indication above and the date 10 December 2019 under the printed heading Date of issue, true as of 1 August 2026. Quote the indication with its mixed-features qualifier intact. Do not turn the 8 mg tablet strength into a dosing instruction. And be clear what the record does not settle: it is an approval-list entry, not a statement about supply, price or whether your pharmacy stocks it.

7.4 How that Indian cell was certified, and the defect planted in it

Quoted correctly and read correctly are two achievements; this row was tested for the second. Three text instruments were run against the primary document: one checking that the row text is verbatim and that the source sentence names the primary, one checking that the row is not the primary cut short, at 146 characters against 146, and one checking that the indication cell is carried in full, the primary cell measuring 94 characters. All three passed against a locator naming the document, page 4, serial number 20, the bounds of the indication column and the row band, with corroboration recorded as trustworthy.

The rule behind that verdict: a cell counts as read when a reader working from the drawn rules of the table agrees with at least one independent reader, and two readers of the same flattened-text kind are not independent, because they share whatever made the first of them wrong.

Now the part that makes this row the most instructive object in the section. This entry is the one the build used to test its own instruments, planting two defects in it. The first cut the indication at a clause boundary and closed it with a full stop where the primary entry continues with or

without mixed features of Bipolar I disorder, dropping a qualifier that changes who the indication covers. The second removed the same qualifier from the middle of the cell and left the ending intact, so nothing was truncated at the end: that plant exists to separate the two instruments, because the prefix instrument must stay silent on it and only the completeness instrument may fire. Both guards fired and both plants were caught.

Note what both plants attacked. It was the clinical qualifier.

TRAP **Quoting an indication that ends in a full stop and assuming it ended there in the source.** Cut at its clause boundary, the Indian entry reads as a complete, plausible sentence with the mixed-features qualifier gone, and a cut closing with valid punctuation leaves no mark, so only comparison against the primary finds it. Reproducing an approved indication means reproducing its qualifiers: population, phase, severity, specifier. And a gate never shown to catch the defect it was built for has not been tested; planting the defect is the test.

3 of 3	0 of 5	228	0 of 2730
INDIA TEXT INSTRUMENTS PASSING	US QUERY ROUTES RETURNING A RECORD	LABEL DOCUMENTS MATCHING THE STRING	EU REGISTER MEDICINE ROWS MATCHING

7.5 The United States: a measured absence, and the sentence it does not license

An absence that was measured is a different object from an absence that was assumed, and only one of the two may be written down. A query of the Drugs@FDA interface returned no application record for the generic name endoxifen on 1 August 2026, the endpoint answering with its own not-found response. That probe found nothing; it does not establish that the agent is unapproved in the United States. To close the row a human must read Drugs@FDA directly and, if there is no application, say so on the agency's authority rather than on this probe's silence. The authority any American claim would rest on is the United States Food and Drug Administration, through Drugs@FDA.

The gap was then strengthened into a **measured absence**. Five query routes were run, every one returned the endpoint's own not-found response, there were zero transport failures, and every route was positive-controlled in the same run against a value known to return records, so a zero here is a route that answered and found nothing, not a route that failed. That **positive control** is the difference: without one, a broken route and an empty answer look identical from outside. The five routes were four fields of the application interface, generic name, substance name, active ingredient name and brand name, and one field of the label archive.

The scope is narrower than it first reads. It measures the Drugs@FDA interface and the label archive only. It is not the agency's own affirmative statement that no application exists, and it is silent on investigational and breakthrough designations, which appear in neither instrument. So the defensible American sentence names the search and stops. Writing it harder is forbidden, because an American gap in this build has already been wrong once: one agent's record carries no cross-reference block at all, so three of five routes returned not-found on it while the active-ingredient route returned the record.

Then the figure showing how a search can look conclusive in the wrong direction. A free-text query of the label archive for the string endoxifen, run during independent adjudication on 2 August 2026, returned a successful response with 228 matching documents, while every structured route above returned zero. The two are not in conflict. A **free-text search** matches a string anywhere in a document, so a document belonging to another product that mentions the substance counts as a hit, whereas a structured field query asks whether the substance is the product's own named ingredient.

TRAP **Collapsing an Indian approval-list entry and an American gap into one sentence about the drug.** This agent is the border-crossing error waiting to happen, both ways. Writing that endoxifen is approved, with no country attached, exports an Indian entry to the United States and Europe. Writing that it is not approved in the United States converts a search that found nothing into a regulator's negative finding, which no instrument here supports. Three jurisdictions, three records, three sentences, each with its own source and date.

7.6 The European Union: a register that records refusals, and the limit that follows

The European position is also a declared gap, and a gap is only as strong as the instrument behind it. The instrument is the European Medicines Agency's own published medicines register, generated by the agency on 1 August 2026, downloaded whole and scanned across all 39 columns of all 2730 medicine rows; this substance returns zero rows under any of its names.

What lifts that above a shrug is the range of outcomes the register carries. It records authorised, refused, application withdrawn, withdrawn, lapsed, expired, revoked, suspended and opinion outcomes, so an absence means no central application of any kind was ever concluded, including one refused or abandoned. The missing document is an agency public assessment report for the substance, or a European Commission implementing decision, and the phrase approved internationally is not a permitted substitute for a named regulator.

Now the limit. The register covers the European Union **centralised procedure** only, so a product authorised nationally through the decentralised or mutual-recognition procedure would never appear in it. That limit is printed identically on every European gap row, so it is graded per agent. For this substance it is graded as biting moderately: a small molecule outside the mandatory centralised scope could genuinely hold a national authorisation this instrument cannot see. The confirming instrument ran on all eight grounded European rows and none of the eight gap rows, so no European gap here has independent corroboration, and the assessment-report page would anyway be a second rendering of the same source. Second-instrument coverage of European gaps is **0 of 8**.

So the defensible European sentence is narrow: no European Union centralised procedure of any kind is on record for this substance as of 1 August 2026, which does not exclude a national authorisation this instrument cannot see. The three text instruments used on the Indian entry report nothing here, because a declared gap carries no indication text: a gap is not a claim about a product, it is a claim about a search. Each record was built in isolation, the Indian row consulting no American or European value, and the European row no American or Indian one.

7.7 The three records side by side, and what a complete answer contains

One molecule, one reading date, three records of different kinds.

JURISDICTION	WHAT THE RECORD HOLDS	THE SENTENCE THAT MAY BE WRITTEN	THE SENTENCE THAT MAY NOT
India	An approval-list entry at serial number 20 carrying the acute manic episode indication with or without mixed features, a bulk-drug leg and a tablet strength, dated 10 December 2019 under the heading Date of issue	The indication whole, with the document, serial number, date heading and reading date	Any dose built from the strength in the name cell, or any claim about supply
United States	Five positive-controlled query routes returning the endpoint's own not-found response, zero transport failures	These named routes, on this date, returned no application record	Not approved in the United States, which converts a probe's silence into the regulator's finding
European Union	Zero rows in an agency register of 2730 medicines that also records refusals and revocations	No centralised procedure of any kind is on record at the reading date	Not authorised in Europe, which a centralised-only instrument cannot support

Reduced to five sentences, the item is this.

- Three jurisdictions, three records, three sentences: an approval-list entry, a measured absence and a register absence, each with its own source and date.
- The Indian indication is quoted whole because the mixed-features qualifier decides who it covers, and the strength beside it is a formulation fact, not a dose.
- A protein kinase C target is a rationale for a trial, not a result from one, and no trial figure is held.
- An absence is a statement about a search: name the routes, their controls, and what the instrument cannot see.
- A date is only as strong as its field name, and a printed column heading is not a regulatory event.

MNEMONIC

Metabolite, Mechanism, Mixed features, Measured

Metabolite is what the drug is. Mechanism is a rationale until a trial says otherwise. Mixed features is the qualifier that must survive into your answer. Measured is the only kind of absence you may write down.

One molecule, three records: an Indian approval-list entry quoted whole with its qualifier, an American absence that was measured rather than assumed, and a European silence a national authorisation could still be hiding behind.

8 · Anti-amyloid monoclonal antibodies as a recent advance (cross-reference to dementia)

This item is a pointer, and knowing why it is a pointer is itself examinable. **Anti-amyloid monoclonal antibodies** reach a recent-advances list because they changed what a therapeutic claim here may sound like, and they sit in another chapter because their mechanism, trial evidence, imaging complication, genotype caveat, selection criteria, monitoring and regulatory record are taught with the Dementias and neurocognitive disorders notes. What is left is what this chapter owns: the class of claim these agents exemplify, the shape such an argument must take, why the regulatory position is not printed here, and what an Indian service must decide.

8.1 Why this is a pointer, and what a pointer owes the reader

This material is taught with the dementia notes, and the item itself is worded as a recent advance carrying a cross-reference there, so a pointer is what is being asked for and the reason is not space. Two accounts of one drug class in one paper are written at different times against different sources and drift apart, and the drift stays invisible until a candidate quotes the thinner one and is corrected out of the fuller one.

A pointer owes the destination named exactly, some idea of what is there, and a plain statement of what is withheld. The owning chapter carries dedicated passages on each of these agents and on the imaging complication, so the material is there and at length. Everything listed at the head of this section is taught with the Dementias and neurocognitive disorders notes and none of it is restated here. Going quiet on all of that without saying so invites a reader to fill the silence from memory.

8.2 The class of claim, and why psychiatry has an interest in it

Almost everything a psychiatrist prescribes makes a **symptomatic** claim: the current state will be better while the drug is taken, and it is judged on that state. A **disease-modifying** claim differs in kind: it asserts an effect on the course of the illness rather than on the state at a point along it, so it cannot be demonstrated at a point. It needs an observation period long enough for two trajectories to separate, an agreed way of locating a patient on one, and an argument that the gap between them matters to the person living it. Each is a place the claim can fail without the drug doing anything wrong.

Which is why the class belongs in a psychiatry chapter: these patients reach **old-age psychiatry** clinics as well as neurology ones, and the first clinician a family asks is often a psychiatrist. And the argument travels, because the way a disease-modifying claim is first pressed becomes the template the next class is held to.

RULE **A symptomatic claim is judged on the state, a disease-modifying claim on the course, and the same evidence cannot settle both.** Decide which claim is on trial before appraising any result: a better state at a point is silent on the course, and separating trajectories show nobody better today.

8.3 The shape of the evidence argument, with no figure from it

Such an argument runs at two levels and keeping them apart is where the marks are. **Target engagement** is the first: the thing the drug acts on has changed. Patient benefit is the second: the person does better for longer. Engagement alone is a **surrogate marker** argument, only as strong as the assumption joining marker to outcome, and the history of therapeutics is largely a history of that assumption failing. A marker result is a reason to keep testing, not to treat.

At the patient level the problem is what a difference on a rating scale means. A difference can be reliably present and too small for anyone to notice, and the bridge is the **minimally important difference**, the change below which no patient or family could tell. Where that threshold sits is contested rather than settled, so one honest appraiser reads a result as a worthwhile gain and another as clinically negligible; state both readings and name the threshold each rests on. Two constraints join the balance: a group difference in an average rate of change is not a prognosis for the individual in front of you, and where a treatment carries a delivery burden and a surveillance requirement the benefit side must weigh more before the balance tips.

No figure from that argument appears here, by rule and not oversight. The chapter holds no grounded evidence lane for this item: no trial name, no sample size, no observation period, no effect size, no adverse-event rate. Writing one from memory is a fabricated citation, the one defect that cannot be repaired later.

8.4 Why the regulatory position is not on this page, and what a delegated gap is

The regulatory position of these agents is not written here, and the reason earns more marks than the position would. The chapter's status ledger holds **48** rows and not one is an anti-amyloid row. That is neither an oversight nor a failed search: the ledger says no row is written there deliberately, so that none can be quoted from there, and it names the three agents covered, lecanemab, donanemab and aducanumab.

Three silences look identical here and mean different things. A searched gap is a question a named instrument was pointed at, which returned nothing; the honest sentence names what was searched and whose authority a claim would rest on, and never hardens into a categorical negative about a jurisdiction. An instrument blindness is a question the instrument could not have answered whatever the truth was, so its silence carries no information. A **delegated gap** is neither: the fact exists, another owner holds it, and this page declines to restate it so two accounts of one fact cannot diverge. This item is the third kind, and the only one that is not an absence of fact.

A delegation is not a warrant, though: nothing read for this chapter establishes the evidentiary state of the owner's account, which predates this chapter's four-field standard and carries its own warning against giving its record false precision. So go to the owner for what it holds, read

anything found there against the jurisdiction it was written about, and never carry a position across a border. Until that chapter is refreshed this class has a delegated status, not an unknown one.

0 of 48	3	131	16
CHAPTER STATUS ROWS ON THESE AGENTS	AGENTS WHOSE STATUS ANOTHER CHAPTER HOLDS	OWNER PASSAGES MATCHING LECANEMAB, DONANEMAB OR THE IMAGING COMPLICATION	OTHER AGENTS THIS CHAPTER HOLDS A STATUS FOR

TRAP **Supplying the regulatory position from memory because the section did not.** A reader given no jurisdiction, no wording and no date often finishes the sentence privately, and a half-remembered headline surfaces attached to the wrong country and year. A status sentence is worth writing only when it carries the jurisdiction, the wording the regulator used, the source it was read from and the date it was true; none of the four is available here for these agents.

8.5 What an Indian service is actually being asked to decide

The decision facing an Indian psychiatrist is not whether to prescribe one of these agents, and treating it as though it were is how the topic gets answered badly. Four decisions are live now, whatever any regulator has done. What to say to a family who arrive having read something: name what kind of treatment is discussed, say what is held elsewhere and can be checked, and offer to find out rather than guess, because a warm guess is repeated as though a doctor confirmed it. Whether raising the class unprompted is kind where any pathway would be long and uncertain, which is a judgment about this family and not a rule. What would have to exist before the question became a real option, which is the pathway set out below. And affordability, which in Indian practice usually settles the question first.

IN INDIA

Write the Indian answer in this order. The regulatory position is not stated here and is not to be inferred from the silence. Nothing read for this chapter holds an Indian position for these agents: the status ledger writes no row for them at all, and the material with the Dementias and neurocognitive disorders notes is written about the United States and Europe, its own gap list recording that current Indian regulatory, availability and cost information is not supplied there. So nothing found at the owner may be read across into an Indian answer. What an Indian old-age service must establish for itself is the pathway: who confirms the diagnosis, where the investigations are done, who owns the decision, who carries the follow-up, and what the family can afford.

8.6 The boundary in both directions, and what a complete answer contains

QUESTION	WHERE IT IS HELD	WHAT THIS PAGE MAY SAY
How the antibodies act, and on what	The owning item	Only that the class name states its target
What the trials showed, in numbers	The owning item	Nothing numerical: no evidence lane exists here
Imaging complication, genotype caveat, selection, monitoring	The owning item	Only that they exist and dominate the safety discussion
Regulatory position in any jurisdiction	The owning item, a delegated gap until refreshed	Nothing, for any agent, in any jurisdiction, on any date
The class of claim, and what a service must decide	Here	Claim type, argument shape, the delegation, the Indian pathway

Reduced to four sentences:

- A pointer by design: two accounts of one drug class diverge, and the thinner loses marks.
- The claim is disease-modifying, not symptomatic, which changes what evidence could settle it and how long it must run.
- The argument has two levels; a marker result licenses no patient conclusion, and the noticeability threshold is contested, so both readings are stated.
- The status is a delegated gap, not an unknown: held by its owner, restated nowhere here, and not yet meeting the four fields a status sentence needs.

GOOD TO REMEMBER

The commonest real-world error here is conversational, not pharmacological: a family told kindly and vaguely that something new exists and might help leaves having heard a promise nobody made. Name what is known, what is held elsewhere, and what you will find out.

MNEMONIC

Claim, Course, Custody, Clinic

Claim: symptomatic or disease-modifying, decided first. Course: judged over a trajectory, never at a point. Custody: another owner holds the record; this page restates none of it. Clinic: pathway, follow-up, affordability.

This item is a pointer: the class of claim and the service decision are taught here; mechanism, evidence and regulatory position are quoted from their owner or not at all.

9 · Moncrieff serotonin umbrella review and the serotonin-hypothesis debate

The examinable object here is a piece of evidence appraisal, not a drug and not a neurotransmitter. In 2022 a group of authors led by Joanna Moncrieff published an umbrella

review in Molecular Psychiatry asking whether the research literature supports the idea that depression is caused by low serotonin, reported that it does not, and set off an argument that reached patients before it reached examiners. Every mark in this topic is won or lost on discipline of attribution: what the review found, what its authors concluded, what its critics answered. The serotonin system itself, its pathways and its receptor subtypes, belongs to the Neurochemistry, Neuroendocrinology, Neuroimaging and Basic Psychopharmacology notes, and the monoamine hypothesis of depression and its limitations belong to the Mood disorders: classification, depressive and bipolar syndromes, neurobiology notes.

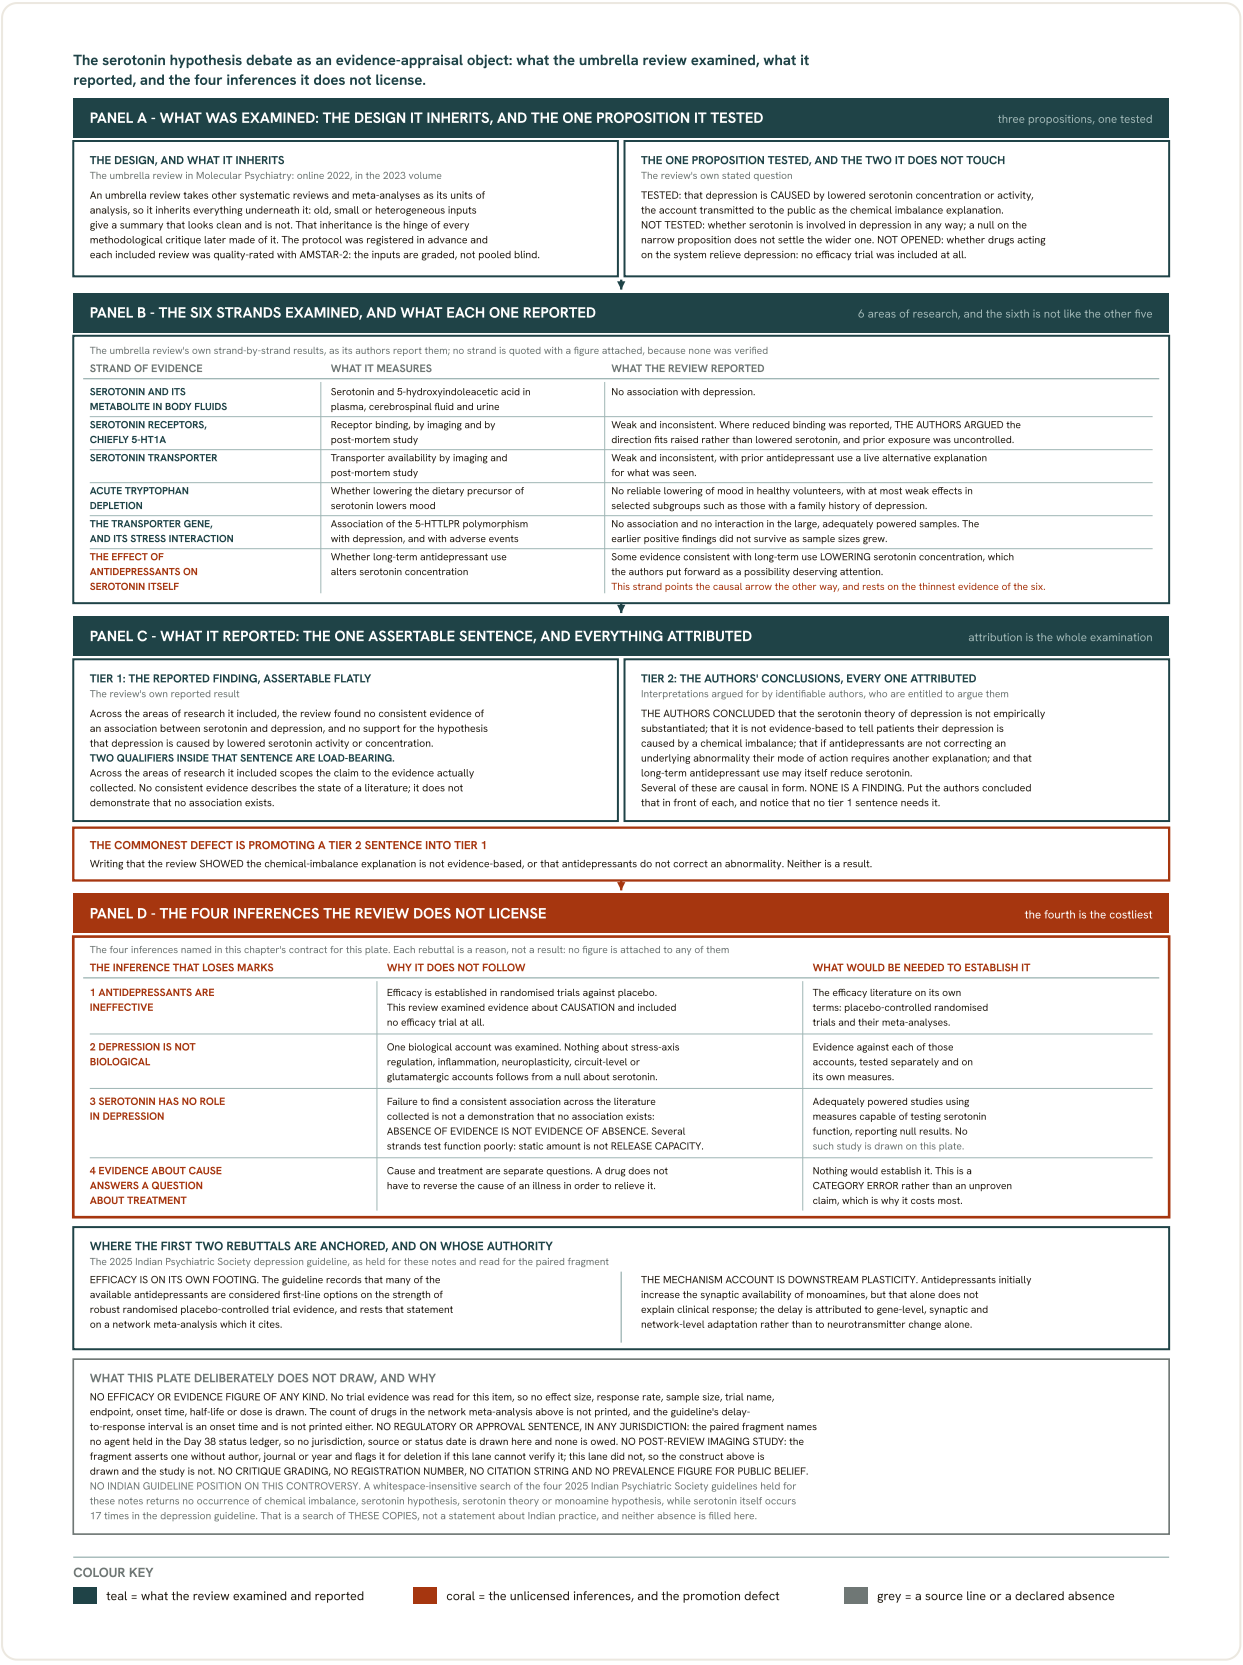

Fig 38.5 The serotonin hypothesis debate: what the umbrella review examined, what it reported, and the four inferences it does not license. One narrow proposition was tested, that depression is caused by lowered serotonin concentration or activity; neither the wider serotonin question nor efficacy was opened, because no efficacy trial was included. Six strands carry a reported finding and no figure, the sixth pointing the causal arrow the other way. What it reported divides into the finding, assertable flatly with both its qualifiers and the authors' conclusions, every one attributed. (The 2022 umbrella review in Molecular Psychiatry; the 2025 Indian Psychiatric Society depression guideline as held for these notes.)

9.1 What an umbrella review is, and why the design carries the whole argument

An **umbrella review** is a systematic review whose units of analysis are other systematic reviews and meta-analyses rather than primary studies. It sits at the top of the hierarchy of evidence and inherits everything underneath it. If the reviews it collects are old, small, heterogeneous or poorly conducted, so is the summary, however clean it looks. That inheritance is the hinge of every methodological criticism later made of this paper.

One housekeeping point before the method. The paper appeared online in 2022 and was carried in the journal's 2023 volume, so both years are correct and a marker who sees the other one has not caught an error.

Three features of the method matter for an answer. The protocol was registered in advance, which matters because a review of a contested hypothesis is exactly the kind whose scope can drift toward the answer its authors expect. The quality of each included review was rated with **AMSTAR-2**, a standard appraisal instrument for systematic reviews, so the paper does grade its own inputs rather than pooling them blind. And where no systematic review existed for a strand, the authors went to large individual studies instead. That decision is defensible, and also a departure from the pure design critics later used against the paper.

The review did not ask whether serotonin is involved in depression in any way. It asked whether the evidence supports a much narrower proposition: that depression is caused by lowered serotonin concentration or activity, the account transmitted to the public as the **chemical imbalance** explanation. Those are different propositions, and almost every error in this topic is a slide between them.

RULE **One narrow proposition was tested, and every sentence written about the review must name which proposition it is about.** "Depression is caused by low serotonin" is not the same claim as "serotonin is involved in depression", which is not the same claim as "drugs acting on the serotonin system relieve depression". The first was tested. The second was not tested and is not settled by a null result on the first. The third belongs to a different literature that this review did not open.

9.2 The six strands, and what each one reported

The evidence was organised into **six** areas of serotonin research, and the organisation is itself examinable: a question asking what the review examined is asking for this list. Reproduce it with a finding attached to each line, never as a bare list.

STRAND OF EVIDENCE	WHAT IT MEASURES	WHAT THE REVIEW REPORTED
Serotonin and its metabolite in body fluids	Concentrations of serotonin and of 5-hydroxyindoleacetic acid in plasma, cerebrospinal fluid and urine, compared between depressed and non-depressed groups	No association with depression
Serotonin receptors, chiefly the 5-HT1A receptor	Receptor binding, by imaging and by post-mortem study	Weak and inconsistent. Where reduced binding was reported, the authors argued the direction fits raised rather than lowered serotonin, and prior antidepressant exposure was not controlled for
Serotonin transporter	Transporter availability by imaging and post-mortem study, and its relation to depression	Weak and inconsistent, with prior antidepressant use a live alternative explanation for what was seen
Acute tryptophan depletion	Whether experimentally lowering the dietary precursor of serotonin lowers mood	No reliable lowering of mood in healthy volunteers, with at most weak effects in selected subgroups such as those with a family history of depression
The serotonin transporter gene, and its interaction with stress	Association of the 5-HTTLPR polymorphism with depression, and the proposed interaction between that polymorphism and adverse life events	No association and no interaction in the large, adequately powered samples; the earlier positive findings did not survive as sample sizes grew
The effect of antidepressants on serotonin itself	Whether long-term antidepressant use alters serotonin concentration	Some evidence consistent with long-term use lowering serotonin concentration, which the authors put forward as a possibility deserving attention

Read the sixth row differently from the first five. The first five ask whether a serotonin abnormality precedes depression; the sixth asks whether treatment produces one, which points the causal arrow the other way, and it is the strand carrying the authors' own hypothesis most visibly. It also rests on the thinnest evidence of the six. An answer that reports it with the same confidence as the genetic strand has flattened the paper into a slogan.

9.3 Three tiers: the finding, the authors' reading, and what neither warrants

Attribution is the whole examination here, so build the answer in three labelled tiers. The first tier is the review's reported finding, and it may be asserted flatly: across the areas of research it included, the review found no consistent evidence of an association between serotonin and depression, and no support for the hypothesis that depression is caused by lowered serotonin activity or concentration. Two qualifiers inside that sentence are load-bearing. "Across the areas

of research it included" scopes the claim to the evidence actually collected. "No consistent evidence" describes the state of a literature; it does not demonstrate that no association exists.

The second tier is what the authors concluded, and every sentence of it carries their name. They held that the serotonin theory of depression is not empirically substantiated; that it is not evidence-based to tell patients their depression is caused by a chemical imbalance; that if antidepressants are not correcting an underlying abnormality then their mode of action requires some other explanation; and that long-term antidepressant use may itself reduce serotonin. These are interpretations, several of them causal in form, argued for by identifiable authors who are entitled to argue for them. They are not findings, and a script that presents them as findings has surrendered the marks this topic exists to award.

The third tier is the set of inferences that neither the findings nor the authors' conclusions warrant. Four recur, and an examiner is watching for them.

TRAP **Promoting a second-tier sentence into the first tier.** The commonest version is writing that the review showed the chemical-imbalance explanation is not evidence-based, or that antidepressants do not correct an abnormality. Neither is a result. The result is that a set of literatures did not consistently support one proposition; the two sentences above are what identifiable authors concluded from it, and they were contested in print within months. The fix costs four words: put "the authors concluded that" in front of every sentence in the second tier, and notice that no sentence in the first tier needs it.

THE INFERENCE THAT LOSES MARKS	WHY IT DOES NOT FOLLOW	WHAT WOULD BE NEEDED TO ESTABLISH IT
Antidepressants are ineffective	Efficacy is established in randomised trials against placebo. This review examined evidence about causation and included no efficacy trial at all	The efficacy literature on its own terms: placebo-controlled randomised trials and their meta-analyses
Depression is not biological	One biological account was examined. Nothing about stress-axis regulation, inflammation, neuroplasticity, circuit-level or glutamatergic accounts follows from a null result about serotonin concentration	Evidence against each of those accounts, tested separately and on its own measures
Serotonin has no role in depression	Failure to find a consistent association across the literature collected is not a demonstration that no association exists, and several strands rested on measures that test serotonin function poorly	Adequately powered studies using measures capable of testing serotonin function, reporting null results
Evidence about causation answers a question about treatment	Cause and treatment are separate questions. A drug does not have to reverse the cause of an illness in order to relieve it	Nothing would establish it. This is a category error rather than an unproven claim, which is why it is the costliest of the four

6	2022	1	4
AREAS OF RESEARCH EXAMINED	YEAR OF PUBLICATION	FINDING ASSERTABLE AS THE REVIEW'S OWN	INFERENCES THAT LOSE MARKS

9.4 Why evidence about cause cannot answer a question about treatment

The mechanism by which an effective drug works is not required to be the reverse of the cause of the illness it treats. Analgesia relieves headache and headache is not caused by a shortage of analgesic. The **corrective model**, in which a drug replaces something the body is missing, describes a small minority of effective treatments rather than the general case, which is why the insulin analogy proves less than it appears to. An aetiological null result and a treatment effect are therefore logically independent, and a paper about the first leaves the second where it found it.

Indian guidance puts efficacy on its own footing, which lets this be answered with a source rather than an argument. The 2025 Indian Psychiatric Society depression guideline records that many of the available antidepressants are considered first-line options on the strength of robust randomised placebo-controlled trial evidence. The guideline rests that statement on a network meta-analysis of **21 antidepressant drugs**, which it cites as having confirmed that all these agents are more effective than placebo. Both rest on trials rather than on any theory of causation, and both would read identically if every strand of the umbrella review had come out the other way.

TRAP **Answering an efficacy question with the umbrella review.** A stem asking whether antidepressants work, or whether this controversy changes prescribing, is testing this boundary, and the review is the wrong instrument. The correct move is to say the question is answered by the efficacy literature, name what that literature consists of, then say in one sentence what the umbrella review does bear on: how the drug is explained to the patient rather than whether it is offered. A candidate who cites a review of aetiological evidence as grounds for a prescribing decision has answered a different question well.

9.5 The critiques, and which of them actually bite

Four objections were published, and are not of equal weight. Grade them rather than listing them.

The first is the straw-man objection: that no well-informed academic psychiatrist held a simple chemical-imbalance theory, so a review dismantling it defeats a position the field had already left. Half of that is true, and the Indian guideline says so in its own voice. Its box on the neurobiological mechanisms of antidepressant action opens by recording that antidepressants initially increase the synaptic availability of monoamines such as serotonin and noradrenaline, but that this alone does not explain clinical response. The other half is where the objection fails: the review's target was not only the academic theory but what patients are told, and that account is widely believed and widely used in consultations. A theory abandoned in the seminar room and still spoken in the clinic is a fair thing to examine.

The second is the tool objection, and technically the strongest. An umbrella review is a good instrument for a question a coherent body of systematic reviews was built to answer, and a poor one for assembling several distinct literatures, each measuring a different construct by different methods, into a single verdict on one hypothesis. Critics argued that the included reviews were

heterogeneous in age, quality and purpose, that the quality gradings were contestable, and that some strands, the depletion literature in particular, were read less favourably than the primary studies allow. A multi-author reply published in the same journal, led by Jauhar with several academic psychiatrists, argued along these lines that the serotonin system is implicated in depression and that this method was not capable of showing otherwise. Note what that reply does not do: it contests the inference and the instrument, and it does not restore a simple low-serotonin account.

The third is the logical one, and the cleanest to write. **Absence of evidence is not evidence of absence.** A literature that is underpowered, cross-sectional, heterogeneous in its measures and collected over decades can fail to detect a real effect. Converting the review's failure to find consistent association into a demonstration that no association exists requires a step the design cannot supply. This objection is sound, and it cuts at the authors' broader conclusions rather than at their reported finding, which is why the three tiers above matter.

The fourth concerns consequences rather than method, and should be named without being overweighted. The review was reported widely and in compressed form, and some coverage carried it as a finding that antidepressants do not work. A paper is not answerable for every headline written about it. What belongs in an answer is the clinical consequence, which arrived as patients asking whether they should stop their medication.

> **PITFALL**
>
> Grading a critique by its volume rather than by what it establishes. The loudest objection here is the straw-man one and it is the weakest: it concedes the review's finding and disputes only its novelty. The quietest is the construct objection in the next section, and it is the strongest: it explains why a null result was likely whichever way the biology turns out.

9.6 What the measures could not test, and what was left standing

The strongest move available is not to pick a side. It is to notice that several strands could not have answered the question well even in principle, which weakens the positive literature and the negative conclusion drawn from it in the same movement. Three construct problems recur, and are worth naming in these words.

Concentration is not function: a metabolite concentration in plasma, urine or cerebrospinal fluid is a distant and heavily confounded proxy for serotonin transmission at a synapse in a specific circuit, so a null on the proxy is weak evidence about the thing. Static is not dynamic: the amount of a transmitter present at rest is a different quantity from **release capacity**, the amount a system can release when it is driven, and imaging methods able to probe release with a pharmacological challenge came into use largely after most of the reviewed literature was collected. A positron emission tomography study using an amphetamine challenge, published after the umbrella review, reported reduced serotonin release in a depressed group. It is one small study, it settles nothing, and it is quoted here only to make the structural point: a null covers the measures a literature had, not the measures that came after it. And group is not individual: a

mean difference absent across a diagnostic category assembled from symptoms does not exclude a serotonergic mechanism operating in some subgroup inside it.

Two things the debate never touched should be stated positively; leaving them out makes a script sound as though it has read only the headline. Selective serotonin reuptake inhibitors act on the serotonin system: that is pharmacology, it is not disputed by anyone in this argument, and it is not an aetiological claim. And the neurobiology of depression is broader than any monoamine, with stress-axis, inflammatory, neuroplastic, circuit-level and glutamatergic accounts all under investigation. The Indian guideline's own account is a downstream plasticity account. It puts the typical delay in clinical response at **2 to 4 weeks** and attributes that delay to the time required for gene-level, synaptic and network-level adaptation, stating that antidepressants act by gradually modulating neural circuits rather than by producing immediate relief through neurotransmitter changes alone.

GOOD TO REMEMBER

The most useful thing this controversy leaves behind is not a verdict about serotonin. It is a habit: before repeating any mechanistic explanation of a treatment, ask what would have to be true for it to be right, and whether anyone has checked. That habit transfers to every other explanation offered in a consultation.

9.7 What changes in the consulting room

Nothing about who is offered treatment changes, and everything about how it is explained does. The chemical-imbalance sentence is short, destigmatising and easy to deliver in a crowded outpatient clinic with the family present, which is why it became the default script. It is also a causal claim that the evidence does not support as stated, and it is fragile: a patient who was given it, and who later meets a headline reporting that serotonin was never the problem, has been handed a reason to stop.

The replacement is not "we do not know". Three sentences are defensible and cover what a patient is actually asking. This medicine acts on the serotonin system, which is a statement about the drug rather than about the illness. Why that produces improvement is not fully established, and the current account is about gradual adaptation in brain circuits rather than the topping up of a missing chemical. And the reason to expect benefit is that the medicine has been compared against placebo in randomised trials, which is a different kind of evidence from any theory of cause. Add the expected time to effect and the common adverse effects, and it still fits inside a consultation.

IN INDIA

The 2025 Indian Psychiatric Society depression guideline directs that before prescribing, clinicians provide psychoeducation covering expected benefits, possible risks, anticipated time to effect, and the addressing of myths or misconceptions about antidepressant use, and in its section on suicidal behaviour it directs that the patient and, with their consent, family members be educated about the bio-psycho-social model. Neither instruction endorses a chemical-imbalance script and the second is explicitly broader than any neurochemical account. Note also what is not there. A whitespace-insensitive text search of the four 2025 Indian Psychiatric Society guidelines held for these notes returns no occurrence of "chemical imbalance", "serotonin hypothesis", "serotonin theory" or "monoamine hypothesis" in any of them, while "serotonin" itself occurs 17 times in the depression guideline alone. That is a search of these copies rather than a statement about Indian practice: no Indian guideline position on this controversy, and no Indian survey of what patients are told about the mechanism, is held by this account, and neither should be invented in an answer.

9.8 Answering the question, whatever form it takes

Reduced to five moves, the topic answers as an essay, a short note or a viva.

- Name the design and its inheritance: an umbrella review of systematic reviews, quality-rated, its reach limited by what it collected.
- Give the six strands with a finding attached to each, and mark the sixth as pointing the other way.
- State the reported finding flatly, then attribute every broader conclusion to the authors by name.
- Grade the critiques instead of listing them, and say which would survive a result in the opposite direction.
- Close on the boundary: this is evidence about cause, the efficacy question is answered elsewhere, and what changes is the explanation given to the patient.

MNEMONIC

Design, Data, Authors, Critics, Boundary

Five steps in one direction, and the order is the argument. Design constrains what the data can show; the data are separable from what the authors made of them; the critics attack the middle three and not the first tier; and the boundary is where the marks are, because it is the step everybody skips.

The review reported that a literature does not support a claim; everything stronger than that belongs to somebody, and an answer that says whose is the answer that scores.

10 · Psychedelic-assisted therapy (psilocybin, MDMA) and regulatory status

The examinable object here is not a molecule, it is a package: psilocybin-assisted therapy and MDMA-assisted therapy. Both are a drug given inside a structured psychological intervention with four components. Half the marks sit on reading the evidence honestly: expectancy, functional unblinding, therapist effects, and who was screened out. The other half sit on regulatory status, where several arrangements that read like approval are not one, and only a marketing authorisation licenses a prescription. The pharmacology of these substances as agents of intoxication and misuse belongs to the Substance use disorders notes; this item covers the therapeutic trial and the regulatory status of both agents in three named jurisdictions.

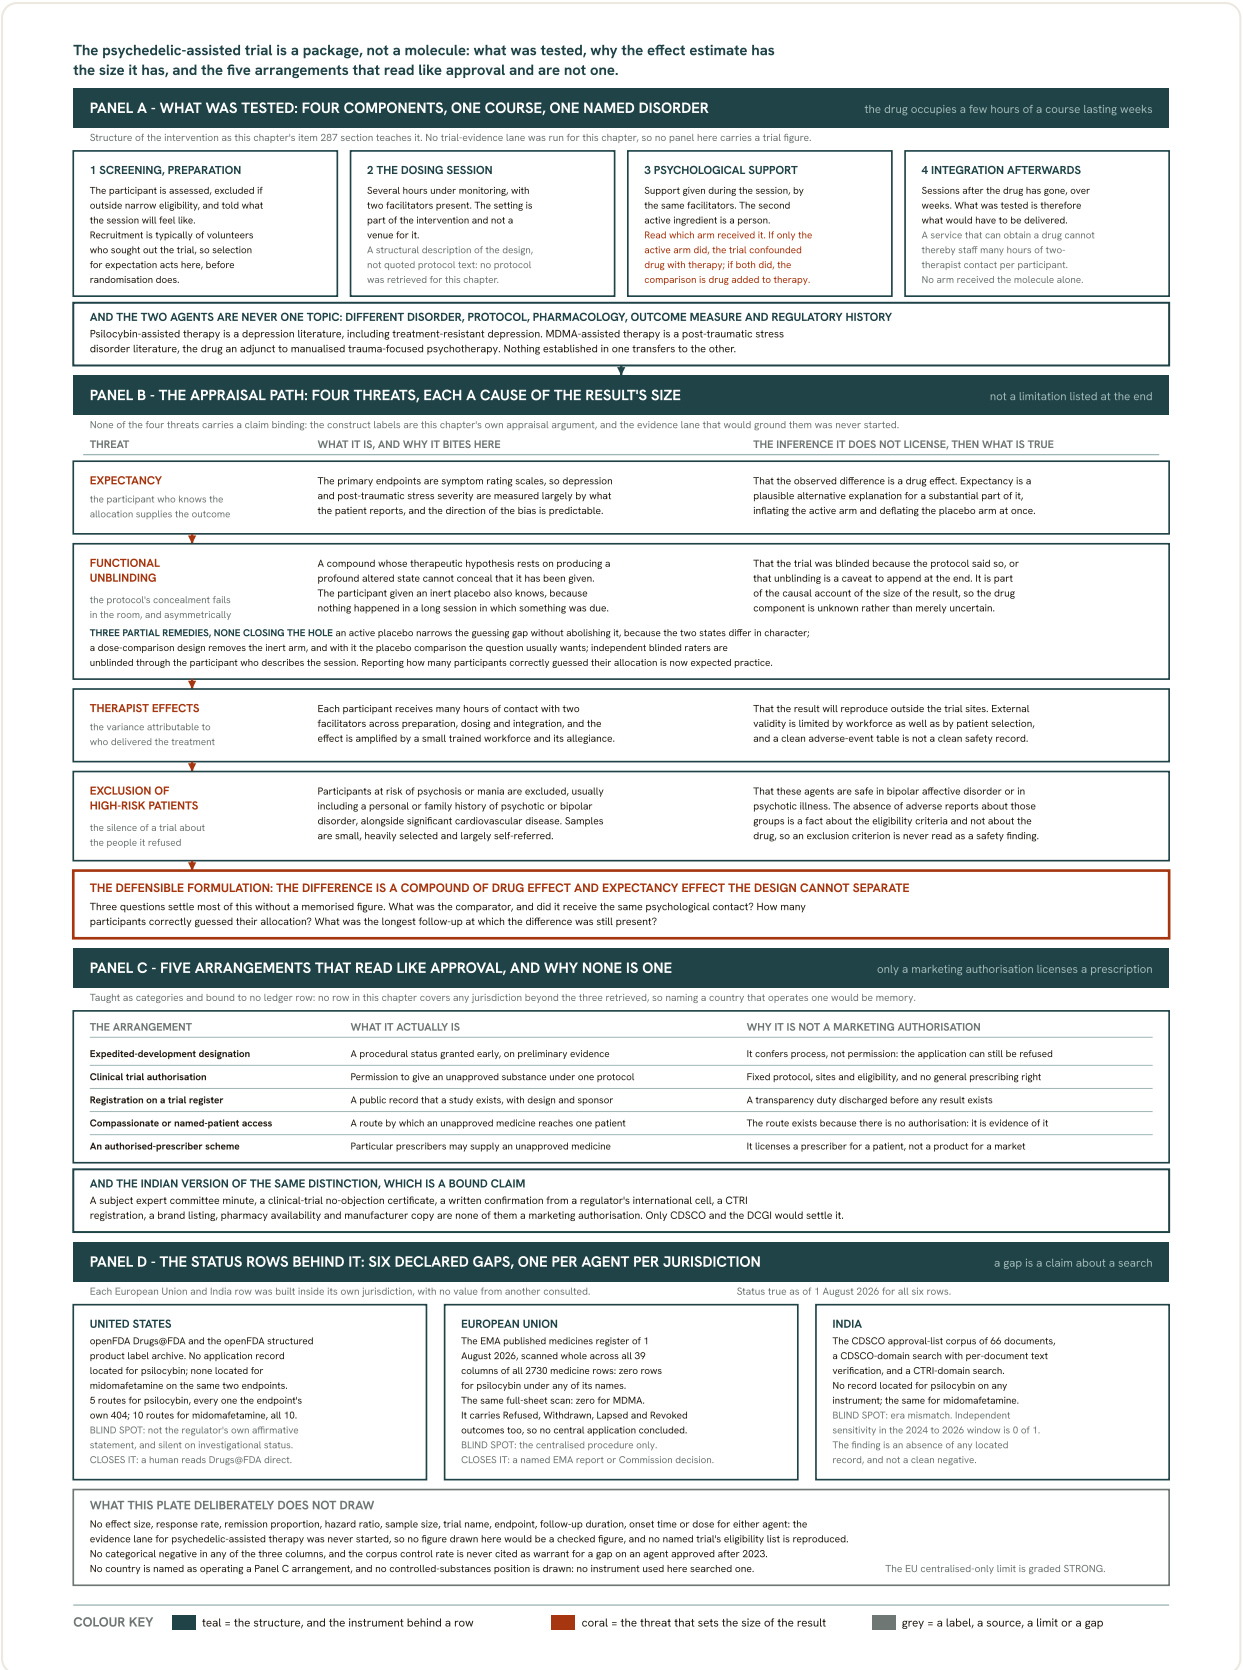

Fig 38.6 Appraising a psychedelic-assisted trial: the package tested, the four threats that set the result's size, and the arrangements that are not a marketing authorisation. The unit of evidence is the package, never the molecule. The four threats are causes of the effect estimate, not caveats after it, so an exclusion criterion is never a safety finding. No effect size, sample size, trial name or follow-up figure is drawn: that lane was never started. Six declared gaps, each naming its instrument: openFDA Drugs@FDA and the label archive, the EMA register scanned whole, and the CDSCO approval-list corpus with CDSCO-domain and CTRI-domain searches, true as of 1 August 2026. (Day 38 status ledger, psilocybin and midomafetamine; the appraisal structure is this chapter's own.)

10.1 What is actually being tested, and why the answer is never "the drug"

Almost every error here is an error of abbreviation. The **intervention package** has four components: screening and preparation, in which the participant is assessed, excluded if outside narrow eligibility, and told what the session will feel like; the dosing session, several hours with monitoring and two facilitators; the psychological support given during it; and integration afterwards. The drug occupies a few hours of a course lasting weeks.

Two consequences follow. The first is attributional: no arm received the molecule alone, so the result cannot be attributed to it, and the intervention's name is psilocybin-assisted therapy, not psilocybin. The second is transfer: what was tested is what would have to be delivered, and a service that can obtain a drug cannot thereby staff many hours of two-therapist contact per participant.

The two agents should never be taught as one topic. The psilocybin literature is a depression literature, including treatment-resistant depression. The MDMA literature is a post-traumatic stress disorder literature, the drug an adjunct to manualised trauma-focused psychotherapy. Different disorder, protocol, pharmacology, outcome measure and regulatory history. Nothing established in one transfers to the other, and a stem that mixes them is testing exactly that.

RULE **Name the package, not the molecule, and never merge the two agents.** The unit of evidence is drug plus preparation plus supported session plus integration, in one named disorder, against one named comparator, over one stated follow-up period. Any sentence that drops a component, or carries a psilocybin depression finding to MDMA in post-traumatic stress disorder, has changed the thing being claimed.

10.2 Two mechanisms, and the reason the trial cannot be blinded

Psilocybin is a prodrug, dephosphorylated to psilocin, an agonist at the **5-HT2A** receptor; the acute state is a marked alteration of perception, affect and self-experience lasting several hours. MDMA is a substituted amphetamine acting principally as a monoamine releaser, with prominent serotonin release, producing emotional openness, reduced defensiveness and sympathomimetic arousal. Its rationale is not that it treats the disorder but that it makes trauma-focused psychotherapy tolerable for people who cannot otherwise engage with the memory.

Read those descriptions as design constraints. A compound whose therapeutic hypothesis rests on producing a profound altered state cannot conceal from the participant that it has been given, so the trial is blinded on paper and unblinded in the room, and every downstream problem descends from it.

These are not agents given daily to steady state. The exposure is one or two supervised sessions, and the benefit is claimed to outlast the drug by weeks or months. That puts a heavy burden on follow-up duration: a result at four weeks says nothing about six months.

10.3 Expectancy and functional unblinding, and what they do to a subjective endpoint

Blinding is not a formality here; it is the load-bearing wall, and it is cracked. **Functional unblinding** means the allocation concealment specified in the protocol fails in practice because the treatment announces itself. It fails almost completely, and asymmetrically: the participant

given an inert placebo also knows, because nothing happened during a long session in which something was expected.

The primary endpoints are symptom rating scales: depression and post-traumatic stress severity are measured largely by what the patient reports. So the participant who knows their allocation also supplies the outcome measurement. **Expectancy** is not a small additive nuisance there; it is a plausible alternative explanation for a substantial part of the observed difference, and its direction is predictable, inflating the active arm and deflating the placebo arm at once.

Three partial remedies exist and none closes the hole. An **active placebo**, producing noticeable but non-psychedelic effects, narrows the guessing gap without abolishing it, because the character of the two states differs. A dose-comparison design, every arm receiving the drug at a different dose, removes the inert arm and the sharpest expectancy contrast, but also the placebo comparison the question usually wants. Independent blinded raters improve on self-report, but a rater interviewing a participant describing their session is unblinded through the participant. Reporting how many participants correctly guessed allocation is now expected practice.

TRAP **Treating unblinding as a limitation to be listed at the end.** It is not a caveat appended to the result; it is part of the causal account of the result's size. The defensible formulation: the between-group difference is a compound of drug effect and expectancy effect the design cannot separate, so the size of the drug component is unknown rather than merely uncertain.

10.4 The therapist is inside the intervention, not outside it

The second active ingredient is a person: each participant receives many hours of contact with two facilitators across preparation, dosing and integration, emotionally charged throughout. **Therapist effects**, the variance in outcome attributable to who delivered the treatment rather than what was delivered, are well recognised in psychotherapy research and amplified here by the small number of trained facilitators, their allegiance to the model, and the intensity of the dyad during an altered state.

Three examinable consequences follow. First, attribution again: if only the active arm receives many hours of skilled psychological contact the trial has confounded drug with therapy; if the placebo arm receives the same contact the comparison is drug added to therapy, not therapy itself. Read which the trial did. Second, replication: delivery depending heavily on individual facilitators is hard to reproduce outside the trial sites, so external validity is limited by workforce as well as patient selection. Third, adverse-event ascertainment: silence collected by an instrument that cannot see a harm is not evidence that the harm did not occur.

PITFALL

Reading a clean adverse-event table as a clean safety record. The suggestibility and dependence on the dyad the model relies on therapeutically are the same features that create the risk of boundary violation, so mechanism and characteristic harm share a root. A safety discussion that lists nausea, headache, transient blood pressure rise and anxiety has described the physiology and omitted the setting.

10.5 Who was enrolled, who was screened out, and what the result therefore covers

Samples here are small and heavily selected. Recruitment is typically of volunteers who sought out the trial, which selects for expectation before randomisation acts. Screening is intensive. And, as a standing feature of the field, participants at risk of psychosis or mania are excluded, usually including a personal or family history of psychotic or bipolar disorder, alongside significant cardiovascular disease.

These trials are silent about the people they excluded. There is therefore no evidence from this literature that psychedelic-assisted therapy is safe in bipolar affective disorder or in psychotic illness, and the absence of adverse reports about those groups is a fact about the eligibility criteria, not about the drug. A candidate who writes that these agents "appear safe, with no cases of induced psychosis reported" has read an exclusion criterion as a safety finding. The same logic bounds every claim: the result describes the population enrolled, the protocol used, the comparator used and the follow-up point reported, and nothing else.

This account prints no effect size, response rate or remission proportion for either agent, and the omission is deliberate. The trial-evidence retrieval for this chapter was not completed, so no figure here would be a checked figure, and a remembered number in this field is characteristically right about the wrong thing: right for a different trial, comparator, endpoint or week. Attach a number only from the paper in front of you, with its population, comparator and time point.

GOOD TO REMEMBER

Three questions settle most viva exchanges here, none needing a memorised figure. What was the comparator, and did it receive the same psychological contact? How many participants correctly guessed their allocation? What was the longest follow-up at which the difference was still present?

10.6 The status ledger for psilocybin and MDMA, jurisdiction by jurisdiction

Regulatory status is recorded on four fields, and a status sentence exists only where a named regulator's record was retrieved: **jurisdiction**, the **exact indication**, the **authoritative source**, and the date the status was true. For both agents, in all three jurisdictions examined, the retrieval found no record. That is six declared gaps, and the correct sentence is not "these agents are not approved" but what was searched, on whose authority a claim would rest, and when.

AGENT AND JURISDICTION	WHAT WAS SEARCHED	WHAT WAS FOUND	STATUS TRUE AS OF
Psilocybin, United States	openFDA Drugs@FDA and the openFDA structured product label archive, 5 query routes, each positive-controlled in the same run	No application record for generic name psilocybin; every route returned the endpoint's own HTTP 404, zero transport failures	1 August 2026
Midomafetamine (MDMA), United States	The same two openFDA endpoints, **10 query routes**, probing midomafetamine, midomafetamine hydrochloride, the full chemical name and the brand-name field	No application record for generic name midomafetamine; all 10 returned HTTP 404, zero transport failures	1 August 2026
Psilocybin, European Union	The EMA published medicines register generated 1 August 2026, scanned whole across all 39 columns of all 2730 medicine rows	Zero rows under any of its names; the register carries Authorised, Refused, Application withdrawn, Withdrawn, Lapsed, Expired, Revoked, Suspended and Opinion outcomes, so this is not merely "not authorised"	1 August 2026
Midomafetamine (MDMA), European Union	The same full-sheet scan of the same register	Zero rows under any of its names; no EU centralised procedure of any kind is on record for this active substance	1 August 2026
Psilocybin, India	The CDSCO published approval-list corpus of 66 documents, a CDSCO-domain search with per-document text verification, and a CTRI-domain search with a positive control	Absent from all 66 lists; the CDSCO-domain search returned zero results at exit status 0, a genuine empty result set rather than a failed query; no indexed CTRI trial record	1 August 2026
Midomafetamine (MDMA), India	The same three Indian instruments	The same finding as psilocybin: no CDSCO record of any kind located on any instrument, and no indexed CTRI trial record	1 August 2026

Two features of that table matter. First, each row was built inside one jurisdiction only: absence in the European Union column was established from EMA sources alone and absence in the India column from Indian sources alone, with no value from another jurisdiction consulted, because a

row may be authored only in the jurisdiction it was grounded in, a declared gap is authorable as a declared gap, and an inferred figure is not authorable at all. Second, the instruments were proved working before their silence was believed: four of four hosts round-tripped a known-present record before any miss was read as a fact, with certificate verification never disabled. An earlier run reported nothing anywhere for any agent; the cause was a broken certificate store, not a fact about a drug.

2730	66	10	0
EU REGISTER ROWS SCANNED	CDSCO APPROVAL DOCUMENTS READ	OPENFDA ROUTES, MIDOMAFETAMINE	RECORDS LOCATED, ALL JURISDICTIONS

Each instrument has a measured blind spot. The American search covers openFDA Drugs@FDA and the label archive only; it is not the regulator's own affirmative statement that no application exists, and it is silent on investigational and breakthrough designations, which appear in neither instrument. That silence is the trap: the same null comes back whatever stage a programme has reached, so it is no evidence that nothing is under way. What either instrument indexes, and what it leaves out, is a property of the instrument, and this chapter did not search it: what was measured is the scope sentence above and nothing wider. A claim about the coverage of either endpoint would rest on the regulator's own description of it, retrieved and dated, and none was retrieved here. Closing the row: a human must read Drugs@FDA directly and, if there is no application, say so on the regulator's authority rather than on this probe's silence.

The European search covers the centralised procedure. A medicine authorised nationally through the decentralised or mutual-recognition route would not appear in the register at all, so absence here means no EU centralised procedure of any kind on record, which is narrower and weaker than "not available anywhere in the European Union". That limit was graded: STRONG for both, because for a small molecule outside the mandatory centralised scope a national authorisation is genuinely possible and wholly unmeasured here. A second weakness: the confirming second instrument was applied to 8 of 8 grounded rows and 0 of 8 gap rows, so it fired only where the first instrument had already found something, and no European gap in this chapter has independent corroboration. A claim here would have to rest on an EMA European public assessment report or a European Commission implementing decision, named as such; the phrase "approved internationally" may never be substituted for a named regulator.

The Indian instrument is the weakest of the three, and its weakness is measured, which is why the India cells are gaps and not negatives. Of 20 drugs taken as approved and marketed in India, 17 appear in the corpus and 3 do not: agomelatine, molnupiravir and trospium. More decisive is the era mismatch. Every one of the 17 present controls appears in a document dated 2023 or earlier, independent sensitivity in the 2024 to 2026 window is 0 of 1, and no sentence may cite the 17 of 20 figure as warrant for a gap on any agent approved after 2023. The corpus also contradicts itself: CDSCO's own subject expert committee minutes of 16 April 2025 state that another agent in this chapter, whose status row is another item's, was already approved in the country, yet that agent appears in none of the 66 lists. Hence the corrected wording on both India rows: "clean negative" overstates what an instrument with a measured 15 per cent miss rate, blind to three of

its own positive controls, can deliver, and the finding is an absence of any located record rather than a clean negative.

TRAP **Writing "psilocybin is not approved in India".** That claims knowledge of the regulator's whole record, and this instrument cannot support it. What it supports is narrower and checkable: no CDSCO approval record for psilocybin was located in the 66 published approval lists, in a CDSCO-domain search that returned a genuine empty result set, or in a CTRI-domain search, as of 1 August 2026. The general form: name the register, name the date, name what would close the row, and let the absence be an absence.

The falsification pass that tested this chapter's status rows against their primary documents scored all six not applicable, on the stated ground that a declared gap carries no indication text, so an instrument that compares text against a primary document has nothing to test: a gap is not a claim about a product, it is a claim about a search. They have been checked for what they say about the search, never independently confirmed as absences.

10.7 Five things that are not a marketing approval

Each of the five below is routinely written up, in press and review articles, in language indistinguishable from approval. A marketing authorisation is a decision by a named regulator that a specific product may be placed on the market for a stated indication.

MECHANISM	WHAT IT ACTUALLY IS	WHY IT IS NOT APPROVAL
Expedited-development designation	A procedural status granted early, giving a sponsor closer regulatory interaction and faster review of a programme for a serious condition	Granted on preliminary evidence, it confers process, not permission: the application can still be refused or withdrawn, with no product reaching the market
Clinical trial authorisation or permission	Permission to give an unapproved substance to defined participants under a defined protocol at defined sites	It authorises research, and its conditions are the opposite of a marketing licence: fixed protocol, sites and eligibility, no general prescribing right
Registration on a trial register	A public record that a study exists, with its design, sponsor and eligibility criteria	A transparency requirement discharged before results exist. It says a study was declared, not that it worked or that anything was licensed
Controlled, compassionate or named-patient access	A route by which an unapproved medicine reaches a specific patient with no alternative, usually with individual authorisation and reporting conditions	The route exists precisely because there is no marketing authorisation. It is evidence of the absence it works around
An authorised-prescriber or special-access scheme	An arrangement permitting particular approved prescribers to supply an unapproved medicine to particular patients	It licenses a prescriber for a patient, not a product for a market. The product remains unapproved, and the scheme's paperwork usually says so

Two distinctions belong beside it. First, controlled-substances law, on which this chapter searched nothing. Every instrument behind these notes is a drug-approval or drug-trial instrument, and not one is a statute, a scheduling notice or a controlled-substances register, so nothing retrieved here establishes what any schedule permits or forbids, what altering one would do, or how a schedule stands beside a marketing authorisation in any jurisdiction. A claim about any of that would rest on the statute itself and on the body that administers it, named, quoted and dated. Until one is read, treat the schedule and the licence as two questions put to two records, and answer only the one these notes hold a record for. Second, chapter hygiene: a subject expert committee minute, a clinical-trial no-objection certificate, a written confirmation from a regulator's international cell, a CTRI registration, a brand listing, pharmacy availability and manufacturer copy are none of them a marketing authorisation, and the only bodies whose record would settle the Indian question are CDSCO and the Drugs Controller General of India.

This section names no country as operating any of the five mechanisms, deliberately: no ledger row covers any jurisdiction beyond the three retrieved, so attaching a named scheme to a named country would be writing from memory.

IN INDIA

The position to hold, and it is narrow. As of **1 August 2026**, no CDSCO or DCGI approval record for psilocybin was located in the 66 published approval lists, in a CDSCO-domain search, or in CTRI, and the finding for MDMA is identical. Say that rather than "not approved", and say what would change it: an affirmative CDSCO or DCGI new-drug permission, a current CDSCO-approved label, or an entry in an official approval list. A CTRI registration, if one appears, establishes that a study exists and does not close the approval question. No instrument used for this chapter looked at the controlled-substances position for either agent in India, so nothing here establishes what that position is or what it requires, and the schedule number stays out of your answer until the statute and the body that administers it have been read. And when a patient or family arrives having read about these treatments abroad, name the gap rather than filling it: no located Indian marketing authorisation for either agent, a multi-session therapy package rather than a prescription, and trials that excluded several groups who reach Indian outpatient departments in large numbers.

10.8 What a complete answer contains

Four moves answer this item, in any form.

- Define the intervention as a package, name its four components, and attribute the result to the package, not to the molecule.
- Give functional unblinding and expectancy as the reason the effect estimate has the size it has, not as a limitation appended afterwards, and say what a design can and cannot do.
- Bound the evidence by the population enrolled: small, selected, self-referred, screened to exclude those at risk of psychosis or mania, so no safety claim is available for bipolar or psychotic illness.

- State regulatory status on the four fields, register named, date attached, gap declared, and separate approval from designation, trial permission, registration, access arrangement and prescriber scheme.

MNEMONIC

Jurisdiction, Indication, Source, Date

The four fields of a status sentence, in writing order. A claim missing any one is not weaker, it is different: without jurisdiction a claim about the world, without indication a claim about a molecule, without a source a claim about the writer's memory, without a date a claim about now, forever.

RULE **Absence anywhere in this section is a statement about a search, never proof of absence.** A queried register's null is evidence and worth stating; it is not proof, and the difference has been demonstrated here. One agent in these notes, brexanolone, was recorded as having no United States record until multi-route probing retrieved application NDA211371, ZULRESSO, approved 17 June 2019 and now of Discontinued marketing status: the record carries no openfda block at all, so three of five query routes returned NOT_FOUND while a fourth returned it. Strengthen a null by widening the routes, not by repeating one: an independent recheck of the psilocybin row on a separate run repeated the probe across 9 routes, including free-text and wildcard searches on both endpoints, returned zero on every one, and had its own positive controls return hits in the same run.

The package is what was tested, unblinding is why the number is uncertain, exclusion is what the number does not cover, and a designation, a trial permission and an access scheme are not a licence.

11 · Artificial intelligence and machine learning in psychiatry

A model does not diagnose anybody; it returns a number, and the whole of this topic is what that number is allowed to mean. The marks sit not on architectures but on four questions asked of any reported figure: what was the model predicting, in whom, against what, and had the data ever been seen before. Candidates lose them in three predictable places: an accuracy figure quoted without its population, a good discrimination statistic read as a good decision, and a performance claim treated as a regulatory permission. The statistics themselves, sensitivity, specificity, predictive values and the appraisal of a diagnostic accuracy study, belong to the research methodology and biostatistics notes; what follows is only what changes when the index test is a fitted model rather than an assay.

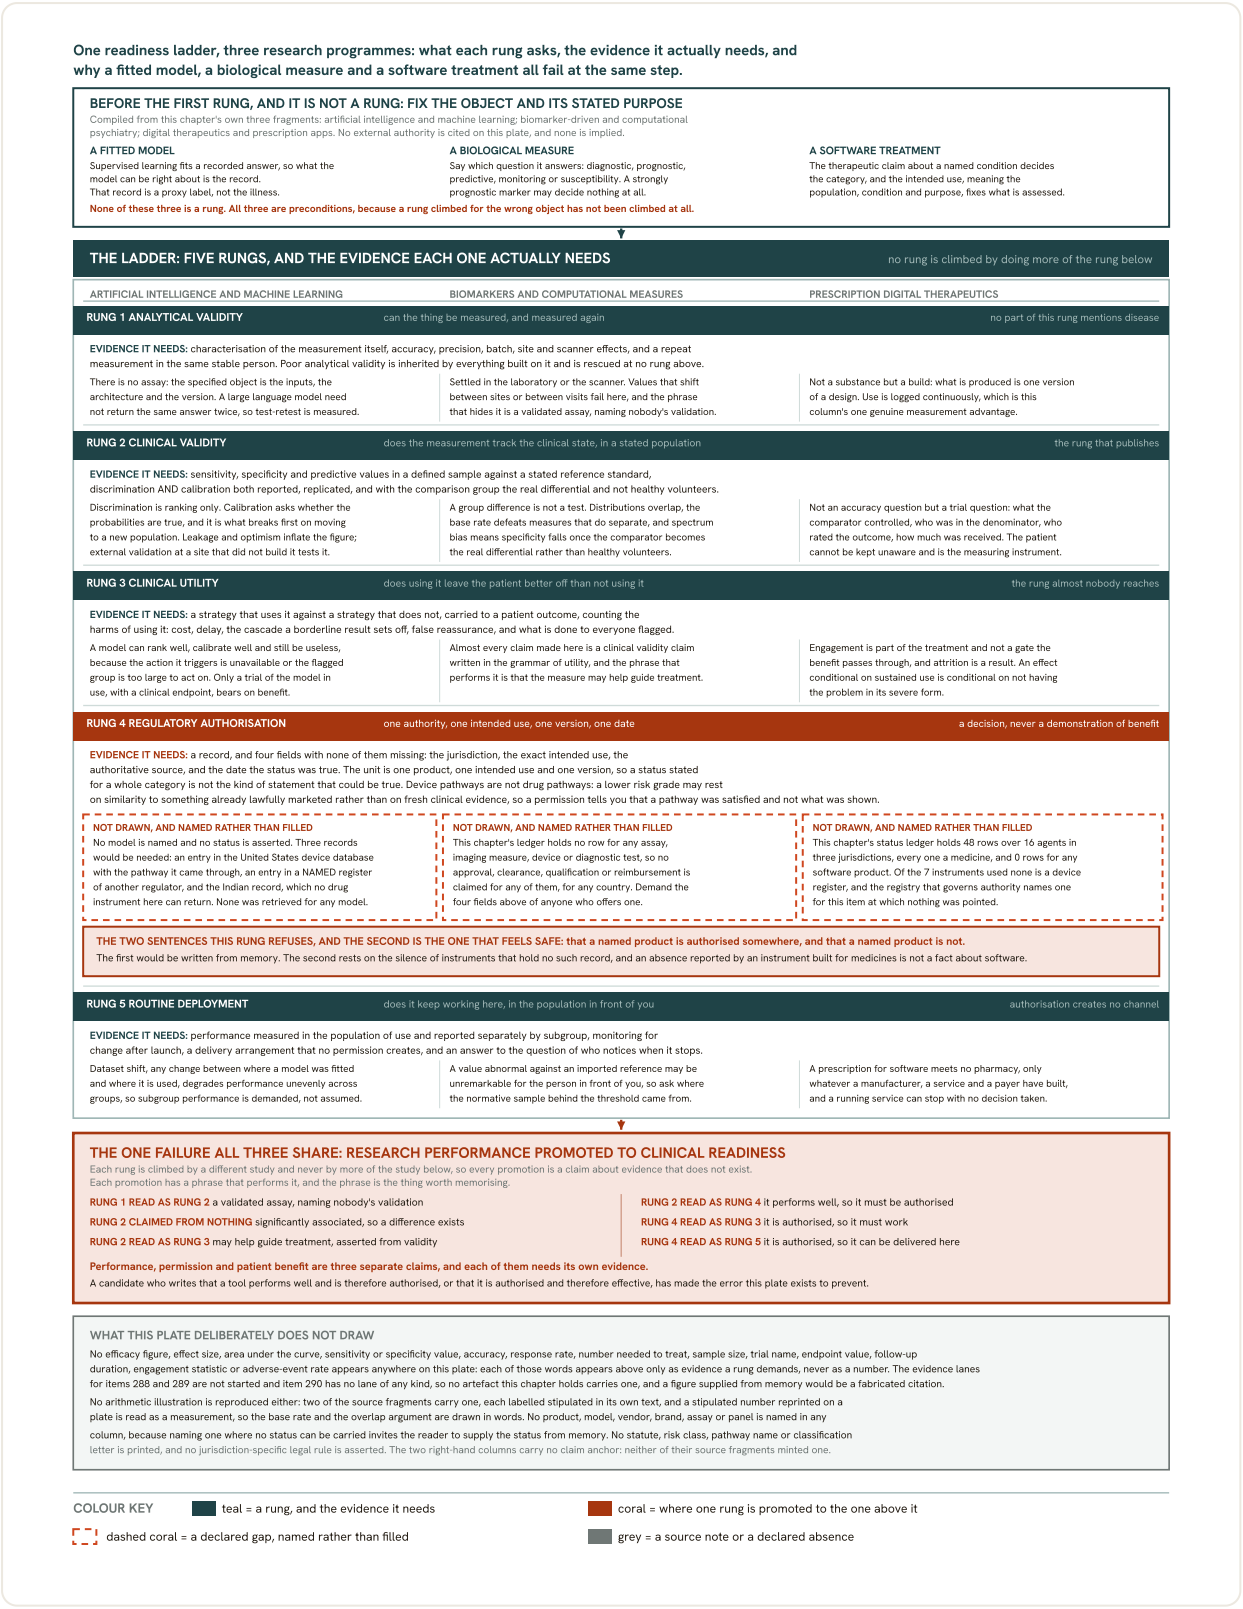

Fig 38.7 One readiness ladder for artificial intelligence, biomarkers and prescription digital therapeutics: analytical validity, clinical validity, clinical utility, regulatory authorisation, routine deployment. Above the first rung the object and its purpose are fixed: supervised learning fits a recorded answer, and that record is a proxy label rather than the illness. Each rung is climbed by a different study, never by more of the study below, so discrimination and calibration settle rung 2 and neither touches rung 3, and external validation at a site that did not build the model answers what leakage and optimism flatter. Rung 4 is drawn EMPTY and named rather than filled: no product is named and no status asserted. Rung 5 is where dataset shift bites. Source: this chapter's own three fragments, items 288, 289 and 290; the evidence lanes for 288 and 289 read as not started and item 290 has no lane at all.

11.1 What the machine is actually predicting

Almost every clinical model here is **supervised learning**: the algorithm is shown examples in which the answer is already recorded, and fits a function from the inputs to that recorded answer. Everything it can ever be right about is therefore the record, not the illness, the first thing to establish about any reported result and the one most often skipped.

The recorded answer is a **proxy label**. In psychiatry the proxies available at scale are administrative or documentary: a diagnostic code entered at discharge, a prescription of a particular class, a rating-scale score above a cut-point, a chart entry flagging risk, a readmission within a stated window. None of these is the construct: a code records what a clinician wrote down in a system that pays for codes. A model trained on codes learns coding practice, which varies by clinician, by unit and by country, and reproduces it faithfully.

The construct validity of the label is a ceiling on everything downstream: no split, no architecture and no sample size repairs a target that does not mean what the paper says it means. And the label determines what the number transfers to, so a model that predicts a recorded diagnosis of depression predicts documentation, and a claim that it predicts depression has quietly changed the target between the methods section and the abstract.

11.2 The six things a performance number carries, or it is not a finding

A performance figure with nothing attached is uninterpretable, not merely imprecise. Six items travel with it, each naming a distinct way a good-looking number goes wrong.

WHAT MUST BE STATED	WHY IT IS NOT OPTIONAL	WHAT A MISSING ENTRY HIDES
The model	Inputs, architecture and version define the thing being reported	A retrained or updated model is a different model with a different number
The target	The exact label, how it was defined and by whom	The proxy problem above, and a target that drifts between sections
The population and setting	Who was included, recruited how, where and when	Case mix and prevalence, which move predictive values without moving the model
The split method	How the evaluated data were separated from the fitted data	Leakage and optimism, the commonest cause of an inflated figure
The comparator	What the model is being judged against	A model beating nothing, or beating a deliberately weakened baseline
External validation status	Whether the number comes from data the model never saw, from a site that did not build it	The single largest source of the gap between published and delivered performance

The comparator row is the one candidates forget and an examiner can mark hardest. A model that predicts an outcome better than chance has been compared with nothing. The comparisons that matter are the ones a service would otherwise use: the existing clinical judgement, an established

structured instrument, or a simple regression on a handful of routinely available variables. That last comparator is unglamorous and frequently wins, which is why a paper omitting it has omitted the informative arm.

RULE **A performance figure belongs to one model, one target, one population, one split, one comparator and one validation status, and it does not travel without all six.** Move any one of them and the number is no longer about the same thing. This is the whole discipline of the topic, and why a sentence of the form "artificial intelligence can detect depression with high accuracy" is not a weak claim but an empty one: it names none of the six.

11.3 Discrimination is not calibration, and neither one is usefulness

Discrimination is the model's ability to rank: given one person who has the outcome and one who does not, how often does it give the first the higher score. That is what the area under the receiver operating characteristic curve measures, and its floor is worth fixing in memory: a model at **0.5** ranks no better than a coin. Discrimination is a property of ordering only, and says nothing about whether the predicted probabilities are true.

Calibration is that second question: among the people the model gave a twenty percent probability, did about twenty percent have the outcome. A model can rank well and be badly calibrated, systematically over-predicting risk in everybody. The distinction has a direct clinical consequence: a threshold is set on the probability, not on the ranking, so a poorly calibrated model puts the operating threshold in the wrong place even when its ranking statistic looks strong. Calibration is also the property most damaged by moving a model to a new population, and the least often reported.

Neither statistic answers the question a service actually has: whether acting on the output leaves patients better off than not acting. That is a question about consequences at a chosen threshold: what is done to the people flagged, what it costs, and what is missed in the people not flagged. Decision-analytic measures of net benefit address it, and no ranking statistic substitutes. A model can discriminate well, calibrate well and still be useless, because the action it triggers is unavailable, or the group flagged is too large to act on.

11.4 The base rate, and why an accurate model flags mostly false alarms

This is the most productive arithmetic in the topic, and where risk-prediction claims in psychiatry come apart. Sensitivity and specificity are properties of the model. Predictive values are not: they depend on how common the outcome is in the people the model is applied to, and psychiatry's most-wanted outcomes are rare. What follows is a worked example with numbers chosen for arithmetic, not measured in any study, and worth reproducing in an answer as a worked example.

Take an outcome occurring in **1 in 100** of those screened, and a model with **80 percent** sensitivity and 80 percent specificity, which would be a respectable psychiatric model. In 10,000 people, 100 have the outcome and the model finds 80 of them. Of the 9,900 who do not, it wrongly flags 1,980. So 2,060 people are flagged, 80 of them with the outcome.

1%	80%	3.9%	99.7%
ASSUMED BASE RATE, NOT MEASURED	ASSUMED SENSITIVITY AND SPECIFICITY	RESULTING POSITIVE PREDICTIVE VALUE	RESULTING NEGATIVE PREDICTIVE VALUE

Read both ends of that strip. About 26 people are flagged for every one who has the outcome, so whatever the flag triggers is delivered, and paid for, overwhelmingly in people who will not have the event. Meanwhile the negative predictive value looks magnificent and is uninformative: with an outcome this rare, predicting no event in everybody already achieves 99 percent, so the model must be judged against that baseline and not against zero. Both figures move whenever the model is applied to a population with a different base rate, which is why a screening claim from a specialist inpatient sample does not survive the move to a general clinic.

PITFALL

Quoting accuracy as the headline figure when the outcome is rare. Accuracy is the proportion of all predictions that were correct: with an outcome occurring in one percent of people, a model predicting no event for everybody is 99 percent accurate and clinically worthless. An answer repeating an accuracy figure on an imbalanced outcome without noticing the imbalance has walked into the oldest trap in the field.

11.5 How the number gets inflated: leakage, optimism and the wrong split

Published performance is usually higher than delivered performance, and the reasons are structural rather than dishonest. **Data leakage** is information about the answer reaching the model through a route that will not exist in use. Its forms are separate examinable errors: preprocessing such as scaling or feature selection performed on the whole dataset before the split, so the held-out data influenced the fitting; a feature that is a consequence of the outcome rather than a predictor of it, such as a treatment started because the event had already occurred; the same patient contributing records to both sides of the split; and a time window that lets the model see data recorded after the moment the prediction is supposed to be made.

Optimism is the second mechanism and it needs no error at all. When many models, many feature sets and many thresholds are tried and the best result is reported, that result is partly a selection from noise, and it shrinks on new data. The same happens when the held-out set is consulted repeatedly during development, at which point it has joined the training process. The problem is worst where candidate features greatly outnumber patients, the ordinary condition of neuroimaging and genomic work in psychiatry.

Both are properties of how the evaluation data were separated, which makes the split method the most informative line in a methods section. The ladder runs weakest to strongest.

SPLIT	WHAT IT HOLDS OUT	WHAT IT STILL CANNOT RULE OUT
Random split of records	Individual rows	The same patient on both sides, and every form of leakage
Patient-level split	Whole patients	Drift over time, and anything peculiar to that one site
Temporal split, trained on earlier data and tested on later	The future of one site	Everything specific to that site: case mix, coding habits, systems
External validation at a site that did not build the model	Site, population and practice	That the model, once acting on care, still performs as measured
Prospective evaluation with the output withheld from clinicians	Retrospective advantage	Whether acting on it changes any patient outcome

Even the bottom rung falls short. A model can be externally validated, prospectively confirmed and well calibrated and have no demonstrated effect on any patient outcome, because performance and benefit are different endpoints and only a trial of the model in use measures the second. Reporting and appraisal frameworks exist and are worth naming: TRIPOD plus AI for the reporting of prediction model studies, PROBAST plus AI for risk-of-bias appraisal, SPIRIT plus AI and CONSORT plus AI for protocols and reports of trials of these models, and DECIDE plus AI for early live clinical evaluation. The mark goes to knowing what each covers, since a paper satisfying the reporting standard is completely reported and not thereby correct.

TRAP **Reading an internal cross-validation figure as though it were an external result.** Cross-validation resamples inside one dataset, so it estimates how the fitting procedure behaves there and nothing else. It does not test a different site, a different case mix, a different coding culture or a different era, and where preprocessing or feature selection was done before the folds were drawn it does not even estimate that honestly. Examinably: internal validation bounds optimism within one sample, and only evaluation on data from an institution that had no part in building the model bears on whether it transfers.

11.6 Large language models: a different tool with a different failure surface

A **large language model** is not a clinical classifier and should not be appraised as one. It is trained to produce plausible continuations of text, so its outputs are fluent by construction and true only incidentally, and the failure modes follow from that rather than from any defect in a particular product. It produces confident, well-formed statements that are false, including references that do not exist. It tends to agree with the framing it is given, so a leading clinical question returns a supporting answer. It emits no calibrated probability alongside its answer, removing exactly the quantity the previous sections were about. And it need not return the same answer twice, so test-retest reliability cannot be assumed and has to be measured.

Two further points are examinable because counter-intuitive. Performance on written examination questions is a poor guide to clinical performance, partly because a question with five options and one defensible answer is not the task of the clinic, and partly because material that has circulated on the internet may sit in the training data, so a benchmark score can reflect

exposure rather than reasoning. And a general-purpose model given clinical text is not thereby a medical device or a validated instrument; what it is depends on the claim made for it and how it is deployed.

GOOD TO REMEMBER

The nearest-term uses in psychiatry are administrative rather than diagnostic: drafting documentation from a recorded consultation, summarising a long record, coding, translation support. These carry real benefit through time returned to the clinician, and a distinct risk profile, since a fabricated or subtly altered detail in a summary enters the record and is read as fact downstream. The safeguard is structural rather than technological. Output is a draft; the clinician who signs it owns every word in it, and the review has to be real, because a summary that is right nine times out of ten trains the reviewer to stop reading it.

11.7 Regulatory status: what this section refuses to say, and why

Nothing in this fragment states that any named model, product or system is approved, cleared, licensed or authorised anywhere. That is a deliberate refusal and the correct examination position, because the approval status of software is per product, per intended use and per version, and there is no class-wide approval of artificial intelligence in medicine of which any individual tool is an instance. The status ledger built for this chapter covers medicines only, and a drug ledger licenses no statement about a device.

Three records would have to be held before any regulatory sentence could be written about a named model, and naming them demonstrates the point better than reciting a status. The first is an entry in the United States device database for that specific product with the pathway it came through, since clearance against a predicate device, authorisation as a novel low-risk device and full premarket approval are different standards with different evidence behind them. The second is an entry in a named register of another regulator, identified rather than assumed from the first, because a marking obtained in one jurisdiction is not a permission in another. The third is the Indian record, and it is where an answer should be most careful, because the instruments this chapter searched are drug instruments: nothing retrieved here establishes which Indian pathway governs a software product, which body administers it, or what class and licence any given product carries. Those are matters of record, and this chapter holds no such record and did not look for one. No such record was retrieved for this chapter for any model, so no product is named here and no status is asserted for any.

Two errors of reasoning persist even when the records exist. A regulatory permission is evidence that a standard was met for a stated intended use; it is not evidence that patients do better, and the evidence supporting a clearance is often accuracy against a reference standard rather than any outcome. And because the object approved is a version, a model that continues to learn, or is retrained, raises the question whether the thing in use is still the thing assessed, which is why change-control for adaptive software is a live regulatory problem rather than a settled one.

TRAP **Sliding from a performance claim to a permission, or from a permission to a benefit.** These are three separate objects and each transition is a separate error. A published accuracy figure is a measurement in a sample; a regulatory clearance is a decision about one product for one stated use; a demonstrated patient benefit needs a prospective study of the model in use with a clinical endpoint. A candidate who writes that a tool is approved and therefore effective, or that it performs well and is therefore approved, has made the error the whole topic exists to prevent.

11.8 Bias, the Indian question, and what a complete answer contains

A model cannot be called fair, and the reason is that fairness is not one quantity. Several formal definitions of fairness exist and conflict mathematically, so a model satisfying one will generally violate another, and a claim of fairness without a stated definition and a measurement is not a finding. The mechanisms producing unequal performance are, however, straightforward. Groups under-represented in the training data are fitted less well. The label itself is socially patterned, since who receives a recorded diagnosis, who is flagged as a risk and who is admitted all depend on who is doing the recording. And **dataset shift**, meaning any change between the setting where the model was fitted and the one where it is used, degrades performance in ways that fall unevenly across groups. The remedy in an answer is not an assurance but a demand: performance reported separately by subgroup, in the population of use.

IN INDIA

The motivation is real and the strongest argument in the topic: the specialist workforce is far smaller than the need, and any tool that extends a clinician's reach is worth taking seriously. The caution is equally concrete. Almost all of this literature is built on structured electronic records from North American and European health systems, and there is no reason to expect a model fitted to those records to hold here, where much of the record is on paper or free text, where clinical documentation is often multilingual and code-switched, where case mix and pathways to care differ, and where the base rates in any given clinic differ from those in the development sample. Nothing about Indian performance is asserted anywhere in this section, because no Indian external validation of any named psychiatric model was retrieved for this chapter. Two positions hold regardless of the evidence. Accountability for a clinical decision rests with the registered practitioner and is not transferred to a vendor by the use of a tool. And identifiable patient information entered into a general-purpose service leaves the clinic, so the confidentiality obligation has to be settled before the tool is used and not after; which statutory instrument governs that transfer is a legal question this chapter has not established and therefore does not answer.

The topic reduces to four decisions.

- Establish the target before the number: what was recorded, by whom, and whether it is the construct or a proxy for it.
- Ask what the number was measured against, both in comparator and in split, and treat internal validation as an estimate of optimism rather than of transfer.
- Take the base rate into the arithmetic before accepting a screening claim, because predictive values belong to the population and not to the model.

- Keep performance, permission and patient benefit as three separate claims, each needing its own evidence.

MNEMONIC

Target, Population, Split, Comparator

The four questions that dismantle any reported figure, and the order to ask them in: what was actually being predicted, in whom, how were the evaluated data kept away from the fitting, and against what was the result judged. A claim that survives all four may then be asked the fifth and hardest: whether acting on it helps anyone.

A model's number is a measurement in one sample of one recorded label; it becomes a clinical claim only when the target, the population, the split, the comparator and the validation status are all named with it.

12 · Brain-based, biomarker-driven and computational psychiatry approaches

Psychiatry has published thousands of candidate biomarkers and holds none of them as a diagnostic test for any of its own disorders. Explaining that sentence is the item, not listing findings: grading any biological claim, from a scan to a polygenic score to a fitted model, on three questions asked in order. Can the thing be measured, does the measurement track the clinical state, and does using it leave the patient better off. Collapsing them into one is the characteristic error of the area, made as often dismissively as enthusiastically. Two neighbours are bounded out: appraising an algorithm, its dataset and its external validation belongs with the artificial intelligence and machine learning material in this chapter, and measures that have entered diagnostic use in neurodegenerative illness belong with the Dementias and neurocognitive disorders notes.

12.1 What a biomarker claim is actually claiming

A **biomarker** is a characteristic measured objectively as an indicator of a biological process or of a response to an intervention. Measured objectively excludes the rating scale, which reports experience, so a depression severity score is not a biomarker of depression however well it performs. Indicator excludes mechanism: a marker need not cause anything, and most psychiatric candidates are downstream or non-specific.

The claim must state which question the measure answers. A diagnostic marker says whether the person has the condition now, needing a reference standard and a stated comparison group. A prognostic marker says what course the person will take whatever the treatment. A **predictive** marker says which of two treatments will suit this person better, an interaction between marker and treatment. A monitoring marker says whether the state has changed, needing sensitivity to change rather than group separation. A susceptibility marker says how likely onset is in someone currently well, a statement about a population, not a person's future.

That pair is the distinction most reliably examined and most reliably muddled. A marker can be strongly prognostic and useless for choosing: knowing a patient will do badly whatever you do changes nothing. Showing a marker is predictive needs patients on different treatments compared across levels of the marker, a far more demanding design. A complete claim carries five things: the measure, the question, the population, the comparator, and the decision it feeds. Supplying the missing ones from expectation invents them.

12.2 The spine: analytical validity, clinical validity, clinical utility

Analytical validity asks whether the measurement is a good measurement, settled in the laboratory or the scanner by the properties in the table below. No part of it mentions disease, and poor analytical validity cannot be rescued downstream: the noise is inherited by every analysis built on the measure.

Clinical validity asks whether the measurement relates to the clinical state in a defined population. **Discrimination** and **calibration** are the components routinely dropped. Discrimination is the ability to rank a person with the condition above one without it, summarised by the area under a receiver operating characteristic curve. Calibration is whether a predicted probability matches observed frequency, so a one in ten risk holds about one time in ten. A model can discriminate respectably and be badly calibrated, and a badly calibrated risk is unusable at the bedside while reading well in the paper.

Clinical utility asks the only question a patient cares about: does using this test lead to better outcomes than not using it. It compares a strategy including the test against a strategy without it, carried to a patient outcome, counting the harms of testing: cost, delay, the cascade a borderline result sets off, false reassurance, and the effect of being told you carry a biological abnormality. Almost every claim made for a psychiatric biomarker is a statement about clinical validity, sometimes only analytical validity, written in the grammar of clinical utility.

QUESTION	WHAT IT ASKS	WHAT ESTABLISHES IT	HOW IT FAILS, AND THE PHRASE THAT HIDES IT
Analytical validity	Does the assay or scan measure the quantity accurately and reproducibly	Laboratory characterisation: accuracy, precision, detection limit, batch, site and scanner effects, repeat measurement	Values that shift between sites or between visits. Hidden by "a validated assay", which names nobody's validation and no population
Clinical validity	Does the measurement track the clinical state in a stated population	Sensitivity, specificity, predictive values, discrimination and calibration, in a defined sample, against a stated reference standard, replicated	Separation that shrinks once the comparison group resembles the real differential. Hidden by "significantly associated", which says a difference exists, not that a test works
Clinical utility	Does using the test improve what happens to the patient	A strategy with the test against a strategy without it, carried to a patient outcome, counting the harms of testing	No such study exists for the marker in question. Hidden by "may help guide treatment", asserting the third question from evidence for the second

RULE **Analytical validity, clinical validity and clinical utility are asked in that order, and none implies the next.** A perfectly reproducible assay may bear no relation to any clinical state, and a measure that separates two groups beyond doubt may change no decision and improve no outcome. Grade every claim by naming which of the three it has established, and say plainly that the others are unaddressed rather than assuming they follow.

12.3 Why a group difference is not a test

A group difference says one distribution's average sits away from another's; a test has to place an individual on one side of a line. A difference can be beyond statistical doubt while the distributions overlap almost completely, because a large enough sample makes a small separation reliably detectable. Reliably detectable and usefully separated are different properties, and the first is what most published biomarker findings have.

The second defeater is the base rate, and it defeats measures that do separate. Take a test right in 90 percent of people who have a condition and in **90 percent** of those who do not, applied where **1 person in 100** has it. Of 10,000 tested, 90 of the 100 with the condition test positive, and 990 of the 9,900 without it also test positive. A positive result is therefore far more often wrong than right: **fewer than 1 in 10** positives is a true positive. The prevalence did the damage, not the test, and no gain in sensitivity undoes it, because the false positives come from the enormous group without the condition.

90%	90%	1%	8%
SENSITIVITY, STIPULATED	SPECIFICITY, STIPULATED	HOW COMMON THE CONDITION IS	CHANCE A POSITIVE IS TRUE

Those four figures are a worked illustration, not a measurement of any real test. The shape is what to carry: at low prevalence positive predictive value collapses while negative predictive value becomes excellent, so a marker can be useful for ruling out and useless for ruling in.

The third defeater is **spectrum bias**. Performance is first measured in clear, established, often severe illness against healthy volunteers; the clinic asks the hard question, an early, partial, comorbid presentation against the other diagnoses on the differential. Move the comparison group to the real differential and specificity falls, sometimes to nothing, because the marker was never specific to the disorder, only to being unwell. An accuracy figure must travel with the comparison group it was earned against; without it the figure is uninterpretable rather than merely imprecise.

TRAP **Repeating a research accuracy figure as though it described the clinic.** Published accuracy is typically obtained in a balanced sample against healthy participants, in people whose diagnosis is already certain. The clinic has none of those properties: low prevalence, a comparison group that is the differential, and patients presenting early and ambiguously, which is why the test was wanted. The defensible sentence names the sample and the comparator beside the number, and states that performance in an unselected population is unknown unless measured there.

12.4 The reference standard problem, and why a research framework is not a diagnosis

The deepest difficulty is not the measure, it is the yardstick. A diagnostic biomarker is validated against a **reference standard**, and in psychiatry that standard is a clinical diagnosis made by interview against the current manuals. Two consequences follow.

The first is a ceiling: a measure judged against clinical diagnosis can at best reproduce it, its apparent accuracy bounded by the reliability of the standard rather than the biology, so where two experienced clinicians would disagree the marker is scored against a coin. The second is a filter running the wrong way: a measurement identifying a real biological grouping that cut across the manual's categories would be scored inaccurate and abandoned, because the criterion for success is agreement with the classification it contradicts. That circularity is why agreement with diagnosis is a weak result and predicting what it does not, such as course or treatment response, a strong one.

Dimensional research frameworks, which organise study around functional constructs measured across levels from genes and circuits to behaviour and self-report, and the hierarchical taxonomies derived from the covariance of symptoms, exist because of that problem: they free research from the assumption that the manual's categories are natural kinds. They are research frameworks, carrying no diagnostic threshold, no validated decision rule and no treatment recommendation attached to any dimension, and none allocates treatment better than a diagnosis made by interview.

GOOD TO REMEMBER

Phenomenology is not a placeholder waiting for biology to replace it. It remains the measurement instrument in psychiatry and the standard every candidate marker is validated against, so it cannot be displaced without a study showing better patient outcomes rather than better agreement. The viva position is neither that biology will soon supply the diagnosis nor that it offers nothing: these approaches produce constructs, stratification hypotheses and research designs, and no claim to have replaced the interview has been made good for any primary psychiatric disorder.

12.5 What is replicated, what it licenses, and what it does not

Group-level findings here are real; the discipline is to say what each licenses. Every row below has been reproduced, none is a test, and the fourth column carries the marks.

MEASURE FAMILY	WHAT REPLICATES AT GROUP LEVEL	WHAT THAT LICENSES	WHAT IT DOES NOT LICENSE
Structural imaging	Enlarged lateral ventricles in chronic schizophrenia, among the field's oldest and most reproduced findings, and small average reductions in cortical and subcortical volumes across several disorders	A statement about averages, and a research target	Individual inference. Distributions overlap heavily with comparison groups and the differences are not specific to one diagnosis
Functional imaging and connectivity	Group differences in task activation and in resting connectivity across mood, psychotic and anxiety disorders	Hypotheses about circuits, and stratification questions worth testing prospectively	A scan for a patient. Effects are small against within-person and between-scanner variability
Electrophysiology	Reduced auditory event-related potential amplitudes and reduced mismatch negativity in schizophrenia, among the most replicated findings in psychiatry	Research into information processing, and endophenotype work in relatives	Diagnosis or exclusion in an individual. The reductions are neither specific nor separating
Peripheral and inflammatory measures	Modest average elevations of circulating inflammatory markers in a subgroup of people with depression	A stratification hypothesis, to be tested rather than applied	Diagnosis, and any causal statement. Confounded by adiposity, smoking, infection and physical comorbidity, and specific to no psychiatric disorder
Neuroendocrine	Group differences in cortisol regulation, the historical example being the dexamethasone suppression test proposed for melancholic depression	A permanent teaching case: it separated groups, and specificity collapsed once the comparison group was other psychiatric patients	Diagnostic use, which was proposed, tried and abandoned
Common-variant genomics	Polygenic scores associated with case status for schizophrenia and for bipolar disorder at the group level, robustly and repeatedly	Research into shared architecture across diagnoses	Individual prediction, diagnosis or counselling. Variance explained is small, distributions overlap almost completely, transfer across ancestries is poor

The one place where fluid and imaging measures have crossed into diagnostic use is neurodegenerative illness, taught with the Dementias and neurocognitive disorders notes; nothing about their performance transfers to a primary psychiatric disorder, and citing them as

proof that psychiatry now has biomarkers is a category error. And this section makes no regulatory statement of any kind: the chapter's status ledger holds one row per drug per jurisdiction and no row for any assay, imaging measure, device or diagnostic test, so no approval, clearance, qualification or reimbursement claim appears here for any country. Demand of anyone who offers one the four fields the chapter uses throughout: the jurisdiction, the exact intended use, the authoritative source, and the date the status was true. An intended use is bound to the jurisdiction that granted it, and a test available in one country establishes nothing about another.

12.6 Computational psychiatry: what a model parameter is, and what it is not

Computational psychiatry states a hypothesis about a mechanism as a formal model, fits it to an individual's behaviour or brain data, and treats the fitted quantities as candidate measures: how a person processes information, in numbers comparable across people.

Two strands run under the name. The theory-driven strand builds a **generative model**, equations describing how choices or percepts are produced, and estimates its parameters for each person: reinforcement learning models yield learning rates and sensitivity to reward and punishment; evidence accumulation models yield an accumulation rate and a decision threshold, separating a slow response caused by cautious responding from one caused by inefficient processing; Bayesian and predictive coding models yield the weight given to prior expectation against incoming evidence, describing hallucination and delusion as an altered balance rather than an unexplained content. The data-driven strand predicts without committing to a mechanism, and its discipline is taught with the artificial intelligence and machine learning material.

A fitted parameter is an estimate produced by fitting a model you chose to data you collected, a property of the model and the data together rather than a substance inside the patient, so changing the model changes it. Four requirements follow beyond the ordinary ones. **Parameter recovery** comes first: simulate data from known values, refit, and check that the known values are recovered, because a parameter unrecoverable from data the model itself generated cannot be interpreted in a patient. Identifiability next: two mechanisms producing indistinguishable behaviour cannot be told apart by fitting. Third, model comparison is relative, selecting the best of the models written down, and the best of a bad set is still that. Fourth, prediction must be out of sample, with any selection of features or participants kept inside the training data.

Apply the spine and a computational measure reads cleanly. Analytical validity becomes parameter recovery plus the stability of the estimate when the same person repeats the task. Clinical validity becomes whether the parameter separates clinical groups or predicts an outcome. Clinical utility becomes whether allocating treatment by the parameter beats allocating it clinically. Computational psychiatry is substantial at the first two and effectively silent at the third, and why the third is a different study and not a bigger one is the examinable point.

12.7 Reliability, replication, and the claim that a biological measure is unbiased

Two mechanical facts explain most of the disappointment here. The first is a reliability trap in task design: a task is optimised to produce a robust average difference between conditions, done

by making everyone respond as similarly as possible, deliberately minimising the between-person variation an individual measure needs. So a group effect that replicates without fail can sit beside a between-session correlation close to nothing in the same individuals, both consequences of one design choice rather than a contradiction. Because reliability caps the correlation a measure can show with anything else, an unreliable measure cannot correlate strongly with symptoms or outcome however real the relationship. A measure built for group inference must be rebuilt before it serves as an individual marker.

The second is that discovery is not validation. Clustering a sample into subtypes always returns clusters, whose number and shape depend on the measures entered, the preprocessing and the algorithm. Several prominent psychiatric subtyping solutions have not been recovered in independent samples. A subtype derived in one dataset is a hypothesis until an independent dataset recovers it and it predicts something outside the data that generated it.

PITFALL

Treating poor test to retest reliability as a minor technical caveat. It is not a footnote to the finding but a limit on it. If a measure taken twice in the same stable person gives substantially different answers, it cannot support an individual clinical decision whatever its group statistics look like. Ask what the between-session agreement was before asking what the between-group difference was, and note how often that question is unanswered.

The claim that measuring biology removes human bias is false, and the four routes by which bias enters are a genuine discriminator. The label carries it first: a marker trained against clinician-assigned diagnoses learns whatever systematic patterns those clinicians produced, reproducing the bias with a more authoritative surface. The sample carries it second: performance is a property of the population studied, shown most clearly by polygenic scores, whose performance falls substantially when transferred from the ancestry group they were derived in. The instrument third: scanner, batch and site effects are real, and where sites differ in whom they recruit, a site effect and a demographic effect cannot be separated afterwards. Access fourth: who is tested determines who can benefit, and private testing is distributed by income rather than need.

IN INDIA

The transfer problem is not abstract here. Reference intervals, normative neuropsychological data and polygenic scores are largely derived from populations in which South Asians are thinly represented, so a value abnormal against an imported reference may be unremarkable for the person in front of you, and a risk score performs worst precisely where it is newest to the market. Two consequences. A group frequency is a prior about a population and never a result about a patient, so no measure may be read off ancestry. And before treating a value as abnormal, ask where the normative sample behind that threshold came from; where local normative data exist, use them.

12.8 Where a biological test does change management, and what a complete answer contains

An answer finishing on scepticism has missed the clinical half of the item. The tests that earn their place are not tests for psychiatric disorders but for conditions that both imitate a psychiatric presentation and carry a different treatment, and their utility is easy to demonstrate because a positive result changes management at once.

The categories follow from the principle rather than a memorised panel: endocrine disturbance, particularly thyroid disease; nutritional deficiency; infective and inflammatory causes; antibody-mediated encephalitis, characteristically a rapidly evolving first episode of psychosis with atypical features, seizures, movement abnormalities or autonomic instability; inherited metabolic disease such as Wilson disease in a young patient with psychiatric and movement symptoms together; structural and epileptic causes; and substance and medication effects, commoner than all the rest. Justify each test by the decision it could change, and notice that this is the one part of the topic where the third question of the spine is genuinely satisfied.

IN INDIA

Two situations recur in outpatient practice. A family arrives having paid privately for a brain mapping report, a neurotransmitter panel or a genetic wellness profile and asks what it means. The question is not whether the number sits outside its range but which decision would change if it were different, and where the honest answer is none, saying so is the correct clinical act, with an explanation of why the test could never answer the question it was sold as answering. An unvalidated test is not neutral: it has cost the family money and it generates false reassurance. The second situation is the opposite failure, the treatable mimic missed because nothing was investigated.

TRAP **Writing that a scan or a blood test can now diagnose a psychiatric disorder, or that it soon will.** Neither half is defensible. There is no validated transdiagnostic blood test or brain scan for a primary psychiatric disorder; a group-level association does not determine an individual diagnosis; and a research classification organises study rather than replacing the interview. The forecast is not safer than the claim, because a prediction about validation is a claim about evidence that does not exist. Say what has been established, name which of the three questions it answers, and state that the others are open.

Four moves answer this item in whatever form it is asked.

- Grade the claim on the spine: analytical validity, clinical validity, clinical utility, named in order, with the one actually established stated and the others called open.
- Give the two arithmetic reasons a group difference is not a test, overlapping distributions and the base rate, with spectrum bias as the reason published accuracy falls in clinic.
- Name the reference standard problem: a marker validated against clinical diagnosis is capped by it and discarded if it disagrees, so predicting course or treatment response is the stronger design.
- Treat a computational parameter as a property of the model and the data, needing recovery, identifiability, out-of-sample testing and test to retest reliability before it measures anything

in a person.

MNEMONIC

Measure, Separate, Decide, Benefit

The first three are the spine and the fourth is the study almost nobody has done: does the result change a decision, and does that change leave the patient better off. Every biomarker claim sits at the step where its evidence stops.

A biomarker is graded on three questions asked in order, a group difference is not a test, and the yardstick every candidate is judged against is still the clinical interview.

13 · Digital therapeutics and prescription apps in psychiatry

A prescription digital therapeutic is a treatment whose active ingredient is software, and almost every difficulty follows from that sentence. The clinical question is how an intervention delivered on a patient's own device is evaluated, when its effect depends on how much of it the patient does, when no convincing dummy version can be built, and when the user cannot be kept unaware of what they are using. The regulatory question is what kind of object it is, since it is not a medicine and does not reach a market by a medicine's route. Marks are lost in three places: appraising the product as though it were a drug, reading an effect measured in the patients who kept using it as the effect of the product, and supplying a regulatory status from memory because none was written down. Two neighbours share this chapter's readiness ladder and neither is rebuilt here: appraising a fitted model, its dataset and its external validation belongs with the artificial intelligence and machine learning material, and grading a measure on analytical validity, clinical validity and clinical utility belongs with the biomarker material.

13.1 What the object is, and the four things it is not

A **prescription digital therapeutic** is a software product that makes a therapeutic claim about a named condition, delivers the intervention to the patient rather than to the clinician, and is gated behind a clinician's authorisation. The claim decides the category, not the content: two products can ship identical exercises and be different objects entirely, because one asserts treatment of a named condition and the other does not.

Four neighbours are routinely collapsed into it. A wellness or self-help application may carry the same material, makes no therapeutic claim, and is therefore assessed by nobody. A telemedicine platform delivers a clinician at a distance, so the treatment remains the clinician's and the software is a channel. A decision-support tool acts on the clinician's judgment and the patient never touches it, which is the object the artificial intelligence and machine learning material appraises. Software supplied alongside a medicine carries no therapeutic claim of its own, because the claim belongs to the drug.

The sentence that does for software what a molecule does for a drug is its **intended use**: the population, the condition and the clinical purpose, written down. Everything is assessed against

it, and a product whose intended use is amended is a different product.

13.2 Why it is a device and not a drug, and the six things that follow

A medicine is a substance and its manufacture reproduces that substance. Software has no substance: what is assessed is a design together with an intended use, and what is produced is a build. Hence the category **software as a medical device**, software intended for a medical purpose that achieves it by processing information rather than by chemical or physical action on the body.

First, the unit of authorisation is one product, one intended use and one version, so there is no class of digital therapeutics of which a product is an instance, and a class-level statement of status is not the kind of statement that could be true. Second, risk classification drives the evidence burden: device frameworks grade by the harm a failure could cause, and lower grades may rest on similarity to something already lawfully marketed rather than on a fresh trial, so two products may be marketed on entirely different evidence. A permission tells you a pathway was satisfied, not what was shown. Third, there is no generic: a second manufacturer cannot show its software equivalent to another company's, so it builds a different product with its own authorisation and evidence.

Fourth, **change control** is continuous rather than exceptional: a tablet's formulation is frozen at approval, software ships updates, and since the object assessed was a version, the question after launch is whether the thing in the patient's hand is still the thing assessed. Fifth, withdrawal has no drug analogue, because a dispensed medicine stays with the patient, whereas a therapeutic depending on a running service can stop working and the patient loses the treatment with no clinical decision taken. Sixth, being authorised creates no way to deliver it: a prescription for a molecule meets a pharmacy, while a prescription for software meets whatever arrangement a manufacturer, a service and a payer have built, and where none exists it cannot be filled.

RULE **The thing authorised is one product, for one intended use, at one version; move any of the three and the permission does not travel with you.** Three errors share that shape: a claim about a category, a claim about a wider population than the intended use names, and a claim about the current release when the evidence came from an earlier one, the last invisible unless somebody asks which version was studied.

13.3 What this chapter can see, and what it structurally cannot

The most useful thing this section can give a candidate is a worked example of an absence that means nothing. This chapter carries a status ledger of one row per agent per jurisdiction, each row carrying the same four mandatory fields, the jurisdiction, the indication or a declared gap in its place, the authoritative source or that same gap, and the date the status was true. It holds **48** rows over **16** agents in three jurisdictions, every one a medicine. The number of rows describing any software product is **0**.

That is not an oversight, and reading more of the same documents would not close it. The instruments recorded as used number **7**. Five can see nothing but medicines: two interfaces onto a national drug application and labelling archive, a register of centrally authorised medicines

with its assessment pages, and a corpus of published new-drug approval lists. The sixth is a whole-domain search of the drug regulator's own website, pointed in this build only at drug names. The seventh searches the national trials registry, which records research and never marketing status. A drug application archive cannot return a device record, because that is not the kind of record it holds. The five archives are silent about software by construction, the other two by what they were pointed at.

Two facts in this chapter's working files make that sharper. The source registry that governs which document is authoritative names, for artificial intelligence and digital therapeutics specifically, a device database, and that database appears neither among the instruments recorded as used nor among those reachable but not yet run. And the grounding lanes name the drug items and do not include this item at all, not even a status lane. The absence here is not a search that came back empty; it is a question none of the records these instruments hold could answer.

48	16	0	7
ROWS IN THE CHAPTER STATUS LEDGER	AGENTS COVERED, ALL MEDICINES	ROWS FOR ANY SOFTWARE PRODUCT	INSTRUMENTS USED, NO DEVICE REGISTER

The falsification pass built to test those rows compares a stored indication text against a cached primary drug document, and a software product would not fail those instruments: having no drug label to read, it is inapplicable to them. An instrument that cannot fail is not a test.

So no product is named in this section, and no approval, clearance, authorisation, licence, marking, date or jurisdiction is asserted for anything. Two sentences are forbidden and the second is the one that feels safe: that a named product is approved somewhere, and that a named product is not approved somewhere. The first would be written from memory; the second would rest an assertion on the silence of instruments that hold no such record.

TRAP **Filling the regulatory blank yourself, in either direction.** A reader who meets a section naming no product and no status will supply both, because a refusal reads as an omission. Half-remembered regulator statements are the commonest fabrication here, and the mirror error is worse, concluding from silence that nothing has been authorised anywhere. The examinable move is to name the record that would settle it, state that such a record is per product, per intended use and per version, and say none was retrieved.

13.4 How the evidence differs from a drug's evidence

The trial machinery looks familiar and diverges at six points.

QUESTION	A MEDICINE	A PRESCRIPTION DIGITAL THERAPEUTIC
What is administered	A fixed quantity of a substance	An opportunity to do a course of work, which the patient may not take
How exposure is known	Inferred from prescriptions and self-report	Logged continuously, module by module
What varies between patients	Absorption, metabolism, adherence	How much was received at all, from none to all
What blinding is possible	Allocation and the treatment itself	Allocation only; the patient knows what they are using
Who measures the outcome	Often a rater unaware of allocation	Usually the unblinded patient, on the same device
After authorisation	A frozen formulation	Successive versions, of which the studied one may no longer be in use

The exposure row cuts both ways. Precise logging is a real advantage, since treatment received is measured rather than assumed. The same precision creates the field's most attractive error: because exposure is known and varies enormously, an analysis restricted to those who completed the programme is available, tempting and severely biased, since completers are the engaged and engagement predicts outcome for reasons unconnected to the software. The randomised comparison lives in the analysis that keeps everybody allocated to it.

13.5 Engagement and attrition, which do something a pill's adherence does not

A tablet delivers its benefit on being swallowed. A therapeutic delivers its benefit only when the patient does the work inside it, so the active ingredient is the patient's own activity. **Engagement** is therefore not adherence renamed: adherence is a gate the benefit passes through, whereas engagement is part of the benefit, which is why an effect size is uninterpretable without a statement of how much of the intervention was taken up.

Attrition then does four separable things. It empties the denominator, steeply, since disengagement is heaviest early. It is not random, so where the arms lose different sorts of patient the randomisation that made the comparison fair has quietly been undone. It is itself an outcome rather than a nuisance, because a treatment patients stop using is not working. And it is entangled with the state the product exists to change, since low motivation, poor concentration and hopelessness are features of the conditions treated and also the commonest reasons a person stops opening an application. An effect conditional on sustained use is conditional on the patient not having the problem in its severe form.

Two further effects have no drug counterpart. Novelty decays, so an effect measured across a short window need not describe the same product used for a year. And the human contact around a trial is a co-intervention: visits, reminders and a coach who telephones when use lapses deliver

support, so a therapeutic evaluated with that scaffolding is a different intervention from the software used alone, and the unsupported version is usually what a service plans to deploy.

GOOD TO REMEMBER

Prescribing one of these is prescribing a course of work, so time the review to where the work stops, not to the end of the programme. Silent abandonment is the ordinary outcome, and a patient who has quietly stopped is often assumed by everyone to be in treatment. Ask what the patient did, in what week they last did it, and what got in the way, and treat disengagement as clinical information, not non-compliance.

13.6 Why the control condition is unusually hard to build

Every comparator here fails to control something, and naming what each leaves uncontrolled is the appraisal skill worth carrying.

COMPARATOR	WHAT IT CONTROLS	WHAT IT LEAVES UNCONTROLLED
Waiting list	Time and spontaneous change	Attention, expectancy, structured activity and being monitored, so the difference is an upper bound, not an estimate
Usual care	Whatever the service delivers	What that is: unstandardised, differing between sites, and in an under-resourced service possibly very little
Attention-matched or sham application	Screen time, contact, expectancy, daily use	Whether it is truly inert, since anything engaging enough to be used is doing something, and whether patients believed it
The same treatment delivered by a person	The content, isolating the mode of delivery	Nothing important, which is why it is the informative arm, the most expensive and much the rarest

The **digital placebo** names the problem: the benefit that comes from using something at all, from the daily ritual, the attention and the expectation of improvement. A **sham comparator** must satisfy three requirements in tension: plausible enough to be believed, engaging enough not to be abandoned faster than the active arm, and inert. Anything meeting the first two risks failing the third, and differential dropout between a dull sham and an interesting therapeutic reintroduces the bias the sham was built to remove.

Blinding compounds it. Allocation can be concealed at randomisation, but a participant cannot be kept unaware of what they are using for weeks, and the outcome is usually their own self-report on the same device, so the person who knows which arm they are in is also the measuring instrument. That is a structural weakness rather than a defect of any one study, and a larger sample does not repair it. Two consequences: an outcome assessed by someone unaware of allocation, or one not self-reported at all, carries much more weight here than a self-rated scale;

and framing is part of the intervention, because content presented as prescribed and authorised generates an expectancy the same content offered as a self-help download does not.

TRAP **Reading a waiting-list-controlled result in completers as the effect of the product.** It stacks two errors working the same way. The waiting-list comparison leaves attention, expectancy and structured activity uncontrolled, so it measures the difference between doing something and doing nothing rather than the difference this product makes; restricting the analysis to completers then removes everyone in whom the product failed to hold attention. Ask what the comparator was, who was in the denominator and who assessed the outcome before accepting any figure.

13.7 What an Indian service would have to establish, and what a complete answer contains

The lens here is the product: what the evidence shows, what kind of regulated object it is, and what a prescription for it would mean. Access, equity, service integration, adoption and programme monitoring for digital mental health in this country are the subject of the Community psychiatry and public health notes, because whether a product works and whether a system can deliver it are answered from different evidence.

IN INDIA

Six things must be established before a service deploys one, and none may be inferred from an application store listing, a company's own description, or a permission granted in another country. First, what kind of regulated object the product is here and on whose authority, with the document named and dated, since no instrument in this chapter's set can return that record and nothing in this section supplies it. Second, whether the evidence was generated in a population and language resembling the patient, and whether the content was rebuilt for that language or merely translated, since a therapeutic is made of words in a way a tablet is not. Third, which version the patient will receive, and whether it is the version studied. Fourth, who holds the data it generates and where that goes, since a therapeutic collects a clinical record continuously as a condition of working. Fifth, what happens when the patient stops, and who notices. Sixth, whether the human support that surrounded the product in its trials can be supplied here, because without it the intervention deployed is not the one evaluated.

Reduced to four decisions, the item is answerable in any form.

- Identify the object first: a therapeutic claim about a named condition, delivered to the patient, gated by a clinician, assessed as one version of one product.
- Appraise it as a device trial: what the comparator controlled, who was in the denominator, who rated the outcome, how much was received.
- Treat engagement as part of the treatment and attrition as a result, and refuse any effect size quoted without both.
- Keep evidence, permission and deliverability separate, and where no regulatory record has been retrieved, name the missing record instead of guessing what it would say.

MNEMONIC

Claim, Version, Comparator, Completion

Claim is what makes software a regulated object and fixes what may be said about it. Version is what was assessed, and the question nobody asks. Comparator is what the trial controlled, and so what its number means. Completion is how many were still using it when the outcome was measured, both a result and the limit on every other result.

The active ingredient is the patient's own work, the object authorised is one version of one product for one intended use, and an absence reported by an instrument built for medicines is not a fact about software.

Individual newer agents

14 · Asenapine: pharmacology and clinical use

One active substance, two routes, and four regulatory records that do not agree on what the drug is for. Asenapine is the most compact item in this chapter and the easiest to answer wrongly with confidence: a candidate who knows it from the bipolar algorithm writes an indication correct in one country and false one border away. What follows is the whole-agent profile: the formulations, the indication set jurisdiction by jurisdiction, and the discipline that keeps the two fastened together. Receptor pharmacology, the sublingual dosing detail and asenapine's place in the bipolar phase algorithm are taught in the Mood disorders: pharmacotherapy notes.

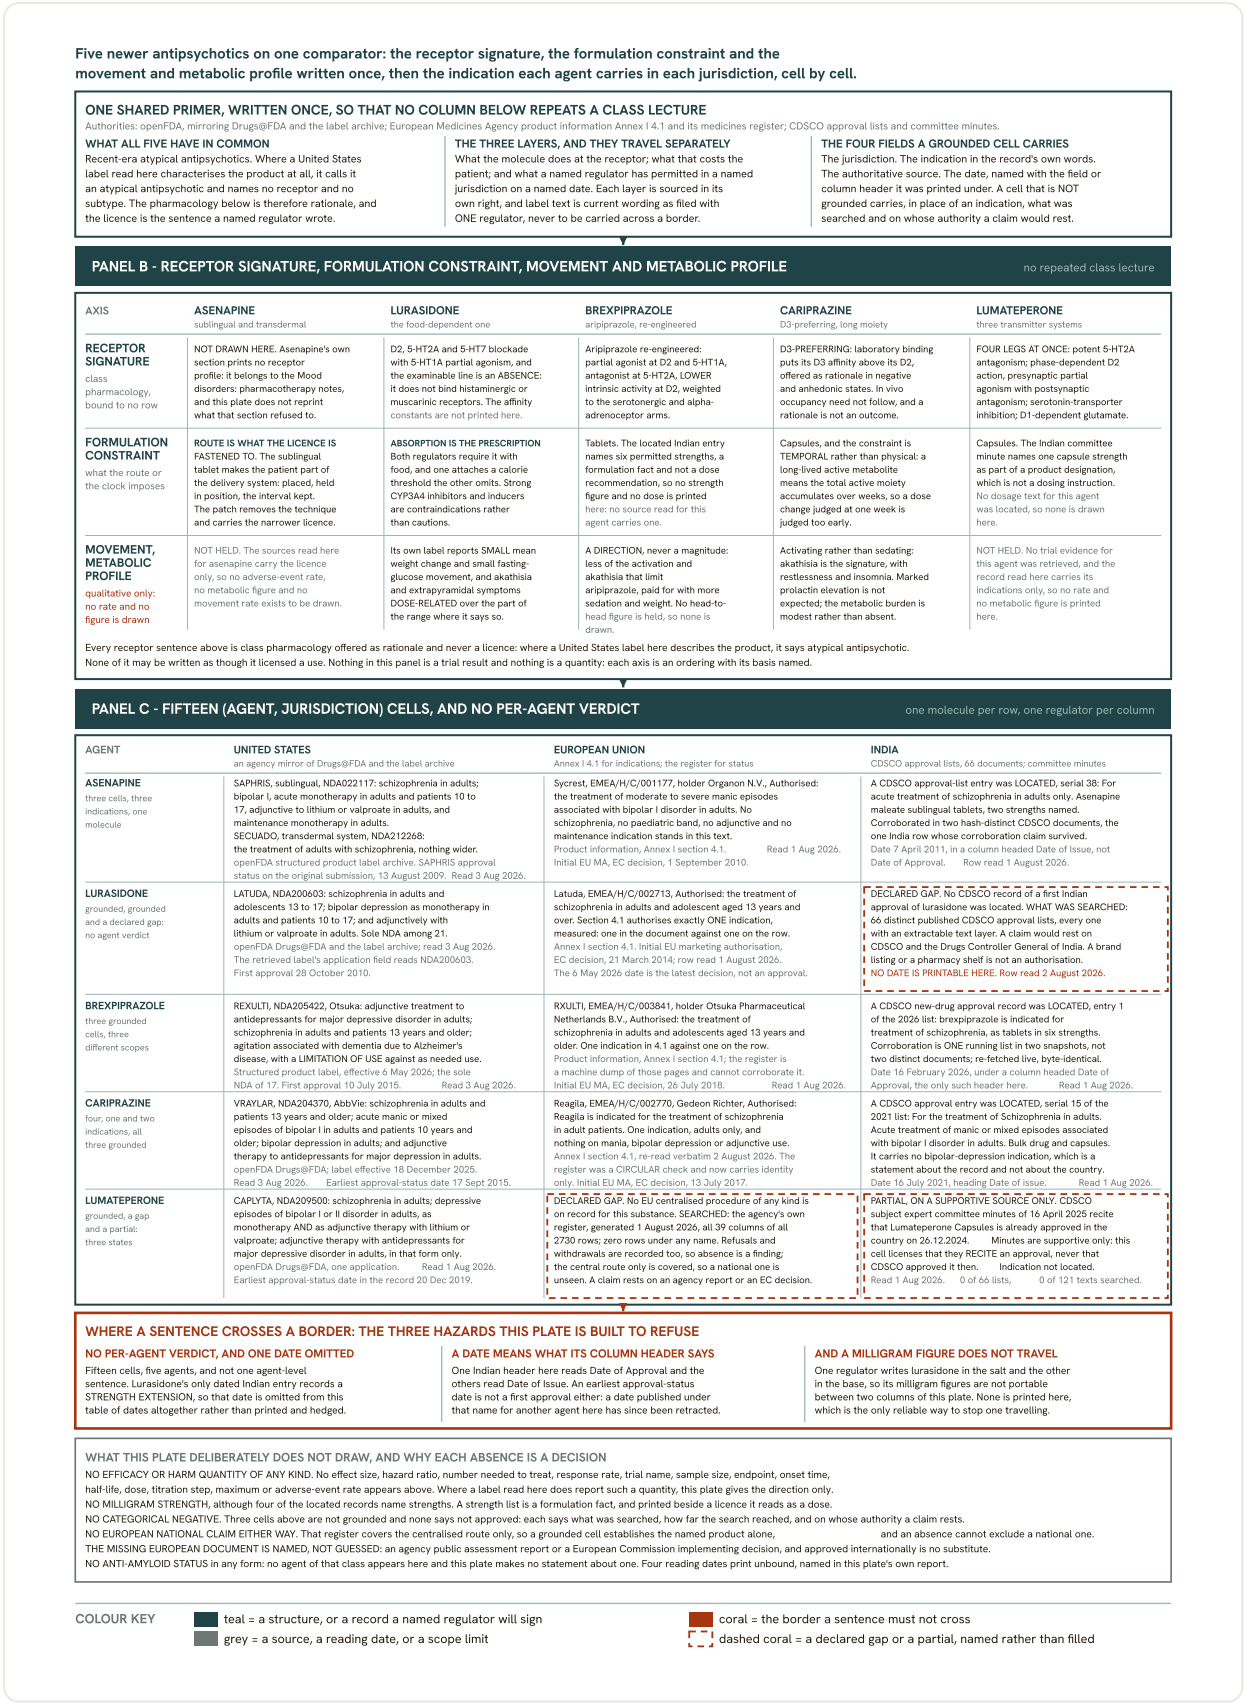

Fig 38.8 Five newer antipsychotics on one comparator: fifteen (agent, jurisdiction) cells, not five verdicts. Where a United States label read here describes the product it says only atypical antipsychotic, so the receptor row is rationale and the licence is the regulator's sentence. Movement and metabolic effects are qualitative: no rate, dose or onset time appears. The states differ inside one molecule: lurasidone's Indian record is a declared gap, lumateperone's recites an approval it does not establish, and no cell is a per-agent verdict. A cell that is not grounded names what was searched. (openFDA; European Medicines Agency Annex I 4.1 and medicines register; CDSCO lists and committee minutes.)

14.1 Two American applications, and why they are not one drug

The United States holds two applications for asenapine, and they are not two names for one product. The **innovator application** is a **sublingual tablet**, SAPHRIS: application NDA022117, sponsor ABBVIE, whose original submission carries approval status dated **13 August 2009**, in three strengths, 2.5 mg, 5 mg and 10 mg expressed as asenapine base. The second is a **transdermal system**, SECUADO: application NDA212268, sponsor HISAMITSU, whose original submission carries approval status dated **11 October 2019**, as three patches delivering 3.8 mg, 5.7 mg and 7.6 mg over 24 hours.

They do not license the same thing. The sublingual label reads: SAPHRIS is indicated for schizophrenia in adults, and for bipolar I disorder as acute monotherapy of manic or mixed episodes in adults and pediatric patients 10 to 17 years of age, as adjunctive treatment to lithium or valproate in adults, and as maintenance monotherapy treatment in adults. The transdermal label reads, whole: SECUADO is indicated for the treatment of adults with schizophrenia. One route carries schizophrenia and a three-part bipolar I indication reaching to age 10; the other adult schizophrenia alone.

Three constructs inside that indication are routinely collapsed together. **Acute monotherapy** of manic or mixed episodes is licensed in adults and in patients aged 10 to 17. **Adjunctive treatment** to lithium or valproate is licensed in adults only, and so is **maintenance monotherapy**. The paediatric band sits on one of the three and not on the other two, so an answer that calls the drug licensed in adolescents without saying for what has widened a licence by omission.

RULE **A regulatory sentence names four things or it is not one: the jurisdiction, the exact indication in the record's own words, the authoritative source, and the date the status was true.** On this agent the fourth field alone splits: the American row was read on 3 August 2026, the European and Indian rows on 1 August 2026. Copying one reading date onto the others is the same error as copying an indication across a border.

14.2 The row that blended three products, and how it was caught

The most transferable thing about this item is not the drug; it is the way its record went wrong. The first American row was built by querying the regulator's interface on the generic name, returning five applications, three of them abbreviated applications for generic products, and a set spanning SAPHRIS, SECUADO and generics. A falsification pass rejected it on two instruments. The earliest date across a mixed set is not a first approval date but the earliest among whatever the query returned; and a set spanning more than one product means the label and dates retrieved may describe different products.

What the repair found is worse than a wrong date. The row cited SECUADO, carried the date belonging to SAPHRIS, and published the sublingual bipolar text that SECUADO does not carry: citation, date and indication text each pointed at a different application. Nothing in its appearance signalled that. It now holds the innovator with its own matching date. The repair instruction is the method: query per application rather than per generic name, paginate to

exhaustion, and write one row per application with its own sponsor, brand, approval date and label, never merging applications into an agent-level row.

The row was then tested rather than trusted. Three text instruments were run against the primary label: that the row text is verbatim, that it is not the primary text cut short, and that the count of indications carried matches the document. All three passed, at 680 characters against 680 and one indication against one. It also carries a caution about itself: the interface is an agency-operated mirror of the approval database and the label archive rather than the application itself, and the wording is current label text as filed, which must never be carried across a jurisdiction.

PITFALL

Searching a regulator by drug name and reading the first date that comes back. A generic-name query returns innovator and generic applications together, and the earliest date in that heap belongs to whichever record happened to be earliest, not to the drug. For asenapine the heap held three generic applications out of five. Ask which application, then which product, then which date, in that order.

14.3 Route is what the indication is attached to

Asenapine is given sublingually because a swallowed tablet does not deliver a useful amount of drug; the pharmacokinetic reason, the dose and the timed post-dose instruction belong to the Mood disorders: pharmacotherapy notes. A sublingual tablet makes the patient part of the delivery system: the tablet has to be placed, left in position, and the interval afterwards kept, or the dose administered is not the dose prescribed. A transdermal system moves that burden onto an application site.

That is why a transdermal asenapine exists, and why the trade is not free. The route that removes the technique is the route with the narrower licence: adults with schizophrenia and nothing more, against a sublingual label that also carries bipolar I disorder. A patient with bipolar I mania who cannot manage a sublingual tablet cannot simply be moved to the patch.

One boundary must be stated. No trial-level evidence is held for this agent in this build: item 291 carries a status lane and no evidence lane, so nothing here names a pivotal trial, a sample size, an endpoint, an effect size or an adverse-event rate. The comparison above is of licences and not of efficacy.

14.4 The European Union: one product, one indication, not the American one

Europe holds one centrally authorised asenapine product: Sycrest, product number EMEA/H/C/001177, status Authorised, whose **marketing authorisation holder** is Organon N.V., with an initial European Union marketing authorisation, by European Commission decision, dated **1 September 2010** and a latest European Commission decision of 25 February 2026.

The indication, verbatim: Sycrest is indicated for the treatment of moderate to severe manic episodes associated with bipolar I disorder in adults. Read what is absent. No schizophrenia. No

paediatric age band. No adjunctive indication with lithium or valproate, and no maintenance indication. And a severity qualifier, moderate to severe, that the American text does not carry.

Where that sentence comes from is examinable in itself. Its authority is the **Summary of Product Characteristics**, Annex I section 4.1. The row originally took its indication from the agency's published medicines register, citing the assessment-report page as an independent second instrument; the register is a machine dump generated from those same pages, so the corroboration was circular and blind to the very failure it existed to catch. The register and that page now corroborate product identity and authorisation status only. When the eight grounded European rows here were re-read against the product characteristics, six differed and two were already verbatim; asenapine was one of the two. A row that turns out to be right is not a row that has been checked.

One limit travels with every European sentence here: this is an authorisation for the named product through the **centralised procedure**. It says nothing about other products containing the same active substance that may be authorised nationally through the decentralised or mutual-recognition procedures, which the register does not cover by construction. The defensible sentence is about Sycrest, not about asenapine everywhere in the Union.

TRAP **Writing the American bipolar indication into a European or an Indian answer.** The European authorisation carries moderate to severe manic episodes associated with bipolar I disorder in adults and nothing else. The Indian entry carries acute schizophrenia in adults and nothing else. Neither carries the American bipolar text. Each record is correct where it was issued and wrong where it was not, and the wrongness is invisible unless the regulator is named.

14.5 India: the one corroboration claim that survived checking

An Indian approval-list entry for asenapine was located, which makes this one of the few agents here whose Indian sentence is affirmative. The entry reads: For acute treatment of schizophrenia in adults only. Asenapine Maleate Sublingual Tablets 5mg/10mg. It sits at serial number 38 of a published CDSCO approval list, dated **7 April 2011**. Note that it names two strengths where the American sublingual product carries three.

Be exact about what that date is, because the field was corrected for saying otherwise. It is the figure printed in a column headed "Date of Issue", not "Date of Approval". The field previously claimed to quote a date of CDSCO approval as printed in the source, which asserts a label the document does not carry; it now names what is actually printed, while recording that the quantity is almost certainly the approval date, since these documents are titled lists of approved new drugs. A date is labelled with the name of the column it came out of.

This is also the only Indian row in the build whose corroboration claim survived checking. Two genuinely distinct CDSCO documents carry the entry with the identical date, verified by content hash; two other agents made the same claim and it did not survive, theirs being two snapshots of one list. Establishing it needed a rendered page rather than a text extraction. One of the two documents draws no vector rules at all, so every rule-based reader refuses it; it was read from the page rendered at 200 dots per inch, showing serial 38, its acute schizophrenia indication and the

date 07.04.11, and serial 39 dated 16.04.11 below. A neighbouring row with a different date is what tells you the reader did not drift a line.

One further control sits in those lists. Entries are tagged as an additional strength when they are strength extensions rather than new approvals, and the tag is used consistently: serials 35, 36, 37 and 41 around asenapine carry it, the asenapine entry does not. That is what makes this a located approval entry rather than a permission for another dose of something approved earlier. The same tag, read carelessly on another agent in this chapter, turned a confident Indian approval date into a retraction.

IN INDIA

Write it in this order, then stop. A CDSCO published approval-list entry for asenapine maleate sublingual tablets, 5 mg and 10 mg, was located; the indication it names is "For acute treatment of schizophrenia in adults only"; the date beside it is 7 April 2011 in a column headed "Date of Issue"; it is corroborated in two content-hash-distinct CDSCO documents; and the status was true as of 1 August 2026. Do not carry the American bipolar indication or the European manic-episode indication into that sentence. Note also the direction in which this instrument fails: no India row in this build asserts a categorical negative about a drug's Indian approval status, because the published approval-list corpus is demonstrably incomplete; each asserts instead that no CDSCO approval record was located, and names what was searched. Here the corpus did display the drug, so this row needs no such hedge.

14.6 The four records side by side

Four records, one molecule, four answers, each read on a stated date.

RECORD AND APPLICATION	PRODUCT, AS THE RECORD CARRIES IT	INDICATION, IN THE RECORD'S OWN WORDS	DATE, AND WHAT KIND OF DATE
United States, NDA022117	SAPHRIS, sublingual tablet, sponsor ABBVIE; 2.5 mg, 5 mg and 10 mg as base	Schizophrenia in adults; bipolar I disorder, acute monotherapy in adults and patients 10 to 17, adjunctive to lithium or valproate in adults, maintenance monotherapy in adults	13 August 2009, approval status on the original submission
United States, NDA212268	SECUADO, transdermal system, sponsor HISAMITSU; 3.8, 5.7 and 7.6 mg per 24 hours	The treatment of adults with schizophrenia	11 October 2019, approval status on the original submission
European Union, EMEA/H/C/001177	Sycrest, holder Organon N.V., status Authorised; no dosage form is carried by this row	The treatment of moderate to severe manic episodes associated with bipolar I disorder in adults	1 September 2010, initial European Union marketing authorisation by European Commission decision
India, CDSCO approval list, serial 38	Asenapine maleate sublingual tablets, 5 mg and 10 mg; no sponsor is carried by the entry	For acute treatment of schizophrenia in adults only	7 April 2011, printed in a column headed "Date of Issue"

680 of 680	3 of 5	2 of 2	9 of 9
CHARACTERS, US ROW AGAINST LABEL	GENERIC APPLICATIONS IN THE REJECTED SET	CDSCO DOCUMENTS CARRYING THE ENTRY	FALSIFICATION CELLS PASSED

Two things about that table are as examinable as its contents. Every one of the nine falsification cells for this agent, three text instruments across three jurisdictions, returned a pass, which is why the row is authorable at all. And the European and Indian rows each record that they were built only from their own regulator's sources, with no value from another jurisdiction consulted. Isolation is built into a record, not added afterwards by an author's promise.

TRAP **Merging the two American applications into one sentence about the drug.** It reads as the tidier answer and is a false one: it produces an agent licensed for bipolar I disorder by patch, which no record here supports. The blend has already happened once in this build's own ledger. If a stem gives you a route, answer within that route's application.

14.7 What a complete answer contains

Reduced to five sentences, the item is this.

- Two American applications, two products: a sublingual tablet carrying schizophrenia and a three-part bipolar I indication, and a transdermal system carrying adult schizophrenia alone.
- Route is not packaging; it is what the indication is fastened to, and moving a patient between routes can move them outside a licence.

- Europe authorises one product for moderate to severe manic episodes of bipolar I disorder in adults, a severity qualifier the American text does not carry.
- The located Indian entry is acute schizophrenia in adults only, dated from a column headed "Date of Issue", corroborated in two genuinely distinct documents.
- Every one of those sentences carries its jurisdiction, its indication in the record's own words, its source and the date it was read, and none of them travels.

GOOD TO REMEMBER

If the patient in front of you has bipolar I disorder and the asenapine available is the product the Indian approval entry describes, the indication being treated is not the indication that entry names. That is a decision to make and document deliberately, not one made by assuming that a licence seen in an American label follows the molecule across a border.

MNEMONIC

Application, Route, Regulator, Column

Application, because two exist here and for licensing purposes they are two drugs. Route, because it is what the indication is fastened to. Regulator, because every indication sentence belongs to one and travels nowhere. Column, because a date means what its column header says it means.

Two applications, three regulators, four indications, and not one of them may be moved to where it was not issued.

15 · Lurasidone: pharmacology, metabolic profile and indications

Lurasidone is the agent on which this chapter's central hazard lands twice, in opposite directions. Clinically it is chosen for what it does not do, and the small metabolic signal in its own label, not any novelty of mechanism, is why it is here. Evidentially it defined this chapter's grounding work: its American row published a generic manufacturer's approval date under a field name meaning first approval and was corrected only on 3 August 2026, while its Indian row is a declared gap that does not recover. Where lurasidone sits in the bipolar phase algorithm belongs to the Mood disorders: pharmacotherapy notes; what follows is the whole-agent profile.

15.1 The receptor profile, and the two absences that do the clinical work

The European Summary of Product Characteristics calls lurasidone a selective blocking agent of dopamine and monoamine effects, ATC code N05AE05, and prints its affinities: 0.994 nanomolar at the dopamine D2 receptor, 0.47 at 5-HT2A and 0.495 at 5-HT7, with partial agonism at 5-HT1A at 6.38 and blockade of the alpha-2C and alpha-2A adrenergic receptors at 10.8 and 40.7. The examinable line is what is missing: the same section records that **lurasidone does not bind to histaminergic or muscarinic receptors**.

The absent histamine binding is the usual explanation for the small weight signal and the absent muscarinic binding for the lack of anticholinergic burden, but that is an inference and should be

labelled as one: the document asserts no causal link, and it states no mechanism at all for the antidepressant effect commonly attributed to the **5-HT7 antagonism** and 5-HT1A partial agonism.

Two pharmacokinetic facts change prescribing. Lurasidone is **metabolised mainly via CYP3A4** and has an active metabolite, ID-14283, itself a CYP3A4 substrate, so parent and metabolite move together whenever the enzyme is pushed. Half-life is **20 to 40 hours** with steady state within 7 days, which makes a week the honest interval before judging a dose change. The European document also records 1.5-fold higher exposure in Asian than in Caucasian subjects in a population analysis, and its posology sets no adjustment for that: worth knowing here, and not a licensed instruction to dose lower.

15.2 The metabolic profile, and exactly what the comparison licenses

In the pooled placebo-controlled adult schizophrenia studies in the American label, mean weight change was **plus 0.43 kg on lurasidone against minus 0.02 kg on placebo**, and the proportion gaining 7 percent or more of body weight was 4.8 percent against 3.3 percent. Fasting glucose moved by no more than 2.6 milligrams per decilitre in any dose arm, and total cholesterol and triglycerides fell in every arm, placebo included.

The same section carries the figures that get misused. It reports, from two of the five studies, a weight change of plus 4.15 kg for olanzapine and plus 2.09 kg for quetiapine extended-release. The clinical studies section says why the arms were there: an **active-control arm was included to assess assay sensitivity**, to show the trial could detect a drug effect at all.

0.43	4.8	22.0	4.6
MEAN WEIGHT GAIN, KG, POOLED ADULT SCHIZOPHRENIA	PERCENT GAINING 7 PERCENT OR MORE	PERCENT WITH AKATHISIA AT 120 MG	MADRS POINTS OVER PLACEBO, MONOTHERAPY

TRAP **Quoting the olanzapine and quetiapine weight figures as a head-to-head metabolic result.** They come from arms included to assess assay sensitivity, in two of five studies, with no comparative hypothesis behind them. The defensible sentence is that lurasidone's own metabolic changes were small and that two active comparators in the same programme changed weight more, stated as what the label reports and not as a ranking it establishes. Note also its statement on duration: the effectiveness of the drug for more than 6 weeks has not been established in controlled studies, so a six-week metabolic comparison is not a maintenance claim either.

15.3 What the profile costs: akathisia, movement effects and prolactin

The American label publishes the price of that profile dose by dose. Akathisia and extrapyramidal symptoms were dose-related in the schizophrenia studies: akathisia in **5.6 percent at 20 mg, 10.7 at 40 mg, 12.3 at 80 mg and 22.0 at 120 mg** against 3.0 percent on placebo, with extrapyramidal symptoms rising over the same range from 5.6 to 22.0 percent. At 160 mg akathisia was reported by 7.4 percent, 9 of 121 patients, and the label states the dose relation only up to 120 mg. That cell rests on far fewer patients and licenses no claim that akathisia falls again at the top of the range.

Prolactin is the effect most often forgotten in an agent whose selling point is metabolic. Both documents record that **lurasidone elevates prolactin through dopamine D2 antagonism**, and the European text asks that patients be counselled on gynaecomastia, galactorrhoea, amenorrhoea and erectile dysfunction. In a young adult on long-term treatment it is the conversation that decides adherence.

PITFALL

Translating "metabolically favourable" into "well tolerated". Those are different axes and the same label carries both. The ward version is a patient started at a dose chosen for speed rather than tolerability, on an agent whose **akathisia rate** runs from 5.6 percent at the lowest arm to 22.0 percent at 120 mg, and then recorded as non-adherent when they stop.

15.4 Absorption is the prescription: food, CYP3A4 and two sets of numbers

In the European food-effect study mean Cmax rose approximately 2 to 3 times and AUC approximately 1.5 to 2 times with food compared with fasting; the American label puts the same phenomenon as an AUC increase of about 2-fold and a Cmax increase of about 3-fold, and attaches a threshold the European document omits: **take with food, at least 350 calories**. A patient taking the tablet on an empty stomach is not taking a low dose of lurasidone. They are taking an unpredictable one.

WHAT THE DOCUMENT SETS	UNITED STATES PRESCRIBING INFORMATION, LATUDA	EUROPEAN SUMMARY OF PRODUCT CHARACTERISTICS, LATUDA
Unit the doses are written in	lurasidone hydrochloride: 20, 40, 60, 80 and 120 mg tablets	lurasidone base: tablets of 18.5, 37 and 74 mg, doses stated up to 148 mg, conversion printed in the document
Food	with food, at least 350 calories	once daily together with a meal, no calorie figure
Schizophrenia in adults	start 40 mg, effective 40 to 160 mg, maximum 160 mg	start 37 mg, effective 37 to 148 mg, maximum 148 mg
Strong CYP3A4 inhibitor or inducer	contraindicated; ketoconazole and rifampin named	contraindicated; ketoconazole and rifampicin named
Moderate CYP3A4 inhibitor added	halve the dose; start 20 mg, maximum 80 mg	start 18.5 mg, maximum 74 mg

The European document states in its own words that lurasidone doses of 18.5, 37, 55.5 and 74 mg are equivalent to 20, 40, 60 and 80 of lurasidone hydrochloride, so the two columns are not a disagreement: one regulator writes the salt and the other the base. A candidate who reports a maximum of 148 mg in an American stem, or 160 mg in a European one, has carried a number across a border, which is this chapter's hazard in miniature. The magnitudes: ketoconazole raised lurasidone exposure 9-fold and the metabolite 6-fold; rifampicin lowered exposure 6-fold. Grapefruit juice is avoided in both documents.

GOOD TO REMEMBER

Carbamazepine, phenytoin and rifampicin are all on the contraindicated list, all three drugs a psychiatric patient may already be taking for a reason nobody mentions at referral. This is not a caution to manage with monitoring; both regulators write it as a contraindication. Read the whole chart, not the psychotropic column, and ask directly about anti-tubercular treatment.

15.5 Bipolar depression: the size of the effect and the edges of the claim

The American label establishes this indication on three placebo-controlled six-week studies, and the effect sizes are modest. As **monotherapy** in adults, 485 patients randomised to one of two flexible ranges, the placebo-subtracted change in Montgomery-Asberg Depression Rating Scale score at week six was **minus 4.6 points, confidence interval minus 6.9 to minus 2.3, for both dose ranges**, and the label states that the higher range of 80 to 120 mg did not provide additional efficacy on average compared with 20 to 60 mg. As **adjunctive therapy with lithium or valproate** in 340 patients who remained symptomatic, the difference was minus 3.6 points, minus 6.0 to minus 1.1.

Two boundaries are examined more often than the effect size. In the label's own words, the efficacy of the drug in the treatment of mania associated with bipolar disorder has not been established: this is a bipolar-depression agent, not a mood stabiliser across phases. And fewer than 1 percent of patients in both the drug and the placebo groups developed a manic or hypomanic episode, the figure to have ready when a stem asks about switch risk. Which patient should be offered this agent rather than another is the Mood disorders: pharmacotherapy notes' question, not this one.

The paediatric headline result is a placebo-subtracted 5.7 points on the Children's Depression Rating Scale, Revised, but the two regulators print different amounts of the same study: the European text records that the primary and key secondary endpoints were not met below 15 years of age, a placebo-adjusted minus 1.8 in 10 to 14 year olds against minus 8.6 in 15 to 17 year olds, and no such age split appears anywhere in the cached American label. The regulator that authorised the paediatric indication printed less of the age detail than the one that did not, so an answer that cites only the pooled figure has taken the more permissive reading without saying so.

RULE **For lurasidone the dose that helps and the dose that harms move in opposite directions, and the label says so in two places.** The higher bipolar-depression range gave no additional efficacy on average over the lower one, while akathisia and extrapyramidal symptoms rose with dose across the schizophrenia range. Escalating because a patient has not yet responded buys a documented rise in movement adverse effects against an effect the manufacturer's own study did not find. Wait the week steady state takes before concluding a dose is too low.

15.6 Three regulators, three different sentences, one that cannot be written

The most examinable fact about this agent is that its indication is not the same in two jurisdictions and is not established from any record located in a third. The American label indicates it for schizophrenia in adult and adolescent patients aged 13 to 17, for bipolar depression as monotherapy in adult and paediatric patients aged 10 to 17, and for bipolar

depression as adjunctive treatment with lithium or valproate in adults. Section 4.1 of the European Summary of Product Characteristics authorises exactly one indication, the treatment of schizophrenia in adults and adolescent aged 13 years and over. That count is measured: the multiplicity instrument found one indication in the European primary document and one carried on the row, and the truncation instrument compared the row's 103 characters against the document's 103.

JURISDICTION	WHAT THE RECORD ESTABLISHES	AUTHORITY READ	STATUS TRUE AS OF
United States	First approval 28 October 2010: application NDA200603, brand LATUDA, original submission 1, status AP, sponsor Sunovion. The only new drug application among 21 applications for this ingredient; the other 20 are abbreviated applications	Drugs@FDA and the label archive via openFDA; the retrieved label's own application-number field reads exactly NDA200603	3 August 2026
European Union	Authorised. Initial marketing authorisation by European Commission decision on 21 March 2014, product number EMEA/H/C/002713. The register's latest Commission decision here is dated 6 May 2026 and the record does not say what it decided	Annex I section 4.1 of the Summary of Product Characteristics for the indication; the EMA register and the EPAR page for identity and status	1 August 2026, indication re-read 2 August 2026
India	No CDSCO record of a first Indian approval of lurasidone was located. What was located is a strength extension. No approval date is printable in this row	CDSCO published new-drug approval lists, 66 distinct documents, every one with an extractable text layer	2 August 2026

The European row was itself repaired on 2 August 2026: the ledger had carried the indication as adults aged 18 years and over, taken from the EMA register while citing the EPAR page as an independent check, and the register is generated from those same pages, so the corroboration was circular. And the 2026 date is not an authorisation date: that column carries the latest Commission decision, proven on this very medicine, where it reads 2026 against a 2014 authorisation. The row is also bounded by procedure: it establishes a centralised European authorisation for the named product and says nothing about products of the same substance authorised nationally, which the register does not cover by construction.

15.7 The row that was wrong, and how a generic's date wore a first approval's name

Until 3 August 2026 the American lurasidone row was false in four ways at once, each a mistake anyone can make with the same public database. Its citation listed ten abbreviated applications and no new drug application at all. Its date was 3 January 2019, a generic manufacturer's approval date, held under a field name meaning first approval, against a true first approval of 28 October 2010, an error of more than eight years. Its indication text was the label of a generic lurasidone hydrochloride tablet and not of LATUDA. And that text had been cut at 900 characters by a fixed-width slice in the grounding script.

The application endpoint paginates at whatever limit is passed, which cut the result set to ten abbreviated applications with the innovator's application absent, and the label endpoint returns a single label for a generic-name query with no guarantee that it is the innovator's. Nothing in the returned text announced the substitution, because **a generic's indication section is a near-copy of the innovator's**. Reading the indication text could never have caught it. What did was checking, for every retrieved label, whether the application number the record itself carries matched the application cited. The repaired row now passes all three falsification instruments, the truncation check reporting 974 characters on the row against 974 in the primary document; the Indian row is exempt from all three, because a declared gap carries no indication text and is a claim about a search rather than about a product.

15.8 India: a declared gap, what it rests on, and what would close it

The Indian position is a gap that is a finding rather than an absence of work. Serial number 65 of the list of drugs approved from the SND Division from 01.01.2020 to 31.12.2020 reads, in its drug-name column, "Lurasidone Hydrochloride Tablets 20mg" followed by the qualifier " (Additional Strength)", with the indication "For treatment of patients with Schizophrenia" and a date of approval of 24-12-2020. The qualifier is the entire finding. An additional-strength permission records the extension of a permission that already exists, and therefore entails a prior CDSCO approval of lurasidone at some other strength, while no such earlier entry exists anywhere in the 66-document corpus. The only date this corpus offers records a strength extension, and it must never appear in a table of approval dates. Nor can the silence be read the other way, as evidence that the extension was itself the first permission, because the source document proves an earlier one exists outside the corpus. The row was demoted from grounded on 2 August 2026 and does not recover on further retrieval of this corpus.

TRAP **Writing a categorical negative about Indian approval.** No instrument used here supports a categorical negative, and the search behind the gap is measurably incomplete: independent sensitivity in the 2024 to 2026 window is zero of one, and CDSCO's own committee minutes of 16 April 2025 record a lumateperone approval dated 26 December 2024 that appears in none of the 66 lists, although the list declaring coverage of that whole calendar year carries an entry dated 30 December 2024. Absence from this corpus is evidence, and never proof. The correct sentence names the search: no CDSCO record of a first Indian approval was located across 66 published approval lists.

IN INDIA

What would close the gap is named on the row and nothing else will do: an affirmative CDSCO or DCGI permission, a current CDSCO-approved label, or an official approval-list entry recording a first approval at any strength. Subject expert committee minutes, clinical-trial no-objection certificates, CTRI registration, brand listings, pharmacy availability and manufacturer copy are none of them marketing authorisation. That last list catches people: a resident meets lurasidone as a strip in a pharmacy long before meeting it in any gazette, and availability feels like proof. Write the search rather than the impression, and where a unit already prescribes the drug, the document it should produce is the approved label it prescribes against.

Reduced to four sentences, the agent is answerable in whatever form the question takes.

- It is chosen for the metabolic profile and paid for in akathisia, and the two are dose-related in opposite directions.
- Food is not optional: one label sets a calorie threshold, the other does not, and both make the dose meaningless without a meal.
- CYP3A4 is the interaction axis, and strong inhibitors and inducers are contraindications rather than cautions.
- The indication set is American and broad, European and narrow, and Indian and not established from any record located.

MNEMONIC

Food, Enzyme, Dose, Salt

The four things that go wrong with lurasidone: given without a meal, given with a strong CYP3A4 inhibitor or inducer, escalated past the dose its own evidence supports, and its milligrams quoted from the wrong regulator's arithmetic.

Lurasidone's dose, its indication and its approval date each mean something different in each of the three jurisdictions, and the Indian date is the one no document read here contains.

16 · Brexpiprazole: pharmacology and indications

This is the agent on which a candidate is likeliest to write a true sentence about the wrong country. Brexpiprazole is a dopamine partial agonist whose licensed scope differs at every border read for this chapter: three indications in one jurisdiction, one in each of the other two. The marks separate on pharmacology, on jurisdiction, and on the comparison with cariprazine. Its position in the depression-augmentation ladder, beside lithium, thyroid hormone and the other atypical agents, belongs to the Mood disorders: pharmacotherapy notes.

16.1 Partial agonism is a claim about intrinsic activity

The word carrying this agent is **partial agonist**, and it states **intrinsic activity** rather than affinity. A partial agonist binds the receptor and produces a submaximal response, so what it does

depends on the tone it meets. Where dopamine transmission is high it competes with the endogenous full agonist and lowers signalling; where transmission is low it supplies a floor of activity instead of removing the little that was there. That asymmetry is the rationale of the class: damp the mesolimbic excess without emptying the nigrostriatal and tuberoinfundibular pathways to the same degree.

Two consequences follow. The burdens of full D2 blockade, extrapyramidal signs and prolactin elevation, are expected to be lighter rather than absent, because partial agonism reduces the depth of blockade and does not abolish it. And the class carries a signature adverse effect of its own rather than the antagonists': activation, inner restlessness and **akathisia**, which is residual agonist drive at D2 seen at the bedside. A candidate who writes that partial agonists are simply better tolerated has stated the first and lost the second.

16.2 Where brexpiprazole sits between aripiprazole and cariprazine

Hold brexpiprazole as a deliberate re-engineering of aripiprazole rather than a new idea: a partial agonist at D2 and at 5-HT1A and an antagonist at 5-HT2A, carrying lower intrinsic activity at D2 than aripiprazole and weighted more heavily toward its serotonergic and alpha-adrenoceptor arms. The proprietary class phrase attached to it, serotonin-dopamine activity modulator, is manufacturer language and not a regulatory category; describe the profile and leave the phrase alone.

The re-engineering exists for a clinical trade, and the trade is the answer: less of the activation and akathisia that limit aripiprazole, paid for with more sedation and more weight gain, because the serotonergic and adrenergic arms do more of the work. Hold that as a direction and not a magnitude: no head-to-head figure is printed here, because no source read for this fragment carries one, and a remembered effect size is worth less than a correctly stated direction.

Cariprazine separates from both on two features: it is D3-preferring at clinically relevant occupancy rather than merely D3-active, and it carries a long-acting active metabolite, so its offset after a dose change is far slower than the parent compound suggests. An adverse effect does not resolve on the timescale a resident expects, and a titration decision expresses itself over weeks. Brexpiprazole carries no comparable metabolite story, which is why examiners ask about the two together.

RULE **The mechanism is shared, the profile is not, and the licence is neither.** Three layers travel with a partial agonist: what it does at the receptor, what that costs the patient, and what a named regulator has permitted in a named jurisdiction on a named date. Each layer is sourced in its own right, and a sentence that slides from one to the next has stopped being checkable.

16.3 The United States licence, read whole, including the limitation

The American label is the widest of the three. It carries adjunctive treatment to antidepressants for major depressive disorder in adults; treatment of schizophrenia in adults and pediatric patients ages 13 years and older; and treatment of agitation associated with dementia due to Alzheimer's disease. Three indications, three populations, one molecule.

Then the clause a truncated reading loses. The label attaches a **Limitation of Use**: REXULTI is not indicated as an as needed, "prn", treatment for agitation associated with dementia due to Alzheimer's disease. Read what that limits. It does not withdraw the dementia-agitation indication; it forbids the way a busy ward is most tempted to use it, as a rescue dose written up in advance. The licensed use is scheduled treatment of a syndrome, not a chemical response to an incident.

The status was read from the openFDA structured product label archive, brand REXULTI, label effective 6 May 2026, whose application-number field returns NDA205422, the only new drug application among 17 applications for this active ingredient, the other 16 being abbreviated applications. First approval is recorded as NDA205422, sponsor Otsuka, original submission 1 carrying an approved status dated **10 July 2015**, and the reading was status true as of 3 August 2026. Jurisdiction, indication in the source's words, named application, dated reading: four fields, and an answer missing any of them is an assertion rather than a record.

TRAP **Quoting the three American indications as though they were the drug's indications.** They belong to one label in one country; the other two jurisdictions read here each carry exactly one. The failure is not ignorance of the other licences; it is the silent generalisation, writing "brexpiprazole is indicated for agitation in Alzheimer's disease" with no country attached. The label text is the current wording as filed with one regulator, and it is not a statement about any other jurisdiction and must never be carried across one. Attach the country to every indication sentence and the trap cannot close.

16.4 Europe: the same molecule, one indication

The European licence is narrower, and short enough to memorise. Section 4.1 of the Summary of Product Characteristics reads that RXULTI is indicated for the treatment of schizophrenia in adults and adolescents aged 13 years and older, and the falsification pass counted one indication in that section against one on the row. No adjunctive-depression indication appears in it. The sentence to write is that the European authorisation read here covers schizophrenia and names nothing else, which is a statement about a document rather than a claim about what exists elsewhere.

The identity fields matter as much as the text. The product is Rxulti, European Medicines Agency product number EMEA/H/C/003841, with Otsuka Pharmaceutical Netherlands B.V. as **marketing authorisation holder**, medicine status Authorised; the initial European marketing authorisation, by European Commission decision, is dated **26 July 2018**, and the most recent Commission decision on it is dated 9 July 2026. The reading was true as of 1 August 2026.

Two disciplines sit behind that paragraph. The first is which document is the authority: the indication text is taken from Annex I section 4.1 of the product information, because the agency's published medicines register is a machine dump generated from the same assessment-report pages and cannot corroborate them independently. Two views of one source are one source. The second is scope. An entry in that register establishes authorisation for the named product through the **centralised procedure**, and says nothing about other products containing the same

active substance that may be authorised nationally through decentralised or mutual-recognition routes, which the register does not cover by construction.

16.5 India: the row whose column header genuinely says approval

The Indian entry is the recent one, and it is the one an Indian examination cares about. The Central Drugs Standard Control Organisation entry read here states that brexpiprazole is indicated for treatment of schizophrenia, as brexpiprazole tablets **0.25, 0.5, 1, 2, 3 and 4 mg**. Those are permitted strengths and not a dose recommendation; no prescribing dose for this agent is printed here, because no source read for this fragment carries one, and the augmentation dose belongs with the ladder in the Mood disorders: pharmacotherapy notes.

The date and its label are the transferable part. The entry is dated **16 February 2026**, printed in a column headed **Date of Approval**, which makes this the only grounded Indian row in the chapter whose source header genuinely says approval rather than issue. Elsewhere the honest field name is the printed one: a date under a column headed date of issue must not be relabelled a date of approval by whoever quotes it. The provenance is entry serial number 1 in the list of new drugs approved in the year 2026 to date, within a corpus of 66 distinct published approval documents, with a separate bulk-drug permission for the substance dated 24 February 2026.

How strong is that row? Stronger than most. Its corroboration is one running list captured in two snapshots and not two distinct documents, a description corrected on 2 August 2026 from the stronger claim; being about five months old at retrieval it is the most recency-sensitive row in the Indian column, so it was re-fetched live and the source list came back byte-identical, which is the best evidence this row has. Two snapshots of one list is weaker corroboration than two independent documents, and saying so is what makes the row trustworthy rather than what weakens it.

TRAP **Turning a located approval into a categorical negative.** The Indian entry names schizophrenia, and the temptation is to write that brexpiprazole is not approved in India for anything else. Do not write that; nothing here supports it. The published approval-list corpus is demonstrably incomplete, so an absence in it is evidence and never proof, and the defensible sentence names what was located and what was searched. The mirror error runs the other way: a brand listing, a pharmacy shelf or a manufacturer's page is not a regulatory approval and must never be quoted as one.

IN INDIA

Write it in this order. A CDSCO new-drug approval record for brexpiprazole was located, dated 16 February 2026, under a column headed Date of Approval, naming schizophrenia and six tablet strengths, with a separate bulk-drug permission a week later. That entry establishes what it says and nothing wider, and it is not an availability or a price claim, neither of which any source read here establishes. For a patient or a family: an approval on a national list is not the same as a drug on the nearest shelf at a price the household can meet, and that has to be checked locally.

16.6 Adjunctive depression, and the comparison with cariprazine

This is where the agent earns its place, and where the cariprazine comparison stops being trivia. In the United States both drugs carry it: brexpiprazole's label reads adjunctive treatment to antidepressants for major depressive disorder in adults, and cariprazine's reads **adjunctive therapy to antidepressants** for the treatment of major depressive disorder in adults. Two dopamine partial agonists, one indication, so the choice between them is made on profile rather than on licence.

Cross the Atlantic and the symmetry breaks. The European product information for RXULTI names schizophrenia in adults and adolescents aged 13 years and older, and cariprazine's names the treatment of schizophrenia in adult patients. Neither European licence read here carries the adjunctive-depression indication, and brexpiprazole's is the one extending below adult age. An answer that reproduces the American adjunctive indication for a European or Indian patient has made the commonest error on this topic.

3	1	1 of 17	9 of 9
INDICATIONS, UNITED STATES LABEL	INDICATIONS, EUROPEAN SECTION 4.1	US APPLICATIONS THAT ARE AN NDA	FALSIFICATION CELLS PASSED

JURISDICTION	INDICATION, IN THE SOURCE'S WORDS	SOURCE AND DATE
United States	Adjunctive treatment to antidepressants for major depressive disorder in adults; schizophrenia in adults and pediatric patients ages 13 years and older; agitation associated with dementia due to Alzheimer's disease, plus a Limitation of Use against as-needed dosing for the dementia indication	Structured product label, application NDA205422, effective 6 May 2026; true as of 3 August 2026
European Union	The treatment of schizophrenia in adults and adolescents aged 13 years and older	Product information Annex I section 4.1, EMEA/H/C/003841; true as of 1 August 2026
India	Treatment of schizophrenia, tablets 0.25, 0.5, 1, 2, 3 and 4 mg	CDSCO published approval list, entry 1, 2026 list; true as of 1 August 2026

16.7 How a status sentence is checked, and the defect on this very row

This row was tested rather than trusted. Three text instruments were run against the primary document for each of the three jurisdictions and all nine cells passed: that the row text is verbatim from and attributed to the primary document; that it is not the primary text cut short; and that the count of indications carried matches the count in the document. The American cell measured 985 characters against 985 and five indications against five, the European 105 against 105 and one against one, and the Indian cell was carried in full. The Indian cell was located

geometrically, at entry 1 on page 1 within a named indication column, with two independent readers agreeing with the drawn table rules.

Now the defect this row carried, because its shape is the lesson. Until 3 August 2026 the American entry cited an abbreviated application, a generic's application, ahead of the innovator NDA205422, and its indication text had been truncated at 900 characters in mid-word by the script that built it. The date was never wrong. Sit with that. A right number under a wrong citation is more dangerous than a wrong number, because nothing about it looks incorrect and every downstream reader inherits a claim its stated evidence does not support. The check that catches it is not a check on the number: it asks whether the cited document could have established the fact, and an **abbreviated application** is a copy of an innovator's licence, never the origin of a first approval.

PITFALL

Completing a sentence that stops in the wrong place. The truncation above cut a label mid-word; its sibling defect cuts text so that it ends in a clean full stop the source never had, and nothing on the page then signals the loss. Both are invisible to a reader willing to finish the sentence from memory. When a quoted indication reads as though a clause is missing, say so and go back to the primary document. Every repair in this chapter's American column began with someone refusing to fill a gap and saying it aloud.

16.8 What a complete answer contains

Reduced to five moves, the item is answerable in any form.

- State partial agonism as intrinsic activity, then what it buys, lighter blockade burden, and what it costs, activation and akathisia.
- Separate the three partial agonists by discriminator: intrinsic activity at D2, the serotonergic weighting, and the long active metabolite that is cariprazine's and not brexpiprazole's.
- Attach a country, a source and a date to every indication sentence, and never carry one across a border in either direction.
- Quote the American limitation on as-needed use for dementia agitation, the clause most often lost and the one that changes ward practice.
- State an Indian record as what was located and where, name the printed column header, and refuse the categorical negative no instrument here supports.

GOOD TO REMEMBER

The commonest real-world error here is not choosing the wrong partial agonist. It is writing a rescue prescription for agitation in dementia against a licence that specifically excludes as-needed use, and then defending it with an indication that does exist. The indication and the manner of use are two separate permissions, and the second is where this label draws its line.

MNEMONIC

Tone, Trade, Territory

Tone: partial agonism acts on what the receptor is already seeing. Trade: less activation, more sedation and weight. Territory: three indications in one country, one in each of the other two, each with its own source and date. An indication sentence with no territory in it is not yet an answer.

Partial agonism is intrinsic activity, the trade is akathisia against weight, and no indication is true until a country, a source and a date are attached to it.

17 · Cariprazine: pharmacology and indications

One molecule, three national records, and four, one and two indications. The pharmacological question is what a D3-preferring partial agonist does that a full antagonist cannot, and what a long-lived active metabolite does to every decision after a dose change. The regulatory question is why it carries four licensed indications in one jurisdiction, one in the second and two in the third, all three grounded and each read on its own day. Marks are lost in three places: candidates upgrade a receptor rationale into a licensed claim, they reason about dose changes on a timescale this drug does not obey, and they carry the bipolar-depression indication across a border where no record read here places it. Phase matching, mixed states and where this agent sits in a bipolar algorithm belong to the Mood disorders: pharmacotherapy notes and are not rebuilt here.

17.1 Partial agonism, and the D3 preference that is the design claim

Begin with what the regulator wrote. The current United States label calls the product an atypical antipsychotic and names no receptor and no subtype. Every receptor sentence below is therefore class pharmacology taught as rationale, carried by no claim row in this build, and must never be written as though a regulator endorsed it.

A **partial agonist** occupies the receptor but produces a submaximal response even at full occupancy, and its intrinsic activity decides the net effect: at high dopamine tone it replaces a stronger signal with a weaker one and behaves as an antagonist, at low tone it supplies signal and behaves as an agonist. That is why marked prolactin elevation is not the expected consequence of adequate occupancy, and why the characteristic adverse effects are activating rather than sedating. It also explains a prescribing hazard: adding a partial agonist to a full antagonist is not additive blockade, because the newcomer competes for occupied receptors and substitutes its weaker signal, so a stable patient can destabilise during cross-titration.

The D3 claim distinguishes this agent from the other dopamine partial agonists here, and is most often overstated. Cariprazine is **D3-preferring**: in laboratory binding work its affinity for D3 exceeds that for D2, and D3 receptors sit in limbic territory tied to motivation and reward, hence the rationale in negative and anhedonic presentations. Two cautions belong beside it. Affinity in vitro need not become preferential occupancy in a living brain, where endogenous dopamine itself binds D3 far more potently than D2. And a rationale is not an outcome: no trial-level

evidence lane exists for this agent in this build, so no negative-symptom result, effect size or comparator is printed here.

RULE **A receptor preference is a hypothesis about mechanism; an indication is a sentence a regulator wrote.** They carry entirely different warrants. Write the pharmacology as rationale, write the indication in the regulator's own words with jurisdiction, source and date attached, and never let the first widen the second.

17.2 The long metabolite, and why this drug's clock runs in weeks

Cariprazine is metabolised to two **active metabolite** species, and the didesmethyl form is eliminated far more slowly than the parent. The relevant quantity is therefore the total active moiety, which accumulates towards steady state over weeks, not the two or three days a clinician's reflex assumes. No half-life figure is printed, because no claim row in this build carries one and a number written from memory is the defect this chapter exists to teach against. The shape of the curve is the examinable part.

Four consequences follow, each a clinical decision rather than a pharmacokinetic fact. A dose increase judged at one week is judged too early, its plasma consequence still rising. A reduction made for an adverse effect will not relieve it promptly, so a clinician seeing no change within days is tempted into a second reduction that compounds the first. Discontinuation does not produce a drug-free patient on the timescale the chart implies, which matters for a planned switch, for pregnancy planning, and for a new adverse effect a fortnight after stopping. And washout arithmetic learned on a short-acting agent gives the wrong answer.

GOOD TO REMEMBER

Write the review interval to the drug's clock rather than the clinic's. Where the active moiety is still accumulating, an unchanged picture at one week is not treatment failure and a new adverse effect at six weeks is not a new drug. Make one change and wait longer than feels natural: the commonest error is a rapid sequence of adjustments that leaves the eventual picture uninterpretable.

17.3 What the mechanism predicts, and the figures this build does not hold

The adverse-effect profile is predictable from partial agonism. Activating effects dominate: **akathisia** is the signature, restlessness and insomnia accompany it, both dose-related. Other extrapyramidal features occur but do not lead, and nausea and dyspepsia are common early. Because adequate occupancy is reached without complete blockade, marked prolactin elevation is not expected, and the metabolic burden is described as modest rather than absent.

Akathisia is where the two sections above meet: most likely to bring a patient back, most likely to be misread as agitation belonging to the illness, slowest to answer a dose reduction because of the long active moiety. A patient told the restlessness will settle in a day or two has been given a promise the pharmacokinetics cannot keep.

Now the boundary. Every sentence in this section is receptor-level and class-level reasoning. No adverse-event rate, no comparative metabolic figure, no weight-change number and no

comparative akathisia incidence is held in this build for this agent, because no evidence lane was grounded and the retrieved label section covers indications only.

PITFALL

Quoting a comparative metabolic or akathisia figure from memory. It sounds like something a monograph carries, which is why the fabricated version passes unnoticed. Two defensible sentences exist: the mechanism predicts an activating rather than a metabolic profile, and the size of that difference is a question for a named trial. Supplying a percentage turns a plausible expectation into a fabricated result.

17.4 The United States record, read field by field

This row carries the widest indication set, so it is the one material leaks from. The label indicates the product for the Treatment of schizophrenia in adults and pediatric patients 13 years of age and older; for Acute treatment of manic or mixed episodes associated with bipolar I disorder in adults and pediatric patients 10 years of age and older; for Treatment of depressive episodes associated with bipolar I disorder (bipolar depression) in adults; and as Adjunctive therapy to antidepressants for the treatment of major depressive disorder (MDD) in adults. Four indications, two reaching below adulthood at different ages, the third the bipolar-depression licence distinguishing this agent among the dopamine partial agonists.

The source is named and narrow: the openFDA Drugs@FDA interface, application NDA204370, brand VRAYLAR, sponsor AbbVie, with the current label effective 18 December 2025. The document is a **structured product label**, and the status true as of date on this row is 3 August 2026. The row cautions about its own instrument: openFDA is an agency-operated mirror of Drugs@FDA and the label archive rather than the Drugs@FDA application itself, and the indication wording is current label text as filed, which is not a statement about any other jurisdiction and must never be carried across one.

Then the date field, where this ledger has been burned. The earliest approval-status date in the record is **17 September 2015**, named for what it holds, not what a reader wants it to mean. It also shows a single application returned for this agent, thirteen approval-status submissions within it, and the most recent dated 18 December 2025, the label date quoted above. Whether the earliest of thirteen is a first marketing approval, the record does not say; elsewhere in this build a generic's approval date was published under a first-approval field name and retracted.

4	1 of 1	1125 of 1125	13
INDICATIONS ON THE CURRENT US LABEL	APPLICATIONS RETURNED FOR THIS AGENT	CHARACTERS, ROW AGAINST PRIMARY	APPROVAL-STATUS SUBMISSIONS IN THE RECORD

This row was tested, not trusted, and it had a real defect. Until 3 August 2026 its indication text was cut at 900 characters, mid-word, by a fixed slice in the grounding script that left no marker; the cited application was correct throughout, so the row was truncated only and never misattributed. The repaired row then passed three instruments against the primary document: the row text is verbatim, it is not the primary text cut short, at 1125 characters against 1125, and

the count of indications carried matches the count in the document at five against five. That last figure is its parse of a label printing the list twice, in the numbered section and the highlights summary; the teaching is that the counts agree, not that five things are licensed.

17.5 The European Union: one indication, and a corroboration that was circular

The European record is grounded and narrow. The authorised indication, in full: Reagila is indicated for the treatment of schizophrenia in adult patients. One indication, adults only, nothing on mania, bipolar depression or adjunctive use. The instrument: Annex I Summary of Product Characteristics, section 4.1 Therapeutic indications, read from the cached product information and re-read verbatim on 2 August 2026.

Product identity and status come from a separate place and corroborate identity only: the agency medicines register lists Reagila, product number EMEA/H/C/002770, status Authorised, and an independent recheck of the assessment-report page returned the same product number, status and authorisation date. The **marketing authorisation holder** is Gedeon Richter. The initial marketing authorisation, a European Commission decision, is dated **13 July 2017**; the most recent Commission decision on the file is dated 8 January 2026.

One correction here is worth more than the dates above. The indication was originally taken from the medicines register, with the assessment-report page cited as an independent second instrument. The register is generated from those same pages, so the corroboration was circular and blind to the very failure it was meant to catch, a stale summary layer. Section 4.1 of the annex is the genuinely independent instrument and is now the authority for indication text. Two renderings of one source are one source; citing a summary and its own summary as agreement checks nothing.

The scope limit travels with it. This establishes marketing authorisation for the named product through the European Union **centralised procedure**, and says nothing about other products containing the same active substance that may be authorised nationally through the decentralised or mutual-recognition procedures, which this register does not cover by construction.

17.6 India: the located CDSCO entry, and the two indications it carries

The Indian row is the one an Indian examination cares about, and here it is affirmative rather than absent. A CDSCO published approval list carries the entry, whose cell reads whole: For the treatment of Schizophrenia in adults. Acute treatment of manic or mixed episodes associated with bipolar I disorder in adults. Cariprazine hydrochloride bulk and Cariprazine capsules 1.5mg/3mg/4.5mg and 6mg. Two indications, both adult, and a product cell naming the **bulk drug** and the capsules at **1.5mg/3mg/4.5mg and 6mg**. Those strengths are a formulation fact from a name cell, not a dose; no dose, titration or schedule for this agent is held in this build.

The locator is exact, the date precisely labelled. The entry is serial number 15 in the 2021 CDSCO approval list, one document in the 66-document published corpus retrieved on 1 August 2026, and the date carried is **16 July 2021**. It is not called an approval date, and the reason is instructive: the field records the date printed in the column headed **Date of issue**, after an earlier version claimed to quote a label the document does not carry. It is almost certainly the approval

date, these being titled lists of approved new drugs, but the field now names what is printed. Corroboration is one CDSCO document, the date confirmed against the raw column layout rather than the flattened text line.

Now the discipline governing what the entry omits. It names schizophrenia and acute manic or mixed episodes, and neither bipolar depression nor adjunctive use in major depressive disorder. That is a statement about the record, not the country. The published approval-list corpus is demonstrably incomplete: every drug it is known to find sits in a document dated 2023 or earlier, its measured sensitivity in the 2024 to 2026 window is nil, and its positive-control tally may not warrant a gap on any agent approved after 2023. No India row in this build asserts that a drug is not approved in India; each asserts that no CDSCO approval record was located, and names what was searched. The same restraint applies to an indication absent from a located entry.

IN INDIA

Write it in this order. A CDSCO approval entry for cariprazine was located, dated 16 July 2021 under the printed heading Date of issue, covering the bulk drug and four capsule strengths, with two adult indications: schizophrenia, and acute manic or mixed episodes of bipolar I disorder. It carries no bipolar-depression indication, a statement about the retrieved record and not about Indian practice. Do not write that any use is unapproved in India: the corpus that would have to be complete for that sentence to be safe is demonstrably not.

TRAP **Carrying the bipolar-depression indication across a border.** It belongs to one record only: the American label carries it, the European annex carries schizophrenia in adults alone, the Indian entry schizophrenia and acute mania. Writing that cariprazine is indicated for bipolar depression, without naming the jurisdiction, is true in one place, unsupported in the second and beyond the located record in the third. The paediatric ages travel no better: 13 and 10 years are American label figures appearing in neither other record.

17.7 How that Indian cell was certified, and what a certified cell is

The entry sits in a scanned document, so reading a cell out of it is an extraction problem before a clinical one. Of three geometric readers in this build, two could not be used here: one refuses the merged block spanning serial numbers 14 and 15, the other is refused across the whole document because its declared page-level invariant is falsified there. The cell was certified instead by agreement between the reader working from the drawn table rules and one rendering the page as pixels and reading it by eye. Two readers of genuinely different kinds agreeing is what certification means; two text readers agreeing is one reading counted twice.

Certification earned its cost at once. The moment the cell became certifiable, the completeness instrument failed the row: the published text had dropped the bulk-drug leg of the name cell, which reads Cariprazine hydrochloride bulk and Cariprazine capsules. A comparable entry on another agent in this chapter retains its bulk leg, so the loss was an inconsistency rather than policy, and the leg is restored. Repaired, the three instruments pass against a locator giving document, page, serial number and the pixel bounds of the indication column and row band: the

text is verbatim, it is not the primary cut short, at 215 characters against 215, and the 133-character indication cell is carried in full.

The lesson is the order of events: the defect was invisible while the cell was unreadable and appeared in the hour it became readable. An unaudited row is not a clean row, and defect counts rise when the instrument starts working.

17.8 The three records side by side, and what a complete answer contains

Three regulators, three reading dates, three indication sets.

JURISDICTION	WHAT THE RECORD HOLDS	THE SENTENCE THAT MAY BE WRITTEN	THE SENTENCE THAT MAY NOT
United States	Four label indications: schizophrenia from 13 years, acute mania or mixed episodes from 10 years, bipolar depression in adults, adjunctive therapy in major depressive disorder in adults, NDA204370, label effective 18 December 2025, read 3 August 2026	Each indication whole, with application, label date and reading date	Any wider indication, and the earliest date called a first approval
European Union	One authorised indication, schizophrenia in adult patients, from section 4.1 of the annex; authorised centrally from 13 July 2017	The indication verbatim, with the centralised-procedure scope limit	Any American indication transferred, and any claim about national authorisations this register cannot see
India	A located CDSCO entry carrying two adult indications, the bulk drug and four capsule strengths, serial number 15, dated 16 July 2021 under the heading Date of issue	The entry whole, with its serial number, document and the heading its date came from	Any negative inference from what it omits, and approval substituted for the printed heading

Reduced to five sentences:

- Partial agonism explains the shape of benefit and harm: submaximal signal at high tone, supplied signal at low tone, an activating adverse-effect profile.
- The D3 preference is a laboratory affinity ranking offered as rationale for negative and anhedonic presentations, neither outcome nor licensed claim.
- The long-lived active metabolite moves every clinical timescale outward: dose changes judged late, adverse effects resolving slowly, stopping that is not clearing.
- The indication set differs by jurisdiction and the bipolar-depression licence sits in one record, so no status sentence may be written without its jurisdiction, source and date.

- What a record omits is a fact about that record, and on the Indian corpus it cannot be converted into a statement about the country.

MNEMONIC

Preference, Persistence, Place

Preference is the D3 story, a binding ranking offered as rationale and never as licence. Persistence is the long active moiety: accumulation, delayed judgment, slow offset. Place is the jurisdiction every indication sentence must name and never leave, and why four, one and two are all correct answers here.

The receptor preference is a rationale, the metabolite makes the clock run in weeks, and the indication count is four, one or two depending on which regulator you are quoting.

18 · Lumateperone: pharmacology and indications

One capsule acts on serotonin, dopamine and glutamate at the same time, and the breadth of the licence follows from that rather than from any single receptor. Lumateperone is examinable for two unrelated reasons, and preparing one loses half the marks. The pharmacology leaves the dopamine-occupancy logic every antipsychotic algorithm is built on, which is what makes one molecule plausible across schizophrenia and bipolar depression. The regulatory record is the sharpest case in this chapter: three national records of one drug in three states, the Indian one neither an approval nor an absence. Receptor principles for the serotonin and dopamine systems belong to the Psychopharmacology I: principles and core drug classes notes and are not rebuilt here.

18.1 One molecule across three transmitter systems

The mechanistic account has four legs, taught as pharmacology rather than as anything a regulator has endorsed.

- Potent antagonism at the 5-HT2A serotonin receptor, the highest-affinity action of the molecule.
- A phase-dependent action at the dopamine D2 receptor, partial agonism presynaptically with antagonism postsynaptically, damping transmission where it is excessive rather than subtracting it everywhere.
- Inhibition of the serotonin transporter, an action shared with antidepressants rather than antipsychotics.
- Indirect enhancement of glutamatergic transmission in prefrontal circuits, dependent on the dopamine D1 receptor and expressed through NMDA and AMPA currents.

A molecule doing all four has a route into psychosis and a route into depressed mood at once, which is why the licence in 18.2 stops looking like three unrelated permissions. That is a rationale, not a demonstration: no trial evidence for this agent is held in this build, so no trial name, sample size, endpoint or effect size appears here.

The licence names none of the four legs. The current United States label calls the product **an atypical antipsychotic** and stops: no receptor, no subtype, no affinity ratio, no occupancy figure. Marks go in a predictable direction, by promoting the mechanism into the licence or by attaching an occupancy percentage to a regulatory sentence. No occupancy or affinity figure is printed here, because none is grounded in this build, and a number recalled from a review and set beside a licence is a fabricated citation whatever its provenance.

RULE **A mechanism explains why a licence might be wide; it never widens one.** Write what the molecule does, then separately what a named regulator has permitted, in that regulator's words, with the date of the reading. The two sentences must stand apart: one is pharmacology that travels everywhere, the other a permission that stops at a border.

18.2 The United States: one application, three indications, quoted whole

Exactly one jurisdiction carries a grounded status row here, and its fields are what make a claim checkable. The source is named and narrow: the openFDA interface to Drugs@FDA, one application, NDA209500, with the current structured product label effective 20 June 2025, and the status was true as of 1 August 2026. The indication text follows, with the label's pointers to its own clinical-studies sections removed and nothing else changed.

CAPLYTA is indicated for: Treatment of schizophrenia in adults. Treatment of depressive episodes associated with bipolar I or II disorder (bipolar depression) in adults, as monotherapy and as adjunctive therapy with lithium or valproate. Adjunctive therapy with antidepressants for the treatment of major depressive disorder (MDD) in adults.

Three permissions, and they are not parallel.

LICENSED INDICATION, UNITED STATES	MAY BE GIVEN ALONE	MAY BE GIVEN WITH
Treatment of schizophrenia in adults	No partner drug named either way	No partner drug named either way
Depressive episodes associated with bipolar I or II disorder (bipolar depression) in adults	Yes, stated as **monotherapy**	Also stated as **adjunctive therapy** with lithium or valproate
Major depressive disorder in adults	No such wording appears	Adjunctive therapy with antidepressants only

The asymmetry is the mark. Bipolar depression is licensed both ways; major depressive disorder one way only, as an addition to an antidepressant. The bipolar row covers bipolar I and bipolar II together, which much of the literature a candidate has read does not. Note what the schizophrenia row does not say: an adult indication, no adolescent extension, no line of therapy, no comparator, no place in any algorithm.

Then the field most often misreported. The earliest approval-status date for this application is **20 December 2019**, and the field is named **the earliest approval-status date in the record**. Whether that is a first marketing approval, a supplement or something else, the record read here does not say. This ledger has already retracted one drug's date after publishing it under a field

name that promised more than the field held. Print a date with the name of the field it came from.

Two disciplines travel with the American row. The interface is an agency-operated mirror of Drugs@FDA and of the label archive rather than the Drugs@FDA application itself, and the indication wording is current label text as filed, which is not a statement about any other jurisdiction and must never be carried across one. And the row was tested rather than trusted. Three text instruments ran against the primary document, checking that the row text is verbatim, that it is not the primary text cut short and closed so that nothing signals the loss, and that the counts of indication statements match. All three passed, at 848 characters against 848, and five indication statements against five. Five rather than three counts the label's highlights repeat of the same list.

GOOD TO REMEMBER

Licensing bipolar depression both as monotherapy and as an addition to lithium or valproate answers the question the ward asks, which is whether the existing mood stabiliser has to come off. On this wording it does not. What the licence does not answer is whether adding this drug beats optimising what is there, because no comparative, sequencing or head-to-head result for this agent is held in this build. Answer the licensing question from the label; refuse the comparative one aloud.

TRAP **Carrying the monotherapy permission across from bipolar depression to major depressive disorder.** The wording gives bipolar I and bipolar II depression as monotherapy and as adjunct; it gives major depressive disorder as adjunctive therapy with antidepressants and in no other form. Writing that the drug is licensed for depression, unqualified, merges two indications with different permissions and different partner drugs, and usually exports an American permission to whichever country the examiner had in mind.

18.3 The European Union: an absence in a register that records refusals too

A declared gap is a statement about a search and not about a product, so its strength is its instrument's strength. The instrument is the European Medicines Agency's own published medicines register, generated by the agency on 1 August 2026, downloaded whole and scanned across all 39 columns of all 2730 medicine rows, where this active substance returns zero rows under any of its names.

What lifts that above a shrug is the range of outcomes the register carries. It records Authorised, Refused, Application withdrawn, Withdrawn, Lapsed, Expired, Revoked, Suspended and Opinion outcomes, so the absence means no central application of any kind was ever concluded, including one refused or abandoned partway. The missing document is an agency public assessment report for the substance or a European Commission implementing decision, and the phrase approved internationally is not a permitted substitute for a named regulator.

Now the limit, where an honest answer separates itself from a confident one. The register covers the European Union **centralised procedure** only. A product authorised nationally in one or more member states through the decentralised or mutual-recognition procedure would never

appear in it, so absence here means no centralised procedure of any kind is on record, which is narrower and weaker than not available anywhere in the Union. That limit sits on every European gap row and does not bite equally on all; on this agent it is graded as biting moderately. Two weaknesses travel with the finding. The confirming second instrument ran on all eight grounded European rows and on none of the eight gap rows, so no European gap here has independent corroboration, and the assessment-report page is in any case a second rendering of the same source, because the register is generated from those pages.

The defensible European sentence is short and worth writing whole: no European Union centralised procedure of any kind is on record for lumateperone as of 1 August 2026, which does not exclude a national authorisation this instrument cannot see.

18.4 India: a committee that recites an approval no list prints

The Indian entry is the one an Indian examination cares about, and it is the only row in this chapter that is neither a grounded approval nor a declared gap. Its state is partial, on a supportive source only. One affirmative document exists, a committee minute rather than a permission. Minutes of the CDSCO **subject expert committee** for neurology and psychiatry, dated 16 April 2025, record verbatim that the committee noted that drug Lumateperone Capsules 42mg is already approved in the country on 26.12.2024. The date recited is **26 December 2024**, and the strength named, **42 mg**, is part of the product designation in that minute and not a dosing instruction; no dosage text for this agent is held in this build.

What the row does not hold is a **marketing authorisation**. Read the next sentence twice, because collapsing it is the most expensive error on this item. Subject expert committee minutes are a supportive source only, so the row licenses the statement that CDSCO committee minutes of 16 April 2025 recite such an approval, and it does not license the statement that CDSCO approved lumateperone on 26 December 2024. Two claims about different things, one about a document and one about a regulatory act, and only the first is in evidence. The second would rest on the Drugs Controller General of India, whose permission was searched for and not located.

The primary record was sought in three forms and found in none. The approved indication wording was not located at all, so the row records the fact of an approval being recited and not its indication. No CDSCO permission and no approval-list entry appears in the 66 published approval-list documents. A run-time scan of all 121 extracted CDSCO texts found the drug's name in none of them.

The list that should have carried it demonstrably covers the date. The list declaring calendar-2024 coverage carries entries dated 17 December 2024 and 30 December 2024, and declares its own range in its running header as covering 1 January 2024 to 31 December 2024, so it is not truncated before 26 December. Two corrections to that argument sit in the row and are worth learning as technique. An earlier version cited entries dated 17, 30 and 31 December 2024, but 31 December occurs only inside the page header and is not an entry; the declared coverage range is the stronger evidence anyway, because it excludes truncation by the document's own statement rather than by inference from its last row. A second leg, that the list carries roughly 15 numbered

rows, was withdrawn as false: there is no single calendar-2024 list, the corpus holds five snapshot vintages across two CDSCO series, and the one declaring full-year coverage carries 30 recoverable rows to a highest serial of 31.

IN INDIA

Write it in this order and stop. CDSCO subject expert committee minutes of 16 April 2025 recite an approval of Lumateperone Capsules 42 mg in the country on 26 December 2024; committee minutes are a supportive source and not a marketing authorisation; the permission, an approval-list entry and an approved label were each searched for and none was located, so the approval is recited here and not established here. Do not write that CDSCO approved the drug on that date, which upgrades a recital into a ruling. Do not write the categorical negative either, because no instrument in this build supports it. For a patient, availability is checked against a current label or a pharmacy record, never inferred from a committee minute.

18.5 Why this one row licenses every declared gap in the India column

This row does more work than its own drug. It is the strongest of the three legs establishing that the CDSCO published approval-list corpus is incomplete, because here CDSCO contradicts itself: its own committee recites an approval that appears in none of the 66 published lists, and the list that should have carried it declares coverage of the date. Every other Indian entry in this chapter depends on that incompleteness, so one compact agent profile is why the rest of the column may be written as declared gaps at all.

The second leg is an era mismatch, and it bears on a chapter of recent approvals: every drug this corpus is known to find sits in a document dated 2023 or earlier, and independent sensitivity in the 2024 to 2026 window is 0 of 1, that one being this drug, whose Indian approval is established from outside the corpus and which the corpus misses. The ledger refuses to count the one agent here that the corpus does find as a second data point, because scoring a corpus hit as proof that the corpus finds hits is circular, and the positive-control tally of 17 of 20 may not warrant a gap on any agent approved after 2023.

848 of 848	0 of 2730	0 of 66	0 of 121
CHARACTERS, US ROW VERSUS LABEL	EU REGISTER MEDICINE ROWS MATCHING	CDSCO APPROVAL LISTS WITH AN ENTRY	EXTRACTED CDSCO TEXTS NAMING THE DRUG

Quote the conclusion rather than improving on it. Absence from this corpus is evidence and not proof; no India row in this build asserts that a drug is not approved in India; each asserts instead that no CDSCO approval record was located, and names what was searched. A categorical negative is a claim about a country, and the instrument only ever supported a claim about a search.

18.6 A date and the label on the date are one record

One correction inside this row is the most transferable thing on the item, and it was made by hand after independent adjudication. The field describing what kind of date 26 December 2024 is once carried the wording the grounded Indian rows carry, which means an entry in an approval list. Anything joining the date to that description would have emitted a false Indian approval

sentence, correctly formatted and entirely wrong. It was raised as a blocker twice by independent cross-family review, and the row's state was left unchanged, because partial on a supportive source was already correct. A date and the label describing it are one record and must be corrected as one unit, and a string true in one row is not therefore true in another.

The falsification pass makes the point mechanically, and its verdict on the Indian row is a term worth owning: **unresolved extraction**. All three text instruments returned it rather than a pass, because this row cites no approval-list entry and therefore offers no indication cell to read. The finding was recorded as measured rather than assumed, through the run-time scan of all 121 extracted texts and a second source check across five cached committee-minute files, in one of which the quoted sentence appears verbatim. The discipline is written into that file in one line: a failed extraction is unresolved extraction, never a pass. An instrument that could not read is not an instrument that found nothing.

MNEMONIC

Recited, not Ruled

Recited is what a committee minute does: it reports an approval. Ruled is what a permission, an approval-list entry or an approved label would do: it constitutes one. The Indian row holds the first and not the second, so the sentence it licenses names the minute, its date and its verb. Naming CDSCO as the actor on 26 December 2024 upgrades a recital into a ruling.

Reduced to three sentences, the item is this.

- The mechanism acts on serotonin, dopamine and glutamate at once, and is a rationale for the licence, never a substitute for reading it.
- The American record is grounded and quotable: schizophrenia in adults; bipolar I or II depression alone or added to lithium or valproate; major depressive disorder only as an addition to an antidepressant.
- The Indian record is a recited approval and not an established one, and that single row is the evidence that the published approval-list corpus is incomplete.

One molecule across three transmitter systems, one licence quoted whole and left inside its own country, and one Indian record that recites an approval no published list prints.

19 · Zuranolone as an individual agent profile (cross-reference to recent advances)

This is the prescribing half of zuranolone, and it is short on purpose. The mechanism, the class lineage, the postpartum against major depressive reading and the regulatory chronology belong to the zuranolone and neurosteroid antidepressants item in this chapter. What follows is the agent-reference residue: the dose, the pharmacokinetics, the interactions, and the points where two labels describe one molecule differently.

19.1 Identity, and the border running under every line below

Zuranolone is an oral neuroactive steroid, classified in the European document under psychoanaleptics, other antidepressants, with ATC code N06AX31, supplied as 20 mg, 25 mg and 30 mg hard capsules. Two regulatory records are held here and a third is empty. The United States label reads that ZURZUVAE is indicated for the treatment of postpartum depression (PPD) in adults, on Drugs@FDA application NDA217369, whose earliest approval-status date in the record is 4 August 2023, status true on 1 August 2026. In the European Union the medicine is Zurzuvae, EMEA/H/C/006488, holder Biogen Netherlands B.V., authorised throughout the Union from 17 September 2025; its indications section names one indication only, quoted verbatim in the neurosteroid item and deliberately not paraphrased here. For India, no CDSCO marketing approval record was located as of August 2026, on the authority of the Central Drugs Standard Control Organisation and the Drugs Controller General of India.

Everything below is label content, and a label describes what one regulator permitted inside its own territory. A dosing table is not a permission, and no figure here crosses a border.

19.2 One dose, one evening, fourteen days, and what moves it

SITUATION	DOSE	WHAT THE LABELS SAY
Standard	50 mg orally once daily in the evening for 14 days	The European document calls this a single course; the United States label states that safety and effectiveness beyond 14 days in a single treatment course have not been established
Not tolerated	40 mg once daily, same 14 days	European trigger is failure to tolerate 50 mg, United States trigger is depressant effects arising inside the period. The European document adds that dosing may be stopped without down-titration
Strong CYP3A inhibitor	**30 mg once daily through the 14 day treatment period**	Both. The United States label adds that no dosage modification is recommended with a moderate CYP3A4 inhibitor
Moderate or severe renal impairment	30 mg, same period	European: moderate eGFR 30 to 59 mL/min, severe under 30 not requiring dialysis. United States: moderate or severe, eGFR under 60 mL/min/1.73 m2. Mild, 60 to 89, unchanged in both
Severe hepatic impairment	30 mg, same period	**Child-Pugh class C** only; class A and class B unchanged in both
Missed evening dose	Nothing extra	Take the next dose at the regular evening time, take no additional capsules the same day, and continue to the end of the course. Both

The capsule arithmetic goes wrong on the prescription, not in the answer. Fifty milligrams is two 25 mg capsules, forty is two 20 mg capsules, thirty is a single 30 mg capsule, so every dose change is a change of strength, not of count.

The administration instruction is an exposure requirement. Capsules are swallowed whole in the evening with fat-containing food, as either a meal or a snack, quantified by the United States label as 400 to 1,000 calories and 25 to 50 per cent fat and left by the European document as everyday examples. Zuranolone may be given alone or alongside stable background oral antidepressant therapy, so it is neither an add-on by licence nor a replacement for one.

RULE **Every dose in this entry is a fourteen-day dose.** There is no titration upward, no loading and no maintenance limb. Both labels specify each reduced dose for the whole treatment period rather than for one evening, so a patient started at 30 mg for an inhibitor, a kidney or a Child-Pugh class C liver stays there to the end. The dose is decided once, at the prescription; the only trigger arising later is tolerability.

19.3 The pharmacokinetics that explain the instructions

Two of these numbers are why the patient is told anything at all. Each is printed with the document it came from, because the two labels do not always use the same measure.

PARAMETER	VALUE	DOCUMENT, AND ANY DIVERGENCE
Time to peak concentration	**5 to 6 hours after the dose**	Both
Steady state	Reached in 3 to 5 days, accumulation about 1.5-fold	Both
Distribution	Volume of distribution greater than 500 L; plasma protein binding greater than 99.5 per cent	Both; the European document adds that the volume is dose-independent
Terminal half-life	**Approximately 19.7 to 24.6 hours in an adult population**	Both
Mean apparent clearance	32.7 L/h European, 33 L/h United States	One quantity, two roundings; quote the one whose document you name
Excretion	45 per cent in urine and 41 per cent in faeces, both as metabolites, with negligible unchanged drug in urine and under 2 per cent in faeces	Both. Renal impairment matters through exposure, not unchanged excretion
Food effect at 30 mg	European: peak up 228 per cent and AUC up 55 per cent low-fat, 334 and 90 per cent high-fat, against fasting. United States: peak up about 3.5-fold and AUClast about 1.8-fold low-fat, 4.3-fold and 2-fold high-fat	Two documents, two metrics; time to peak unaffected in both

50 mg	30 mg	5 to 6 h	19.7 to 24.6 h
THE ONLY DAILY DOSE	THE REDUCED DOSE, THREE TRIGGERS	TIME TO PEAK CONCENTRATION	TERMINAL HALF-LIFE

A half-life near a day with once-daily dosing keeps the course at steady state throughout, so the twelve-hour restriction both labels attach to each dose is not a wash-out and does not lengthen as the fortnight goes on. It is set against a performance threshold, worked through in the neurosteroid item, not against elimination.

The exposure figures behind those thresholds: in Child-Pugh class C the peak concentration was 24 per cent lower and AUCinf 56 per cent higher than in matched healthy subjects, while class A and class B were unchanged, which is why only the severe class moves the dose. Exposure rose in moderate and severe renal impairment, and the drug has not been studied at an eGFR under 15 or in patients requiring dialysis. No adjustment is made for weight, race or age; Black or African American subjects showed a 14 per cent higher apparent clearance, which the European document itself calls not clinically meaningful. There is no geriatric experience in this indication.

19.4 Interactions: a victim of CYP3A, almost never a perpetrator

Metabolism is extensive with CYP3A primary, so the interactions worth knowing run one way. A **strong CYP3A inhibitor** raises exposure, quantified as AUCinf up 62 per cent with itraconazole, and the answer is 30 mg rather than avoidance; the European examples are protease inhibitors, azole antifungals and some macrolides, with grapefruit avoided for the same reason. Induction reverses both magnitude and management: AUCinf falls 85 per cent with rifampin, and inducers are avoided outright with no dose-adjusted alternative. The European list names carbamazepine, phenobarbitol, phenytoin, primidone, rifampicin, St John's Wort and efavirenz; the last three are the ones candidates omit.

In the other direction the drug is quiet. Repeated zuranolone did not alter exposure to simvastatin, a CYP3A substrate, or bupropion, a CYP2B6 substrate, and it is not a substrate of P-glycoprotein, nor expected to inhibit the common cytochromes or the major transporters at clinically relevant concentrations. The one important interaction that is not pharmacokinetic at all is with other central nervous system depressants: repeated 50 mg daily doses with alcohol or alprazolam produced increased impairment of psychomotor performance, yet the United States pharmacology records that alprazolam and ethanol did not alter zuranolone exposure, and zuranolone did not alter theirs. The additive effect is pharmacodynamic, so no concentration would predict it, and the management is dose reduction where the combination is unavoidable.

19.5 Where the two labels do not say the same thing

Contraindications first, because the divergence is total. The European document contraindicates hypersensitivity to the active substance or excipients, and pregnancy. The United States contraindications section reads, in its entirety, None. That is not a disagreement about foetal risk: both advise effective contraception during treatment and for one week after the final dose, and the United States label carries an embryo-fetal toxicity warning on the same animal findings. One regulator used a contraindication, the other a warning.

Dependence next. The European special-warnings section states that, on clinical-trial data, zuranolone has low physical dependence potential. The United States label states that it may produce physical dependence, and prints the evidence: in healthy subjects given 50 mg for 6 to 7 days, discontinuation was followed by insomnia, palpitations, decreased appetite, nightmare, nausea, hyperhidrosis and paranoia, all mild to moderate. In that jurisdiction zuranolone is a **Schedule IV controlled substance**, a classification belonging to United States law that must not be carried elsewhere. Quoting either sentence and calling it the position on **physical dependence** quotes half a field.

The United States label also carries the antidepressant-class warning on suicidal thoughts and behaviour, with pooled figures showing 14 additional patients per 1,000 under 18 and 5 additional at 18 to 24 against 1 fewer at 25 to 64, adding that zuranolone does not directly affect monoaminergic systems. The European special-warnings section, read whole, carries five headings, on driving, depressant effects, interactions, abuse and dependence, and excipients; suicidality is not among them.

The paediatric sentences differ in kind and must not be merged. The European document records that safety and efficacy in postpubertal females less than 18 years old have not been established, and that there is no relevant use in prepubertal females. The United States label records only that safety and effectiveness in paediatric patients have not been established. Reading either as a gloss on the other manufactures a floor neither document sets.

TRAP **Quoting a frequency without its population.** The European pooled figure for somnolence among subjects given 50 mg is 26.5 per cent; the United States table for the same dose in its Study 1 gives 36 per cent against 6 per cent on placebo. Both are correct and both are 50 mg figures; the poolings differ. The trap runs the other way on tolerability: the European frequency for dose reduction or interruption is 14.3 per cent, while the United States figure for reduction alone is 16 per cent, so the narrower construct carries the larger number, which is possible only because the denominators are different patients.

19.6 The prescribing points, in the order they are decided

One intentional overdose was reported before marketing: 330 mg, about 6.5 times the maximum recommended dose, producing an altered state of consciousness that resolved the next day after intravenous fluids. There is no specific antidote and management is supportive.

- Decide the dose before the first capsule: a strong CYP3A inhibitor, a moderate or severe eGFR, or a Child-Pugh class C liver each fixes the course at 30 mg, and all three are readable from the chart.
- Check inducers separately, because they are an avoidance and not a dose problem: carbamazepine, phenytoin, phenobarbitol, primidone, rifampicin, St John's Wort, efavirenz.
- Counsel the evening, the fat and the twelve hours as one instruction with three parts.
- Name the jurisdiction whenever a status, a schedule, a contraindication or a frequency is quoted, because each of those four differs between the documents or exists in only one.

GOOD TO REMEMBER

Three of the four reasons to reduce are known before the prescription is written and all three land on the same 30 mg capsule; the fourth, tolerability, lands on 40 mg and arises during the course. Settle renal function, liver status and the interacting list at prescribing, and keep the 40 mg step in reserve for the first two evenings.

IN INDIA

Every figure in this entry comes from two foreign labels, and a label describes a permission granted elsewhere. As of August 2026 no CDSCO marketing approval record was located for zuranolone; the missing document is an affirmative CDSCO or DCGI new-drug permission, an approved Indian label, or an entry in an official approval list. A CTRI registration, expert-committee minutes and a brand in a distributor catalogue are none of them an Indian marketing authorisation. This item holds no instrument that measured Indian availability in either direction, and the measured limits of the approval-list corpus are set out in the neurosteroid item.

MNEMONIC

Evening, Fat, Fourteen, Thirty

Evening is when it is given and why the restriction runs into the next morning. Fat is the condition of absorption. Fourteen is the whole exposure, with no titration and no second course. Thirty is the reduced dose and its three triggers, all knowable before the first capsule.

One dose for fourteen evenings, one reduced dose for three chart-readable reasons, and a jurisdiction attached to every status, schedule, contraindication and frequency you quote.

Consolidate and apply

20 · Worked vignettes

A vignette in this chapter is almost never a question about a drug; it is a question about a record. The stems that carry marks open with somebody wanting something: a patient who has read about a new treatment, a colleague who prescribed it in another country, a committee asked to stock it. Then the stem plants the fact that decides the answer, and in this territory that fact is almost always a jurisdiction, a document, a date, or a kind of permission. What the closing vignettes rehearse is the reading skill the chapter was built to install: finding the status question inside a clinical stem, and answering it at the grain the evidence actually supports.

The discipline that earns marks is refusing to answer a regulatory question with a pharmacological one, and refusing to answer it about the wrong country. A patient asking whether they can have a treatment they have read about is not asking what it does at the receptor; they are asking whether a named regulator has authorised it for them, here, now. A candidate who supplies the American record for a patient in an Indian outpatient clinic has answered the right question in the wrong place, which costs more because it looks like knowledge. Where a stem turns on mechanism, or on choosing within a class, that reasoning belongs to the Mood disorders: pharmacotherapy notes and the Psychopharmacology I: principles and core drug classes notes. This chapter supplies the layer above the prescription: whether the thing may be prescribed at all, on whose authority, and how to say so when the answer is not known.

20.1 Four questions locate the status claim

Before deciding what a recent-advances stem is asking, run the same four questions across it. Between them they cover almost every way an examiner can turn a request for a new treatment into a regulatory problem, and each opens onto a different part of this chapter.

Border	Document	Date	Verb
WHICH JURISDICTION IS ASKED	WHAT WOULD SETTLE IT	WHEN IT WAS TRUE	WHAT KIND OF PERMISSION

Border asks which country's record the stem is asking about, and that is set by where the patient is, not by where the literature was written. Document asks what record would settle the question and which body issues it: a published approval list, a current approved label, a public assessment report, a commission decision. Date asks when the status was last checked, because a regulatory statement with no date is a claim about the present made from an unspecified past. Verb asks what kind of permission is described, since permission to run a trial, an approval-list entry, a recital inside committee minutes and a product being supplied are four different facts about one agent. A well-built stem makes one of the four decisive and leaves the others as scenery.

RULE **A status sentence with no jurisdiction, no source and no date is not an answer.** Those three fields, with the indication itself, are what a regulatory claim here has to carry, and a sentence missing any of them cannot be checked. "It is approved" is not a shorter version of the answer; it is a different and unsupportable claim, because it silently asserts the same status everywhere. If you cannot give all three, say what was searched and what would settle it: a complete answer of a different shape, not a weaker version of the same one.

20.2 The vignette that resolves on a border

The commonest stem names an agent and asks whether the patient in front of you can have it, and the candidate answers from whichever country's record they happened to revise. The reading move is to fix the border first, and to treat the answer as a property of the pair, agent and jurisdiction, rather than of the agent. Regulatory maturity does not run in one fixed order, and this chapter holds the counter-example. One of the orexin receptor antagonists holds an Indian approval-list entry with an insomnia indication, dated **1 July 2021** under the printed column heading Date of issue, while for the same substance no European centralised procedure of any kind was found on record, both status true as of 1 August 2026. A candidate who reasons that an agent must be available in India because it is available in the United States, or that it cannot be because Europe has no record of it, has assumed a ladder that does not exist.

The other half of the move is knowing what a European absence is worth. The instrument behind it is the agency's own register of centrally authorised medicines, which records refusals, withdrawals, lapses, revocations and suspensions alongside authorisations, so an agent absent from it has never concluded a central application of any kind. That is a real finding, and narrower than it sounds, because the register covers the centralised procedure only and a product authorised nationally through the decentralised or mutual-recognition route would never appear in it. One further weakness belongs in a careful answer: the confirming second instrument ran on

all eight grounded rows and none of the eight absences, so no European absence here has independent corroboration.

20.3 The vignette in which the record was searched and not found

A second family hands the candidate an agent for which nothing was found, and the examinable content is entirely how that is said. A patient asks for an intranasal treatment they have read about; the Indian record was searched, and no approval was located. The wrong answer converts an absence of record into a regulator's negative finding. The right answer is a **declared gap**: name what was searched, name the authority that would settle it, and name the document that is missing. For the Indian column that means three instruments, namely a corpus of published approval lists, a search of the regulator's own domain in which every returned document is read rather than counted, and a search of the national trial registry run with a positive control. **Marketing authorisation** is what would settle it, and nothing softer will do.

The instrument's blindness has been measured, which is why this is not pedantry. The published approval lists are demonstrably incomplete, shown most strongly by the regulator contradicting itself: its own expert committee minutes of April 2025 recite an approval for an agent that appears in **0 of 66** of those documents, and the list declaring calendar-2024 coverage states its own range in its running header, so it is not truncated before the recited date. A corpus that misses a real approval cannot then be offered as evidence that some other approval does not exist. Absence here is evidence and not proof, and the sentence to write is that no approval record was located, naming what was searched.

IN INDIA

Write it in this order. The authority is the Central Drugs Standard Control Organisation and the Drugs Controller General of India. Expert committee minutes, **clinical-trial no-objection certificates**, International Cell written confirmations, CTRI registration, a brand listing, pharmacy availability and manufacturer copy are none of them marketing authorisation. So the honest sentence to a patient or a referring colleague is that no Indian approval record was located as of the date you checked, that what would close the question is a CDSCO or DCGI new-drug permission, an approval-list entry or a current approved Indian label, and that a pharmacy being able to source something is a different fact.

TRAP **Converting a search that found nothing into a regulator's negative finding.** Writing that an agent is not approved in India, or not approved in the United States, asserts that a body has stated something no instrument here asked it. The probes measured named routes and named documents; they are silent on what a regulator would say if asked directly. Worse, an American gap in this build has already been wrong once: one agent's record carries no cross-reference block at all, so three of five routes returned not-found on it while the active-ingredient route returned the record. A declared absence is written at the strength the instrument supports and never one notch harder, and an examiner marks the notch.

20.4 The vignette in which the approval stands and the product does not

A stem describes a woman with severe postpartum depression whose team has read about an intravenous neurosteroid and wants to know whether it can be arranged. An approval and a marketing status are two separate facts about one product. The American record for the first neurosteroid in this class carries an approval dated 17 June 2019 together with marketing status Discontinued. Both fields, approval and Discontinued marketing status, sit on that one record, which carries nothing relating them, so an answer gives both and reasons from neither to the other. Naming the approval and dropping the Discontinued marketing status tells the family half of what the record says. Saying the drug was withdrawn as unsafe is the more instructive overreach, because it reads a reason into a field that gives none: the Discontinued marketing status is a fact about the product rather than about the approval, and no field on this row states why marketing stopped or names any action taken about it by a regulator or a sponsor, so a candidate who supplies one has left the record, in either direction. Say that the approval stands on the record and the marketing status is Discontinued, and stop where the record stops.

The same row, the Discontinued one, carries a second object worth a sentence in a viva. Its date of approval and the date its approval letter was signed are different quantities, because the approval letter sets the date of approval as the date of a later scheduling notice, and the earlier date has been retracted from the field a reader would take a first-approval date from. Publishing a signature date under a first-approval field name is a true date of one thing wearing the field name of another, which is the commonest way a correct number becomes a false claim. Where an answer usually lands instead is the oral agent in the same class, whose rows sit in this chapter's neurosteroid section.

20.5 The vignette that resolves on the kind of document

Four different things get called approval in conversation and only one is a marketing authorisation, so a stem can be built entirely out of the difference. The first is a trial permission. The Indian file for the muscarinic combination is documented at pre-approval stage: no-objection certificates name the combination, and committee minutes for neurology and psychiatry dated 30 May 2025, 10 December 2025 and 22 December 2025 record a named sponsor presenting Phase III protocols, with the committee recommending permission to conduct the trial. That is affirmative evidence about the file and it is not an approval. The second is a recital: minutes of a **subject expert committee** mentioning an approval for another agent license the statement that those minutes recite such an approval, and do not license the statement that the regulator approved the drug on that date. The third is supply, a fact about a market. The fourth is a strength printed beside a product name in a list, which is part of the product's identity and not a dosing instruction.

The value sits in the three errors this catches. A candidate who writes that the muscarinic combination is approved in India has upgraded a trial permission into a marketing authorisation. One who writes that the other agent was approved on the recited date has upgraded a recital into the permission itself, when the primary permission or label was never located. And one who writes that either agent is unapproved has downgraded affirmative documentary evidence into a

negative nobody established. A committee recommending that permission be granted is a step towards permission and not the permission, so say which document you are describing before you say what it shows.

20.6 The vignette that resolves on a record that is authoritative and wrong

The next family teaches a reading habit rather than a fact. A record can come from the right regulator, cite the right document and still say something false, and both shapes it takes are silent. The first is truncation. The European indication for the oxybate medicine reads Treatment of narcolepsy with cataplexy in adult patients, adolescents and children from the age of 7 years. An earlier stored version of the same field read "Treatment of narcolepsy with cataplexy in adult patients." The words "adolescents and children from the age of 7 years" had been dropped and the surviving prefix closed with a full stop the source does not have. Nothing looked wrong, because a cut closing with valid punctuation is invisible to the eye. The vignette that follows is paediatric: a child with narcolepsy and cataplexy, and a candidate whose remembered indication has quietly excluded them.

The second shape is a wrong product wearing the right citation. The cited application and the date were both correct and both belonged to one product; the indication text was not, because it was the text of a different application by a different sponsor, whose label reads almost identically in structure. A reader comparing structure or length would see nothing. Both defects were found the same way, by somebody reading a stored field, noticing it did not close properly or did not name the product it claimed to, and refusing to complete it from memory. That refusal is the transferable skill: check the product's identity against the application's, quote an indication whole or say you are paraphrasing, and treat a quotation ending on a tidy full stop as unverified.

20.7 The vignette that resolves on what the evidence does not license

Not every stem here is regulatory. The other family gives a finding and asks what follows, and the mark sits in the inferences refused rather than the ones drawn. The umbrella review of the serotonin literature is the standing example. What it examined and what it reported are one question; what it licenses is another; and it does not license the conclusion that antidepressants do not work, that depression is not biological, that serotonin has no role in mood, or that evidence about aetiology settles a question about efficacy. Aetiology and efficacy are separate claims answered by separate designs, and a stem offering the review as grounds for stopping a patient's treatment is testing exactly that separation.

The same discipline runs through the newer research territory. A psychedelic-assisted trial is an intervention package, drug with preparation, setting and psychological support, so a question about what worked is a question about which component the design can separate, with expectancy, functional unblinding, therapist effects and the exclusion of higher-risk patients all on the appraisal path; and an access arrangement for a named patient is not a product approval. A stem describing an algorithm, a candidate biomarker or a prescription application is asking which rung the evidence has reached, across analytical validity, clinical validity, clinical utility, regulatory authorisation and routine deployment. No rung is inherited from the one below, and a **measured absence** of evidence at one rung is not a claim about the rung beneath. Those

arguments are developed in this chapter's serotonin-hypothesis, psychedelic-therapy, machine-learning, biomarker and digital-therapeutics sections; an answer here names the rung and stops.

20.8 Look-alike stems and the answering spine

Consolidation is easiest in pairs. The table sets out the stems most often confused here, against the fact that separates them and the axis the reasoning lands on.

TWO STEMS THAT LOOK ALIKE	THE FACT THAT SEPARATES THEM	THE AXIS IT LANDS ON
An agent available in one country, against the same agent asked about in another	Which jurisdiction's document was actually read, since the answer belongs to the pair and not to the drug	Border
An absence of record, against a regulator's negative finding	Whether any body has stated that nothing exists, or only that named searches found nothing	Document
An indication quoted whole, against one truncated at a full stop the source does not have	Whether the population at the end of the sentence survived the quotation	Document
A clinical-trial permission, against a marketing approval	What the document permits: conducting a study, or marketing for an indication	Verb
Committee minutes reciting an approval, against the approval record itself	Whether the permission, the list entry or the approved label was ever located	Verb
A status checked this month, against one carried in from memory	Whether the claim carries the date on which it was true	Date

With the axis identified, an answer that earns marks follows four moves in order.

- Fix the border. Name the jurisdiction the question is being asked in, before naming any status at all.
- Name the document that would settle it, and the body that issues that document.
- Give the verb its correct strength: authorised, permitted for a trial, recited in minutes, supplied, discontinued.
- Say what the record does not settle, and what you would have to read to close it.

That fourth move is where regulatory reasoning becomes visible to an examiner. A candidate who answers that a drug is approved has made a claim about a molecule; one who answers that a named regulator authorised a named product for a named indication, on a document they can identify, true as of a date they can give, and that the Indian record was searched on three named instruments with no approval located, has made a claim about a record, and a claim about a record can be checked. Every vignette in this territory rewards the second answer.

Answer at the grain of agent and jurisdiction, with the document, the date and the strength of the verb attached, and turn a search that found nothing into a declared gap rather than into a negative.

21 · Consolidation and quick review

This page teaches nothing and asks everything. The eighteen sections behind it have each been taught once, in the section that owns them, and consolidating them is not rereading them. It is finding out what can be produced from a blank page with the book shut, because that is the only form in which any of this will be available in a viva. What follows is a list of prompts rather than a summary: each names a section and the answer it should be possible to build cold.

Two habits make it easy to consolidate badly. One is revising the chapter as eighteen unrelated topics, which yields eighteen lists and no method. The other is holding a regulatory position as a property of a molecule; recalled that way it is unmarkable rather than merely weak, and it is usually wrong about which regulator it belongs to.

21.1 The two things to hold before any prompt below

The first is the unit of recall. Nothing here is held at the level of an agent: a status is held at the level of the **agent and jurisdiction cell**, and the cells of one agent are independently sourced and free to disagree. The ledger behind these notes carries **48** such cells, and this chapter holds pairs in which one cell is grounded while its neighbour is a declared gap. A single verdict about an agent is therefore not a compressed answer but a claim about cells that were never read. Producing one is the **border crossing** this chapter exists to prevent, and it costs marks both ways: an approval reported for a regulator holding no record, and a categorical negative written where only an instrument was silent.

The second is the audit. Four questions to run against any status answer the moment it is written, one per field such a sentence carries, the last being the date the cell was true, which these notes record as status true as of.

- Which regulator is this sentence about, and does the sentence itself say so?
- Where did the wording come from, and is it the document's own wording rather than a paraphrase that has quietly tightened it?
- On what date was this true, and does that date appear beside the claim?
- If the answer is a negative, what was actually searched, and whose authority would the claim finally rest on?

RULE **Recall by cell, never by agent, and produce the sentence rather than the verdict.** An answer naming an agent and a status has answered a question nobody can mark. An answer naming the regulator, the wording, the document and the date has answered the question asked, even when what it reports is a gap.

18	48	1	0
SECTIONS TO PRODUCE COLD	AGENT AND JURISDICTION CELLS BEHIND THEM	CELL A STATUS SENTENCE MAY SPEAK FOR	EVIDENCE LANES THIS CHAPTER HAS RUN

21.2 Twelve prompts for the recent advances band

One prompt per section. The middle column is what to produce; the right-hand column is what an otherwise fluent answer still misses, which is where the marks sit. No cell supplies the answer it asks for, with two exceptions the chapter's own rules force: a declared gap can be named only by naming what was searched, and one product's approval can be named only beside its marketing status, which a hard rule of this chapter requires in the same sentence as the product.

SECTION	PRODUCE FROM A BLANK PAGE	STILL INCOMPLETE WITHOUT
Esketamine and intranasal therapy	The indication each regulator's own record carries in its own words, the monotherapy and adjunctive positions separated per regulator, and any limitations of use the United States wording attaches	A jurisdiction on every clause, and the Indian cell written in whichever of the three states its own record supports
Zuranolone and the neurosteroid antidepressants	The neurosteroid rationale, the postpartum and the major-depression evidence read separately, and what brexanolone teaches about an approval that stands while the product's United States marketing status is recorded as Discontinued	The two populations kept apart, and the reason a date of approval can be set by something other than the approval letter
Rapid-acting antidepressants as a class	What makes the category a category rather than a list, and its members placed against onset, durability, evidence maturity, treatment setting and regulatory maturity	Each axis ordered qualitatively with its basis named, and not one figure on any of the five
Dual orexin receptor antagonists and sodium oxybate	The agents cell by cell, and the pair of cells that defeats reading the three regulators as a ladder of maturity	Whichever population a quotation of the European oxybate wording silently drops when it is cut at a full stop
Xanomeline, trospium and the muscarinic antipsychotics	Why a peripheral antagonist is paired with the agonist, and where the strategy sits beside rather than inside the dopamine algorithm	Which of the two named substances the Indian approval-list corpus cannot display, and what that does to any negative about the pair
Endoxifen and the protein-kinase-C-targeted agents	The Indian cell and the United States cell as two sentences that never meet, with protein kinase C inhibition named as a rationale and not a result	The refusal to merge the two cells into one agent-level statement; the United States cell given as the named routes that were run against Drugs@FDA and found nothing, never as a verdict, and any negative left to rest on the Food and Drug Administration's own reading of that register; and no comparison against an established mood stabiliser
Anti-amyloid monoclonal antibodies	The class of claim these agents exemplify, why this chapter prints no position for them, and what an Indian old-age service would have to establish first	The delegation named as one, the material handed to the Dementias and neurocognitive disorders notes, and no status and no date anywhere

SECTION	PRODUCE FROM A BLANK PAGE	STILL INCOMPLETE WITHOUT
The serotonin hypothesis debate	What the umbrella review examined and what it reported, then the four inferences it does not license	All four stated, and evidence about aetiology kept apart from evidence about efficacy
Psychedelic-assisted therapy	The intervention as a package of drug, preparation, setting and psychological support, with psilocybin and MDMA both named and neither given a status	Expectancy, functional unblinding, therapist effects and the exclusion of high-risk patients marked on the appraisal, and access arrangements kept apart from product approval
Artificial intelligence and machine learning	What a performance claim is bound to before it can be read at all, and where external validation sits in that list	The step from performing to deployable stated as a step, and no performance figure of any kind
Biomarker-driven and computational psychiatry	Analytical validity, clinical validity and clinical utility separated, with the evidence each one actually needs	The rungs kept in order, and the reason a marker result licenses no conclusion about a patient
Digital therapeutics and prescription apps	What a prescription digital therapeutic is as a regulatory object, why it is a device and not a drug, and what engagement and attrition do to an effect that a tablet does not have	The blindness of this chapter's instruments stated on your own authority, no regulatory verb on any named product, and deployment left to the Community psychiatry and public health notes

21.3 Six prompts for the individual agents

These sections are compact and are marked on the same two things: what the receptor signature commits the agent to, and what each regulator's record says. Write each as cells and a pharmacology, not a paragraph about a drug.

- Asenapine: the receptor signature, the formulation constraint that follows from it, and then, cell by cell, which regulators hold a grounded record and what each one's wording covers.
- Lurasidone: the metabolic and movement profile and the indications, then the reason no first Indian approval date appears in this chapter, and what the Indian corpus does hold for it instead.
- Brexpiprazole: the receptor signature and the indications it carries, and what its United States record teaches about a citation whose fields do not all point at the same thing.
- Cariprazine: the receptor signature that separates it within its own class, the indications, and what a verbatim quotation loses when it is cut at a fixed character count instead of at a clause.
- Lumateperone: the receptor signature and the indications, then the jurisdiction whose record is supportive-source-only rather than grounded, and the sentence that record does not license.
- Zuranolone as an agent profile: the compact agent fields alone, the neurosteroid case left where it was argued, and what a profile may carry that a narrative section already owns.

21.4 A second pass, sorted by the way an answer fails

Once the eighteen prompts run cleanly, run the chapter in the other direction, sorted by how an answer goes wrong rather than by topic, because a supplementary question arrives as a defect and not as a heading.

HOW THE ANSWER FAILS	THE PROMPT THAT TRAINS IT	WHERE IT IS TESTED
A status carried across a border	Take any agent this chapter names and write its cells one at a time, refusing to let a full cell fill an empty one	The esketamine, orexin and endoxifen sections, and the agent prompts above
An answer given at the wrong grain	For every agent whose cells do not read alike, say why a single agent-level verdict cannot be written at all	The orexin and endoxifen sections
A negative built out of a silence	For each gap, say which instrument was pointed at it, how sensitively, and whose authority a claim would finally rest on	The muscarinic, psychedelic and digital-therapeutic sections
A recited approval read as a granted one	Name the state that is neither a grounding nor a gap, and the sentence it licenses in place of the obvious one	The lumateperone section
A figure supplied where no lane holds one	For each evidence-driven section, list the quantities that are unavailable and say why writing one would be a fabricated citation	The neurosteroid, rapid-acting, serotonin-hypothesis, psychedelic, machine-learning and biomarker sections

21.5 Where these marks are actually lost

Three silences in this chapter look identical on the page and license entirely different sentences: one where a named instrument was pointed at the question and found nothing, one where the instrument could not have answered whatever the truth was, which is **instrument blindness**, so its quiet carries no information, and one where another chapter holds the fact and this one declines to restate it so two accounts cannot drift apart, which is a **delegated gap** and the only one of the three that is not an absence of fact. Say which of the three a silence is before writing anything from it; the section owning the third case works the discrimination out in full.

The other loss is quantitative. Every evidence lane behind this chapter is unrun, so no efficacy figure, effect size, response rate, trial name, sample size, endpoint, onset time, half-life, dose or adverse-event rate is available to any section in it. Supplying one from memory is not a weak answer but a **fabricated citation**, which nothing said afterwards can repair. Rehearse the substitution: say what is known qualitatively, name the ordering, and name what would have to be read for a quantity to be stated.

TRAP **Mistaking recognition for recall.** A section that reads as familiar on a second pass has been recognised, not retrieved, and recognition collapses under the first supplementary question. A prompt that withholds its answer leaves nothing to recognise. If a prompt cannot be written out in full sentences, with a jurisdiction on every status clause and a named source beside it, it is not yet known, however familiar the section felt.

21.6 The Indian limb, rehearsed as a separate answer

Write the Indian part of any answer separately, and last, because it is the limb most often filled in from whichever record the candidate has read.

IN INDIA

Write the Indian limb from an Indian document or do not write it. The authority is CDSCO and the Drugs Controller General of India, and a committee minute, a clinical-trial no-objection certificate, a CTRI registration, a brand on a pharmacy shelf and a manufacturer's own copy are none of them a marketing authorisation. Where no Indian record was located, the answer that earns the marks names what was searched, on what instrument, and whose authority a claim would rest on, and stops there rather than hardening into a categorical negative, because the corpus behind these notes carries a measured limit and an absence in it is evidence and not proof. Then take the question the examiner is actually asking: what an Indian service must establish first, meaning who confirms the diagnosis, who owns the decision, who carries the follow-up, and what the patient can afford.

21.7 What to carry into the paper

Consolidation buys faster access rather than more material, so the last week on this chapter should look nothing like the first. Four habits, in order.

- Produce rather than review. Write one section out cold each sitting and mark it against its source, instead of rereading three and feeling three times as prepared.
- Write the cells before the pharmacology. If the status will not come, no amount of receptor detail rescues the answer.
- Rework each vignette with the sections shut, because a vignette is where a border crossing surfaces as a decision rather than as a sentence, which is the form the examiner will use.
- Close every answer by naming what you hand to another chapter, or, where this chapter owns the section in full, by saying so and giving the full account.

What survives when the detail goes is short. Most questions here are about a record, so name the regulator before the agent; where a section has no regulatory record, name the construct and its limit instead. Every silence is a statement about an instrument, so say which instrument and how sensitively it looked. Every quantity is unavailable, so give the ordering and name what would have to be read. Every boundary is a sentence handed over rather than material rebuilt. Those four moves let a candidate answer on a section they revised badly.

Consolidating this chapter means producing it and not rereading it: one section at a time, cold, written as cells before pharmacology, with every status clause carrying its regulator and its source, and every silence carrying what was searched.

PAPER IV

Community psychiatry and public health

Nine bands . one complete notes document

National programmes and mental health legislation

1 · Community psychiatry and public health: what this chapter owns, and what it points to

A programme that exists on paper is not a service, and a service that exists in a district is not yet care that a patient has received. The distance between those three things is the subject of this chapter. The national programmes, the money that moves them, the routes by which a person with an illness arrives at somebody able to treat it, and the evidence that any of it worked are all statements about a system rather than about a patient. That change of unit is easy to describe and hard to hold under examination pressure, because every other chapter in this paper has trained you to answer at the level of the person sitting in front of you.

So it is worth stating plainly what this chapter is for: programmes, financing, access pathways, service architecture, population interventions and their evaluation. It is not a second course in mental health law, not a course in professional ethics, not a course in bedside consultation, and not a course in epidemiological method, although it borrows vocabulary from all four and is examined alongside them. The marks here are given for saying what a health system does, at which level it does it, with what resources, for which population, and how anybody would know whether it made a difference. A candidate who answers that with the provisions of an Act, or with the assessment of one patient, has written a good answer to a question nobody asked.

1.1 The lens: the programme, the service and the population

The organising move is a change of unit. Clinical psychiatry takes the individual patient as the unit of analysis and asks what is wrong and what should be done about it. **Public-health implementation** takes the population and the service as its unit and asks a different set of questions: how many people in a defined group carry a condition, how many of them reach treatment, where along the route the remainder are lost, who is expected to act at each level of the health system, and what evidence exists that the arrangement changes anything at all. The clinical facts do not disappear when the lens changes. They stop being the answer and become inputs to a question about delivery.

Two constructs carry most of the weight and recur in every band ahead. **Service architecture** is the arrangement of who does what at which level: the community health worker, the medical officer in a primary care facility, the district team, the general hospital psychiatry unit, the state mental health institution and the specialist tertiary centre. **An access pathway** is the route an individual actually travels, from the first recognition that something is wrong to the point where an effective treatment is delivered, including the long stretches of that route that lie outside the

health system entirely. Almost every intervention taught in these notes acts on the architecture or on the pathway, and deciding which is usually the first useful thing to say about it.

RULE **The answer is written at the level of a population or a service, not at the level of one consultation.** Before answering any question in this territory, say which population is being described and which level of the system is expected to act. A clinically impeccable account of how a patient should be assessed and treated earns very little here, because the question was about who reaches that assessment, who is available to deliver it, and who pays for it. Keep the clinical content in a clause and spend the answer on the delivery decision.

1.2 What this chapter deliberately does not teach

These notes border four others closely enough that material leaks in both directions, and each border is worth rehearsing as a sentence. Naming the owning chapter accurately is faster and better rewarded than rebuilding its material from memory, and it is the only way an examiner can see that you knew where the boundary was.

- The statutes themselves are not taught here. Their provisions, the machinery they create, the rights they confer, the safeguards they impose and the procedures they prescribe belong to the Mental health legislation and forensic psychiatry notes. What belongs here is the service consequence: what a law obliges a system to provide, who has to be in post before that provision can exist, and how it is financed and counted.
- Professional conduct, capacity and consent, custodial procedure and the statutory frame governing disaster response belong to the Forensic ethics, consent and legal procedure notes. These notes take the same events from the service side: how a response is organised, who staffs it, at which phase, and what happens to routine care while it runs.
- The bedside act belongs elsewhere as well. The cultural formulation of an individual case, the idioms in which a particular patient describes distress, the named culture-bound presentations and the clinical assessment of a patient already under the care of a traditional or faith healer are taught in the Consultation-liaison, geriatric and transcultural psychiatry notes. This chapter takes the same ground at population level: help-seeking, the sequence of providers a community actually consults, and the relationship between the health system and the other places people go.
- Method belongs to the Research Methods, Biostatistics and Epidemiology notes: what incidence and prevalence are as measures, how a survey is designed and sampled, what a study design can and cannot support, and how a rate is standardised. These notes consume the products of that method rather than teaching it, and the discipline they add is about reading a published figure correctly rather than about producing one.

Two narrower handovers are worth the same treatment. The clinical assessment and management of the individual patient at risk of suicide belongs to the Somatic-symptom, sexual, impulse-control disorders and suicide notes, while the population-level prevention of suicide is taught here in full. The clinical care and protective assessment of the individual child belongs to the

Child psychiatry: assessment, treatment, services and protection notes, while the service and programme interface with child protection law sits here.

TRAP **Answering a programme question by reciting the statute.** Asked how mental health services are organised in a district, candidates produce the sections and safeguards of the governing legislation, because that material is adjacent enough to feel responsive and was revised harder. The recitation may be accurate and still earn little, because the examiner asked what is delivered, by whom and at what level. State the legal obligation in a clause, then spend the answer on the structure built to discharge it.

1.3 What makes a national figure true

This is the most number-heavy territory in the paper, and almost every figure in it is one you have heard quoted at a seminar. That is exactly the problem. A national figure carries meaning only when four things travel with it, and a figure quoted without them is not a fact but a rumour with a decimal point.

Source	Reference year	Population	Denominator
WHICH BODY ISSUED IT	THE PERIOD IT DESCRIBES	WHOM IT COUNTS	WHAT IT IS A PROPORTION OF

Each field fails in its own way. Drop the source and the number rests on the speaker, which under examination means on memory. Drop **the reference year** and a survey that describes one period is offered as a description of the present, which matters more here than anywhere else in the paper because the national instruments in this field are re-run rarely and their findings stay in circulation long after the period they measured. Drop the population and the commonest error in the whole territory follows: the same survey's finding for one group is quoted as though it applied to another, so a figure that is perfectly accurate becomes a false statement about the wrong people. Drop **the denominator** and a count is read as a rate.

The last field needs one remark, because the honest answer is sometimes that no valid denominator exists. A total of sanctioned units, a cumulative count of calls to a helpline and a national count of deaths in an occupational group are all real numbers with no meaningful proportion attached, either because nobody counted the base or because the base is not knowable. The correct sentence says so, and stops: a cumulative count of calls is a count of calls, never a count of people. Refusing to supply a denominator is not weakness in an answer. It is the only version of the sentence that is true.

PITFALL

Reading a sanctioned figure as a delivered one. Programme documents in this field count what has been approved, funded or covered on paper, and those counts are published, quotable and entirely genuine. They are not counts of functioning services. A district may appear in an approved list with posts unfilled, and a facility may be listed with no specialist attached. The same trap runs through activity data: a service that reports contacts is reporting contacts, not distinct individuals, and certainly not individuals who completed treatment. Before quoting any coverage figure, ask what the noun beside the number actually is, and say that noun out loud in your answer.

1.4 The map of the territory

Nine bands follow. They are set out below not as a list to memorise but as a routing table: given a question, it says which band holds the answer. The bands themselves supply the programmes, the figures, the models and the attributions.

BAND	WHAT IT ESTABLISHES	THE KIND OF ANSWER IT REWARDS
National programmes and the legislative frame around them	What the state has undertaken to provide, through which programme structures, and at which level of the system each acts	Components and objectives, the level each one operates at, and the difference between what is sanctioned and what is running
Burden and the treatment gap	How much illness a defined population carries, and what proportion of it reaches treatment	A figure with its source, its reference period, its population and its denominator attached, and the determinants behind the shortfall
Suicide prevention at population level	Which population-level actions bear on deaths by suicide, and which groups carry raised risk	Actions classified by the population they address rather than by the individual they treat, with the level of action named
Stigma and the interventions aimed at it	How stigma operates in the public, in the person and in institutions, and what has been tried against each	The type of stigma identified first, then the intervention matched to that type and the evidence behind it
Rehabilitation and community care	What happens after the acute episode, and where a person then lives, works and is supported	The components of a rehabilitation package and the setting each belongs to, with residential and daytime options distinguished
Primary care, integration and delivery models	Who delivers mental health care where no specialist exists, and what supports them in doing it	The task each cadre performs, the supervision structure behind it, and the model that organises both
Special settings and disaster	How services are organised for populations that ordinary outpatient care does not reach	The constraints the setting imposes first, then the service response adapted to those constraints
Prevention, economics and digital care	What can be prevented, what illness costs, how care is paid for, and what technology changes about reach	The level of prevention named, the economic question stated precisely, and a claim about reach kept separate from a claim about benefit
Culture, global mental health and traditional healing	How explanatory models and existing sources of help shape the route into care	The pathway described as it is actually travelled, and the working relationship between the health system and other providers of help

1.5 The spine underneath the map

The bands are not nine separate topics; they are one argument told in sequence. Burden establishes the size of the problem in a defined population. The treatment gap converts that burden into a statement about the service, because a gap is not a fact about illness at all but a measure of how badly access has failed. The pathway work then explains where along the route people are lost, and the architecture says who might have caught them at each of those points. The intervention bands, from suicide prevention through stigma, rehabilitation and primary care integration, are all attempts on one or the other: they change who can act, or they change how a person reaches somebody who can. Prevention and economics ask which of those attempts is worth making and who pays for it. Evaluation asks whether any of it moved.

Read that way, the last band is not an appendix. Culture, explanatory models and existing healers sit at the beginning of the pathway rather than at the end of the chapter, because for a large part of the population the first consultation for a mental health problem is not with the health system at all. A reader who meets that band last but places it first has understood the sequence.

1.6 Inputs, outputs and outcomes

Evaluation is the part of this territory candidates most often skip, and it is where an understood answer separates fastest from a memorised one. Programme evidence comes in three kinds, and confusing them is the single most productive source of wrong statements in the whole field.

WHAT THE FIGURE COUNTS	A QUESTION IT CAN ANSWER	A QUESTION IT CANNOT ANSWER
An input: what was committed, sanctioned, staffed or funded	Whether the system undertook to act, and on what scale	Whether anything was delivered to anybody
An output: what the service did, counted as activity	Whether activity took place, and how much of it	Whether the people who most needed the service were the ones who got it
An outcome: what changed in the population	Whether the health of a defined group moved, and in which direction	Which part of the arrangement produced the change, unless the evaluation was designed to attribute it

The distinction has a companion in the idea of **functional coverage**, which asks not how many units exist but how many are staffed, supplied, open and used by the population they were built for. Sanctioned coverage is an input; functional coverage sits between an input and an output; and neither is an outcome. Where the functional figure has not been measured, the correct statement gives the approved figure, says that it is an approval, and declares the working figure unavailable. That declaration is a complete answer, and a better one than a confident number that quietly promotes a sanction into a service.

GOOD TO REMEMBER

Before quoting any national figure in a case presentation, a ward round, a teaching session or an answer script, ask four questions in order. Who issued this number. What period does it describe, as distinct from when the document was published. Which population does it count, and is that the population I am about to apply it to. And what is it a proportion of, or is it a bare count with no valid denominator. A clinician who runs those four before speaking will not be the person who quotes a survey's finding for one group as though it described another, which is the most frequently repeated error in this whole field.

1.7 What a good answer in this territory looks like

A small number of moves earn most of the marks here, and they recur across all nine bands in different clothing. They are worth learning as habits, because the detail here changes while the moves do not.

- Naming the level of the health system at which the answer operates, before describing what happens there. Community, primary care, district, general hospital, state institution and tertiary centre are not interchangeable settings, and most questions here are really asking which one you would use.
- Separating what a policy or programme undertakes from what a service delivers, and saying which of the two the evidence you are quoting actually measured.
- Attaching the source, the period, the population and the denominator to every figure, and declining to give a figure at all where any of the four is unavailable to you.
- Handing over what a neighbouring chapter owns in a single sentence that names it, rather than reconstructing statute, ethics, bedside method or epidemiological technique from memory in the middle of a service answer.

Those four are also, in the same order, the four ways an answer here goes wrong. An answer written without a level reads as an opinion about mental health in general. A figure without its scope is a wrong number wearing a citation. And an answer that drifts into the law has left the marks on the table while writing accurately about something else.

1.8 A scaffold to carry into essays and vivas

Under examination pressure the detail goes first, and in this field the detail is exactly what is hardest to hold, because it consists of programme names, structures, reference periods and figures that resemble one another. What has to survive is a routing sequence. The scaffold below is a teaching device rather than a validated framework, and it will structure an answer on any band in these notes, from a programme to a delivery model to a question about culture and help-seeking.

MNEMONIC

Population, Pathway, Programme, Proof

Population: name the group the question is about and, if a number is coming, what it is a proportion of. **Pathway**: describe how that group actually reaches care and at which step it stops, including the steps taken outside the health system. **Programme**: name the level of the system expected to act, what has been put there to act with, and who supervises it. **Proof**: say what would count as evidence that it worked, and whether the figure you have is an input, an output or an outcome.

For a short answer, run the four and stop. For a long essay, expand each into a paragraph and take the specifics from the band that owns them. In a viva, make the sequence audible: say whom you are talking about, how they reach care, who is meant to be there, and how you would know whether it helped. That last sentence separates a candidate who has learned a list of programmes from one who has understood why they exist, and it is also what a district team needs from the psychiatrist it consults.

A programme is not a service, a service is not access, and access is not care: name which of the three a question is asking about, and attach the source, the period, the population and the denominator to every figure you offer.

2 · National Mental Health Programme (NMHP): components, objectives and evolution

A national programme is not a policy, not a statute and not a scheme, and the marks in this area are lost by candidates who cannot tell the four apart. The **National Mental Health Programme** is the instrument through which the Union government made mental health a delivery obligation of the general health system rather than the business of a handful of specialist hospitals. Everything else in Indian community psychiatry hangs off it: the district limb that carries services to the population, the training and workforce apparatus, the money that reaches a state, and the reporting through which any of it becomes visible. Understand what kind of object it is and the rest of this chapter becomes a set of consequences.

This section teaches the programme as programme architecture: what it is for, what it consists of, how it has moved, how it is financed and monitored, and what can honestly be said about how far it has reached. Its district implementation is a separate section of this chapter. Its role as the delivery frame for community rehabilitation of a person with a psychotic illness, set against assertive community treatment, is taught in the Schizophrenia: management, antipsychotics and adverse effects notes, and is not restated here. The statutes the programme now runs inside are taught in the Mental health legislation and forensic psychiatry notes.

2.1 Four instruments, four different kinds of authority

Before the programme, the vocabulary. Indian mental health administration uses four words that examiners deliberately mix, and each carries a different kind of force.

INSTRUMENT	WHAT IT FIXES	WHO IS BOUND	HOW FAILURE SHOWS
Statute	Rights, duties, offices, procedures and remedies	Everyone within the jurisdiction, on pain of legal consequence	An entitlement exists and is not honoured; the remedy is legal
Policy	Direction, priorities and the populations named as vulnerable	Government, as a statement of intent	The direction is stated and nothing is funded to move in it
Programme	Objectives, components, delivery architecture and reporting	The health system that operates it	Approved on paper, unstaffed in practice
Scheme	A defined benefit or activity with its own budget line	The implementing agency and the beneficiary	Money released, benefit not received

The programme sits in the third row, and its characteristic failure mode is the third one. That single row is the most examinable idea in this section and it recurs in every part of this chapter: an approved unit is not a functioning unit, a sanctioned post is not a filled post, and a released instalment is not a service delivered. Hold the distinction and you will not misread a coverage figure again.

RULE **A programme is an architecture plus a reporting system, and it can only be judged on what it reports.** Its objectives tell you what it was designed to change; its components tell you the machinery it intends to use; its monitoring tells you what evidence of change will ever exist. Where the third is thin, no amount of the first two will let you say whether the programme worked.

2.2 Objectives, and the one this chapter can put a source against

The objectives of this programme are among the most recited facts in Indian psychiatry and among the least reliably sourced. The founding programme document, the one that sets out the original objectives, could not be retrieved from a serving official source during the preparation of this chapter: the ministry's own page returned nothing after a domain migration, a repair attempt returned the same dead address, and no archived snapshot was available. That is stated here rather than papered over, because the honest position is itself an answer. The objectives as they are usually recited in teaching may well be accurate; this chapter simply cannot certify them against a document it could open, and it will not print a list it cannot stand behind.

What can be certified is the objective the programme's current official page carries. The Directorate General of Health Services states an objective of the National Mental Health Programme in these terms: **to enhance human resource in mental health sub-specialties**. That is a live official statement, read from the programme's own live page, and it describes the mental health subspecialty workforce of India. It is not a rate and it has no denominator, which is correct and not a defect: an objective is a direction of travel, not a proportion of anything.

Notice that this objective is itself evidence of evolution, which is the second half of what this item covers. An objective about human resource appearing on the current page tells you that the

programme, whatever it was designed to do at the outset, now regards the production of specialist and subspecialist manpower as one of its own deliverables rather than as something the education system supplies to it from outside.

IN INDIA

Because the programme names enhancement of human resource in mental health sub-specialties as an objective of its own, a department planning against it should treat training capacity as a programme output to be planned and reported, not as an academic by-product of clinical work. That changes what a unit counts: not only patients seen, but trainees trained, supervisors available, and the subspecialty posts that a trained person can actually move into. A workforce objective without a post at the end of it produces qualified people for other systems.

2.3 Why human resource is the binding constraint on this programme

Public health programmes usually fail on one of four constraints: money, materials, people or information. Mental health services are unusual in that the first two are comparatively cheap. The essential medicines are old, off patent and inexpensive; the physical infrastructure is a room, a record and a reliable supply. What the service cannot substitute for is trained people, because the intervention *is* a trained person's time, whether that person is a psychiatrist, a clinical psychologist, a psychiatric social worker, a nurse or a trained medical officer at the first level of care.

That has three design consequences which run through the rest of this chapter.

- **Capacity is built slowly and lost quickly.** Specialist training takes years, while a transfer, a resignation or an unfilled sanctioned post removes the capacity immediately. A programme that expands its coverage faster than it produces people converts a staffing problem into a coverage illusion.
- **Task-shifting is not optional, it is arithmetic.** If the specialist workforce cannot be enlarged at the rate the population needs, some part of the work must move to a broader cadre with supervision. The mechanism, the guidance behind it and the medical officer's role in it are taught in their own sections of this chapter.
- **Retention is a programme variable.** Where a trained person is posted, whether the post is at the level they were trained for, and whether supervision exists, determine whether training converts into service. None of that is visible in a count of trainees.

2.4 The architecture, from the national programme down to the district

A national programme in India is not delivered nationally; it is delivered by states, in districts. Health is administered at state level, so the Union instrument sets objectives, defines components, provides a share of the money and asks for returns, while the actual service is run by a state health department through a district unit. That two-level structure explains most of what is puzzling about Indian programme data. The centre knows what it approved and what it released; the district knows what it staffed and what it delivered; and the two are not the same fact.

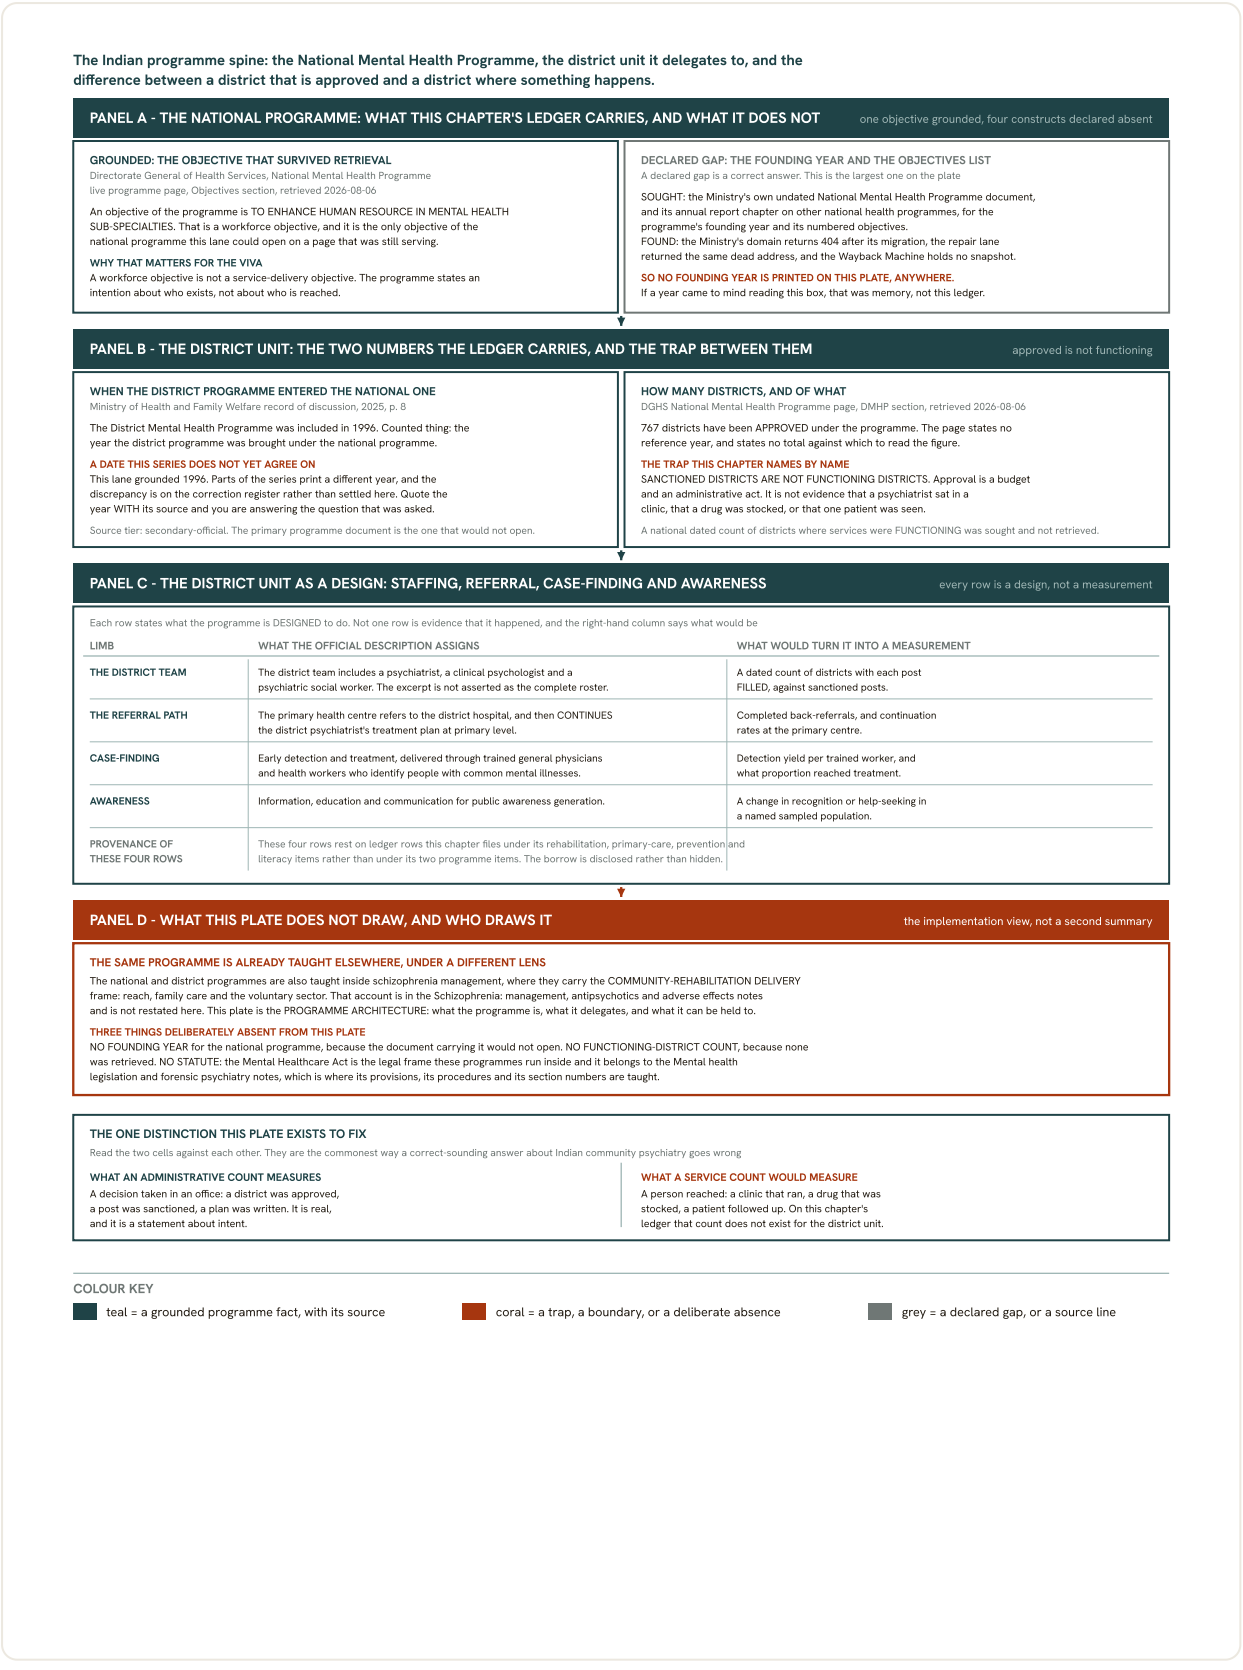

Fig 39.1 The Indian programme spine, drawn as an implementation view. The national programme contributes one retrievable objective, to enhance human resource in mental health sub-specialties; its founding year and numbered objectives are a declared gap, because the Ministry's own documents no longer serve and no archived snapshot exists, so no year is printed. The district programme was included in 1996 and is reported as approved in 767 districts, with no reference year and no stated total. The chapter's own trap sits between those two facts: approval is an administrative act, and a national count of districts where services were functioning was sought and not retrieved. The staffing, referral, case-finding and awareness rows state design, never delivery.

The accompanying figure sets out that spine, from the national programme down through the district unit to the components, staffing and referral arrangements at the point of delivery, and marks the boundary where the community rehabilitation account in the Schizophrenia: management, antipsychotics and adverse effects notes takes over. The district limb, the District Mental Health Programme, has its own section immediately after this one and its structure, components, staffing and coverage evidence are taught there rather than here.

What belongs here is the logic of the relationship. A national programme can do four things and only four: it can set an objective, define a component, move money, and require a return. Everything else, including whether a post is filled, whether a drug is on the shelf and whether a patient is seen, happens at a level the national instrument can influence only through those four levers. When you are asked why a national programme underperforms, the answer is almost always that one of the four levers is weak, and most often it is the fourth.

2.5 Evolution, and the document that could not be opened

The programme has moved considerably since it began: from an initial concentration on integrating mental health into general health care, through the addition of a district implementation limb, towards a wider portfolio that now includes workforce production, tertiary capacity and digital service delivery. The programme's own annual reporting is where those movements are recorded plan period by plan period, and it is the document a candidate should ideally cite.

Two of this chapter's declared evidence gaps sit exactly there. The ministry annual report chapter that records the programme's position among the other national health programmes could not be retrieved from a serving official address: the domain returned nothing after migration, a repair pass returned the same dead address, and no archived copy was available. Two separate records in this chapter's evidence ledger point at that same unreachable section. The consequence is that this chapter describes the direction of the programme's evolution, which is visible from its current official page and from the instruments that surround it, and prints no dated milestone list, because the document that would date the milestones could not be opened.

TRAP **Writing the year a programme started from memory.** Programme years, policy years and Act years are the most quoted and most misquoted facts in this whole area, and they feel exactly as certain from the inside as a year you have actually read in a document. This chapter prints a programme year only where a source it could open carries one. Where it could not, it names the programme without the year and says so. In a viva, "the founding document is not currently retrievable from an official source, so I would not quote a year I cannot cite" is a stronger answer than a confident wrong date.

2.6 How you would actually judge this programme, and what a figure must carry

Judging a national programme means choosing a denominator, and most published commentary skips that step. There are four honest questions and they get progressively harder to answer.

- **Reach.** How many districts, units or facilities are covered? This is the easiest to answer and the easiest to misread, because approval and function are recorded by different people for different purposes.
- **Function.** Of the covered units, how many are staffed, supplied and open? This is the number that matters and the number most often missing.
- **Contact.** Of the people in the population who need care, how many make contact with the service? This requires a population estimate as a denominator, which comes from a survey rather than from the programme.
- **Outcome.** Of those who make contact, how many are adequately treated and how many improve? This requires a follow-up system, which is the weakest layer of Indian programme reporting.

Source	Year	Population	Denominator
WHICH BODY ISSUED THE FIGURE	WHICH YEAR IT REFERS TO, NOT WHEN PUBLISHED	WHICH PEOPLE IT DESCRIBES	WHAT IT IS A PROPORTION OF

Those four tiles are the discipline this entire chapter runs on, and they are why so few programme figures appear in it. A national number missing any one of them is not a fact; it is a recollection with a decimal point attached. Where a programme figure carries all four, this chapter prints it with all four. Where it does not, the chapter names the construct without its number and records the absence, which is the correct answer and not an evasion.

MNEMONIC

Objectives, components, delivery, money, returns

The five things any national health programme consists of, in the order you should describe one. An answer that gives the objectives and stops has described a fifth of the instrument.

PITFALL

Describing the programme entirely through its objectives. Objectives are the most memorable part and the least informative, because every national programme's objectives read approximately alike. What differentiates one programme from another is its delivery architecture, the level at which the money stops, and what it requires anyone to report. If you can describe those three for the National Mental Health Programme, you can answer almost any question in this area, including ones about programmes you have never studied.

The National Mental Health Programme is a Union instrument that sets objectives, defines components, moves a share of the money and requires returns; states and districts do the delivering, which is why approval and function are never the same number.

3 · District Mental Health Programme (DMHP): structure, components and implementation

The district is where Indian mental health policy either becomes a service or stays a sentence. The **District Mental Health Programme** is the operational limb through which the National Mental Health Programme reaches a population: a team, a budget line, a place to work from, a referral route in both directions, and a training obligation towards the general health workforce of the district. Every national ambition in this chapter, integration into primary care, task-shifting, closing the treatment gap, reaching a rural population, is discharged at this level or nowhere.

This section teaches the district limb as a service architecture and as an implementation problem. The parent programme's objectives, evolution and national machinery are taught in the section immediately before this one and are not repeated here. The way this same district structure functions as the community delivery vehicle for rehabilitation in schizophrenia, set beside assertive community treatment, is taught in the Schizophrenia: management, antipsychotics and adverse effects notes.

3.1 Why the district, and not the state or the block

The choice of the district as the unit is not administrative convenience; it is the level at which the three things a mental health service needs coincide. The district is small enough that a single specialist team can physically reach its facilities and large enough to justify one existing at all. It is the level at which the health administration already holds a budget, a stores system, a supervisory hierarchy and a reporting line, so a new programme can be attached to machinery that exists rather than built beside it. And it is the level at which secondary care sits, which matters because a mental health service that has no bed and no acute pathway becomes an outpatient clinic that refers its sickest patients away.

Compare the alternatives and the logic becomes obvious. A state-level unit can plan but cannot deliver; the distances defeat it and the specialists sit in the capital. A block-level unit can reach people but cannot be staffed with a specialist team at that density, and it has no bed. The district is the compromise, and like every compromise it inherits both problems in miniature: it is still far from the periphery, and it is still thin at the top.

RULE **A district programme is defined by what it does to the district's existing services, not by what it does itself.** Its clinic is the smallest part of it. Its real product is a general health system that can identify, start, continue and refer mental health care, which is why training and supervision, not consultations, are the components that determine whether it works.

3.2 When the district limb came in, and what that means

The **District Mental Health Programme** was brought in under the national programme in **1996**, and that year is stated in an official Ministry of Health and Family Welfare consultation record rather than in the founding instrument itself. That distinction matters and is worth carrying: the source is official but secondary, meaning it restates the fact rather than being the document that created it. A different year for the same event circulates widely in teaching

material, and this chapter prints the year its own retrievable official source carries rather than the year that is most often repeated.

The substantive point behind the date is that the district limb was an addition. The national programme began as an integration argument directed at the general health system; the district structure came afterwards as the vehicle for making that argument operational. That sequence explains a persistent feature of Indian mental health administration, which is that the district programme is always described as a component of something larger and is always funded as one, so its fortunes rise and fall with decisions taken about the parent programme rather than about itself.

3.3 What a functioning district unit actually consists of

Describe a district unit by its components and you will be able to say, for any real district, exactly which part has failed. Six things have to be simultaneously true.

- **A team.** A specialist core with psychiatry, clinical psychology, psychiatric social work and psychiatric nursing, plus programme and record staff. The composition matters less than the completeness: a team missing its psychosocial cadre becomes a prescribing clinic, and a team missing its record staff becomes invisible to the reporting system.
- **A place, at more than one level.** A base at the district hospital and outreach to peripheral facilities, because a service that exists only at the district headquarters has simply relocated the travel burden from the state capital to the district town.
- **An uninterrupted drug supply.** The essential psychotropics are cheap and off patent, so a stock-out is a logistics failure and never a cost one. A single interrupted supply undoes months of adherence work and teaches a family that the service cannot be relied on.
- **Referral in both directions.** Upward referral is easy to arrange and easy to overuse. Back-referral, the deliberate return of a stabilised patient to a peripheral facility with a plan the medical officer can follow, is the harder half and the one that determines whether the specialist team ever has capacity for new patients.
- **A training cascade.** The district team trains medical officers, health workers, counsellors and teachers, who then identify and manage what they can. This is the multiplier; without it the programme's reach is capped at the number of patients four or five specialists can personally see.
- **Records and returns.** Whatever is not recorded did not happen as far as the programme is concerned, and whatever is recorded without a denominator cannot be interpreted by anyone above the district.

Read that list again as a diagnostic instrument. When a district programme is described as non-functional, one of those six has failed, and the failure is usually the team or the supply. When it is described as functional but ineffective, the failure is almost always the fifth or the sixth.

3.4 The training cascade, and the school component that belongs elsewhere

The cascade is the part of the design that carries the public health logic. A specialist team that spends its time in direct consultation converts a scarce resource into a small number of individual encounters. The same team spending part of its time training, supervising and supporting a much larger general workforce converts the scarce resource into system capacity. That is the argument for task-shifting expressed at district scale, and the guidance and the medical officer's role in it are taught in their own sections of this chapter.

The programme's school outreach component is part of the same cascade, and it is taught in the Child psychiatry: assessment, treatment, services and protection notes rather than here. That chapter carries the school component in detail, including the teacher-training model with its own coverage figures for master trainers and schools. This section names the component as one limb of the district cascade and reproduces none of its numbers, so that a reader who meets a teacher-training figure meets it once, in one place, with one set of denominators.

3.5 Coverage: the number that exists, and exactly what it counts

There is one national coverage figure for this programme that can be printed with its provenance intact, and reading it correctly is the single most examinable skill in this section.

The Directorate General of Health Services reports that **767 districts** have been approved under the programme. That is approved coverage. It is not functioning coverage, and the source itself does not state the total number of Indian districts against which it should be read, so even the proportion approved cannot be computed from it without importing a denominator from somewhere else.

767	1996	Not stated
DISTRICTS APPROVED UNDER THE PROGRAMME, NOT DISTRICTS FUNCTIONING	YEAR THE DISTRICT LIMB CAME IN UNDER THE NATIONAL PROGRAMME	DISTRICT TOTAL, SO NO APPROVAL PROPORTION IS COMPUTABLE

Set the four fields against that figure and its limits are plain. The source is the programme's own official page. The population is districts of India considered for approval. The counted thing is districts approved. The denominator is not supplied by the source at all. Three of the four are strong; the fourth is missing, and the honest sentence says so rather than filling the hole with a district total remembered from elsewhere.

3.6 The number that does not exist, and why that is the answer

The obvious next question is how many of those districts have a service actually running in them. That figure was sought for this chapter from the national programme, from the directorate and from the ministry, including by targeted searches of official domains for functioning or operational districts, and by attempted retrieval of the ministry's own annual report. It was not obtained. There is, in this chapter's evidence position, no national, reference-dated, official count of districts in which district mental health services were functioning.

That absence is content, not a hole in the teaching. A candidate who says that the approved figure is the only national coverage number available, that approval is a sanctioning decision rather than

a service fact, and that the functional count is not published in a citable form has described the Indian evidence position accurately. A candidate who converts the approved figure into a claim about services running has made an error that no amount of confidence repairs.

COVERAGE QUESTION	WHAT WOULD ANSWER IT	WHAT EXISTS NATIONALLY
Is the district sanctioned?	An approval count from the programme's own records	Published: 767 districts approved under the programme
Is the service running?	A reference-dated count of districts with services functioning	Sought from the programme, the directorate and the ministry; not obtained
Is the team complete?	Filled posts against sanctioned posts, by cadre and by district	Not held in this chapter's evidence
Are people being reached?	Contacts against an estimated population needing care	Requires a survey denominator, taught in the survey section of this chapter

TRAP **Reading a sanctioned district as a functioning district.** This is the classic error in Indian community psychiatry and it is built into the way the data are produced: approval is recorded centrally because the centre approves, while function is a state and district fact that nobody aggregates. The approved count is real, official and correctly reported; it simply answers a different question from the one the reader is usually asking. Say "approved" every time you say the number.

IN INDIA

When a district is described to you as covered by the programme, treat that as an administrative statement and ask three follow-up questions before you plan anything on it: which posts in the team are filled today, whether the essential psychotropics were in stock last month, and whether any patient has been back-referred to a peripheral facility with a written plan. The published national figure is 767 districts approved under the programme, and approval is where those three questions begin rather than where they end.

3.7 What monitoring would have to look like

The reason the functional count does not exist is not indifference; it is that nobody has defined the unit of observation. Deciding whether a district service is functioning requires an operational definition that a clerk can apply consistently: how many days open, which cadres present, what stock position, what minimum activity, over what reference period. Without that definition, every state answers a slightly different question and the national total means nothing.

- An operational definition of a functioning unit, applied uniformly, with a stated reference period.
- Filled against sanctioned posts by cadre, because a team is not staffed if only the psychiatrist post is filled.
- Stock-out days for the essential psychotropics, which is the fastest single indicator of whether a service is real.

- Back-referrals as a proportion of stabilised patients, which measures whether the cascade is working rather than whether the clinic is busy.

MNEMONIC

Team, place, drugs, referral, training, returns

The six components of a district unit, and the six ways one fails. Name the six and you can diagnose any district service you are asked about, including one you have never visited.

PITFALL

Judging a district programme by its outpatient numbers. A busy district clinic can coexist with a completely failed cascade, and often does, because direct consultation is the easiest activity to increase and the easiest to count. Rising attendance at the district base with no back-referral and no trained medical officers means the specialist team has absorbed the district's workload instead of distributing it, and the service will saturate.

The published national figure is 767 districts approved under the programme; approval is a sanctioning decision, no national count of functioning districts is published, and the two must never be quoted as one.

4 · Mental Healthcare Act 2017: key provisions, advance directives, nominated representative

Every programme in this chapter runs inside a statute, and the statute is not this chapter's to teach. The Mental Healthcare Act is the legal frame within which India's national and district mental health programmes now operate. It fixes the entitlements a service has to honour, it creates instruments a patient may use to direct their own future care, and it establishes bodies that supervise both. Its provisions, including the advance directive and the office of the nominated representative, are taught in full in the Mental health legislation and forensic psychiatry notes. This section names the frame, prints that pointer, and stops.

That is a deliberate structural decision and not an omission. A statutory entitlement is a text with a fixed wording, and the fastest way to corrupt it is to let two chapters paraphrase it independently. The second account will differ from the first in a modal verb, a threshold or a procedural step, and neither reader will be able to tell which drifted. One owner, one wording.

4.1 The boundary, drawn once, and applied everywhere in this chapter

The division of labour is easier to hold if it is stated as a question rather than as a list of topics. A statute answers **what a service owes**: the right, the duty, the instrument, the procedure and the remedy. A programme answers **what a service has**: the posts, the drugs, the budget line, the referral route and the coverage. The two questions have different owners because they have different failure modes. A wrong entitlement misleads a patient about their rights; a wrong coverage figure misleads a planner about a population.

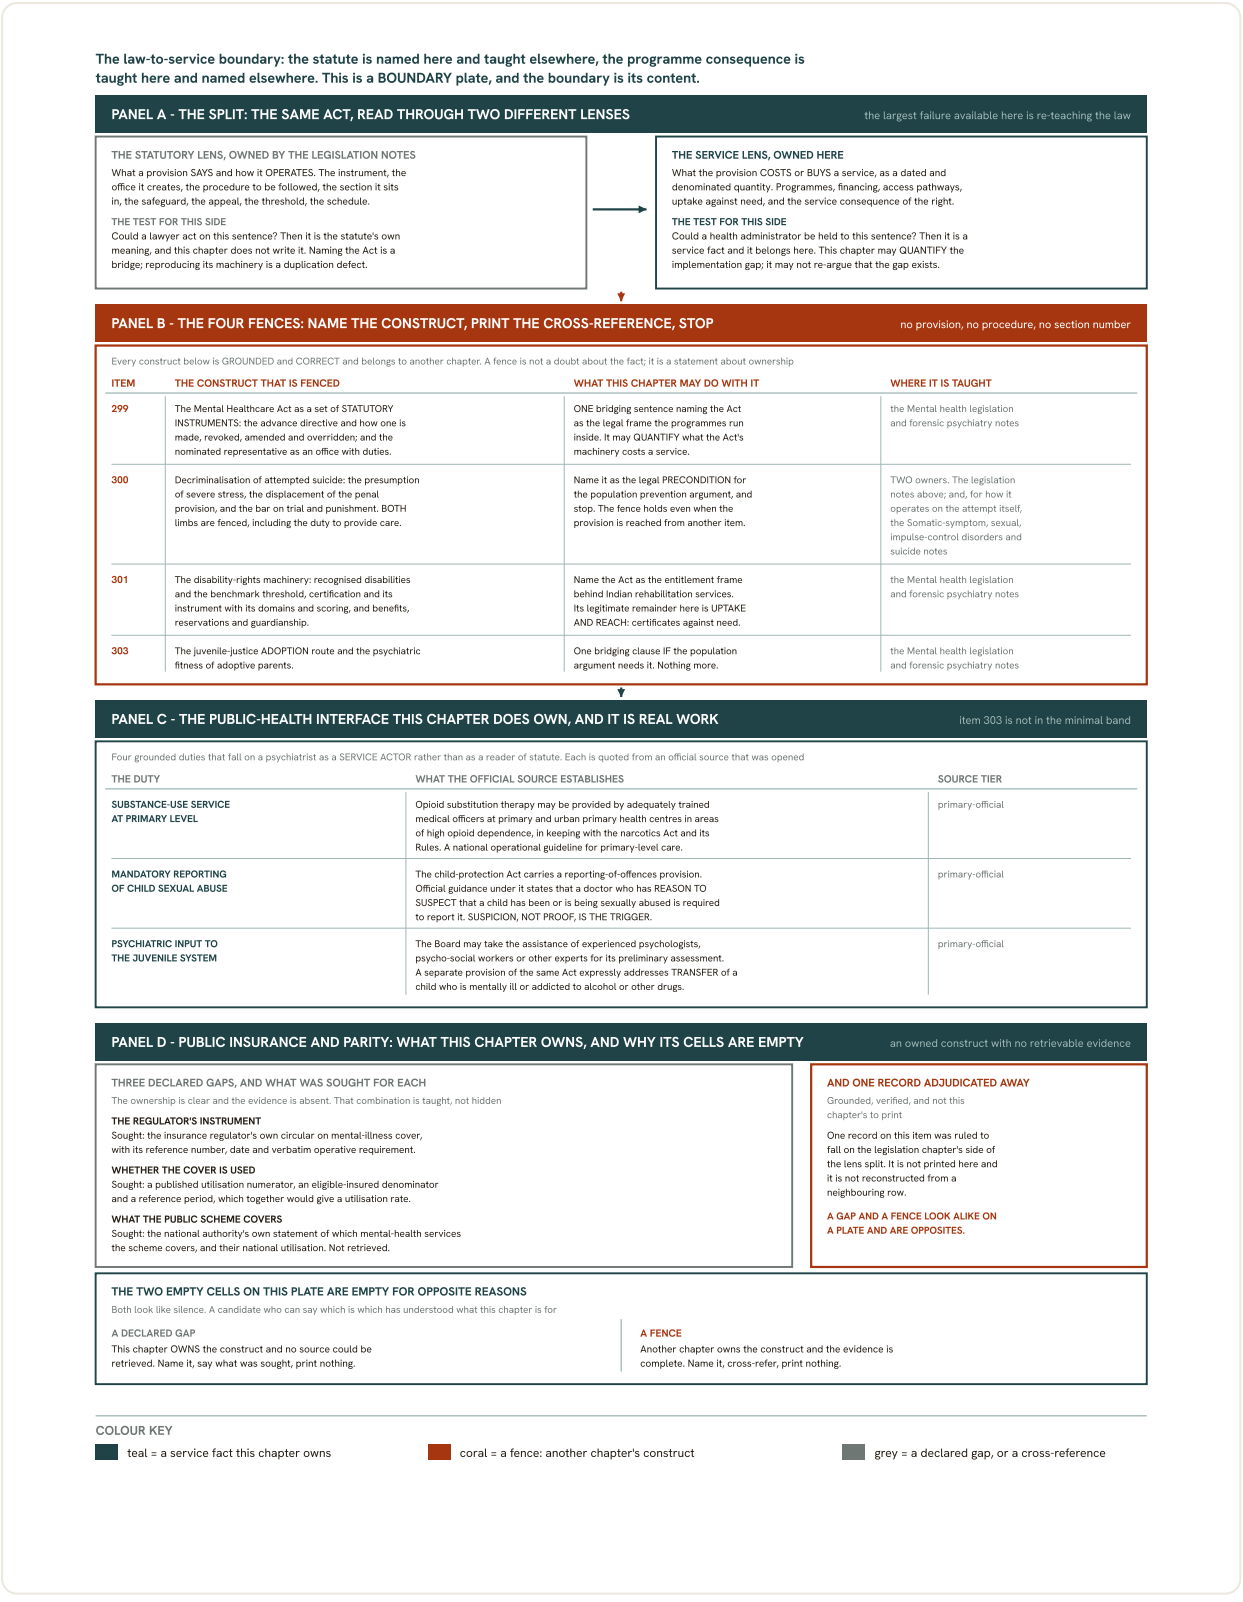

Fig 39.2 **The law-to-service boundary, drawn as an exclusion map.** The statute is named here and taught in the Mental health legislation and forensic psychiatry notes; what a provision costs or buys a service is taught here. Four constructs are fenced: the Act's statutory instruments, the decriminalisation of attempted suicide, the disability-rights machinery, and the juvenile-justice adoption route. No provision, procedure or section number is reproduced on this plate. The interface this chapter does own is real work and it is grounded: opioid substitution therapy provided by trained medical officers at primary level, a doctor's duty to report suspected child sexual abuse on reasonable suspicion rather than proof, expert psychological and psycho-social assistance to the juvenile-justice Board, and a transfer route for a child who is mentally ill or addicted. The insurance and public-scheme cells are empty because the regulator's own instrument could not be retrieved, which is the opposite kind of emptiness from a fence.

The accompanying figure is the exclusion map this chapter applies whenever a statute appears in it. Everything on the legal side is named here and taught elsewhere. Everything on the service side, meaning programmes, financing, access pathways, service architecture and population consequences, is taught here in full. No arrow crosses the line without a pointer attached to it.

RULE **Naming a statute is not teaching it, and pointing at its owner is the assertion that you did not teach it.** A section that names the Act and gives no provision, no procedure and no locator has discharged its obligation exactly. A section that adds one more paragraph has started writing a second copy of somebody else's chapter.

4.2 What legitimately remains here, and why it is not written

There is real work on this side of the line, and it is a counting job rather than an interpretive one. Statutory machinery has a running cost, and that cost is a service fact. An entitlement to make an advance directive implies somewhere it is lodged, somebody who retrieves it at the point of admission, and a record system that can produce it under pressure. An office such as the nominated representative implies people who know it exists, staff trained to identify one, and documentation that survives a transfer between institutions. Supervisory bodies imply members, sittings, quorum and a caseload. None of that is law; all of it is establishment, workload and coverage, which is what a public health chapter measures.

- Sites at which the Act's instruments can actually be lodged, retrieved and acted on, counted against the sites that admit patients.
- Staff trained to operate the machinery, counted against the establishment a district service is sanctioned for.
- Supervisory bodies constituted and sitting, counted against the units they are meant to supervise, with the reference year attached.
- The interval between an entitlement taking legal effect and the service being resourced to deliver it.

Each of those is a legitimate sentence for this chapter, and each becomes a defect the moment it is written without a source, a reference year, a population and a denominator. This chapter's evidence ledger holds no such dated, denominated quantity for the implementation load of this Act. The consequence is stated plainly rather than covered over: the argument that the Act's machinery is unevenly resourced is already in print in the legislation chapter and is not repeated here, and the quantification that would be this chapter's own contribution to it does not yet exist in a form that can be cited.

TRAP **Answering a service question with a statutory one.** Asked what the Act changed for a district service, candidates recite the rights. The examiner has already heard the rights. What distinguishes an answer is the operational consequence: who now has to be found, what now has to be recorded, and what has to be staffed for the entitlement to be real. If you cannot put a number on that, say so and say why, because at present nobody can.

Name	Point	Stop
THE ACT, AS THE LEGAL FRAME A SERVICE RUNS INSIDE	TO THE CHAPTER THAT TEACHES ITS PROVISIONS	NO PROVISION, NO PROCEDURE, NO LOCATOR HERE

MNEMONIC

Name it, point at it, price it

The three moves of a boundary section. The first two are always available. The third is the only one that belongs to this chapter, and it is the one that needs evidence this chapter does not hold for this Act.

The Mental Healthcare Act is named here as the legal frame the programmes operate inside; its provisions, instruments and procedures are taught in the Mental health legislation and forensic psychiatry notes, and this section reproduces none of them.

5 · Rights-based provisions and decriminalisation of suicide under the MHCA 2017

One provision of the Mental Healthcare Act changed the legal status of the suicide attempt in India, and it is the precondition for everything this chapter says about population suicide prevention. Before it, a person who survived an attempt met the health system through a door that also led to a police station. After it, the attempt is treated in law as the presentation of a person under severe stress rather than as an offence to be tried. That change is the reason a national prevention argument can be made at all in this country, because a population strategy cannot ask people to come forward while the coming forward is itself an offence.

The provision itself, its wording, the presumption it creates, the offence it displaces and the duty it places on government are taught in the Mental health legislation and forensic psychiatry notes, and the way the same provision operates on the individual suicide attempt is taught in the Somatic-symptom, sexual, impulse-control disorders and suicide notes. Both limbs are named here and neither is reproduced. This section is the bridge between them and the programmes that follow.

5.1 Why a public health chapter names a legal change and then stops

The rights architecture of the Act and the **decriminalisation** of the attempt are single texts with fixed wordings, and a statutory entitlement paraphrased twice in one book is an entitlement that will eventually be printed at two strengths. The risk is not abstract. The difference between a duty and a discretion lives entirely in the modal verb, and a public health author reaching for a summary sentence is precisely the author most likely to soften one. So the boundary here is drawn hard: no wording, no procedural step, no locator, no penalty, and no restatement of the duty that the appropriate government carries. Those belong to the two chapters named above and are complete there.

RULE **The fence on this construct holds wherever you approach it from.** The same provision is reached from the suicide prevention strategy, from psychiatric rehabilitation and from the emergency presentation, and it is fenced identically each time. A reader who meets it in three different sections should meet the same pointer three times, not three summaries that have drifted apart.

5.2 The service consequence, which is what remains here

Decriminalisation is a legal fact with an epidemiological shadow, and the shadow is this chapter's business. Three service consequences follow from it, and none of them requires reproducing a line of the statute.

- **Presentation.** A legal deterrent to disclosure suppresses presentation, and suppressed presentation is invisible in service data. When the deterrent is removed, recorded contacts can rise while the true rate is unchanged or falling. A service that reads a rise in attendances after a legal change as a rise in incidence has misread its own denominator.
- **Recording.** National mortality and morbidity data on suicide in India come through a police-recorded route, and what a legal category counts is not what a clinical category counts. The counting problem is taught with the national figures in the sections on suicide epidemiology and on farmer suicide in this chapter.
- **Obligation.** The provision does not merely remove a penalty; it places an affirmative duty of care on the state. A duty of that kind is discharged by services that exist, are staffed and are reachable, which is a coverage question, and coverage is what the programme sections of this chapter measure.

The third of those is where a candidate can distinguish themselves and where this chapter is most exposed. Naming the duty is the legislation chapter's work. Quantifying its discharge, meaning dated and denominated counts of the services that would actually deliver it, is this chapter's work, and it is done in the sections that own the national and district programmes rather than here.

TRAP **Answering "what did decriminalisation change" with the law rather than with the service.** The legal answer is already owned and already examined elsewhere. What a public health answer adds is the mechanism by which a legal change alters who arrives, what gets recorded and what the state is now obliged to provide. Candidates who recite the provision have answered a different question competently.

Named	Owned	Kept
THE LEGAL PRECONDITION FOR POPULATION PREVENTION	ELSEWHERE, IN BOTH ITS LEGAL LIMBS	PRESENTATION, RECORDING AND THE DUTY TO PROVIDE

MNEMONIC

Who arrives, what is written down, what is owed

The three service consequences of a legal change, and the only three this section carries. Everything else about the provision is taught in the two chapters named here.

Decriminalisation of the suicide attempt is named here as the legal precondition for population suicide prevention in India; its wording, its presumption, the offence it displaces and the duty it creates are taught in the Mental health legislation and forensic psychiatry notes and, as they operate on the attempt itself, in the Somatic-symptom, sexual, impulse-control disorders and suicide notes.

6 · Rights of Persons with Disabilities Act 2016 and mental illness as disability

Rehabilitation in India is not only a clinical activity; it is an entitlement system, and the Rights of Persons with Disabilities Act is the instrument that creates the entitlements. Everything this chapter later says about supported living, supported employment, day care, family-based care and long-term community support sits downstream of a legal architecture that recognises mental illness as a disability and attaches benefits to that recognition. This section names that architecture and points to where it is taught.

The Act itself, the conditions it recognises, the threshold at which a disability becomes a benchmark disability, the certification process, the Indian Disability Evaluation and Assessment Scale used within it, and the benefits, reservations and guardianship arrangements that follow, are taught in full in the Mental health legislation and forensic psychiatry notes. No schedule, no percentage, no procedure, no instrument domain and no score range is reproduced here. The whole band belongs there and it is complete there.

6.1 The one distinction worth carrying away from this boundary

An entitlement has two separate existences and candidates routinely collapse them. There is the **statutory entitlement**, which is what the law says a person is owed, and there is **uptake**, which is the proportion of the people who qualify who actually hold the document that unlocks it. The first is fixed the day the statute commences. The second is a service and administrative outcome that can stay near zero for years afterwards while the entitlement remains, on paper, complete.

That distinction is the reason a rights statute appears in a public health chapter at all. Legislation converts a clinical population into an eligible population. Certification converts an eligible population into a benefiting population. The gap between those two conversions is a coverage problem with all the ordinary features of one: it is unevenly distributed, it rewards the literate and the connected, it costs the applicant time and money, and it is invisible in any dataset that counts only the people who succeeded.

RULE **A right is a legal fact; a certificate is a service outcome; a benefit received is a population outcome. They are three different numbers and only the first is guaranteed by the statute.** An answer that moves from the Act straight to the benefit has skipped the step where Indian implementation actually fails.

6.2 What remains here, and the shape of the missing evidence

The legitimate remainder on this item is reach, and reach is a ratio. A defensible sentence about disability certification for mental illness in India would name an issuing authority, a

reference year, a numerator of certificates issued for mental illness, and a denominator of people estimated to meet the threshold. It would then say what proportion of the eligible population holds the document, and how that proportion varies by state, by sex and between rural and urban residence.

- Certificates issued for mental illness, nationally, in a stated year, from a named issuing authority.
- An estimate of the population meeting the threshold, derived from a survey whose own reference year and population are stated.
- The ratio of the two, presented as coverage and never as prevalence.
- The interval between application and certificate, and the proportion of applications that fail, because a process people abandon has the same population effect as a process that refuses them.

This chapter's evidence ledger holds none of those quantities for this item. That is stated here in prose rather than hidden in a footnote, because it is examinable in itself: a resident who can say that the entitlement is statutory, that the binding step is certification, and that the national uptake ratio is not established in a citable form has given a better answer than one who quotes a benchmark percentage from a slide and attaches it to the wrong denominator.

TRAP **Quoting a disability threshold as though it were a prevalence, or as though holding it were automatic.** The threshold is a legal criterion applied to an individual assessment; it says nothing about how many people cross it and nothing about how many of those who cross it are certified. The threshold, the assessment instrument and the certification procedure are all taught in the Mental health legislation and forensic psychiatry notes and none of them is reproduced in this chapter.

Named	Owned	Kept
THE ACT, AS THE ENTITLEMENT FRAME FOR REHABILITATION	SCHEDULE, THRESHOLD, INSTRUMENT AND BENEFITS, ELSEWHERE	UPTAKE AND REACH, WHICH ARE NOT YET GROUNDED

MNEMONIC

Eligible, certified, benefiting

Three shrinking populations, one statute. The law fixes the first, the certification process fixes the second, and only the third is a service outcome anybody experiences. This chapter owns the shrinkage; the statute belongs elsewhere.

The Rights of Persons with Disabilities Act is named here as the entitlement frame behind Indian rehabilitation and community services, and is taught in the Mental health legislation and forensic psychiatry notes; what belongs to this chapter is uptake, meaning certificates issued against estimated need, and no such national ratio is available to be printed.

7 · National Mental Health Policy and Tele-MANAS initiative

A policy states a direction and a programme builds something; India acquired one of each within a decade, and the pair is the cleanest worked example of the difference in this whole chapter. The National Mental Health Policy set out what the country said it wanted mental health care to become. **Tele-MANAS**, the national tele mental health programme, is a piece of national infrastructure that was actually built, that runs continuously, and that publishes reach figures. Teaching them together lets you see exactly where a stated intention turns into a countable service, and exactly where the counting starts to mislead.

Two internal boundaries apply throughout. The clinical workflow of a remote consultation and the regulatory framework governing it are taught in this chapter's section on telepsychiatry, and evidence on apps and digital products is taught in its section on digital mental health. This section owns the policy instrument and the national programme architecture, and nothing else.

7.1 The Policy: what a policy instrument is for

India's first national mental health policy was launched in **October 2014**. Being first matters more than the date itself. Until then the country had a programme without a policy, which is an odd arrangement: an implementation machine running without a published statement of what it was implementing towards. A policy supplies that statement. It names the values, the priorities, the populations regarded as needing particular attention, and the sectors expected to contribute.

What a policy cannot do is compel. It creates no right, imposes no duty and releases no money. Its influence is exerted through three indirect routes: it gives programme designers something to point at when they ask for resources, it gives advocates a published standard against which to measure performance, and it sets the vocabulary in which subsequent instruments are written. Judged as a legal instrument a policy is weak; judged as an agenda-setting instrument it can be decisive.

RULE **Ask of any policy what it would take for it to have been implemented, and whether anybody is required to report on that.** A policy with no named indicator and no reporting obligation cannot be shown to have failed, which sounds like protection and is actually the reason it can be quietly abandoned.

7.2 The scope the Policy claimed, and why that scope is unusually wide

The most consequential sentence in the Policy is not about services at all. Its stated scope includes **addressing the social determinants of mental health, including poverty, environmental issues and education**, as reproduced in the official national survey report's account of the mental health system. A policy that commits itself to social determinants has committed to something no health department can deliver alone, and that is deliberate rather than careless.

Three consequences follow, and they are examinable.

- **Intersectoral by construction.** If poverty and education are inside the scope, then departments of rural development, social welfare, labour and school education are

implementing agencies whether or not they know it. The health department becomes a coordinator as well as a provider.

- **The indicator problem becomes hard.** Service indicators are countable: contacts, admissions, prescriptions. Social determinant indicators belong to other sectors, move slowly, and cannot be attributed to a mental health policy even when they improve.
- **The accountability question sharpens.** A wide scope with no cross-sectoral reporting obligation produces a policy that is easy to agree with and impossible to audit. That is the single most useful criticism a candidate can make of any national mental health policy, and it applies well beyond India.

Which populations the Policy identifies as needing particular attention, and one population that a published policy analysis found it does not name among them, are examined in the Perinatal/women's mental health and emergency psychiatry notes. That finding is presented there as an analysis of the instrument rather than as a statement made by the instrument, and this chapter does not re-argue it.

7.3 Tele-MANAS: infrastructure rather than intention

The Government of India launched the national tele mental health programme, **Tele-MANAS**, on **10 October 2022**. Understand first what problem it is shaped around. India's specialist workforce is small and geographically concentrated, and it cannot be enlarged quickly. A telephone service breaks the geographical constraint immediately: it decouples where the caller is from where the responder is, it operates continuously rather than during clinic hours, and it can be staffed from wherever trained people happen to live.

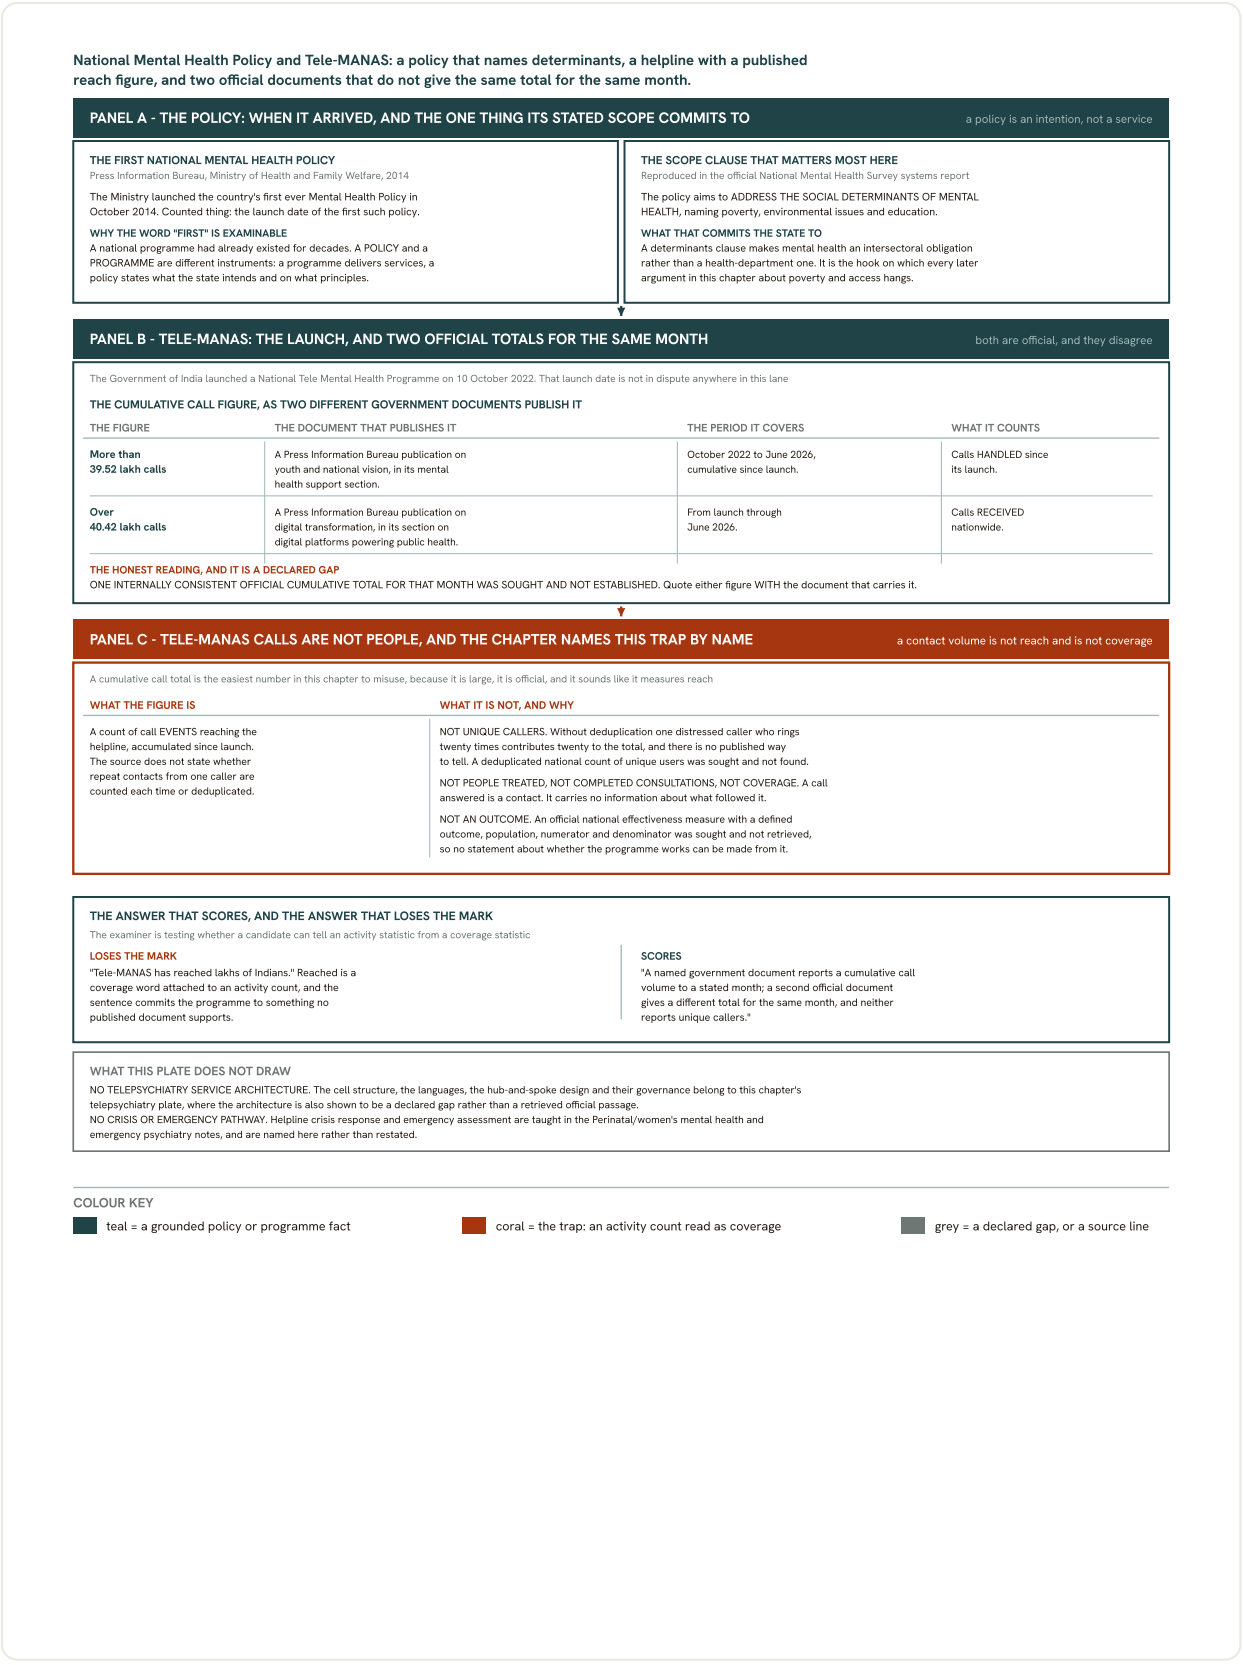

Fig 39.3 Policy and Tele-MANAS: an intention, a helpline, and a number that two official documents report differently. The country's first national Mental Health Policy was launched in October 2014 and its stated scope commits to addressing the social determinants of mental health, naming poverty, environmental issues and education. The national tele mental health programme was launched on 10 October 2022. For the same month one government publication reports more than 39.52 lakh calls handled since launch and another reports over 40.42 lakh calls received; one internally consistent official total was sought and could not be established, so either figure must be quoted with the document that carries it. Neither is a count of people: no deduplicated national count of unique users exists and no official effectiveness measure with a stated numerator and denominator was retrieved.

The accompanying figure sets out the policy instrument and the programme architecture together, including the tiered structure by which a call is answered, escalated and routed onwards, and it sets out alongside them exactly what the published reach figures do and do not count. Read the architecture as three separable claims: that a call is answered, that it is answered by somebody competent, and that it connects to onward care where onward care is needed. Only the first of the three is directly visible in any published figure.

7.4 The reach figures, and the disagreement between two official documents

This is the passage to read twice, because it is the chapter's whole discipline compressed into one construct. Two official documents report the cumulative volume this service has handled, and they do not agree.

One official release reports that Tele-MANAS handled **more than 39.52 lakh calls** by June 2026, counted cumulatively since launch, the reference period running from October 2022 to June 2026. A separate official release reports that the service had received **over 40.42 lakh calls** nationwide as of June 2026, again counted from launch. Two arms of the same official information apparatus, the same construct, the same stated month, two different totals.

10 Oct 2022	39.52 lakh	40.42 lakh
TELE-MANAS LAUNCH	CALLS HANDLED SINCE LAUNCH, ONE OFFICIAL RELEASE, TO JUNE 2026	CALLS RECEIVED SINCE LAUNCH, A SECOND OFFICIAL RELEASE, SAME MONTH

Do not reconcile them. There is no internally consistent official cumulative total for that month available to this chapter; the programme's own live dashboard was sought and could not be reached. The correct answer names both, attributes each to its own release, notes that one speaks of calls handled and the other of calls received, and says that the difference between those two verbs is not defined in either document. A resident who can do that has understood something more valuable than a memorised figure: that two official numbers for one construct usually differ because they are counting slightly different events, and that the difference is invisible unless you read the noun each one attaches to.

7.5 What a call total is not

Both figures count call events. Neither counts people. No official deduplicated national count of unique users of this service since launch was obtained for this chapter, and it was sought from the ministry and from the programme's own dashboard. That is not a small omission; it is the difference between a reach statistic and a workload statistic.

QUESTION ABOUT A NATIONAL HELPLINE	WHAT IT NEEDS	EVIDENCE POSITION IN THIS CHAPTER
How much work does it do?	A cumulative count of call events, with a reference period	Two official cumulative totals, differing, both printed above with their sources
How many people has it reached?	A deduplicated count of unique callers	Sought from the ministry and the programme dashboard; not obtained
What proportion of those who need it use it?	Unique callers over a population estimate of need	Not computable, because the numerator above does not exist
Does it help?	An operationally defined outcome, with numerator, denominator and reference period	Sought; no official national effectiveness measure was obtained

Work down that table and the shape of the evidence becomes clear. The service publishes the number that is easiest to produce and hardest to misinterpret innocently. Each successive row is more useful to a planner and less available. That pattern is not peculiar to this programme; it is what happens whenever a service is monitored by the system that runs it rather than by one that evaluates it.

TRAP **Converting calls into people.** A cumulative call total counts contacts, and neither source states whether repeat contacts from the same caller are counted each time or removed. One distressed person calling weekly for a year contributes many calls and one user. Writing that the service has "reached" that many people, or dividing the total by the population to produce a coverage rate, manufactures a statistic that no document supports. Say "calls handled, cumulative since launch, as reported by" and then name the release.

IN INDIA

When you are asked to justify a tele mental health service in a proposal or a viva, quote the volume as volume and then say what you would need to justify it as reach: a deduplicated user count, a population denominator and a defined outcome. Both published totals here are cumulative call counts, more than 39.52 lakh in one release and over 40.42 lakh in another for the same month, and neither is a count of people. Building a service case on the larger figure without that qualification is how a planning document acquires an error nobody can later trace.

7.6 Effectiveness, and the measure that is not published

The question that matters clinically is whether calling the service leaves people better off. Answering it requires an operationally defined outcome, a stated population, a numerator and a denominator, and a reference period. No official national effectiveness measure of that kind was obtained for this chapter, despite searches of the programme dashboard and ministry statements.

It is worth being precise about what that absence does and does not mean. It does not mean the service is ineffective; nothing here supports that claim either. It means the evidence that would settle the question in the direction of either answer is not published in a citable form, and that any confident statement about the programme's effect, positive or negative, is currently an

opinion. For an examination, the sequence to give is: what is published, what is not, and what would be needed. That sequence works for every programme in this chapter.

MNEMONIC

Volume, users, coverage, outcome

Four questions about any national service, in increasing order of usefulness and decreasing order of availability. Tele-MANAS publishes the first. The second, third and fourth were sought for this chapter and not obtained.

PITFALL

Treating a helpline as a substitute for a service rather than as a front door to one. A call answered competently is a triage and a beginning; its value depends almost entirely on whether the person can be connected to continuing care afterwards, which is a district-level question. A national telephone layer built over a thin district layer moves the bottleneck rather than removing it, and it makes the bottleneck harder to see, because the call is counted and the failure to connect onwards is not.

The Policy states a direction and creates no duty; the national tele mental health programme is real infrastructure whose published totals count calls, cumulatively since launch, and never people.

8 · Narcotic Drugs and Psychotropic Substances Act, Protection of Children from Sexual Offences Act and Juvenile Justice Act as they intersect psychiatry

Three statutes reach into psychiatric practice from outside psychiatry, and each one hands a mental health service a population it did not choose and a duty it did not write. The narcotic drugs legislation, the NDPS Act, defines who is an offender and who is a patient in substance use. The child sexual offences legislation, POCSO, places an affirmative reporting duty on the doctor who suspects abuse. The juvenile justice legislation creates forums that need psychiatric expertise and provides for children in institutional care who turn out to be mentally ill or dependent on substances. None of the three was written by health administrators, and all three determine what a health service has to be able to do.

This section teaches the public health and service interface only: prevention, referral, the population consequences of a legal frame, and the intersectoral machinery each statute presumes. The statutes themselves, their provisions, classifications, procedures, penalties and time frames, are taught in the Mental health legislation and forensic psychiatry notes, and the child protection procedure and the juvenile justice machinery are taught in the Child psychiatry: assessment, treatment, services and protection notes. No provision is reproduced here.

8.1 One question asked of three statutes

The productive way into this material is not to summarise three Acts, which is what an unstructured answer does and what the owning chapters already do properly. It is to ask each

statute the same two questions and compare the answers.

STATUTE	THE POPULATION IT CONSTRUCTS	WHAT IT ASKS OF A MENTAL HEALTH SERVICE
Narcotic drugs legislation	People who use controlled substances, split between an offender frame and a treatment frame	Treatment capacity that a person can reach without the reaching being risky, and services able to operate lawfully within the drug-control rules
Child sexual offences legislation	Children who have been or are being sexually abused, and the adults who encounter them	A clinician who recognises and reports, and a service organised so that reporting leads somewhere
Juvenile justice legislation	Children in conflict with law and children needing care and protection	Expert assessment capacity for its forums, and a route for children in institutional care who are mentally ill or substance dependent

Read across the third column and a single service requirement appears three times: someone competent has to be reachable, and there has to be somewhere for the person to go afterwards. That is a district service question, and it is why these three statutes belong in a public health chapter at all rather than only in a legal one.

RULE **A statutory duty on a clinician is only as real as the service standing behind it.** Legislation can require a doctor to act; it cannot by itself create the trained person, the pathway or the receiving service that makes the action useful. The gap between the duty and the capacity is a health system problem, and it is the part of this material that belongs here.

8.2 Drug control as a public health instrument

Every drug-control regime does two things at once, and the two pull in opposite directions for a health service. Supply reduction attacks availability through prohibition, interdiction and penalty. Demand reduction attacks consumption through prevention, treatment and rehabilitation. A statute that carries both creates a population that is simultaneously a target of enforcement and a target of care, and the person in that population has to decide which of the two they are approaching when they walk into a clinic.

That ambiguity has measurable service consequences and they are the substance of this subtopic.

- **Delayed presentation.** Where disclosure carries legal risk, people present later, sicker, and often through an emergency rather than through a clinic. The delay is invisible in service data because the earlier presentations that never happened leave no trace.
- **Incomplete disclosure.** A person who fears legal consequence under-reports quantity, route and the other substances used. Every clinical decision downstream, including dose, is then made on a corrupted history.

- **Family and employer concealment.** Legal risk attaches to the household as well as the individual, so the informants a clinician relies on have their own reason to minimise.
- **Distorted surveillance.** Enforcement data count seizures and cases; health data count contacts. Neither counts prevalence, and a rise in either can reflect activity rather than epidemiology.

The reformative side of the drug-control frame, meaning the statutory routes by which a person who undergoes treatment is treated differently by the law, and the arrangements for recognising treatment institutions, are taught in the Mental health legislation and forensic psychiatry notes. What that chapter also already establishes is that such routes work only where a qualifying institution is genuinely within reach, so this section does not re-derive that point and instead takes it as given.

8.3 Where the treatment actually has to sit

If reach is the binding constraint, then the design question is what level of the health system can lawfully and safely provide substance use treatment. National operational guidance for mental, neurological and substance use care at the first level of care takes a clear position on the hardest case. It states that **opioid substitution therapy may be provided by adequately trained medical officers at primary health centres and urban primary health centres, in areas with high levels of opioid dependence, in keeping with the drug control Act and Rules**.

Read the qualifiers, because they carry the whole design. The provider is a medical officer, not a specialist, which is task-shifting applied to the most tightly regulated treatment in psychiatry. The condition is adequate training, which converts the sentence from a permission into a training obligation. The targeting is geographical, directed at areas where opioid dependence is concentrated rather than spread thinly everywhere. And the whole permission sits inside the drug-control rules, so the regulatory frame is not bypassed but worked within.

> **IN INDIA**
>
> Where opioid dependence is concentrated, do not design the service around a specialist centre that people travel to. National operational guidance places this treatment at the first level of care, with adequately trained medical officers at primary health centres and urban primary health centres as the providers, within the drug-control rules. The practical decisions that follow are about training, supervision and regulated supply at that level, not about building another specialist clinic; a treatment that requires daily or near-daily attendance fails on distance long before it fails on efficacy.

8.4 Mandatory reporting as a service obligation, not only a personal one

The child sexual offences legislation is the point at which a clinician's private judgement stops being private. Official guidance issued under that legislation is explicit about the clinician's position: **a doctor who has reason to suspect that a child has been or is being sexually abused is required to report it**. Two features of that sentence do the work. The trigger is suspicion with a reason behind it, not certainty and not proof, which is a deliberately low

threshold. And the verb is one of requirement, not of discretion, so the decision the clinician faces is not whether to report but how to do it well.

The procedural detail, meaning who the report goes to, what form it takes, what protection the reporter has and what follows for the child, is taught in the Child psychiatry: assessment, treatment, services and protection notes. What belongs here is the systems consequence, which is routinely underestimated.

- **The duty falls on every clinician, so the service must assume every clinician will meet it.** A duty discharged well by the one consultant who happens to know the pathway is a service that has not implemented anything.
- **Confidentiality is reshaped rather than suspended.** The child and the accompanying adult need to be told, in advance and in plain language, what a clinician cannot keep to themselves. Saying it before the disclosure is honest; saying it afterwards is a betrayal the family will remember.
- **Reporting is the beginning of a service obligation, not the end of one.** The child still needs assessment, treatment and follow-up, and the reporting event frequently disrupts exactly the therapeutic relationship in which that would have happened.
- **A service needs a named route and a rehearsed one.** Which staff member acts, whom they contact, what is recorded and who supports the family afterwards should be settled before the first case, because the first case will present out of hours to the least experienced person present.

TRAP **Treating mandatory reporting as an ethical dilemma to be weighed case by case.** Candidates reach for the confidentiality argument because it is the interesting one. Where an official duty to report exists, the weighing has already been done by the legislature and the clinician's judgement is engaged in how to report, how to prepare the child and family, and how to preserve continuity of care afterwards. The examinable skill is the service design, not the deliberation.

8.5 Juvenile justice: two places psychiatry is written into the system

The juvenile justice framework creates forums that a mental health service interacts with directly. The Juvenile Justice Board and the Child Welfare Committee are, from a service point of view, destinations: places a child is routed to and routed from, each with its own decisions to make and its own need for information a clinician can supply. Their constitution, composition and procedure are taught in the Child psychiatry: assessment, treatment, services and protection notes.

Two provisions of that legislation reach psychiatry directly and both are service-shaping rather than merely procedural.

The first concerns expertise. In carrying out its preliminary assessment, **the Board may obtain assistance from experienced psychologists, psycho-social workers or other experts**. The modal is permissive and that is the important part. The statute contemplates expert input rather than compelling it, which means whether the expertise is actually available in a district is a

service question and not a legal one. A permissive provision in a district with no available expert is a provision that does nothing.

The second concerns children already inside the system. The legislation expressly provides for **the transfer of a child who is mentally ill or addicted to alcohol or other drugs**. That is a statutory recognition that institutional care will contain children who need psychiatric or addiction treatment, and it presumes a receiving service exists to transfer them to. Whether it does is, again, a district capacity question.

One further limb of the same legislation, the adoption route and the psychiatric fitness of prospective adoptive parents, is named here in a single clause because a reader tracing the statute will look for it, and it is taught in the Mental health legislation and forensic psychiatry notes. No eligibility criterion, regulation or fitness assessment procedure appears in this chapter.

Reach	Report	Receive
DRUG CONTROL: TREATMENT A PERSON CAN SAFELY APPROACH	CHILD PROTECTION: A DUTY ON EVERY CLINICIAN	JUVENILE JUSTICE: EXPERTISE AND A PLACE TO TRANSFER TO

8.6 What the three have in common, and what a service can do about it

All three statutes make a mental health service a downstream consumer of categories it did not define. The categories are legal, the thresholds are legal, and the timing is set by legal processes. A service that treats this as somebody else's problem discovers its consequences one crisis at a time. A service that plans for it does four things, and none requires a change in the law.

- **Identify the interfaces in advance** and name, for each, the person in the service who acts and the external counterpart they contact.
- **Train for the trigger rather than the statute.** Staff need to recognise the situation that starts the duty; the legal detail can be looked up, and the recognition cannot.
- **Build the receiving capacity, not only the referring pathway.** Every one of these statutes presumes somewhere to send a person. Pathways into services that do not exist generate paperwork and nothing else.
- **Record at the interface.** Cross-sector work is where documentation is weakest and where it is most likely to be examined later.

MNEMONIC

Reach, report, receive

What each of the three statutes asks a mental health service for: treatment a person can safely approach, a clinician who recognises and reports, and a service able to receive a child the system sends. Every one of the three is a capacity question rather than a legal one.

PITFALL

Assuming an intersectoral pathway exists because a statute presumes one. Legislation routinely presumes a counterpart service, a trained expert or a receiving institution, and says nothing about creating any of them. Before promising a court, a committee or a family that a route exists, confirm that the person at the other end of it is currently in post. The commonest failure at these interfaces is not a wrong decision; it is a correct referral into a vacancy.

These three statutes are named here and taught elsewhere; what this chapter owns is the capacity each one presumes, which is treatment a person can safely reach, a clinician who recognises and reports, and a service able to receive the child the system sends.

9 · Ayushman Bharat, insurance parity for mental illness and the IRDAI mandate

Who pays decides who is treated, and in mental health the answer has historically been the household. A person with a chronic psychiatric illness in India typically needs medication continuously for years, review appointments indefinitely, occasional admission, and travel to reach any of it, while earning less because of the illness. Every one of those costs falls on a family whose earning capacity the illness has already reduced. Financing is therefore not an administrative appendix to this chapter; it is one of the determinants of whether care is used at all.

This section teaches the financing and insurance machinery: how publicly financed health insurance is built, what parity means and how it is implemented, why mental illness fits an insurance model badly, and what can and cannot currently be said with evidence about coverage and utilisation in India. The legal right to **insurance parity**, its statutory wording and the account of how that right came in practice to move the insurance regulator, are taught in the Mental health legislation and forensic psychiatry notes. What that chapter does not name is the regulator, and this one does: the Insurance Regulatory and Development Authority of India, the **IRDAI**.

One boundary inside the Ayushman Bharat umbrella needs stating at the outset, because the shared brand causes real confusion. This section teaches the insurance and benefit-design limb, meaning the publicly financed hospitalisation scheme and the regulation of insurance products. The school health and wellness limb of the same umbrella is a different programme with a different delivery mechanism, and it is taught in the Child psychiatry: assessment, treatment, services and protection notes. One brand, two programmes, and their figures must never be pooled.

9.1 Four ways a health system pays, and what each does to psychiatric care

Any health system pays for care through some combination of four mechanisms, and each has a characteristic effect on a chronic, stigmatised, outpatient-dominant illness.

MECHANISM	HOW IT WORKS	EFFECT ON CHRONIC PSYCHIATRIC CARE
Tax-financed direct provision	Government funds and runs facilities; care is free or nominal at the point of use	Best fit in principle, because it can cover continuing outpatient care; limited in practice by staffing and reach
Publicly financed insurance	Government buys defined packages of care for defined beneficiaries from empanelled providers	Fits admissions and procedures; fits continuing outpatient treatment poorly unless deliberately designed to
Private voluntary insurance	Individuals or employers buy a product from an insurer, subject to regulation	Historically excluded or restricted psychiatric cover; the reason a parity requirement was needed at all
Out-of-pocket payment	The household pays at the point of use	Default when the other three fail; the mechanism through which illness produces impoverishment

Read the fourth row as the residual. Out-of-pocket payment is not a policy choice anybody makes; it is what happens when the first three do not cover something. Every argument for parity, for benefit-package design and for public financing in mental health is ultimately an argument about shrinking that fourth row.

RULE **An insurance benefit is defined by the event it pays for, and psychiatric care is mostly not an event.** Hospitalisation insurance pays for admissions. Chronic psychiatric care is a long sequence of inexpensive contacts with occasional expensive ones. A benefit designed around discrete admissions can be generous, well administered and still leave the ordinary course of a mental illness entirely unfunded.

9.2 The machinery of a publicly financed insurance scheme

To criticise a scheme intelligently you have to know where its joints are. A publicly financed hospitalisation scheme has six moving parts, and a mental health service can fail at any of them.

- **Beneficiary identification.** Somebody has to be established as entitled before care, which requires a document, a database entry and usually literacy or an intermediary. People who are homeless, wandering, undocumented or estranged from family fail here first, and that population overlaps heavily with severe mental illness.
- **Empanelment.** Only listed facilities can provide the benefit. If the psychiatric facilities in a district are not empanelled, the entitlement is real and unusable.
- **Benefit package design.** The scheme pays for named packages. What is not named is not paid for, and naming psychiatric care in package terms is genuinely hard because much of it is time rather than procedure.
- **Pre-authorisation.** Approval before treatment suits planned surgery and suits acute psychiatric admission badly, since the admission decision is often urgent and made out of

hours.

- **Package rates.** A fixed price per package determines whether providing the care is financially survivable for the facility. A rate set below cost produces empanelled facilities that quietly decline the cases.
- **Claims and audit.** Payment follows documentation. Psychiatric documentation is narrative rather than numerical, which makes claims slower to settle and easier to reject.

Notice that four of the six failure points are invisible to a patient. A family that is told the scheme does not cover this is rarely told which joint failed, and the distinction matters enormously for anybody trying to fix it.

9.3 Parity, and its three separable limbs

Parity is a word that hides three different demands, and an answer that treats it as one has lost most of the available marks.

- **Coverage parity.** Mental illness is included at all, rather than excluded by a clause. This is the crudest limb and the easiest to verify.
- **Benefit parity.** Where it is included, the limits, sub-limits, waiting periods, co-payments and caps are no less favourable than those applied to physical illness. A product can satisfy coverage parity and fail here completely, and this is where formal compliance most often stops.
- **Administrative parity.** The pathway to claiming is no harder: the same documentation burden, the same pre-authorisation friction, the same likelihood of settlement. This limb is almost never measured and is where a formally compliant product can still deliver very little.

The value of separating them is diagnostic. When you are told that a market has achieved parity, the follow-up questions are which limb, measured how, and by whom. A regulator can require the first with a stroke of a pen; the second requires product-level scrutiny; the third requires claims data that nobody publishes.

TRAP **Treating a regulatory requirement as evidence that products changed.** A direction to insurers is an input. Whether the products in the market now carry psychiatric cover on comparable terms, and whether people actually claim under it, are two further questions that require product analysis and claims data. Candidates routinely answer the second and third by asserting the first more loudly.

9.4 The regulator's instrument, which this chapter could not open

Here the honest position has to be stated in full, because this section's central document is one this chapter does not hold. The insurance regulator is the body that turns a statutory entitlement into a requirement on insurance products, and it does so through circulars addressed to insurers. The specific circular concerning mental illness coverage, its reference number, its date and its verbatim operative requirement, was sought for this chapter through the regulator's own health department circular index, through its master circular on health insurance business, and

through searches for the specific circular references that circulate in secondary discussion. It was not obtained.

What follows from that is a set of refusals, and they are deliberate. This chapter prints no circular number, no circular date and no quotation of what the regulator directed. It does not paraphrase the requirement, because the strength of a regulatory obligation lives in its modal verb and a paraphrase of an unread document invents that verb. It does not state when the requirement took effect. And it does not assert that any particular class of product must now behave in any particular way.

The corresponding examination answer is available and is a good one. A resident can say that the statutory right sits in the mental health legislation, that the regulator responsible for translating it into product requirements is the Insurance Regulatory and Development Authority of India, that this translation is effected through circulars to insurers, and that they would cite the specific circular by number and date rather than from memory. That answer is complete, correctly attributed and contains nothing invented.

9.5 Utilisation, and the rate that does not exist

Suppose the requirement is in force and products comply. The question that then matters for a population is how much psychiatric care is actually being funded through insurance. Answering it needs four things: a numerator of claims or of people treated, a denominator of eligible insured lives, a reference period, and the resulting rate.

No such published utilisation figure was obtained for this chapter. Searches of the regulator's circular index, its health department material and its master circular on health insurance business did not yield a numerator, a denominator or a rate for mental illness coverage. The consequence is that no proportion, no growth trend and no comparison with physical illness utilisation appears anywhere in this section.

The same applies on the public side. A publication of the national authority that administers the publicly financed scheme, specifying which mental health services are covered and, if published, their national utilisation, was sought and not obtained. So this chapter names the scheme and the machinery, and does not list its psychiatric packages or quote their uptake.

Sought	Sought	Sought	None held
THE REGULATOR'S CIRCULAR, ITS NUMBER, DATE AND WORDING	A UTILISATION NUMERATOR, DENOMINATOR AND RATE	THE COVERED-SERVICES LIST FOR THE PUBLIC SCHEME	SO NO FIGURE IS PRINTED IN THIS SECTION

Four tiles, three searches, no figures. That is an uncomfortable result for a section about financing and it is reported rather than concealed, because the alternative is worse. Financing figures are the easiest numbers in this whole chapter to half-remember from a seminar slide, and a coverage percentage attached to the wrong denominator is a fabrication that no digit check will catch.

9.6 What a resident should actually be able to say

The absence of figures does not make this material unanswerable; it changes what a good answer consists of. Structure it in four moves.

- **Name the layers.** A statutory right to parity, a regulator that translates it into product requirements, a publicly financed hospitalisation scheme for a defined beneficiary population, and out-of-pocket payment as the residual.
- **Say where mental illness fits badly and why.** Outpatient-dominant, longitudinal, time-based rather than procedure-based, and expensive in aggregate through frequency rather than through unit cost.
- **Separate the three limbs of parity** and say which of them any given claim about compliance actually addresses.
- **State the evidence position honestly.** That the operative regulatory instrument and the utilisation data were sought from the regulator and the national authority and are not available to you in citable form, and that you would not quote a coverage or utilisation figure you cannot attribute.

MNEMONIC

Identify, empanel, package, authorise, price, pay

The six joints of a publicly financed insurance scheme, in the order a case passes through them. Ask which joint failed before concluding that a scheme does not cover psychiatry.

PITFALL

Reassuring a family that a scheme will cover an admission before checking the two joints that most often fail: whether the facility is empanelled for this care, and whether the beneficiary record is in order today rather than in principle. Both fail silently and both fail at the point of admission, when the family has already committed. Check them at the outpatient visit, not at the door of the ward.

Parity is three separate demands, coverage, benefit and administration; a health system that has met the first has usually not been tested on the other two, and in India the instruments that would test them were sought for this chapter and are not available in citable form.

Epidemiology, burden and treatment gap

10 · National Mental Health Survey of India: prevalence figures and key findings

Every service argument in Indian psychiatry eventually rests on one survey, and most people who quote it cannot say what it counted. The **National Mental Health Survey** is the country's reference estimate of how much mental illness there is, who has it, and how much of it is going untreated. Its figures are the denominators behind almost every planning claim in this chapter. They are also the figures most often quoted at the wrong value, for the wrong population, without the year they refer to, and against a denominator that belongs to something else.

This section teaches the survey as a planning instrument: what it sampled, how it defined a case, what it found, and what those findings can and cannot be used to decide. How the estimates were

derived and what they mean epidemiologically are taught in the Research Methods, Biostatistics and Epidemiology notes. The treatment gap as a construct, its determinants and what closes it are taught in their own section of this chapter, and the burden of mental disorders expressed in disability-adjusted life years is taught in another; no figure from either is reproduced here.

10.1 What a national survey is for, and what it is not

A national survey produces a population estimate. A service produces a service statistic. The two answer different questions and are constantly confused, so fix the difference before anything else. A service statistic tells you about the people who arrived: how many were seen, what they had, what was done. It is silent about everyone who did not arrive, and in mental health that silent group is the larger one. A population survey goes out and asks, so it sees people who never present at all. This is why a national survey is the only instrument that can tell you the size of the problem rather than the size of the workload.

What it cannot do is tell you about a district. Survey estimates are constructed for the populations the design was powered to describe. Applying a national figure to a particular district, or a state figure to a taluka, imports an assumption about similarity that the survey never tested. This is the single commonest analytical error made with these numbers in Indian service planning.

RULE **A prevalence figure is a statement about a defined population in a defined period, measured with a defined instrument under a defined case definition.** Change any one of those four and the number changes. Quote a prevalence without them and you have quoted a rumour that happens to be accurate.

10.2 The design, and why the state list matters

The survey was undertaken during **2015-16**. Its fieldwork reached **39,532 individuals**, sampled across 720 clusters from 80 talukas in 43 districts of the 12 selected states. It covered 12 states, namely Punjab, Uttar Pradesh, Tamil Nadu, Kerala, Jharkhand, West Bengal, Rajasthan, Gujarat, Madhya Pradesh, Chhattisgarh, Assam and Manipur, drawn to represent the regions of the country.

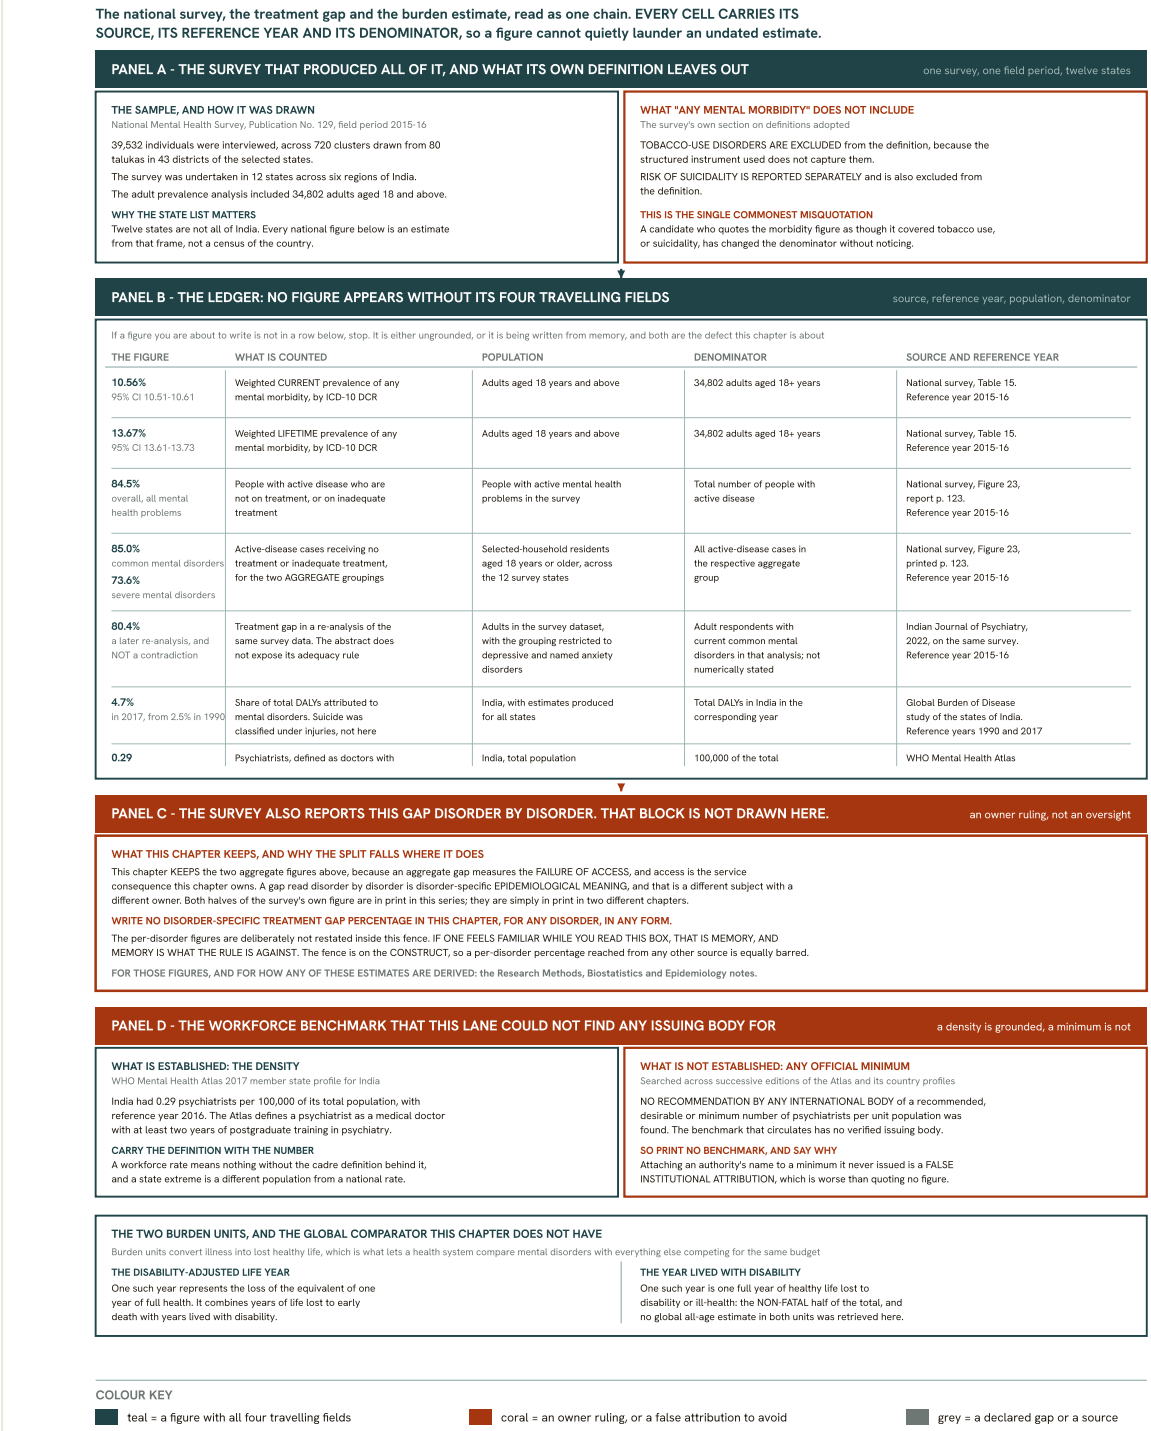

Fig 39.4 **The survey, the gap and the burden, with every figure carrying its four travelling fields.** The national survey interviewed 39,532 individuals across 720 clusters in 43 districts of 12 states, and its morbidity definition excludes tobacco-use disorders and reports risk of suicidality separately. Current prevalence was 10.56 per cent and lifetime 13.67 per cent. The treatment gap is printed here only in its AGGREGATE forms: 84.5 per cent overall, 85.0 per cent for common and 73.6 per cent for severe mental disorders, with 80.4 per cent from a later re-analysis whose disorder grouping was narrower. The survey's disorder-by-disorder block is owned by the Research Methods, Biostatistics and Epidemiology notes and no per-disorder percentage appears on this plate. Mental disorders accounted for 4.7 per cent of total DALYs in India in 2017, against 2.5 per cent in 1990. India had 0.29 psychiatrists per 100,000 population, and no international body's recommended minimum could be found, so none is printed.

The accompanying figure sets out the chain these findings sit in, from the survey's prevalence estimates through the treatment gaps derived from them to the burden expressed as health loss, with the source, reference year and denominator printed against every cell so that no figure in the chain can be read without them.

Read the state list rather than skipping it, because it is the survey's most important limitation and its most quotable one. Twelve states were sampled out of a much larger number, deliberately spread across the regions of the country so that the whole could be described from the parts. That is a legitimate and standard design. It also means that a state not on that list has no estimate of its own from this survey, and that any national figure derived from it is a construction from twelve sampled populations rather than a measurement of every state.

TRAP **Quoting the reference year as the year you are reading it.** These are figures from fieldwork conducted in 2015-16, and the reference year travels with them permanently. An estimate does not become current by being repeated, by being reprinted in a later document, or by being cited in a recent policy paper. Every time you quote one of these numbers, say the period it describes.

10.3 The case definition, which is where most misquotation begins

If you learn one thing from this section that other candidates will not know, make it this. The survey's headline category, any mental morbidity, is a constructed definition with explicit inclusions and, more importantly, explicit exclusions. Diagnoses were made against ICD-10 criteria and captured through a structured diagnostic interview, the Mini International Neuropsychiatric Interview, which fixes both what could be detected and what could not.

Two exclusions in particular change what the headline number means. **Tobacco-use disorders were excluded from the definition, and risk of suicidality, although captured, was reported separately and also excluded from it**. Both decisions are defensible and both are consequential. Tobacco dependence is extremely common, so including it would have raised the headline figure substantially and would have made it a different sort of number. Risk of suicidality is a risk state rather than a disorder, so folding it into a morbidity total would have mixed two kinds of thing.

The consequence for a reader is precise. When somebody quotes the national prevalence of mental disorders in India, the correct follow-up question is which construct they mean, because this headline excludes the commonest substance-use problem in the country and excludes the risk state that most service planning around suicide is directed at.

IN INDIA

Do not size a tobacco cessation component or a suicide prevention component from this survey's headline morbidity figure. Tobacco-use disorders are excluded from the definition and risk of suicidality is reported separately and excluded from it, so the headline number contains neither. A district plan that budgets for either on the basis of the overall morbidity estimate has sized it from a denominator that deliberately leaves it out, and will under-provide in exactly the two areas where demand is highest.

10.4 The headline findings, with their denominator attached

The adult prevalence analysis was conducted on **34,802 adults** aged 18 years and above. That figure is the denominator of the prevalence estimates, and it is smaller than the total number of people interviewed because the adult analysis is a subset of the whole sample. Carry it with the percentages; a proportion without its denominator cannot be interrogated.

Among adults aged 18 years and above, the weighted current prevalence of any mental morbidity was 10.56 per cent, with a 95 per cent confidence interval of 10.51 to 10.61. The corresponding weighted lifetime prevalence of any mental morbidity was 13.67 per cent, with a 95 per cent confidence interval of 13.61 to 13.73. Both are weighted percentages, which is stated in the report's own table footnote and is not a detail: weighting is what allows a sample drawn unevenly across strata to speak for the population it was drawn from.

The survey also reports how much of that morbidity was going untreated. Its treatment gap for mental health problems was **84.5 per cent**. Read the denominator carefully, because this is where the number is most often mangled: it is a proportion of the total number of people with active disease, counting people with active disease who are not on treatment or on inadequate treatment. It is not a proportion of the population. The treatment gap as a construct, its determinants and the interventions that narrow it are taught in their own section of this chapter, and the gap read disorder by disorder, with its epidemiological meaning, is taught in the Research Methods, Biostatistics and Epidemiology notes.

39,532	10.56%	13.67%	84.5%
INDIVIDUALS INTERVIEWED ACROSS THE SELECTED STATES	CURRENT ANY MENTAL MORBIDITY, ADULTS AGED EIGHTEEN AND OVER	LIFETIME ANY MENTAL MORBIDITY, SAME ADULT SAMPLE	TREATMENT GAP, OF PEOPLE WITH ACTIVE DISEASE

10.5 Four numbers, four denominators

Set the headline figures side by side with what each is a proportion of, and the difference between them stops being memorisable trivia and becomes a working tool.

FIGURE	POPULATION IT DESCRIBES	WHAT IT IS A PROPORTION OF	WHAT IT DOES NOT TELL YOU
Current prevalence 10.56 per cent	Adults aged 18 years and above in the sampled states	34,802 adults in the analysis	How many will develop illness later, or how many are in treatment
Lifetime prevalence 13.67 per cent	The same adult sample	34,802 adults in the analysis	How many are unwell now, which is the number a service needs
Treatment gap 84.5 per cent	People with active mental health problems in the survey	The total number of people with active disease	Why they are untreated, which is a separate section of this chapter
39,532 individuals interviewed	The whole sampled population, adults and others	Not a proportion; a sample size	Anything about states outside the sampling frame

The second row repays attention. Lifetime prevalence is always the larger and more quotable figure, and it is the less useful of the two for planning a service, because a service treats people who are unwell now. Where a planning document quotes a lifetime figure to justify current establishment, it has quietly inflated its case.

10.6 Children, and the limit this survey states about itself

The adult findings above are exactly that: adult findings, from an adult analysis, with an adult denominator. The survey carried an adolescent component, but it was a feasibility sub-sample confined to some of the survey states rather than a nationally representative adolescent survey, and it does not support an all-India childhood estimate.

The adolescent figure, the limits attached to it and the position that no established all-India psychiatric prevalence can be quoted for younger children are taught in the Child psychiatry: assessment, treatment, services and protection notes. No child or adolescent prevalence figure appears in this chapter, and no adult figure here is extended downwards to children. Extrapolating an adult rate to a child population is not a conservative approximation; it is a different claim about a different population made without evidence.

10.7 Using the findings for priority-setting without misusing them

The reason to know the design so well is that priority-setting arguments are won and lost on the denominator. Four disciplines make the difference between a survey-based argument that holds and one that collapses under a single question.

- **Name the construct before the number.** Any mental morbidity, current, adults, with tobacco-use disorders excluded and suicidality reported separately, is a specific thing. Saying "the prevalence of mental illness in India" and then giving a figure omits every part that makes it true.
- **State the reference period every time.** The estimates describe fieldwork in a stated period and nothing since. If you are asked how much of this is still true, the honest answer is that the survey cannot say, because a survey speaks only about when it was done.
- **Keep current and lifetime apart.** Use the current figure for establishment and workload arguments and the lifetime figure for arguments about population exposure over a life course.
- **Never mix denominators.** A prevalence is a proportion of a population, a treatment gap is a proportion of the people with the condition, and no arithmetic combining the two directly produces anything meaningful.

MNEMONIC

Who, when, how defined, out of what

The four fields that make a survey number a fact. Which population, which reference period, which case definition and instrument, and which denominator. Any of the four missing, and the figure cannot be checked by anybody who hears it.

PITFALL

Presenting the national estimate to a district administration as though it described their district. The survey sampled a defined set of states through a clustered design, and the national figure is built from those samples. A district that differs in its age structure, its urban proportion, its migration pattern or its substance-use profile will differ in its true prevalence, and nobody knows in which direction. Use the national estimate to argue that a service is needed, and local data, however imperfect, to argue how much.

Current weighted prevalence of any mental morbidity in adults was 10.56 per cent and lifetime was 13.67 per cent, both from fieldwork in 2015-16, on a definition that excludes tobacco-use disorders and reports suicidality separately.

11 · Treatment gap for mental disorders in India and its determinants

The treatment gap is the single most quoted number in Indian community psychiatry and the one most often quoted against the wrong denominator. It is not a measure of how much illness there is. It is a measure of how completely a health system is failing to reach the people who already have it. That distinction is the whole of this section: everything that follows is about what makes the gap the size it is, who is left on the wrong side of it, and what has actually been shown to move it.

How the estimates are derived, and what the gap means read disorder by disorder, are taught in the Research Methods, Biostatistics and Epidemiology notes. The national survey that produced the Indian estimates, its design and its own overall reported figure are taught in the section of this chapter that owns the survey. What belongs here is the causal and service account: determinants, inequities, consequences and interventions.

11.1 What the gap measures, and out of what

A **treatment gap** is the proportion of people with a condition who are not receiving treatment, or who are receiving treatment inadequate to their condition. Three features of that definition do all the work and each is a route to error.

- **The denominator is the diseased, not the population.** A gap of four fifths means four of every five people who have the condition are untreated. It says nothing about how common the condition is. Multiplying a gap by a population is arithmetic on two unrelated things.
- **Inadequate treatment counts as gap.** The measure is not simply contact. A person prescribed a subtherapeutic dose, seen once and never followed up, or treated by someone unqualified to treat them, sits inside the gap despite having reached a service. This is why closing a gap is harder than opening clinics.
- **The gap is population-specific.** It differs by disorder, by severity, by state, by sex and by wealth, so a single national number is an average across all of those and describes nobody exactly.

RULE **Never quote a treatment gap without naming the population it belongs to.** The commonest defect in this whole area is a figure carried across from the population it was calculated for to a different one. A correctly transcribed percentage attached to the wrong group is still a false statement, and it is one that no arithmetic check will catch.

11.2 The national figures, and the values that do not agree

India's national survey reports the gap for two aggregate groupings. **The treatment gap was 85.0 per cent for common mental disorders and 73.6 per cent for severe mental disorders**. The population is selected-household residents aged 18 years or older across the 12 survey states, the reference period is 2015-16, and the denominator in each case is all active-disease cases in the respective common-mental-disorder or severe-mental-disorder group. What is being counted is active-disease cases receiving no treatment or inadequate treatment.

Notice what the pair tells you before you go any further. The gap is *larger* for the common disorders than for the severe ones. That inversion surprises people who expect severity to track access, and it is one of the most instructive facts in this chapter. Severe illness is disruptive, visible to families and hard to ignore, so it eventually generates a contact even where services are poor. Depression and anxiety are survivable in a way that lets a person and a household absorb them indefinitely without anyone deciding that this is illness.

A lower figure circulates widely for the same construct, and a resident who meets it should be able to place it. A later analysis based on the same national survey data reported a treatment gap of **80.4 per cent** for its own analysis of common mental disorders. It is not a competing measurement of the same thing: that analysis restricted common mental disorders to depressive disorders and six named anxiety disorders, so its denominator is adult respondents with current common mental disorders included in that analysis and not the survey's own broader grouping. The opened abstract reports the treatment gap but does not expose its detailed numerator, its treatment-adequacy rule or its treatment window, and does not state the numeric denominator.

A third figure for common mental disorders also circulates and is not printed here. It was sought directly, in the published analysis and through several routes to its own tables, and it could not be established whether it is an overall pooled estimate or a subgroup estimate. A percentage whose population cannot be determined is not a fact yet, and this chapter does not print it in either reading.

TRAP **Treating two treatment gap figures from one survey as a contradiction to be resolved.** They usually differ because the analyses defined the disorder grouping differently, applied different adequacy rules, or used different time windows. The right response is not to pick one and dismiss the other; it is to state which grouping each describes. A candidate who says "the survey's own figure for common mental disorders, against a later re-analysis restricted to depressive and named anxiety disorders" has demonstrated exactly the discipline the examiner is testing.

11.3 What is deliberately not printed here

The same survey also reports the treatment gap disorder by disorder. Those per-disorder percentages are not printed anywhere in this chapter. They are neither missing nor doubtful: they

are grounded, verified against the survey's own report, and taught, with their derivation and their epidemiological meaning, in the Research Methods, Biostatistics and Epidemiology notes. A per-disorder gap figure is a statement about the epidemiology of that disorder, which is that chapter's subject; an aggregate gap is a statement about access failure, which is this one's.

That boundary is worth stating explicitly rather than silently observing, for a practical reason. If a per-disorder figure feels familiar as you read this, that familiarity is memory rather than evidence, and memory is exactly what the rule exists against. Write the aggregate figures, say that the survey reports the breakdown, and send the reader to the chapter that carries it.

11.4 Demand-side determinants, and the first person a family actually consults

A gap that large is not produced by one barrier; it is produced by a sequence, and the sequence begins before anybody has thought of a clinic. The national survey itself identifies the demand-side conditions behind it: **limited awareness, sociocultural beliefs, values and stigma** are named as demand-side barriers contributing to the treatment gap.

Qualitative work in Indian states fills that in from the point of view of the people making the decision. In a situational analysis of the mental health pathway in one southern state, stakeholders including policymakers, health professionals, non-governmental organisation staff and clients identified stigma, knowledge and expectations, lack of practical treatment access, and cost as influences on decisions about seeking care, drawn from 10 semi-structured interviews and 5 focus groups, each focus group containing 6 to 8 participants.

Stigma is not merely one item on that list; in some populations it is the decisive one. Among 100 consecutive included patients in a Kerala study of people who had attended a faith healer before reaching tertiary psychiatric care, **44 per cent** reported stigma of psychiatric illness as a main reason for avoiding psychiatric treatment.

The pathway data show where people go instead. In a South Indian tertiary outpatient sample of 104 patients and informants, the first carer consulted was an allopathic practitioner for 51.0 per cent, a religious healer for 26.9 per cent, and a mental-health professional for 22.1 per cent. Read those three proportions as a service design brief rather than as a curiosity. Roughly half of first contacts were with a doctor who was not a psychiatrist, which is the strongest available argument for integrating mental health into general and primary care. Around a quarter were with a religious healer, which is the argument for the partnership work taught in this chapter's section on traditional and faith-based care. Fewer than a quarter reached a mental health professional first.

IN INDIA

Design the first contact around where people actually go, not around where you wish they went. In the pathway sample above, 51.0 per cent of first carers were allopathic practitioners and 26.9 per cent were religious healers, against 22.1 per cent mental-health professionals. The service decision that follows is to invest in the recognition and referral capacity of general practitioners and in structured, respectful working relationships with faith-based providers, because both of those sit upstream of any psychiatric service and will continue to whatever the psychiatric service does. Note the limit as you use it: this is one tertiary outpatient sample of 104 patients and informants, not a national estimate.

11.5 The supply side, and the benchmark that does not exist

Demand-side barriers do not act alone. Situational work in northern India identified a dearth of mental-health professionals and inadequate services and facilities as adversely affecting the mental health treatment gap, drawn from 13 purposively recruited interview participants, plus local health-facility records and policy documents.

The workforce position can be put more precisely. For India, **0.29 psychiatrists per 100,000 total population** is reported in WHO Mental Health Atlas 2017, for the reference year 2016, against a denominator of 100,000 of India's total population using the official population estimate shown in the country profile. The definition matters as much as the value: the figure counts a medical doctor who has had at least two years of postgraduate training in psychiatry, which is the Atlas's own workforce definition and not necessarily the definition another source would use.

Now the part that most teaching gets wrong. It is conventional to follow a density figure with a recommended minimum, usually attributed to an international body. No such recommendation could be established for this chapter. An explicit recommended, desirable or minimum number of psychiatrists per lakh of population attributable to the World Health Organization or to the refugee agency was sought across the Atlas report and country profiles for several editions, the global health observatory indicator metadata, the intervention guide, and both agencies' own pages, and it was not found.

The consequence is a refusal that a candidate can make confidently: this chapter prints no workforce benchmark. Attributing a minimum ratio to an international body that has not issued one is a false institutional attribution, and it is worse than printing no benchmark at all, because it borrows an authority that was never given. The defensible sentence is that the density is low in absolute terms, that it is reported by a named body for a stated reference year against a stated denominator, and that no internationally issued minimum could be verified to compare it against.

85.0%	73.6%	0.29	None found
TREATMENT GAP, COMMON MENTAL DISORDERS, OF ACTIVE CASES	TREATMENT GAP, SEVERE MENTAL DISORDERS, OF ACTIVE CASES	PSYCHIATRISTS PER LAKH OF TOTAL POPULATION, ATLAS REFERENCE YEAR 2016	VERIFIED INTERNATIONAL MINIMUM WORKFORCE RATIO

11.6 Distance against money: what actually predicts reaching care

The intuitive model of access is geographical, and the best Indian evidence available here does not support it. In a rural implementation area in Madhya Pradesh, road distance to the nearest public provider of depression treatment was not associated with the probability of seeking treatment: the odds ratio was 1.00, with a 95 per cent confidence interval of 0.98 to 1.02, among 568 adults with probable depression.

In a population-based survey in the same district, what did predict contact coverage was economic position. Among 576 adults with probable moderate to severe depression within a 3,220-adult baseline survey, higher-income occupation was associated with a prevalence ratio of 7.17, with a 95 per cent confidence interval of 1.23 to 41.70, and land ownership with a prevalence ratio of 1.83, with a 95 per cent confidence interval of 1.21 to 2.76 for higher contact coverage.

Read those two findings together and the model of access changes. Building a clinic nearer to people does not, by itself, appear to be the binding constraint; being poorer and owning nothing appears to be. Treat the wide interval on the occupation ratio with the caution it deserves, and note that both studies concern one district and depression rather than the country and mental illness in general. Even with those limits, the direction is a corrective to the standard assumption, and it points service design at cost, lost wages and social position rather than at distance alone.

What is not available is the national quantification of that inequity. Quantified Indian treatment-gap or contact-coverage inequities comparing rural with urban populations, or comparing groups by sex or by education, without resorting to the disorder-specific figures owned by another chapter, were sought in the national survey report, in a summary of it, and in each of the primary Indian studies named above. None was obtained. So the inequity is taught here as a mechanism supported by district-level studies, and no national inequity percentage is printed.

11.7 What closes the gap, and what the trials actually measured

India has produced an unusually strong body of trial evidence on delivering psychological treatment through non-specialists. It is worth knowing well, and it is worth knowing precisely, because almost every trial measured a symptom outcome rather than a coverage outcome, and the distinction is the difference between showing that a treatment works and showing that a gap has closed.

STUDY AND SETTING	RESULT	WHAT WAS MEASURED
Lay health worker led collaborative care in primary care, Goa	A 30 per cent reduction between arms in the prevalence of an ICD-10 common mental disorder diagnosis	A symptom-diagnosis outcome across follow-up, not contact coverage
Brief psychological treatment for depression added to enhanced usual care, Goa	Remission 63 per cent against 48 per cent	Participants meeting the trial's remission criterion; a symptom outcome, not treatment contact or population coverage

STUDY AND SETTING	RESULT	WHAT WAS MEASURED
Brief counselling for harmful drinking added to enhanced usual care, Goa	Remission 54.3 per cent against 31.9 per cent, adjusted prevalence ratio 1.71	A trial-defined remission outcome, not contact coverage
Community champion led psychosocial intervention, Gujarat	Recovery odds ratio 2.2, with a 95 per cent confidence interval of 1.2 to 4.6	Categorical recovery from depression or anxiety symptoms; not service contact or population coverage
Peer-delivered perinatal depression intervention, Goa	Six-month remission 73 per cent against 60 per cent	A trial remission definition assessed six months after childbirth; not contact coverage
Anti-stigma and mental health service delivery in rural primary care, Andhra Pradesh	94.5 per cent of the intervention group against 2.5 per cent of controls self-reported receiving mental-health treatment at 12 months	Self-reported receipt of treatment, not independently verified treatment, symptom remission or whole-population coverage
Grass-roots community programme, rural Maharashtra	Associated with a substantial increase in equitable contact coverage for depression and improved mental health literacy	Contact coverage and literacy indicators before and after implementation

Work down the third column, because that column is the point. Five of the seven measured whether people got better, in populations already identified and enrolled. Only the last two measured whether people were reached at all, and one of those is described qualitatively here because its exact baseline and follow-up coverage figures could not be retrieved from any accessible copy of the original report. So the Indian evidence that non-specialist delivered treatment works is strong. The Indian evidence that any of it has closed a population gap is much thinner, and rests largely on those two.

The control arm figure in the rural Andhra Pradesh trial deserves separate attention. 2.5 per cent of controls self-reported receiving mental health treatment over twelve months, in a high-risk cohort identified by screening. That is the treatment gap seen from inside a trial, in people who had already been identified as needing care, and it is the most concrete illustration in this section of how little happens by default.

TRAP **Citing a remission rate as evidence that an intervention closes the treatment gap.** Remission is measured in people who were enrolled, and enrolment is the very step the gap consists of failing at. An intervention can produce excellent remission in everyone it reaches and change population coverage not at all. When you are asked what closes the gap, name the outcome the study measured before you name the effect size.

11.8 The evaluation nobody has published, and how to answer this

The standard answer to the treatment gap in India is the district programme. An official Indian evaluation reporting a measured before-and-after or controlled change in treatment gap attributable to that programme was sought for this chapter from the ministry, the directorate, the national health mission and the official assessment of the mental health system. None was

obtained: programme objectives, approved districts, administrative activity and service reporting are all documented, and an attributable effect on the gap is not.

That absence is the most useful single thing in this section. The country's principal instrument for closing the gap has not been shown, in any citable official evaluation, to have changed the gap. That is not a claim that it has failed; it is a claim that the question has not been answered, and the reason is that programme reporting was designed to record activity rather than to support attribution.

MNEMONIC

Know, seek, reach, receive, continue

The five steps between having a mental illness and being adequately treated. The gap is the sum of everyone lost at each step, which is why an intervention aimed at one step alone rarely moves the total.

PITFALL

Assuming the gap will fall as services expand. Expansion adds capacity at the reach step and does nothing for the know, seek or continue steps, which is why services can grow while the gap stays where it is. The corollary is practical: if you are given resources to reduce a gap, spend some of them on identification and on retention in care, not all of them on capacity, because capacity that nobody enters is invisible in every outcome measure that matters.

The treatment gap is a proportion of people with the condition, not of the population: 85.0 per cent for common mental disorders and 73.6 per cent for severe mental disorders in India's national survey, and the higher figure belongs to the milder group.

12 · Global and Indian burden of mental disorders: DALYs and YLDs

Counting people with an illness tells a finance ministry almost nothing, because it makes a fatal cancer and a mild phobia the same size. Health accounting solves that by measuring what is lost rather than who is affected, and the instrument it uses is the disability-adjusted life year. This is the measure through which psychiatry competes for resources against cardiology, obstetrics and infectious disease, and a resident who cannot explain how it is built cannot make the case for a mental health service in the room where the money is allocated.

This section teaches the metric and the Indian result. The definitions of incidence, prevalence and the measures of association, and the study designs behind them, are taught in the Research Methods, Biostatistics and Epidemiology notes. The national survey's prevalence findings and the treatment gap have their own sections in this chapter and no figure from either is reproduced here.

12.1 From counting cases to counting lost health

A case count answers how many. It cannot answer how bad, how long, or how much of a life is affected, and those are the questions any allocation decision turns on. Burden metrics were built to make different diseases commensurable by converting everything into a single currency: time lived in less than full health, plus time not lived at all.

The disability-adjusted life year is that currency. **One disability-adjusted life year corresponds to one year of full health lost, and the measure combines years of life lost through premature mortality with years lived with disability**. It therefore adds a severity dimension to a prevalence count, which is exactly what a prevalence count lacks.

Its two components answer different questions and they behave differently.

- **Years of life lost** capture mortality: how many years of expected life a death removed. A disease that kills young generates a great deal of this.
- **Years lived with disability** capture morbidity: how long people live with the condition, weighted by how disabling it is. **One year lived with disability represents one full year of healthy life lost due to disability or ill health, with prevalent conditions weighted by their disability weights**.

RULE **A burden estimate is the product of how many, how disabling, and for how long.** Change any one factor and the total changes without the number of cases moving at all. This is why a condition can become a larger share of national burden while becoming no more common.

12.2 Why psychiatry lives almost entirely in one half of the measure

Mental disorders are, in health accounting terms, a morbidity problem rather than a mortality problem, and that single fact explains most of psychiatry's position in these tables. They begin early, often in adolescence or early adult life. They persist or recur for decades. They impair function substantially while people remain alive. So they accumulate years lived with disability at a high rate and contribute comparatively little through years of life lost.

Three consequences follow, and they are the examinable content of this subtopic.

- **Psychiatry looks small in mortality-based accounts and large in disability-based ones.** Any argument built on death rates alone will understate mental illness, which is why mortality-led health planning has historically neglected it.
- **Duration does the work.** A condition that begins at twenty and persists accumulates burden for decades. This is the quantitative form of the argument for early intervention: preventing or shortening a long illness saves far more health than treating a short one.
- **Disability weights are a modelling choice, not a measurement.** How disabling a condition is judged to be is derived through survey and modelling methods, and a change in weights changes every downstream total without anybody's health having changed. Treat a burden figure as a model output, not as a count.

12.3 The Indian result, and the classification that sits underneath it

The Indian state-level burden work reports the contribution of mental disorders to total health loss in the country and how it has moved. **Mental disorders accounted for 4.7 per cent of total disability-adjusted life years in India in 2017, compared with 2.5 per cent in 1990.** The published estimates carry uncertainty: 2.5 per cent with a 95 per cent uncertainty interval of 2.0 to 3.1 in 1990, and 4.7 per cent with an interval of 3.7 to 5.6 in 2017. The denominator in each case is total disability-adjusted life years in India in the corresponding year, and the estimates were produced for all states of India as part of the global burden of disease work for that cycle.

Now the qualification that changes how the figure should be read, and which most people who quote it have never seen. What is being counted is disability-adjusted life years attributed to mental disorders as defined in that burden cycle, in which suicide was classified under injuries. Self-harm and suicide therefore sit outside this share. Whatever burden India's suicide mortality represents, it is not inside the figure above.

That is not a criticism of the estimate; it is how the classification works, and the same convention is applied across countries so that the comparisons hold. It is, however, decisive for how you use the number. A mental health service argument built on this share is built on non-fatal psychiatric morbidity alone, and a candidate who states that limitation while quoting the figure has demonstrated the four-field discipline more convincingly than one who simply recites the value.

2.5%	4.7%	Not held
MENTAL DISORDERS AS A SHARE OF TOTAL INDIAN DALYS, 1990	THE SAME SHARE IN 2017, SUICIDE CLASSIFIED SEPARATELY	GLOBAL ALL-AGE ESTIMATE IN BOTH DALYS AND YLDS

IN INDIA

When you are making the case for a mental health service to an administrator, use the share-of-burden framing rather than a case count, because it is the currency the allocation decision is already made in: 4.7 per cent of total Indian disability-adjusted life years in 2017, against 2.5 per cent in 1990. Then say, in the same breath, that suicide was classified under injuries in that cycle and sits outside the figure. Volunteering the limitation is what makes the rest of your numbers credible in a room where somebody else is arguing for cardiology.

12.4 How to read a rising share without over-reading it

A share that nearly doubles looks like an epidemic and usually is not one. The share of total burden attributable to a condition can rise for at least five reasons, and only one of them is that more people are becoming ill.

- **Other causes fell.** A share is a ratio. When communicable disease, maternal and child mortality and nutritional deficiency burden decline, everything else rises as a proportion without changing in absolute terms. This is the dominant mechanism in most middle-income countries.

- **The population aged and grew.** More adults living longer means more person-years at risk of conditions that persist.
- **Detection and reporting improved.** Better data produce higher estimates for conditions that were previously invisible.
- **Methods changed.** Successive burden cycles revise disability weights, case definitions and models, and a revision can move a share on its own.
- **Incidence genuinely rose.** Possible, and the hardest of the five to demonstrate.

The disciplined sentence is therefore that the share of India's health loss attributable to mental disorders roughly doubled over that period, that this is consistent with an epidemiological transition in which other causes fell faster, and that a share cannot by itself establish that the underlying rate of illness rose.

TRAP **Reading a rising share of burden as a rising incidence of illness.** A proportion moves when either its numerator or its denominator moves. In a country where the denominator has been falling for other reasons, the numerator can be flat and the share can still climb. Say "share of total burden" every time, and the error becomes impossible to make.

12.5 Three ways to express the same burden

One population, one set of illnesses, three ways to describe them. Each is right for a different audience and each hides something.

EXPRESSION	WHAT IT ANSWERS	WHAT IT HIDES	WHO USES IT
Case count or prevalence	How many people are affected	Severity, duration and mortality; a mild and a severe case count the same	Service planners sizing establishment and workload
Years lived with disability	How much non-fatal health is being lost	Deaths entirely; a condition that kills quickly scores low	Advocates for chronic and disabling conditions
Disability-adjusted life years	Total health lost, fatal and non-fatal together	Who exactly is affected, and the modelling assumptions behind the weights	Finance and planning bodies comparing across disease areas

A complete argument uses all three in sequence: how many people, how much health is being lost, and therefore what share of the allocation is defensible. An argument that uses only the first is easy to dismiss on the ground that the conditions are not serious, and an argument that uses only the third is easy to dismiss on the ground that it is a modelling artefact.

12.6 The global figure this chapter does not print

This item is titled for the global and Indian burden, and no global figure appears in it. That is a declared evidence position rather than an oversight. A global, all-age, both-sex estimate for all mental disorders expressed in both disability-adjusted life years and years lived with disability, with a stated reference year and the corresponding global totals as denominators, was sought

from the international health agency and from the institute that produces the burden estimates, through their observatories and through targeted searches of both. It was not obtained in a form carrying all four fields.

Two further gaps sit alongside it and both concern access rather than existence. A serving address for the published Indian state-level burden analysis could not be reached: the hosted copy returned an error, a repair attempt returned the same dead address, and neither a keyword search nor an exact-title search of the biomedical databases resolved the article. Two separate records in this chapter's evidence ledger point at that same unreachable source. The Indian figures above are printed because they are carried with their full provenance in this chapter's own evidence, not because the article could be opened afresh.

The consequence for a candidate is a specific and defensible position: quote the Indian share with its reference years, its uncertainty intervals, its denominator and its suicide classification; and, if asked for the global figure, say that a global estimate carrying both metrics with their denominators was sought and not obtained in a citable form, rather than reaching for a percentage that is widely repeated and rarely sourced.

MNEMONIC

How many, how bad, how long, how fatal

The four inputs to any burden estimate. Prevalence supplies the first, disability weights the second, duration the third, and mortality the fourth. Psychiatry scores heavily on the first three and lightly on the fourth, which is precisely why it needs this metric to be visible at all.

PITFALL

Mixing burden figures from different estimation cycles in one argument. Successive cycles revise weights, definitions and models, so a figure from one release and a figure from another are not two observations of the same quantity, and the difference between them can be entirely methodological. Take every figure in a single argument from one declared release, and say which one.

Mental disorders accounted for 4.7 per cent of total Indian disability-adjusted life years in 2017 against 2.5 per cent in 1990, a share of total health loss in which suicide was classified under injuries and therefore does not appear.

13 · Basic epidemiological concepts in psychiatry (incidence, prevalence, study designs)

This chapter uses epidemiological measures on almost every page and defines none of them. Incidence, prevalence, the relation between them, relative risk, the odds ratio, attributable risk and the observational designs that produce all of these are taught in the Research Methods, Biostatistics and Epidemiology notes. That is where the definitions, the derivations and the worked arithmetic live, and they are not repeated here.

The division is worth stating precisely because it is unusually clean. Defining a measure is a methods question. Using a measure to decide what a health system should do is a public health question. This chapter is entirely the second, and the three sections immediately before this one are where the using happens: the national survey and its prevalence findings, the treatment gap and its determinants, and the burden of mental disorders expressed as disability-adjusted life years and years lived with disability.

13.1 Where each measure is actually applied in this chapter

A reader who wants to see these concepts working rather than defined should read the three sections named above in that order, because they form a chain and each link uses a different measure for a different decision.

- **Prevalence answers how many people have the condition now.** That is the number a district uses to forecast caseload and to size an establishment. It is applied in the section on the national mental health survey.
- **The treatment gap answers how many of those people are not receiving adequate care.** That is a proportion of the diseased population, not of the general population, and it measures the failure of access rather than the frequency of illness. It is applied in the section on the Indian treatment gap.
- **Burden answers how much health is being lost, weighted by severity and duration.** That is the number a finance ministry compares across diseases when it allocates. It is applied in the section on disability-adjusted life years and years lived with disability.

Read as a chain, those three answer three different questions that are constantly confused with one another in examinations: how common, how untreated, and how costly. They can move in opposite directions. A condition can be common and cheap, or rare and devastating, or common and almost entirely untreated, and each of those combinations implies a different service response.

RULE **Every measure in this chapter is quoted with what it is a proportion of, and that denominator is part of the number.** A prevalence is a proportion of a population. A treatment gap is a proportion of the people with the condition. A burden share is a proportion of total health loss. Three proportions, three denominators, and the commonest examination error in this whole area is carrying one number across to the other's denominator.

13.2 The boundary, and why holding it protects the reader

There is a specific reason this section refuses to give a short definition of prevalence and move on. The measures are written in the same words on both sides of the boundary, so a short restatement here would look identical to correct teaching and would be impossible to police mechanically. What makes it a defect is not the wording but the consequence: two definitions of one measure in one book eventually diverge, and a reader who has met both cannot tell which is authoritative. One owner, one definition.

TRAP **Treating a treatment gap as though it were a prevalence.** They are reported in the same units and in adjacent sentences of the same survey report, and their denominators are entirely different. A gap of the order of four fifths does not mean four fifths of the population is ill; it means that of the people who are ill, roughly four in five are not adequately treated. Say the denominator out loud before you quote the figure.

How common	How untreated	How costly
PREVALENCE, APPLIED TO CASELOAD FORECASTING	TREATMENT GAP, APPLIED TO ACCESS	BURDEN, APPLIED TO ALLOCATION

MNEMONIC

Common, untreated, costly

Three questions, three measures, three denominators, three different service decisions. The measures themselves are defined in the Research Methods, Biostatistics and Epidemiology notes; this chapter only ever uses them.

Incidence, prevalence, measures of association and the observational designs that yield them are taught in the Research Methods, Biostatistics and Epidemiology notes; this chapter applies them and defines none of them.

Suicide prevention and farmer's suicide

14 · Farmer's suicide in India: epidemiology, determinants and prevention

Farmer suicide is the one public health statistic in India that everybody has heard and almost nobody can state correctly. It is quoted in politics, in journalism and in examinations, usually as a bare count and usually without the two things that would make it interpretable: what the counting category actually contains, and what the figure is a proportion of. This section teaches the number properly, and it teaches why the most important quantity in this whole area, the rate at which people in farming die by suicide compared with everybody else, cannot currently be computed at all.

The farming sector as a recognised at-risk group within general suicide epidemiology, and the population prevention levers that apply to it, are taught in the Somatic-symptom, sexual, impulse-control disorders and suicide notes. The national suicide prevention strategy, means restriction as a programme, and the epidemiology of suicide in India generally have their own sections in this chapter. What belongs here is the occupational count itself, its classification, its denominator problem and what would count as evidence that anything has worked.

14.1 Why an occupational category is a public health object

Suicide surveillance in India runs through a police-recorded route. The National Crime Records Bureau (NCRB) compiles cases reported through the police system and publishes them classified in several ways, one of which is by profession. That classification is what turns a distributed

personal tragedy into a countable population, and it is the reason a farming category exists in the national data at all.

An occupational category is worth having for three reasons. It identifies a population that shares an exposure, which is what makes targeted prevention possible. It allows a trend to be watched over time. And it creates political visibility, which in this case has been considerable. It also carries three costs, and the whole of the rest of this section is about them: the category has to be operationally defined, the people in it have to be correctly assigned to it, and the count has to be divided by the right denominator before it means anything.

RULE **An occupational count without an occupational denominator is a workload figure, not a risk figure.** It tells you how many deaths fell in this category. It cannot tell you whether people in that occupation are at higher risk than anyone else, because that comparison requires dividing by the number of people in the occupation, which is a different data source entirely.

14.2 The number, in full

The current published figure is this. **In 2024, 10,546 persons involved in the farming sector died by suicide in India, consisting of 4,633 farmers or cultivators and 5,913 agricultural labourers, accounting for 6.2 per cent of all suicide victims**. The denominator of that percentage is 1,70,746 total suicide victims recorded in India in 2024. The source is the National Crime Records Bureau's annual compilation of accidental deaths and suicides, the reference year is 2024, and the population is persons recorded by NCRB as involved in the farming sector, comprising the farmer or cultivator and agricultural labourer categories.

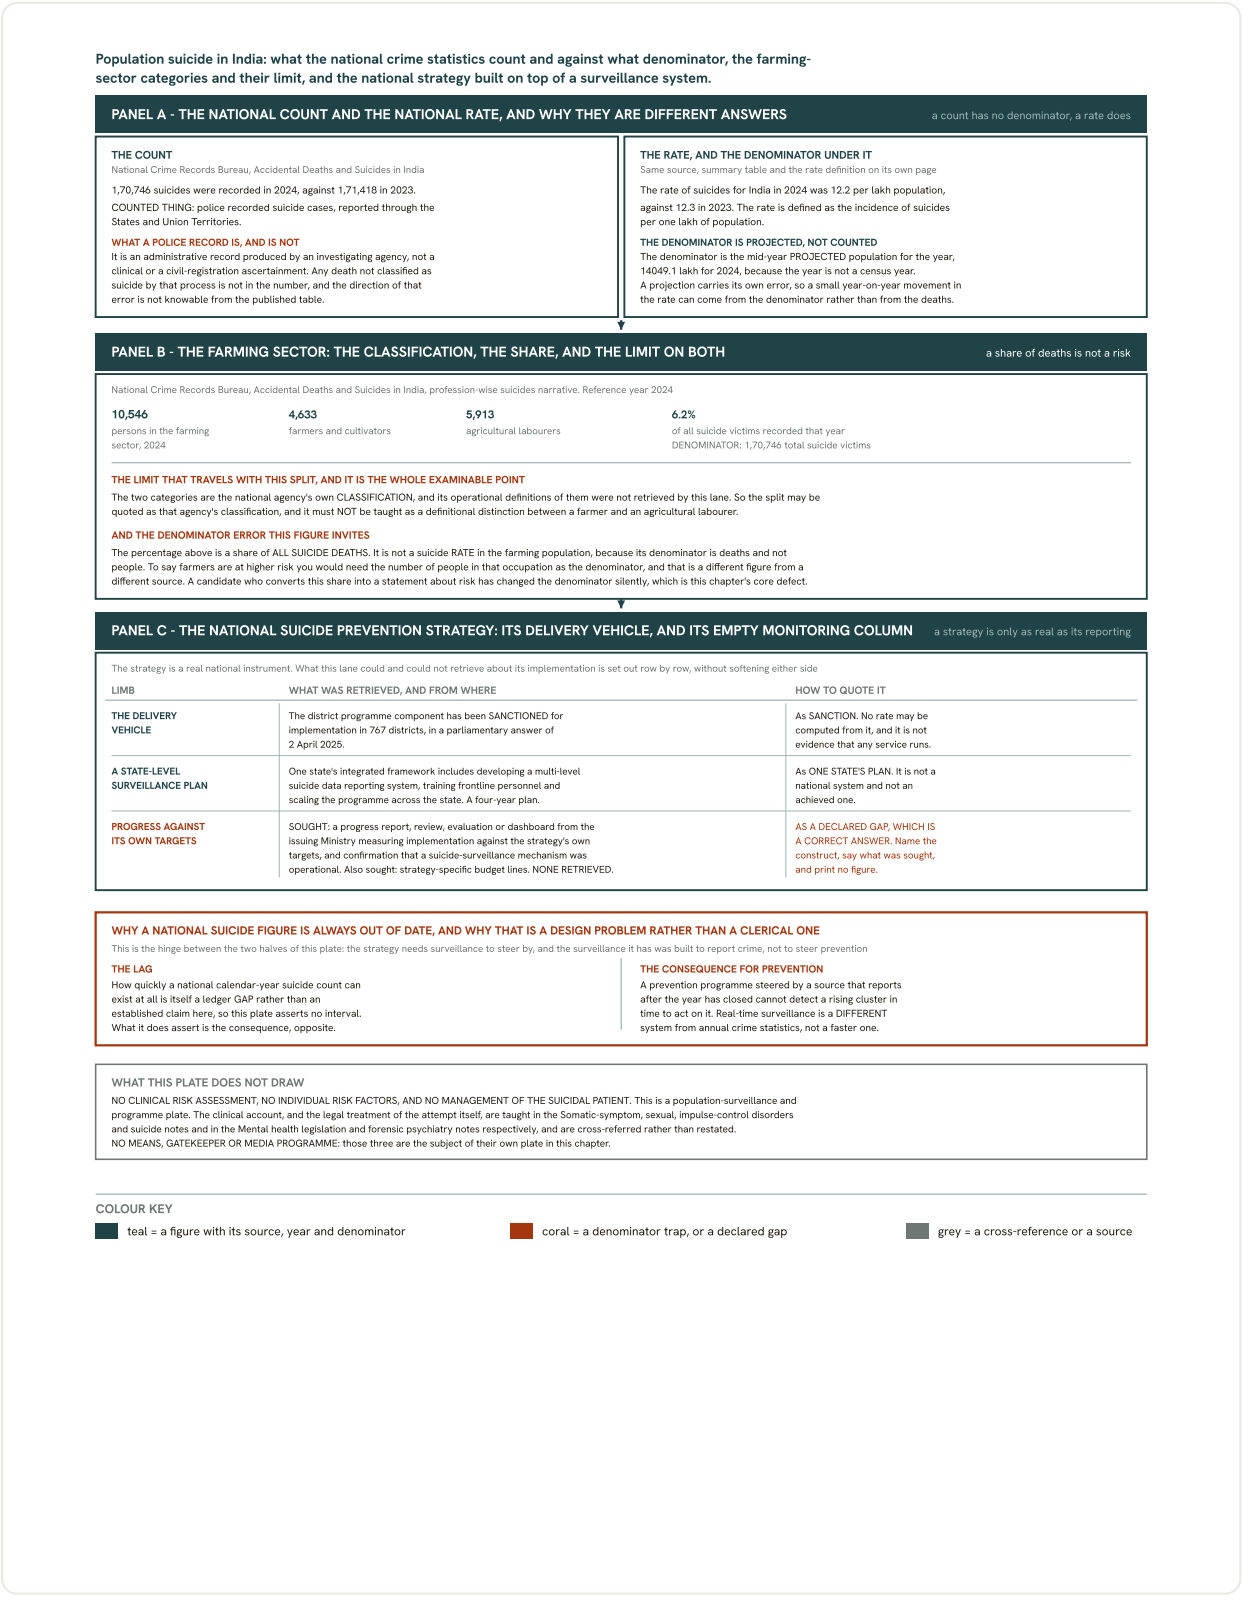

Fig 39.5 Population suicide in India: the count, the rate, the farming-sector categories and the strategy above them. The national agency recorded 1,70,746 suicides in 2024, against 1,71,418 in 2023, at a rate of 12.2 per lakh against 12.3, computed on a projected mid-year population because the year is not a census year. In the farming sector 10,546 deaths were recorded, comprising 4,633 farmers and cultivators and 5,913 agricultural labourers, 6.2 per cent of all suicide victims that year; because the agency's own operational definitions of those two categories were not retrieved, the split is quotable as its classification and not as a definitional distinction, and the percentage is a share of deaths rather than a rate in the farming population. The strategy's delivery vehicle is sanctioned in 767 districts, while progress against its own targets, confirmation that a surveillance mechanism was operational and its specific budget lines were all sought and none retrieved.

The accompanying figure sets out the surveillance architecture this figure comes out of, the categories the bureau publishes and the denominators available for each, alongside the governance of the national prevention strategy. Read it with the two limitations of the next two subtopics in mind, because the figure shows what the system counts and this text explains what the counting cannot support.

10,546	4,633	5,913	6.2%
FARMING-SECTOR SUICIDES RECORDED BY NCRB IN 2024	CLASSIFIED AS FARMERS OR CULTIVATORS	CLASSIFIED AS AGRICULTURAL LABOURERS	OF ALL RECORDED SUICIDE VICTIMS, NOT OF PEOPLE IN FARMING

Two features of that set deserve immediate attention, because both are routinely lost. The larger of the two component groups is agricultural labourers rather than landowning cultivators, which cuts against the way the issue is usually framed in public discussion. And the percentage is a share of all suicides in the country, which is a statement about the composition of the national total and not about risk in the farming population.

14.3 The classification, and the definition that could not be obtained

The split between the two categories is the most quoted feature of this data and the one this chapter is least able to explain. The bureau publishes the farming sector total divided into farmers or cultivators and agricultural labourers, and this chapter prints that split because it is what the source prints. What could not be obtained is the bureau's own operational definition of either category: the rule a recording officer applies to decide which of the two a particular deceased person belongs in.

That absence sets a hard limit on what may be said, and the limit is worth stating as a rule of method. The split may be reported as the bureau's classification. It may not be taught as a definitional distinction between two groups, because exactly what separates them in the bureau's coding is the thing that was not obtained. Anyone who tells you that the categories divide people by landholding, by tenancy status or by whether the work is paid is supplying an operational definition from inference, and the inference may be right, but it is not sourced.

This matters practically and not just pedantically. If a service or a state government wants to target the larger group, it needs to know who is in it. A category whose boundary rule is unpublished cannot be used to design an intervention with any confidence about whom it will reach.

14.4 The denominator problem, which is the heart of this topic

Here is the central analytical point of the section, and the one most worth carrying into an examination. To say that people in farming are at elevated risk of suicide, you need a rate: deaths in the farming population divided by the size of the farming population, compared with the corresponding rate elsewhere. The numerator exists and is published. The **denominator** does not exist in any form that can be validly matched to it.

The reason is that the two quantities are produced by different systems that do not share a definition of who is a farmer.

- **The numerator is an administrative classification made at the time of death,** by a recording officer, using a coding rule that this chapter could not obtain, applied to whatever information about the deceased was available at that moment.
- **Any candidate denominator is a census or survey classification,** made under its own definition of agricultural work, in a different reference period, and with its own treatment of people who do several kinds of work.
- **Neither system was designed to be divided by the other.** Combining them produces a rate whose numerator and denominator describe overlapping but non-identical populations, which is the classic route to a fabricated statistic that looks entirely respectable.

So the published share, being of all suicide victims rather than of people in farming, is doing something quite different from what most readers assume. It tells you what proportion of India's recorded suicides occurred among people classified as being in farming. It cannot tell you whether being in farming raises the risk, and it will move if the total number of suicides in the country changes even when nothing whatever happens in agriculture.

TRAP **Converting the share of all suicides into a statement about risk in farmers.** A share of the national total has the national total as its denominator, so it responds to changes anywhere in the country. Saying that farming accounts for a given percentage of suicides is correct. Saying that farmers are therefore at that level of risk, or comparing the share with the proportion of the workforce in agriculture as though the comparison were a risk ratio, is an error of denominators dressed up as an analysis.

IN INDIA

If you are asked to design a district response, do not begin from the national share. 6.2 per cent of all recorded suicide victims is a composition figure whose denominator is 1,70,746 total suicide victims recorded in India in 2024, and it tells you nothing about your district's farming population. Begin instead by establishing what your local denominator would be and who defines it, because until that is settled you cannot tell whether an intervention has worked, only whether the count went up or down for reasons you cannot attribute.

14.5 Who gets counted as a farmer, and who does not

Even before the denominator problem, the numerator has an assignment problem. Occupational classification at the time of death rests on what somebody records about a person's work, and agricultural work in India is unusually hard to record cleanly.

PERSON	HOW THE DEATH MAY BE CLASSIFIED	WHY THE ASSIGNMENT IS UNCERTAIN
An owner-cultivator working land held in their own name	Most likely within the farming sector	The clearest case, and the one public discussion imagines as typical
A tenant or sharecropper working land held by somebody else	Could fall in either component, or outside the sector	Whether cultivation without ownership counts as cultivating depends on a coding rule that is not published
A woman working on family land without holding it	Frequently recorded by household role rather than by occupation	Unpaid family labour is systematically under-recorded as work in many administrative systems
A person who farms in one season and does other paid work in another	Depends on which occupation the record captures	Multiple occupation is common and the record usually accommodates one
A landless labourer working across several holdings	Most likely the agricultural labourer component	Casual and migratory work is the hardest to attribute to any single occupation

Read that table as a description of measurement error with a direction rather than as a list of exceptions. The cases that are hardest to classify are concentrated among the poorest, the landless, the migratory and among women. Measurement error that is heavier at one end of a social gradient does not simply add noise; it biases the picture, and it biases it towards the group that is easiest to identify, which is the landholding cultivator.

14.6 What the data can and cannot say about causes

Determinant claims about this population are made constantly and are rarely qualified. Two limits govern how far a police-recorded surveillance system can support them.

The first is that a cause field in an administrative record captures the reason recorded by an investigator, from information available shortly after a death, in a context where the family may have strong reasons to present some explanations and not others. It is a recorded attribution, not an aetiological finding, and treating it as one imports the recorder's framework into what looks like epidemiology.

The second is that the same denominator problem prevents any comparison of determinant frequency between the farming population and everybody else. Without a rate, a determinant that appears often in this group cannot be shown to appear more often than in another group, which is what a risk factor claim requires.

The determinants of agrarian distress themselves, and the general aetiological models of suicide within which they sit, are taught in the Somatic-symptom, sexual, impulse-control disorders and suicide notes, and are not re-established here. What this section adds is the measurement caution that has to travel with them.

14.7 Prevention, and what would count as evidence

Targeted prevention for this population has been attempted in several forms, and this chapter holds no evaluation of any of them: no controlled comparison, no before-and-after estimate with a stable denominator, and no published attribution of change in the count to any programme. That absence is worth teaching directly, because it lets a candidate say something more useful than a list of interventions.

Set out what an evaluation would need, and the difficulty becomes obvious.

- **A stable denominator** over the evaluation period, so that a falling count can be distinguished from a shrinking population working in agriculture.
- **A comparison group** not exposed to the intervention, since counts in this area move with agricultural, economic and reporting conditions that no programme controls.
- **A consistent classification rule** across the period, because a change in coding practice would move the count on its own.
- **A pre-specified outcome and period,** since with year-to-year variation a favourable window can be found after the fact in almost any series.

Population-level prevention levers that apply here, including restriction of access to means and the national strategy that organises them, are taught in their own sections of this chapter, and this section does not restate them.

MNEMONIC

Who counted, who was counted, out of what

Three questions for any occupational suicide statistic. Which system produced the count, which coding rule assigned people into the category, and which denominator the figure is a proportion of. For this statistic the first is answerable, the second was not obtained, and the third does not exist in matchable form.

PITFALL

Comparing this year's count with last year's and calling the difference a trend. Year-on-year movement in an administratively recorded count reflects changes in reporting and classification practice as well as changes in deaths, and neither is separable without a stable denominator and a stable coding rule. Report the count with its year and its source; say that a trend claim requires both of those to have held constant, and that this chapter cannot establish that they did.

The farming-sector figure is a count with a national denominator, not a rate: 10,546 recorded farming-sector suicides in 2024, being 6.2 per cent of 1,70,746 total recorded suicide victims, and no valid occupational denominator exists to turn it into a risk.

15 · National suicide prevention strategy and population-level suicide prevention approaches

A national strategy is a governance document, not a treatment. It states what a country intends to do about a cause of death, names the sectors that will do it, and sets targets against which somebody is later supposed to measure it. That last clause is where most of the examinable content of this topic lives, because it is the clause that most often goes unhonoured. Candidates are rarely asked to recite a strategy's contents; they are asked what a strategy is for, what has to exist underneath it before it can work, and how one would know whether it had. Those are service questions, and this section answers them.

The prevention framework itself, the tiering of interventions into universal, selective and indicated, the four evidence-based population interventions in the World Health Organization's implementation guidance, the strategy's own headline goal and its staged action horizons, is taught in full in the Somatic-symptom, sexual, impulse-control disorders and suicide notes and is not restated here. What this section adds is the layer above and below that framework: how a strategy is delivered through an existing programme, what a surveillance system has to be able to do before a target can be checked against it, what the financing question is, and, unusually for a textbook section, a candid account of what is not published at all.

15.1 What a population-level strategy actually is, and what it is not

India has a **National Suicide Prevention Strategy**, which is the national governance instrument for suicide prevention and the reference point for every state and district plan written after it. A resident should be able to say three things about any such document. First, it is **multisectoral** by necessity: the levers that move population suicide mortality sit largely outside health, in agriculture, in commerce, in education and in the media, and a strategy that binds only the health ministry has already conceded most of its own case. Second, it is *staged*, because the levers act on different timescales; a regulatory restriction can act within a year, while a schools programme acts over a generation. Third, and this is the part candidates skip, it is *accountable*, meaning it names targets and therefore commits somebody to measuring them.

What a strategy is not is a service. It does not by itself open a clinic, train a worker or restrict access to anything. Everything it promises must be delivered through machinery that already exists or must be built, and in India that machinery is overwhelmingly the district-level mental health programme sitting under the national programme. This is why a question about the national strategy is very often, in substance, a question about district implementation.

RULE **A strategy is judged by its delivery vehicle and its measurement system, never by its text.** Two countries with identical strategy documents will produce different mortality curves if one has a functioning district service and a timely surveillance system and the other has neither. When you are asked to appraise a national strategy, appraise those two things first and the document second.

15.2 The delivery vehicle, and the single most misread figure in Indian community psychiatry

The vehicle for population suicide prevention in India is the **District Mental Health Programme**, the district-level component of the national programme. Its administrative scale is published: the district programme has been sanctioned for implementation in **767** districts. That is a governmental statement of approval, made in reply to a question in Parliament, and it is the number a candidate will meet on a slide.

Read what it counts. It counts districts for which implementation has been *sanctioned*. It does not count districts in which a suicide-prevention service exists, in which a gatekeeper has been trained, or in which a person in crisis could be seen. Sanction is an act of the centre; function is a property of the district. The two are separated by staffing, by the release of funds, by the state's own absorption capacity and by time, and nothing in a sanction figure carries information about any of them. Nor does the figure support a rate: there is no valid denominator against which a count of approved districts becomes a proportion of anything meaningful, because approval is cumulative and administrative rather than a measurement of a population at a point in time.

TRAP **Reading a sanctioned-district total as coverage.** Candidates write that the programme "covers" the sanctioned number of districts and then reason from that to national access. The word in the source is approval, and the correct sentence in an answer is that the programme is sanctioned in that many districts while the number in which suicide-prevention services actually function is not established. That second half of the sentence is worth more marks than the number is, because it shows you know what the number measures.

IN INDIA

When you are asked what a district psychiatrist can actually do under the national strategy, answer through the district programme, because that is the only route the strategy has. The practical consequence is that a district's suicide-prevention capability is decided by whether its programme post is filled and its funds released, not by whether the district appears on the sanctioned list. A resident asked to plan district suicide prevention should begin by establishing which of the sanctioned components are staffed and running locally, and treat the national total as a statement about paperwork rather than about services.

15.3 Surveillance read as an instrument, not as a table of numbers

A strategy that sets a mortality target needs a measurement system capable of telling it whether the target moved. In India **suicide surveillance**, meaning the routine national counting of deaths by suicide for programme purposes, is produced by the police-reporting system and published annually as a compendium of accidental deaths and suicides. Treated as a data instrument rather than as a source of quotable totals, it has three properties that decide what it can and cannot be used for.

- **Case definition.** The unit is a case recorded by police, which is an administrative event with legal consequences and not a clinical determination. Anything that changes the willingness of families or of the police to record a death as suicide changes the series without anything changing in the population.

- **Timing.** The annual publication collates a full calendar year, so collection can only begin once that year has ended. The interval between an event and its appearance in the national series is therefore at least a year and in practice longer.
- **Granularity.** The series is compiled upward from states, so its usefulness for targeting depends on the quality of state-level reporting, which is not uniform.

The timing property is the one with programme consequences and it is worth stating plainly as a declared limitation rather than glossing it. A system whose national picture arrives a year or more after the events it describes cannot function as an early-warning instrument, cannot support the rapid evaluation of a newly introduced intervention, and cannot tell a state within a planning cycle whether what it did last year worked. Whether India now has a suicide-surveillance mechanism that is operational, nationally complete and timely enough to monitor strategy outcomes is not established: this chapter sought an official assessment of exactly that question through the health ministry, the bureau that publishes the national series and the national institute that advises on the programme, and none was retrieved. The honest examination answer is that the strategy names a surveillance objective and that no published assessment confirms the objective has been met.

Sanction	None	Over a year	Not established
WHAT THE DISTRICT TOTAL COUNTS, NOT SERVICE DELIVERY	VALID DENOMINATOR FOR THE DISTRICT TOTAL, SO NO RATE	MINIMUM LAG BEFORE A CALENDAR YEAR ENTERS THE NATIONAL SERIES	PROGRESS MEASURED AGAINST THE STRATEGY'S OWN TARGETS

15.4 The state as the real implementing unit

Health is administered by the states, so a national strategy is realised as a set of state strategies and state programmes, and the interesting variation is between states rather than around the national mean. At least one state has taken this seriously enough to build an integrated framework of its own for suicide prevention and response, spanning health workers, communities and law-enforcement agencies. Its programme is designed around three components that are worth learning as a template: **a multi-level suicide data reporting system, training for frontline personnel, and scale-up of the programme across the whole state**.

Notice the order and the logic. The reporting system comes first because without it the state cannot know its own baseline or detect change; training comes second because it converts the strategy into an act somebody performs; scale-up comes third because a pilot in two districts answers no population question. That sequence is the generalisable teaching point, and it is a better answer to "how would you implement the national strategy in your state" than any recitation of the national document.

The specifics of any individual state's instrument, including the date on which such a strategy was released and the contents of its published text, are not established in this chapter's sources and should not be reconstructed from a seminar handout. Name the state layer, describe the template, and say that the state documents themselves are the primary sources a candidate would need to read.

15.5 Financing, which is where most strategies are actually decided

A strategy without money attached is a statement of intent. This is not a cynical observation; it is the standard first question in any appraisal of a public-health programme, and it has been raised officially in India in relation to both the mental health legislation and the suicide prevention strategy, where the absence of dedicated budgetary allocation has been identified as a concern about implementation. An early official parliamentary assessment recorded that whether the strategy was being implemented effectively remained undetermined.

What this chapter cannot tell you, and says so rather than inventing it, is how much money the strategy has. Allocations, releases and utilisation specific to the suicide prevention strategy, separated from the broader mental health programme and from the national institutions, were sought from the health ministry, from budget documentation and from parliamentary answers, and were not retrieved. Two things follow for an examination answer. First, do not quote a rupee figure for the strategy; there is none you can defend. Second, the fact that a national strategy's own financing cannot be isolated from the wider programme is itself a finding about the strategy, and saying so demonstrates more understanding than a number would.

> **PITFALL**
>
> Treating an allocation as an outcome. Where a programme's spending is published, clinicians frequently quote the allocation as evidence of activity. An **allocation** is a budget line, a **release** is money that has left the treasury, and **utilisation** is money that has been spent; the three routinely differ, and none of them is a service. If you use a financial figure at all, say which of the three it is, and for which year.

15.6 Evaluating a strategy against its own targets

The cleanest way to appraise any national strategy is to hold it to the standard it set for itself, because that standard was chosen by the authority that wrote it and cannot be dismissed as an outsider's benchmark. That approach requires a progress report, a review, an evaluation or a live dashboard that measures implementation against the strategy's stated targets, published by the issuing body or by an independent auditor.

No such assessment was retrieved for the Indian strategy. The search covered the health ministry's own programme pages and its published strategy location, parliamentary answers in both houses, a parliamentary standing committee report, government press releases and the national institute's own domain. The absence is the finding, and it should be taught as one: India has a national strategy, a delivery vehicle with a published sanction footprint, a surveillance system with a structural reporting lag, and no published measurement of the strategy against its own targets. A candidate who can lay out those four statements in order has given a better account of Indian suicide prevention than one who recites the strategy's contents.

It is worth setting the four appraisal questions out against each other, because the pattern that emerges is the section's real teaching point. In every case the design statement is published and traceable to an authority, and in every case the delivery statement is either missing or is a different quantity wearing the design statement's clothes.

APPRAISAL QUESTION	WHAT IS PUBLISHED AS DESIGN	WHAT DELIVERY WOULD REQUIRE	STATE OF THE DELIVERY EVIDENCE
Reach	Districts for which the district programme is sanctioned, stated by the health administration in reply to Parliament	Districts in which a suicide-prevention service is staffed and seeing people	Not established; sanction and function are different quantities and only the first is published
Measurement	A surveillance objective inside the strategy, and an annual national compendium of recorded suicides	A system that is nationally complete and timely enough to detect change within a planning cycle	Not established; the annual series can only begin collecting a calendar year once it has closed
Money	The mental health programme's own budget lines	Allocation, release and utilisation attributable to the strategy itself	Not retrieved; strategy-specific financing cannot be separated from the wider programme
Effect	Targets stated by the strategy for itself	A progress report or evaluation from the issuing body or an auditor, measured against those targets	Not retrieved from the ministry, from Parliament, from a standing committee or from the national institute

Two features of that table are examinable in their own right. The first is that the left-hand column is answerable for almost any country and the right-hand column is answerable for very few, which is why international comparison of suicide-prevention strategies is so much weaker than it looks. The second is that a candidate who has learned only the left-hand column will answer a delivery question with a design statement and will not notice the substitution, because the design statement is a real, sourced, governmental figure. The error is not one of accuracy but of scope, and scope errors are invisible from the inside.

MNEMONIC

Vehicle, Surveillance, Sectors, Money, Measurement

The five questions to ask of any national suicide prevention strategy, in the order in which they decide whether it can work. What delivers it, what measures it, who outside health is bound by it, what funds it, and who checks it. Every one of the five is answerable for India, and two of the answers are that nothing is published.

15.7 Writing about this in an examination

Three habits separate a strong answer from an average one here. The first is scope discipline: every national figure you print must travel with the body that issued it, the period it refers to, the population it describes and what it is a proportion of, and if you cannot supply all four you should describe the thing without its number. The second is the distinction between design and delivery, which recurs in every subtopic above: a sanctioned district, a stated objective and an allocated budget are all statements of design, while a functioning service, a measured outcome

and spent money are delivery. The third is the willingness to declare an absence. In a viva, "that figure is not reliably published, and here is what was looked for" is a stronger answer than a confidently quoted number of unknown provenance, and it is the answer this chapter is built to let you give.

The other suicide-prevention material in this chapter divides cleanly. The specific population interventions, means policy, gatekeeper programmes and media guidance, are configured and evaluated in their own section; the agrarian category argument and its denominator problem belong with farmer suicide; the national data series read as a distribution belongs with suicide epidemiology. The clinical prevention framework, the intervention tiers and the international implementation guidance behind all of them belong to the Somatic-symptom, sexual, impulse-control disorders and suicide notes.

> A national suicide prevention strategy is only as real as its delivery vehicle, its surveillance timeliness and its financing, and in India the first is sanctioned in a published number of districts, the second reports a calendar year only after that year has closed, and the third cannot be separated out at all.

16 · Means restriction, gatekeeper training and media guidelines in suicide prevention

Three interventions, and each of them is two different things. Means restriction, gatekeeper training and media guidance can each be described as something a clinician does with a person in front of them, and each can be described as something a state designs, funds, delivers and evaluates across a population. The clinical readings are taught elsewhere and are cross-referred below. This section takes the second reading throughout, because that is where the marks in a public-health paper sit and because the two are genuinely different objects: a gatekeeper programme is commissioned and evaluated, a gatekeeper referral is made.

The mechanisms behind the three, why restricting access to a method works when crises are short and ambivalent, what the evidence says about gatekeeper training's effect on recognition and on mortality, and the paired imitation and protective effects of media coverage, are taught in full in the Somatic-symptom, sexual, impulse-control disorders and suicide notes. Means restriction as a task carried out with a young person and their family, including the household conversation and the safety plan it belongs to, is taught in the Child behavioural, emotional and other disorders notes. Neither is restated here. What follows is the Indian implementation layer: which instruments exist, who issues them, what has actually been measured, and what has not.

16.1 The three levers, read as programmes

A population lever has four parts that a clinical act does not: an issuing authority, a legal or administrative instrument, a delivery route, and an evaluation endpoint. Run the three interventions through those four parts and the differences between them become obvious.

- **Means restriction** is issued by a regulator, not by a health department, and its instrument is usually a statute or a subordinate order. Its delivery route is the market and the supply chain

rather than the clinic, which is why it reaches people who never present to a service. Its endpoint is method-specific mortality.

- **Gatekeeper training** is issued by a health or education authority, its instrument is a curriculum, its delivery route is a workforce, and its endpoint is contested: recognition and referral are measurable, whereas an effect on deaths is not demonstrable from a training programme alone.
- **Media guidance** is issued by a press or broadcast regulator, its instrument is a code of conduct, its delivery route is editorial practice, and its endpoint is the content of reporting itself rather than any clinical event.

That table of four parts is the frame for everything below, and it is also the answer to the commonest structural mistake in this topic, which is to compare the three on effectiveness as though they were competing treatments. They are not substitutes. They act on different populations through different institutions, and a national programme runs all three because each reaches people the other two miss.

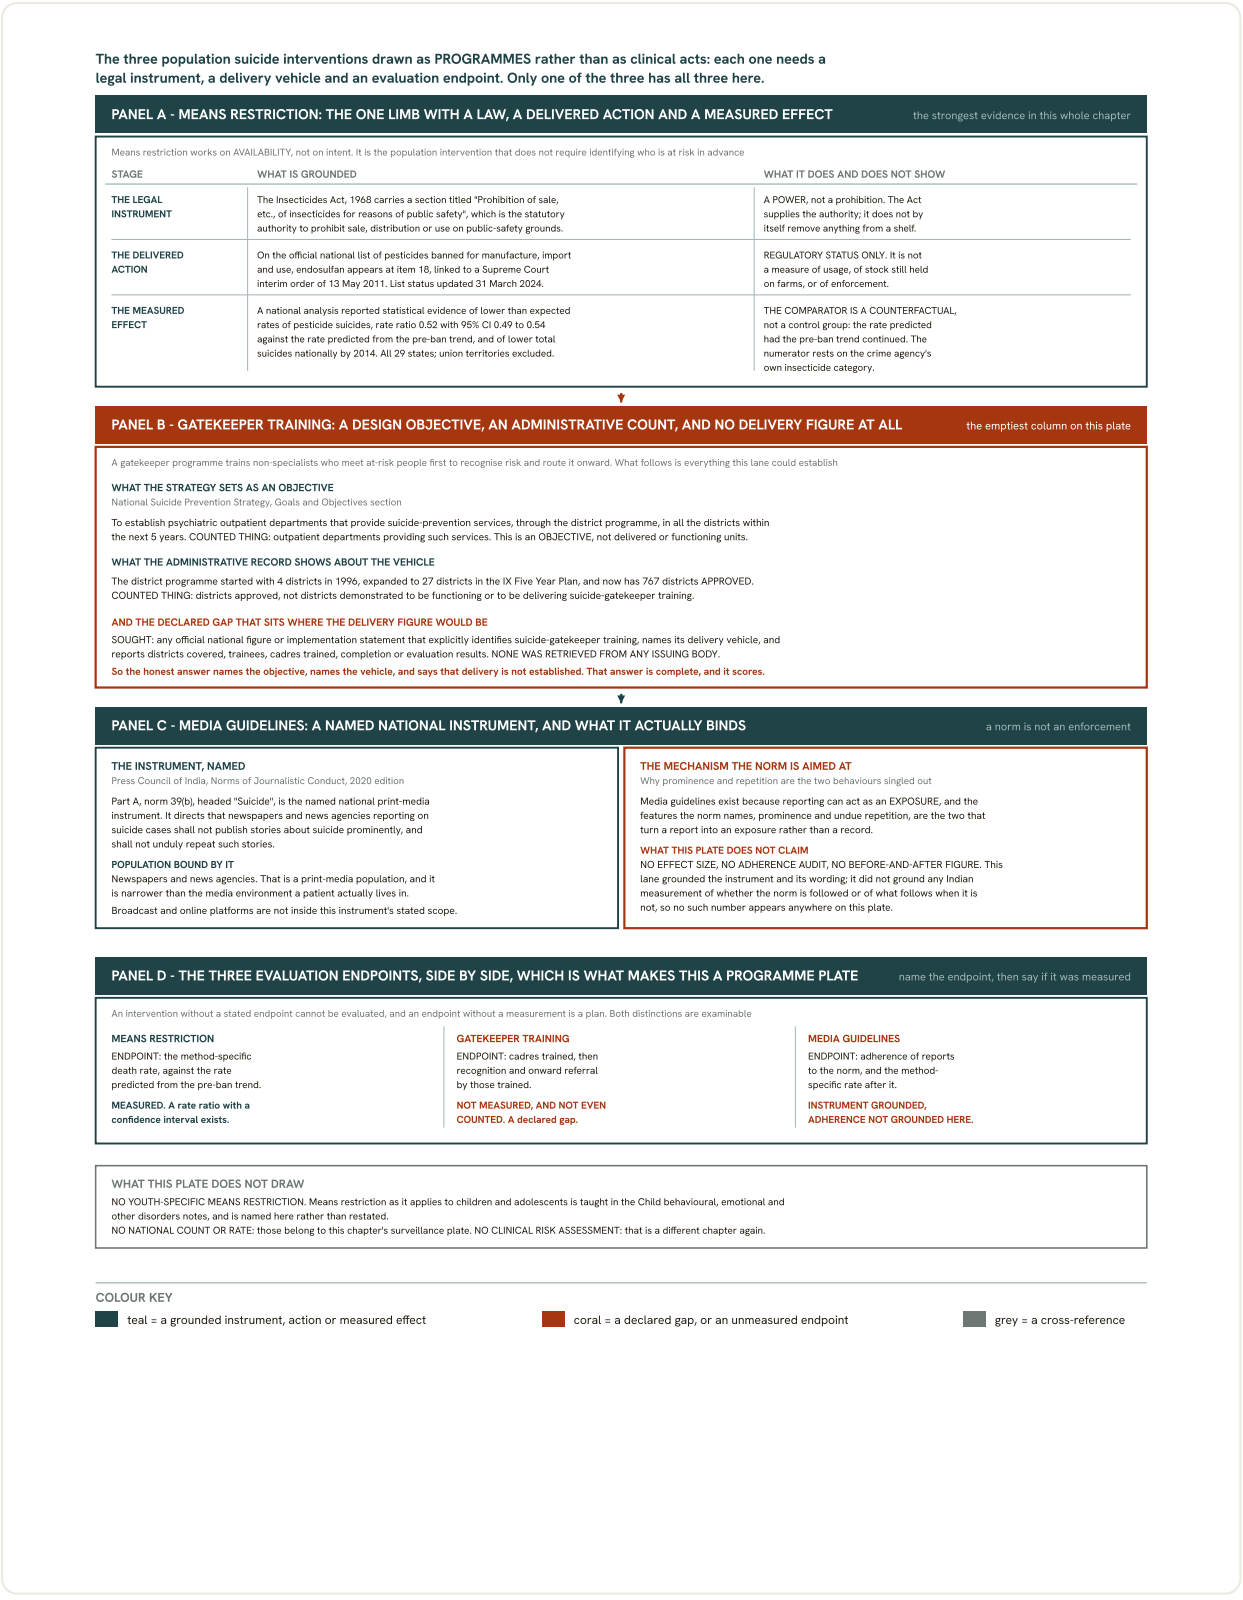

Fig 39.6 Means restriction, gatekeeper training and media guidelines, each drawn as a programme with its own evaluation endpoint. Means restriction is the one limb with all three stages grounded: a statutory power to prohibit an insecticide for reasons of public safety, a delivered ban listing endosulfan at item 18, linked to a Supreme Court interim order of 13 May 2011, and a measured effect, a pesticide-suicide rate ratio of 0.52 with 95% CI 0.49 to 0.54 against the rate predicted from the pre-ban trend. Gatekeeper training has an objective set by the national strategy and a vehicle approved in 767 districts, but no official figure naming trainees, cadres, completion or evaluation was retrieved from any issuing body. The media limb has a named national instrument directing that newspapers shall not publish suicide stories prominently or unduly repeat them, bounded to print media, with no Indian adherence measurement grounded here.

RULE **Name the issuing authority before you discuss the intervention.** A population lever that no institution is empowered to pull is a wish. In India the three levers sit with three different authorities, only one of which is the health ministry, and half of the implementation difficulty in this topic follows from that single fact.

16.2 Means restriction in India: which instruments actually exist

India regulates agricultural chemicals through a dedicated statute. The **Insecticides Act, 1968** carries a provision, at Section 27, headed as a prohibition on the sale and related dealings in an insecticide for reasons of public safety. Read as a public-health instrument rather than as an agricultural one, that is the legal hook on which access restriction hangs: it is the power to take a compound off the market, and it exists independently of any mental health law.

The operational expression of that power is a published national list of pesticides that are banned, refused registration or restricted in use, maintained by the plant-protection directorate. Compounds move onto it by different routes, including judicial ones: **endosulfan appears in the banned-for-manufacture, import and use section of that list at item 18, linked to an interim order of the Supreme Court made in 2011**. That detail is worth carrying because it shows the mechanism by which access restriction is achieved in practice, which is administrative and judicial rather than clinical, and because it locates the document a resident should cite.

It is worth pausing on why the instrument is agricultural rather than medical, because the point generalises. Population access restriction almost always runs through the law that governs the commodity, not through the law that governs health: a pesticide through an insecticides statute, a medicine through drug scheduling and pack regulation, a structure through building and transport rules. The health system's role in each case is to supply the mortality evidence that justifies the restriction and then to measure what follows, not to issue the restriction itself. A resident who understands that will not waste an answer proposing that a mental health authority ban anything, and will instead describe the correct route, which is evidence to the sectoral regulator and, where that fails, to the courts.

Two cautions travel with any statement about that list. It records *regulatory status*, not use and not enforcement; a compound can be banned on paper and remain in circulation in a district. And a list is a statement about compounds, not about deaths, so nothing about mortality follows from the list itself. The mortality question is separate and is answered below.

16.3 What the regulation bought, and how anyone knows

Regulation of a method is one of the few population interventions in psychiatry that can be evaluated at national scale, because the exposure changes on a known date for the whole country and the outcome is recorded routinely. The Indian evaluation used exactly that design. Comparing the observed rate of pesticide suicides against the rate predicted by extrapolating the stable pre-ban trend, a national analysis reported **a pesticide-suicide rate ratio of 0.52, with a 95 percent confidence interval of 0.49 to 0.54**, together with a finding that total suicides nationally were lower than expected by 2014.

Learn the structure of that claim, not just its value. The comparator is a counterfactual, a modelled rate rather than an observed one, which means the estimate inherits every assumption in the trend model. The outcome is drawn from routine national records of deaths classified as pesticide poisoning, and the way those record categories are defined, and what they can and cannot bear, is the argument taken up where farmer suicide is taught in this chapter; it is not repeated here. The second finding, that total suicides also fell below the predicted line, is the analytically interesting one, because it is the finding that speaks to whether restriction merely displaces the method.

PITFALL

Quoting a rate ratio as though it were a proportion. A ratio below unity from a counterfactual analysis says the observed rate was about half of what the pre-ban trend predicted for that year. It does not say half of suicides were prevented, it does not say half of pesticide deaths stopped, and it cannot be converted into a number of lives without the predicted rate and the population it applies to. State it as a ratio against a predicted rate, or do not state it at all.

16.4 Gatekeeper programmes: what has to be specified before one exists

A **gatekeeper** programme is a training intervention aimed at people who meet those at risk before any clinician does. As a programme rather than as a course, it is defined by six specifications, and a plan that omits any of them is not yet a programme: which cadre is trained, what competency the training is supposed to produce, who delivers and refreshes the training, what the trainee is expected to do when they identify somebody, what receives the referral, and what will be counted afterwards. The sixth is the one most often left blank, and it is the one that decides whether the programme can ever be shown to have worked.

India's obvious delivery routes for such a programme are the district mental health programme and the national tele-counselling service, both of which already reach a workforce and a public. What is *not* available is any official national statement that identifies suicide-gatekeeper training as a named component, names its delivery vehicle, and reports districts covered, personnel trained, cadres included, completion rates or evaluation results. That was sought from the health ministry, the health services directorate, the national health mission and the bodies responsible for programme implementation, and it was not retrieved. Say so in an answer, because it is the truthful position and because it explains why the Indian literature on gatekeeper training consists of individual studies rather than programme reports.

Choosing that endpoint honestly is harder than it looks. Recognition and referral behaviour are the endpoints a training programme can plausibly move and can measure within a reasonable period, and they are legitimate. Deaths are the endpoint everybody wants, and a single training programme is almost never powered to detect a change in them, because the event is rare in any one district and because a trained workforce is only one link in a chain that also requires a service to refer into. Writing mortality into the evaluation plan of a district training programme is therefore not ambition; it is a design error that guarantees a null result and discredits a

reasonable intervention. State the intermediate endpoint, state that it is intermediate, and say what would have to be true downstream for it to matter.

TRAP **Treating an approved district as a trained district.** The national administrative scale of the district programme is published, and it is regularly imported into answers about gatekeeper coverage. Approval of a district under the programme carries no information at all about whether anybody in that district has been trained to recognise suicide risk. Approval is an accounting fact about the centre; training is a fact about a workforce, and no published national count of the second exists.

16.5 Media guidance: the instrument, and the reach it does not have

A **media guideline** is a code binding on publishers, and in India the named national instrument for print is the Press Council of India's **Norms of Journalistic Conduct, 2020**, which contains a suicide-specific norm directed against reporting suicide prominently and repeating such stories unduly. Two features of that instrument matter more than its contents.

The first is its scope. It is a code for newspapers and news agencies, which is to say for print journalism and the agencies that feed it. Broadcast media and the online and social platforms on which most people now encounter a suicide story sit under different regulators or under none, so compliance with a print code is not compliance across the media environment. The second is its force. A council code operates by adjudication and censure rather than by penalty, so its effect depends on editorial willingness in a way that a pesticide ban does not.

The practical consequence for a resident is that the evaluation endpoint for media guidance is the content of coverage, measured against the code's own requirements, rather than any mortality outcome. If you are asked how you would evaluate an Indian media-guidance intervention, the answer is a content audit of reporting before and after, sampled across the outlets the code actually binds, and an honest statement that the outlets it does not bind are the ones carrying most of the audience.

16.6 Delivering all three through one district system

Whatever the national strategy says, everything it promises arrives in a district through a single service. The strategy addresses this directly: **the 2022 strategy sets, as a design objective, the establishment of psychiatric outpatient departments providing suicide-prevention services through the district mental health programme in all districts within the next five years**. That is a target, and reading it as an achievement is the single commonest error in this topic.

Against that target sits the administrative position: the health services directorate reports the district programme's national scale as **767** approved districts. Approval is what that number counts. It is not a count of districts with a functioning suicide-prevention outpatient department, and it must not be rewritten as gatekeeper delivery or as any other service output. The gap between a design objective expressed in all districts and an approval figure expressed in a count of districts is not a contradiction; the two are simply different quantities, and an answer that treats them as one has made a scope error rather than an arithmetic one.

Regulator	Press council	District programme	Not established
ISSUING AUTHORITY FOR MEANS RESTRICTION IN INDIA	ISSUING AUTHORITY FOR THE PRINT MEDIA CODE	DELIVERY ROUTE THE STRATEGY NAMES FOR ALL DISTRICTS	NATIONAL GATEKEEPER TRAINING COVERAGE, ANY CADRE

16.7 The evidence state of each lever, side by side

The most useful thing a candidate can carry out of this section is not a set of figures but a map of what is and is not established for each lever in India. The pattern is asymmetric in an instructive way: the lever with the strongest legal instrument is also the only one with a national effect estimate, and the lever that is easiest to run is the one with no national data at all.

LEVER	INDIAN INSTRUMENT, AND WHO ISSUES IT	WHAT IS ESTABLISHED ABOUT EFFECT	WHAT IS DECLARED NOT ESTABLISHED
Access restriction	A dedicated insecticides statute with a public-safety prohibition power, plus a national banned and restricted list maintained by the plant-protection directorate	A national counterfactual analysis reporting a pesticide-suicide rate ratio below unity against the predicted pre-ban trend, with a total-suicide finding in the same direction	Enforcement and actual availability at district level, which regulatory status does not measure
Gatekeeper programmes	No named national instrument retrieved; the district programme and the national tele-counselling service are the available delivery routes	Nothing at national level	Districts covered, personnel trained, cadres included, completion and any evaluation result
Media guidance	A press council code of journalistic conduct with a suicide-specific norm, binding on newspapers and news agencies	Nothing at national level as an outcome; the endpoint is compliance in content	Compliance auditing, and coverage of broadcast and online outlets the code does not bind

IN INDIA

The operational decision this section forces is which lever a district team can actually pull. Access restriction is not theirs: it sits with an agricultural regulator and with the courts, so the district contribution is surveillance and advocacy rather than action. Media guidance is not theirs either, beyond a local relationship with editors. Gatekeeper training is the one lever a district service can commission itself, which is precisely why it is the lever most often run without a specified endpoint. If you are asked to plan district suicide prevention, commission the training you control, and write the count you will report before the first session is delivered.

MNEMONIC

Authority, Instrument, Route, Endpoint

The four parts of any population lever, and the order in which to write them. Missing authority makes the intervention unenforceable; missing instrument makes it voluntary; missing route makes it undeliverable; missing endpoint makes it unevaluable, which is the failure mode of gatekeeper programmes worldwide.

The remaining suicide material in this chapter divides as follows. The national strategy as a governance instrument, its delivery vehicle and its financing are taken up in their own section; the national data series read as a distribution belongs with suicide epidemiology; the occupational category argument belongs with farmer suicide. The mechanisms and the international evidence base for all three levers remain with the Somatic-symptom, sexual, impulse-control disorders and suicide notes, and the family-level task with the Child behavioural, emotional and other disorders notes.

Means restriction is the only one of the three levers with an Indian legal instrument and an Indian national effect estimate; gatekeeper training is the only one a district can commission for itself and has no national coverage figure at all; media guidance binds print alone and is evaluated on the content of reporting, never on deaths.

17 · Epidemiology of suicide in India and high-risk groups

Every national suicide figure you will ever quote is the output of a data system, not a measurement of the world. That is not scepticism, it is the first thing a public-health reader has to understand about this topic, and it is what separates an answer that recites a number from an answer that can defend one. India's national suicide statistics come from a police-reporting chain, are published annually, and describe a case category with a legal existence. Everything that follows about counts, rates, trends and high-risk groups is conditioned by that fact.

The clinical material adjacent to this section is owned elsewhere and is not restated. Individual risk assessment, the weighing of risk against protective factors, structured evaluation and the limits of prediction belong to the Somatic-symptom, sexual, impulse-control disorders and suicide notes, as do the aetiological frameworks that explain why populations differ. Custodial suicide prevention, including screening on reception into prison and the advisory machinery around it, belongs to the Forensic ethics, consent and legal procedure notes. What this section owns is the surveillance instrument itself, the distribution it produces, and what that distribution licenses a programme to do.

17.1 What the national statistic is a statistic of

The published national series is compiled by the **National Crime Records Bureau, the NCRB**, from **police-recorded suicide cases** reported upward by states and union territories and collated for a calendar year. Three consequences follow immediately and each is examinable.

- The unit of count is a *recorded case*, so anything that changes recording changes the series. A family's reluctance to have a death recorded as suicide, a local practice of recording an ambiguous death as accidental, or a change in police procedure will all move the number without anything moving in the population.
- The determination is administrative rather than clinical. No psychological autopsy stands behind a national count, and the intent judgment is made in a legal rather than a diagnostic frame.
- The compilation is annual and closed, which means the whole apparatus is retrospective by at least a full year. A surveillance system with that latency describes the past accurately and cannot warn about the present.

RULE **Name the recording system before you quote its number.** "The suicide rate in India is X" is an incomplete sentence. The complete sentence is "the police-recorded suicide rate in India for the year Y, per lakh of the projected mid-year population, is X". Everything a candidate is likely to get wrong about this topic is contained in the words the short version leaves out.

17.2 The count and the rate, and how they differ

For the most recent published year the Bureau **recorded 1,70,746 suicides in India in 2024, against 1,71,418 in 2023**. The corresponding rate is defined as the incidence of suicides per one lakh of population, a lakh being 1,00,000 people, and the recorded rate is a series rather than a constant, so a figure quoted for an earlier reference year in the Somatic-symptom, sexual, impulse-control disorders and suicide notes belongs to an earlier point on the same series and does not compete with this one: for **2024 the rate is 12.2 per lakh, against 12.3 in 2023**.

A count and a rate answer different questions and are not interchangeable. The count answers a service-planning question, because a mortuary, a crisis service and a bereavement service all deal in people rather than in rates. The rate answers a comparison question, because only a rate can be set beside another year, another state or another country. A year in which the count falls while the population grows will show a falling rate for two different reasons at once, and separating them requires the denominator.

1,70,746	12.2	Recorded case	Over a year
POLICE-RECORDED SUICIDE CASES, INDIA, 2024	PER LAKH OF THE PROJECTED MID-YEAR POPULATION, 2024	THE UNIT BOTH FIGURES COUNT, NOT A CLINICAL DETERMINATION	LATENCY BEFORE A CLOSED CALENDAR YEAR IS PUBLISHED

17.3 The denominator, which is where rates are quietly built

India conducts a census at long intervals, so for every year that is not a census year the population **denominator** is not counted but projected. The published rate for the most recent year uses a projected mid-year population of 14049.1 lakh, and the rate for any non-census year is computed on a projection of that kind rather than on an enumeration.

That has two implications a resident should be able to state. The first is that a national rate carries the uncertainty of the projection as well as the uncertainty of the numerator, and neither is usually reported with an interval. The second is that projections drift: the further a year sits

from the last enumeration, the more the denominator depends on assumptions about fertility, mortality and migration, and a small systematic error in the denominator moves every rate in the series in the same direction. A trend computed across a long inter-census interval is therefore a weaker object than it looks, and this is worth saying explicitly in any answer that discusses whether the Indian rate is rising.

TRAP **Comparing a rate for one population against a count for another.** The classic version is to set a national rate beside a group's absolute number and conclude that the group is over-represented. A count of deaths in any group is a function of the size of the group, and without the group's own denominator it says nothing about risk. Where a valid denominator for a subgroup does not exist, the honest position is that the group's rate cannot be computed, not that its count is small or large.

17.4 What the system cannot see, and what else could see it

Undercount in a police-based series is not a defect to be apologised for; it is a structural property with a describable mechanism. Deaths that never reach police attention are absent; deaths that reach it but are recorded under another manner are misclassified; deaths recorded correctly but not transmitted upward are lost. Each of those acts in one direction, so the national series is best understood as a floor rather than an estimate with symmetric error.

The direction of that structural bias has a practical corollary that examiners like. If the series is a floor, then a district or a state reporting a low recorded rate has two possible explanations, a genuinely low incidence and a weak recording chain, and the second explanation is at least as common as the first. A programme that reads a low recorded rate as reassurance and withdraws attention from that district has therefore drawn exactly the wrong conclusion from a weak signal. The correct reading of an unexpectedly low figure is that the recording chain should be examined first and the population second.

India also maintains civil registration of deaths and a sample-based demographic survey, and the natural analytic move is to compare a police-derived suicide count against a registration-derived one for the same period. That comparison is the correct way to ask how large the undercount is. This chapter's sources do not establish the size or the direction of the difference for India, so no reconciliation figure is offered here, and a candidate should say that the comparison is the right method and that its published answer is what they would look for.

17.5 High-risk groups, read as population strata

A **high-risk group** in a public-health frame is not the same object as a high-risk patient. It is a stratum of the population whose rate exceeds the population rate, identified so that a finite intervention can be aimed somewhere rather than everywhere. Three things have to be true before a stratum is useful for targeting, and the national series satisfies only the first of them for most groups.

- **The stratum must be identifiable in the data.** The national record carries profile characteristics collected on the police form, so the series can be cut by sex, by age band, by state and by occupation and other social descriptors. The definitions of those recorded

categories, and what they will and will not bear, are the argument taken up where farmer suicide is taught in this chapter, and they are not repeated here.

- **The stratum must have its own denominator.** Without a population count for the group itself, a group rate cannot be computed and over-representation cannot be established. This is the point at which most confidently quoted group statistics fail.
- **The stratum must be reachable.** A group that can be described but not addressed through any existing service or regulatory route generates a finding, not a programme.

The third condition is worth dwelling on because it is where epidemiology becomes service planning. Strata differ enormously in how reachable they are. A group defined by an occupation can be reached through the sector that employs it and through the regulator that governs its inputs. A group defined by contact with a health service can be reached at that contact, which is why service-contact populations attract prevention effort out of proportion to their share of deaths. A group defined only by a demographic characteristic, such as an age band, has no institution attached to it at all, and reaching it requires a mass channel such as schooling, broadcast media or a helpline. When you are asked to design a targeted intervention, name the institution before you name the intervention, because the institution is what makes targeting possible.

Groups conventionally discussed in the Indian literature include young adults, students, people in agrarian occupations, people in custody and people with severe mental illness in contact with services. Naming a group is legitimate; attaching a proportion to it is not, unless the proportion carries its own denominator. This section prints no group-specific proportions, because none is established in its sources, and that absence should be stated in an answer rather than filled from a slide.

PITFALL

Confusing relative and absolute risk when planning. A stratum can carry a high relative risk and contribute few deaths because it is small, while a low-risk but very large stratum contributes most of the total. Targeting the first reduces risk for individuals; only action on the second moves the national count. A plan that names only high-relative-risk groups will be defensible clinically and useless at population scale, and this is the single most common weakness in resident-written prevention plans.

17.6 Inter-state variation, and why it is the useful unit

Health is administered by states, so the national rate is an average over administrative units that differ in almost everything that matters: recording practice, service availability, urbanisation, the dominant method available, and the age structure of the population. A national figure is therefore the least actionable number in the series. The state figure is the one a programme can be built on, and the district figure is the one a service can be built on.

Two cautions apply when reading variation between states. Differences in the recorded rate confound true differences in incidence with differences in recording, and there is no way to

separate them from the published series alone. And states differ in age structure, so a raw comparison between them is not a like-for-like comparison; the standard remedy is **age standardisation**, and any inter-state comparison that has not been standardised should be described as a comparison of **crude rates**. This chapter prints no state figures, because none is in its sources.

17.7 Reading the trend as a data series

The two most recent published years sit close together, with the count and the rate both marginally lower in the later year. A one-year movement of that size is not a trend and should never be described as one. A movement in a routinely collected series can arise from a real change in incidence, from a change in recording behaviour, from a change in the projected denominator, or from ordinary year-to-year variation, and a single comparison cannot distinguish them.

What an examiner is looking for is the discipline to say all four aloud, in that order, before offering an interpretation. If a candidate must commit, the defensible statement is that the national recorded rate has been broadly stable across the two most recent published years, that the level is what matters for planning rather than the direction of the last step, and that any claim about a sustained trend requires the series over many years together with a stated treatment of the denominator.

IN INDIA

The operational decision this section drives is what you plan against. Because the national series is retrospective by more than a year, is administratively defined, and averages over states that differ in recording as much as in incidence, a district service should not wait for the national publication to tell it what its problem is. It should treat the national figure as the background level and build its own local numerator from the sources it can see directly, meaning its own casualty and mortuary records and its own crisis presentations, while accepting that a locally built count is a count and never a rate unless the district's population denominator is stated with it.

17.8 What the distribution licenses, and what it does not

The final discipline is to be clear about what an epidemiological description entitles anyone to do. It licenses the aiming of finite resources at strata with a demonstrably higher rate, provided that the rate has a denominator. It licenses surveillance of the strata over time, which is the only way to know whether targeting worked. It does not license a prediction about any individual, and it does not license the inference that a correlate observed at population level operates as a cause in a person.

QUANTITY	WHAT IT ANSWERS	WHAT IT NEEDS TO BE VALID	WHAT IT CANNOT DO
National recorded count	How many recorded cases arose in a closed calendar year	A stated recording system and a stated year	Support comparison across years or places without a denominator
National recorded rate	How the level compares with another year, state or country	The same numerator plus a stated population base, projected for non-census years	Describe any subgroup, and cannot be applied to an individual
Group rate	Whether a stratum is over-represented	A numerator and a denominator for that same group	Be computed at all where the group's population base is unavailable
Trend	Whether the level is moving	Many years, a stable case definition and a stated denominator method	Be read from a single year-on-year step

India's national suicide figures are police-recorded counts and rates for a closed calendar year, computed for non-census years on a projected mid-year population, so they describe the past accurately, warn about nothing in the present, and support a statement about any subgroup only where that subgroup has a denominator of its own.

Stigma and anti-stigma interventions

18 · Stigma: concepts, types (public, self, structural) and measurement instruments

Stigma is not one thing, and a service that treats it as one thing will intervene in the wrong place. The word covers at least four distinct objects, each sitting in a different location, each moved by a different intervention and each measured by a different instrument. Typing stigma is therefore not an academic refinement; it is the step that decides whether an anti-stigma budget buys a media campaign, a workforce training programme, a change to an insurance rule or a support group for families. This section supplies the typology, its consequences for access to care, and the measurement layer that lets any of it be evaluated.

Two neighbouring accounts are owned elsewhere and are named rather than rebuilt. The social-psychological mechanism behind stigma, prejudice as a structure of belief, feeling and behaviour, the theoretical lineage that explains how in-groups and out-groups form, and the intergroup evidence base, belongs to the Social, Learning and Personality Psychology notes. The clinical reading, in which stigma is treated as a variable inside one consultation and divided into what a patient has met, what a patient anticipates and what a patient has internalised, with concealment as the behavioural pathway to a worse outcome, belongs to the Consultation-liaison, geriatric and transcultural psychiatry notes. What follows is the population and structural reading, which no other chapter carries.

18.1 Why a service types stigma rather than deploring it

Deploring stigma is free and changes nothing. A public-health reading asks four questions of any stigma phenomenon, and the answers differ by type.

- **Where does it live?** In a population, in a person, in a rule, or in a family.
- **Who holds it?** The answer identifies the respondent any later measurement will have to use.
- **What does it do?** Specifically, what does it do to whether a person seeks care, receives care and keeps a role, because a stigma that changes nothing is a sentiment rather than a public-health problem.
- **What would count as evidence that it had shifted?** This has to be answerable before the intervention is designed, not afterwards.

Running those four questions produces the typology below rather than presupposing it, which is the right order and the one an examiner rewards. Note that the fourth question is the one that most often has no good answer, and that a type of stigma for which no endpoint can be named is a type nobody will be able to show they reduced.

RULE **Locate the stigma before you choose the intervention.** An intervention aimed at the wrong location will produce a measurable change in the wrong outcome and no change in access. A campaign that improves public attitudes will not amend a discriminatory insurance rule, and a support group that reduces a patient's shame will not alter what a stranger believes. Both may be worth doing; neither substitutes for the other.

18.2 Public stigma

Public stigma is what a population believes, feels and does about people with mental illness. It is held by other people, it is distributed across a society and it is the type most people mean when they use the word without qualification. Its behavioural expression is **discrimination**, which is the part that has consequences: a tenancy refused, a job offer withdrawn, a marriage negotiation abandoned, a family member excluded from a decision.

Two distinctions matter for measurement, and both are frequently collapsed. The first is between an attitude and a behaviour: what someone reports believing about mental illness in the abstract predicts, but does not equal, what they do when a person with mental illness applies for a room. The second is between the general public and specific gatekeeping populations, notably employers, landlords, teachers, police and health professionals. Health professionals are a gatekeeping population in their own right, and stigma held inside the health system is the version with the most direct effect on whether a person gets treated at all.

18.3 Self-stigma

Self-stigma is what happens when a person who is aware of a public stereotype applies it to themselves and endorses it. The location has moved: this now lives inside the person, and its consequences are demoralisation, withdrawal from roles the person could still occupy, and reduced help-seeking. Its practical importance in a service is that it is a mechanism by which a

public phenomenon becomes a clinical one, and that it is largely invisible to any measure of public attitudes.

The service consequence is specific. Self-stigma degrades exactly the behaviours a chronic-illness service depends on: turning up, disclosing symptoms, accepting a rehabilitative role, applying for entitlements. A programme that reduces public stigma may leave self-stigma untouched, because a person can know that attitudes in general have improved and still hold the belief about themselves, so the two require separate measurement and separate intervention.

18.4 Structural stigma

Structural stigma is the version that requires no person to hold any attitude at all. It is the accumulation of rules, budgets, laws, institutional practices and physical arrangements that disadvantage people with mental illness, and it persists after every individual in the system has changed their mind. Recognising it is what turns a clinician into a public-health practitioner, because it is the only type of stigma whose remedy is administrative rather than educational.

Its examples in any health system are structural rather than attitudinal: mental health services funded at a lower share than the burden they carry, insurance products that exclude or limit psychiatric cover, facilities sited away from general hospitals so that attending one is itself a disclosure, records systems that make a psychiatric contact more visible than a medical one, and application forms that ask about psychiatric history in terms no medical condition attracts. Each of those is fixable by a decision, and none is fixable by a campaign.

TRAP **Answering a structural stigma question with an attitude intervention.** Asked how to reduce stigma affecting access to care, most candidates describe awareness work. Awareness addresses public stigma. Where the barrier is a funding rule, a siting decision or an insurance exclusion, the intervention is a change to that rule, and naming the rule is what distinguishes a public-health answer from a well-meaning one.

18.5 Associative stigma

Associative stigma, also called courtesy stigma, is the discredit that attaches to people connected to the affected person rather than to the person themselves. It falls on family members, on carers, and in some settings on the professionals who work in the field. It is the type most under-measured and, in a family-based care system, arguably the most consequential, because it operates on the people whom services rely on to deliver most of the care.

Its behavioural signature is concealment at the family level rather than at the individual level, with predictable effects on presentation delay, on treatment continuity and on marriage and employment decisions taken about other members of the household. A service that asks only the patient about stigma will not detect it.

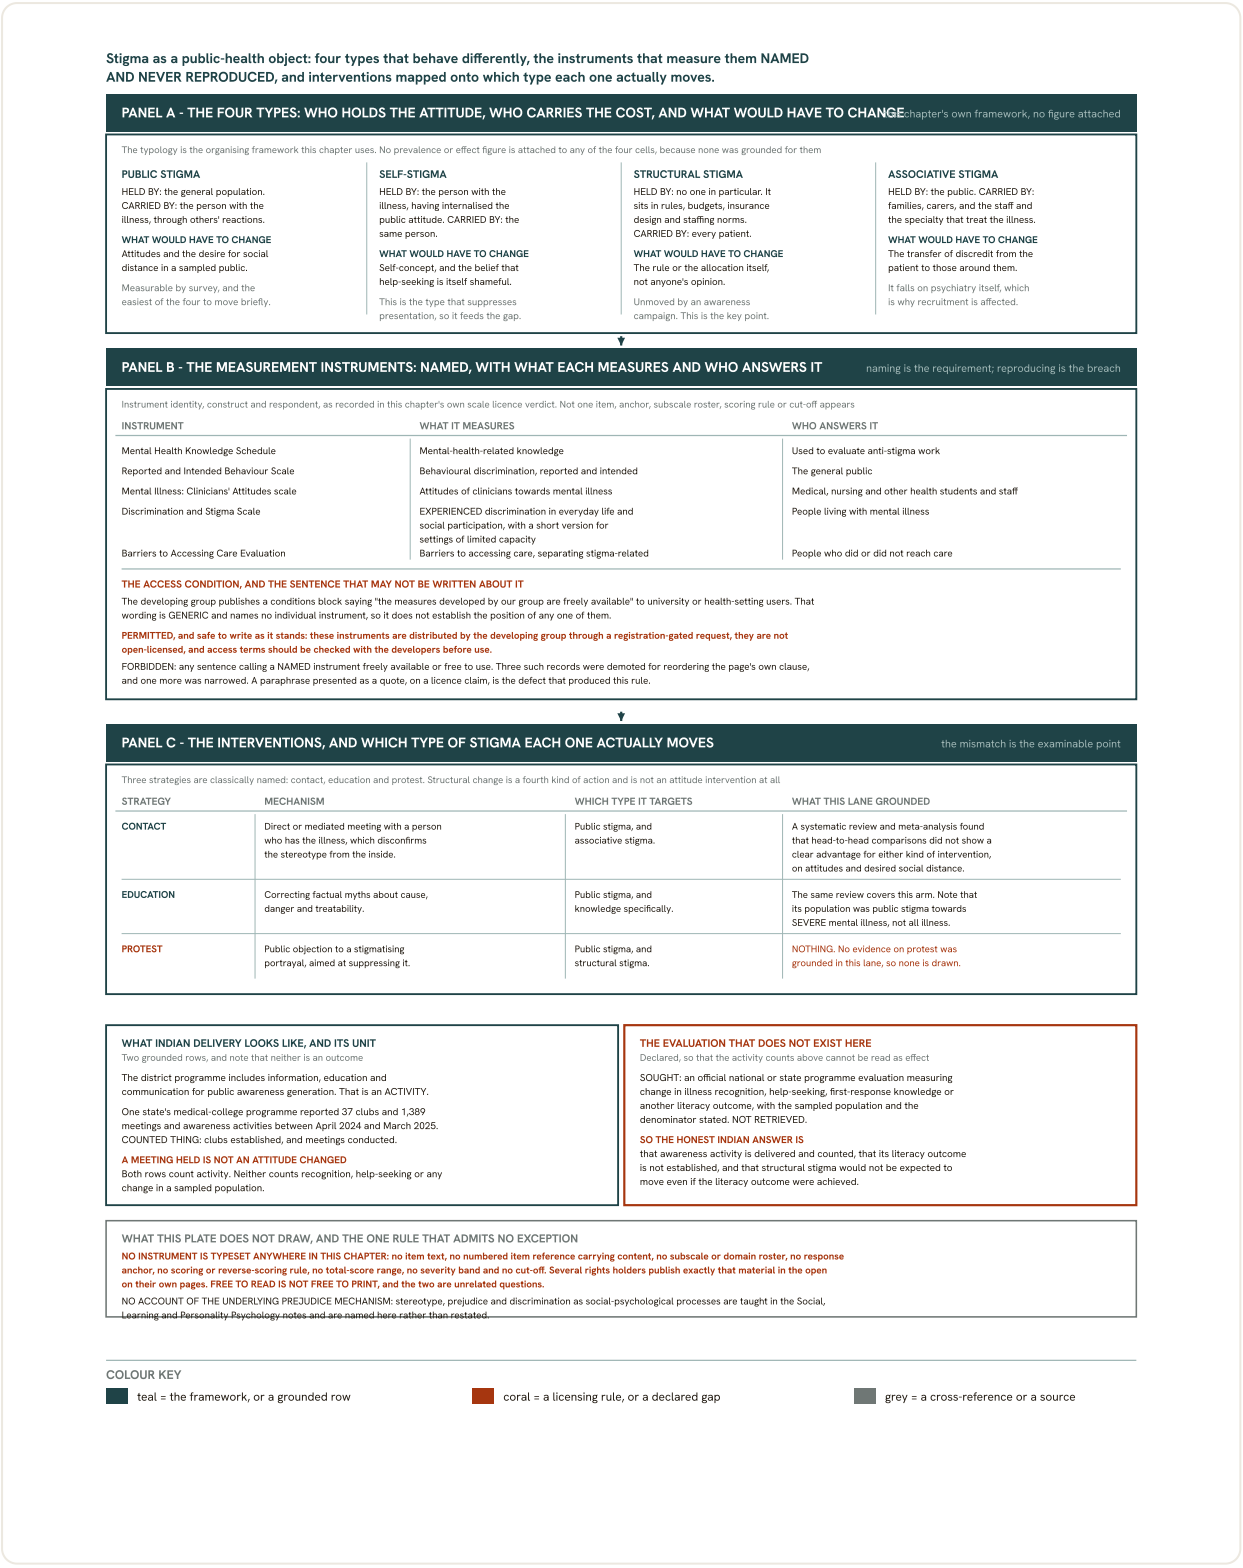

Fig 39.7 Stigma typed, measured and intervened on, with the measurement instruments named and none reproduced. The four types differ in who holds the attitude and who carries the cost, and structural stigma is the one an awareness campaign would not be expected to move. The instruments are named with their construct and respondent only. On access, the developing group's conditions block says its measures are freely available to university or health-setting users, but the wording is generic and names no individual instrument, so no named instrument may be called freely available; records that did so were demoted for reordering the page's own clause. On interventions, head-to-head comparisons showed no clear advantage for contact over education, and nothing on protest was grounded. Indian delivery is counted as activity, awareness generation through the district programme and 37 clubs with 1,389 meetings in one state between April 2024 and March 2025, while no official evaluation of any literacy outcome was retrieved.

MNEMONIC

Them, Me, The rules, Mine

The four locations of stigma, in the order in which a service should look for them. What others hold, what the person has taken on, what the system enforces without holding any view at all, and what falls on the family. Each location has its own intervention and its own measure, and an answer that covers all four has typed the problem rather than deplored it.

18.6 Where the clinical cut fits

A clinician assessing one patient will more often use a different cut of the same material, dividing stigma into what the person has actually met, what they anticipate meeting, and what they have internalised. That reading is taught in the Consultation-liaison, geriatric and transcultural psychiatry notes and is not re-derived here. What is worth stating in a public-health section is how the two cuts relate: the clinical cut is organised by the patient's relationship to the experience and is therefore useful in a consultation, while the population cut is organised by where the phenomenon lives and is therefore useful when choosing an intervention and an evaluation endpoint. They are not rival taxonomies and a candidate should not be trapped into defending one against the other.

18.7 Measuring stigma: what the instruments are for

Item by item this is the part of the topic candidates find hardest, because the instrument names are numerous and superficially interchangeable. They are not. Each was built to measure a specific construct, in a specific respondent, for a specific purpose, and using one in place of another produces a number that answers a question nobody asked. This section names them and describes them; it prints no item, no domain roster, no response option, no scoring rule and no threshold from any of them, and neither should you.

INSTRUMENT	CONSTRUCT IT MEASURES	WHO COMPLETES IT	WHAT IT CANNOT DO
Mental Health Knowledge Schedule (MAKS)	Mental health related knowledge in the general population	Members of the public	Detect discrimination, since knowing something is not doing something
Reported and Intended Behaviour Scale (RIBS)	Reported past and intended future contact behaviour toward people with mental illness	Members of the public	Establish that intended behaviour was enacted
Discrimination and Stigma Scale (DISC), and its ultra-short form (DISCUS)	Experienced discrimination across areas of everyday life and social participation	People with lived experience of mental illness	Measure what the public believes, since it records the receiving end only
Mental Illness: Clinicians' Attitudes scale (MICA)	Attitudes toward mental illness and psychiatry within a health workforce	Health students and health professionals	Stand in for public attitudes, since the respondent group is a gatekeeping profession
Internalized Stigma of Mental Illness scale (ISMI)	Internalised stigma in the affected person	People with lived experience of mental illness	Say anything about the surrounding population
Attribution Questionnaire (AQ) and Self-Stigma of Mental Illness Scale (SSMIS)	Attributional reactions to mental illness, and the self-directed form of the same process	Members of the public, and affected individuals respectively	Substitute for one another, despite sharing a theoretical origin
Community Attitudes toward Mental Illness (CAMI) and the Perceived Devaluation-Discrimination scale (PDD)	Community attitudes, and perceived societal devaluation as seen by the affected person	Community samples, and affected individuals respectively	Be read as measures of the same thing, since one records what a community holds and the other what a person believes a community holds
Barriers to Accessing Care Evaluation (BACE)	Barriers to accessing mental health care, distinguishing stigma-related barriers from other kinds	People who have needed or sought care	Attribute a barrier to a specific policy or institution

Two structural points about that table are worth more than the names in it. First, the respondent column is doing most of the work: some of these instruments interrogate the population and some interrogate the person receiving the population's behaviour, and a study that mixes them has measured two different phenomena and averaged them. Second, the last column is the one to reproduce in an answer, because knowing what an instrument cannot do is the evidence that you know what it does. Social distance measures, a family of instruments in this literature rather than a single named tool, sit alongside these and are usually treated as a behavioural proxy for public attitude.

GOOD TO REMEMBER

If you are going to evaluate anything you do about stigma, choose the respondent before you choose the instrument. If your intervention acts on staff, measure staff. If it acts on the public, measure the public. If your claim is that access improved, then the only respondent who can confirm it is the person who did or did not access care, and the instrument has to be one that asks them about barriers rather than one that asks anybody about attitudes.

18.8 Access to the instruments, and what is actually established about it

This is where a chapter can quietly go wrong, and it is worth being exact. The research group that developed a large part of the stigma instrument suite publishes a conditions block on each instrument's page. That block states that **the measures developed by the group are freely available to users who work or study in a university or health setting**, and it also forbids modification, forbids passing the measures to a third party and forbids charging for them. Every sentence of that block speaks of "the measures" generically and names no individual instrument.

The consequence is precise and it is the teaching point. Because the permissive sentence names no instrument, it does not establish the access terms of any particular one. Whether the clinicians' attitudes scales in that suite, the reported and intended behaviour measure, or the discrimination scale and its short form are individually free to a university or health-setting user is *not established* by the text that was sought and read. The defensible formulation, and the one to use, is that these instruments are distributed by the developing group through a registration-gated request, are not open-licensed, and that access terms should be confirmed with the developers before use. Other instruments in the field sit with individual rights holders or with commercial publishers and carry their own, different terms.

PITFALL

Assuming that a scale you can read online is a scale you may reproduce. Several rights holders publish item text, response options and scoring information openly on their own pages, for their own good reasons. Free to read is not free to print, not free to translate, not free to embed in a records system and not free to modify. A dissertation, a poster or a teaching handout that reproduces an instrument without checking its terms is a copyright problem regardless of how easy the material was to find.

18.9 Choosing an endpoint, which is the whole examination question

The last step is to connect type, instrument and endpoint into one line of reasoning, because that is what a viva question about stigma is really testing. If the target is public stigma, the endpoint is population knowledge, attitude or reported behaviour, and the measure is a public-facing instrument. If the target is the health workforce, the endpoint is professional attitude and the respondent is staff. If the target is self-stigma, the endpoint is internalised stigma in affected people. If the target is structural stigma, no attitude instrument will do at all, and the endpoint is the rule, the budget line or the entitlement itself, measured as a document rather than as a questionnaire. And if the claim is that any of this improved access, the endpoint is a barrier measure completed by people who needed care.

Anti-stigma interventions and their comparative evidence are taken up in their own section of this chapter, and mental health literacy, which overlaps with public knowledge but is a distinct programme class with its own outcomes, in the section after it. Neither of those names an instrument; the measurement layer stays here.

Location	Respondent	Rules	Not established
WHAT TYPES STIGMA: PUBLIC, SELF, STRUCTURAL, ASSOCIATIVE	WHAT DECIDES WHICH INSTRUMENT IS VALID	THE ONLY EVIDENCE THAT STRUCTURAL STIGMA MOVED	PER-INSTRUMENT ACCESS TERMS IN THIS SUITE

Type the stigma by where it lives, choose the respondent before the instrument, and remember that structural stigma is the only type whose remedy is a change to a rule and whose evidence is a document rather than a questionnaire.

19 · Anti-stigma interventions: contact, education and protest strategies and evidence

Anti-stigma work is a programme class, not a good intention. Three strategies are conventionally named, contact, education and protest, and a fourth family of structural measures sits alongside them without usually being counted as a strategy at all. Each has a design, a cost, a delivery workforce, a plausible mechanism, a characteristic failure mode and an outcome that can in principle be measured. This section treats them in exactly those terms, because a resident who can say what an anti-stigma programme would look like on the ground and how it would be evaluated has answered a public-health question, while a resident who can only assert that stigma should be reduced has not.

The social-psychological mechanism behind the contact strategy, the conditions under which intergroup contact reduces prejudice and the meta-analytic evidence establishing it, belongs to the Social, Learning and Personality Psychology notes and is named here rather than rebuilt. The stigma typology on which everything below depends, and the measurement instruments used to evaluate any of it, are taught in the section of this chapter that owns them; no instrument is named here.

19.1 Four families, and what each is actually trying to change

Before comparing the strategies it is worth being explicit that they act on different things, because most of the confusion in this topic comes from treating them as interchangeable ways of doing the same job.

- **Contact** puts members of a target audience into structured interaction with people who have lived experience of mental illness. Its target is the audience's beliefs and, more importantly, its behavioural intentions.
- **Education** supplies correct information in place of a false belief. Its target is knowledge, and its assumption is that stigmatising belief is partly an information deficit.
- **Protest** publicly objects to a stigmatising representation or practice and demands its withdrawal. Its target is not the audience at all, but the producer of the representation.

- **Structural measures** change a rule, a budget, a siting decision or an entitlement. Their target is the disadvantage itself, and they require no one to change their mind.

Two things follow immediately. First, only the last of the four addresses structural stigma, so a programme built entirely from the first three has left the most durable form of the problem untouched. Second, protest is aimed at a different recipient from the other three, which is why its evaluation looks different and why it carries a risk the others do not.

RULE **Match the strategy to the type of stigma and to the audience that holds it.** Contact and education act on people who hold attitudes. Protest acts on people who produce representations. Structural measures act on institutions. An intervention aimed at the wrong recipient can be delivered perfectly and still be incapable of changing the outcome it claims.

19.2 Contact as a programme rather than as a mechanism

Taking the mechanism as read, the programme questions are the ones a service actually has to answer. Who are the people with lived experience who will deliver it, how are they recruited, prepared and supported, and what happens to them afterwards? Contact-based programmes run on the disclosure of individuals, which is a genuine cost borne by the very people the programme exists to help, and a programme design that does not address the safeguarding, remuneration and sustainability of its speakers is exploiting them.

The other programme decisions are the audience, the dose and the medium. Audience matters because a gatekeeping group such as health staff, employers, landlords, teachers or police will produce a larger change in real-world discrimination per person reached than the general public will. **Dose**, meaning the number and spacing of encounters, matters because a single session is the commonest design and the least likely to produce durable change. Medium matters because live and mediated delivery differ in reach and in cost in opposite directions, and a filmed or written encounter can reach a population that no live programme could, at the price of some of what makes the encounter work.

19.3 Education as a programme

Educational anti-stigma work replaces a false belief with a correct one, and its natural home is any setting with a captive audience and an existing teaching structure: schools, colleges, professional training and workplace induction. Its advantages are that it is cheap, scalable, deliverable by people who are already employed to teach, and easy to standardise. Its limitations are equally clear. Knowledge and attitude are different constructs and correcting the first does not reliably move the second; attitude and behaviour are different again; and a message pitched to correct one stereotype can, if it is framed carelessly, reinforce the belief that the condition is a fixed and alien state.

The framing question inside educational work is genuinely contested and is worth knowing. Messages that present mental illness as an illness like any other are intended to reduce blame, and they can succeed at that while making the audience perceive greater difference and greater unpredictability. Messages that emphasise continuity between ordinary distress and disorder reduce perceived difference but can dilute the case for treatment. There is no framing that

optimises everything, and an examiner will be satisfied by a candidate who can name the trade-off rather than one who asserts a winner.

19.4 Protest, and why it is the least taught of the three

Protest challenges a specific stigmatising representation: an advertisement, a film, a headline, a product name, a public statement, an institutional practice. It is the only strategy of the three whose outcome is immediate, visible and binary, because either the material is withdrawn or it is not.

Its limitation is that suppressing a representation is not the same as changing the belief behind it, and there is a well-recognised risk of **reactance**, a defensive or contrary response in an audience that reads a public demand for withdrawal as censorship. It is therefore usually described as effective at the level of the representation and unreliable at the level of the attitude. In practice it is best understood as a tool for removing amplifiers rather than for persuading anyone, and it sits most comfortably alongside the structural family, because both act on institutions.

TRAP **Claiming attitude change from a protest outcome.** A withdrawn advertisement is evidence that a producer responded, not that a population's beliefs moved. The two are frequently reported together in programme write-ups, and separating them is exactly the discrimination an examiner is looking for.

19.5 Structural measures, which are where the durable gains are

Structural measures in anti-stigma work act on the rules. Removing an exclusion of mental illness from an insurance product, equalising an entitlement, siting a psychiatric service inside a general hospital, removing a psychiatric history question from a form that asks nothing comparable about physical illness, and correcting a funding allocation that is out of proportion to burden are all anti-stigma interventions, and none of them is a campaign.

Three features make them attractive and one makes them hard. They are durable, because a rule stays changed after enthusiasm fades; they are universal, because they apply to everyone the rule touches rather than to those who attended; and their evidence is a document, so evaluation is cheap and unambiguous. What makes them hard is that they require access to decision-makers rather than to audiences, which is a different competence and a longer timescale, and it is the competence a psychiatrist in a public system is uniquely placed to supply.

19.6 What the comparative evidence actually says

The question candidates most want answered is whether contact beats education. The best available synthesis is more useful and less satisfying than a winner: in a systematic review and meta-analysis of interventions to reduce stigma towards people with severe mental illness, **head-to-head comparisons did not show a clear advantage for either kind of intervention**. The outcomes in view were stigmatising attitudes and the desire for social distance, and the population in view was public stigma towards people with severe mental illness, defined in that review as schizophrenia, psychosis or bipolar disorder.

Read the scope before you use the conclusion. It concerns public stigma towards severe mental illness, not stigma towards common mental disorders, not self-stigma, not structural stigma and not the health workforce. It concerns short-term attitudinal and social-distance outcomes, not discrimination as experienced by patients and not access to care. A finding of no clear head-to-head advantage within that scope is not a finding that the two strategies are equivalent in every setting, and it is certainly not a finding that either changes behaviour.

The practical implication is liberating rather than deflating. If neither strategy is clearly superior on attitudinal outcomes, then the choice between them should be made on the grounds a programme manager can actually control: cost per person reached, availability of a willing and supported speaker group, existing delivery structures, the ability to reach the audience whose behaviour matters most, and the feasibility of measuring anything afterwards.

PITFALL

Reading "no clear advantage" as "both work well". A head-to-head comparison that fails to separate two interventions says nothing on its own about whether either produced a meaningful change against no intervention, and nothing at all about whether any change persisted or reached behaviour. Quote the comparison for what it is, a comparison, and keep the separate questions of efficacy, durability and behavioural transfer separate.

19.7 Targeting: everybody, or the people who decide

The last design decision, and the one with the largest effect on what a fixed budget buys, is whom to aim at. A whole-population campaign has the appeal of universality and the disadvantage that most of the people it reaches will never be in a position to discriminate against anyone with mental illness. A targeted programme aimed at a gatekeeping group accepts a smaller reach in exchange for a much higher density of consequential decisions per person reached, because every member of that group is repeatedly in a position to grant or withhold something: a job, a tenancy, a school place, an arrest decision, a referral, a bed.

Health professionals deserve a separate mention, because they are the gatekeeping group a psychiatric service can reach at zero marginal cost and the one whose stigma has the most immediate effect on whether a person is treated. Diagnostic overshadowing, in which a physical complaint in a person with known mental illness is attributed to the illness and not investigated, is the concrete form the problem takes inside a hospital, and it is a discrimination outcome rather than an attitude, which means it can be audited from records rather than surveyed. An anti-stigma programme aimed at one's own institution with an auditable endpoint of that kind is more evaluable than most of what appears in the published literature.

19.8 Endpoints, decay and the transfer problem

Three measurement problems recur across every anti-stigma programme and a good answer names all three.

The first is **endpoint selection**. Knowledge, attitude, intended behaviour, reported behaviour, experienced discrimination and access to care form a ladder, and each rung is harder to move and

more meaningful than the one below. Almost all published anti-stigma evaluation sits on the lower rungs, and the respondent has to change as you climb: the top of the ladder can only be reported by people who needed care.

The second is **decay**. Attitudinal change after a brief intervention tends to fade, so a design with a single post-intervention measurement taken immediately afterwards cannot distinguish a durable effect from a transient one. A follow-up measurement at a meaningful interval is not a refinement, it is the difference between an evaluation and a satisfaction survey.

The third is **transfer**. Attitude measured in a classroom does not automatically become behaviour in a rental market or a recruitment decision, and the gap between the two is where anti-stigma programmes most often fail without knowing it. Where a programme's real claim is about behaviour, the design has to include a behavioural or access-based endpoint, and if it cannot, the claim has to be scaled back to what was actually measured.

STRATEGY	STIGMA TYPE IT CAN MOVE	WHO RECEIVES IT	ENDPOINT THAT WOULD SHOW IT WORKED	CHARACTERISTIC FAILURE
Contact	Public, and workforce attitudes	An audience, ideally a gatekeeping one	Attitude and intended behaviour in that audience, remeasured after an interval	Single-session dose, unsupported speakers, and no follow-up measurement
Education	Public knowledge, and workforce knowledge	A captive audience in an existing teaching structure	Knowledge in that audience, and separately any attitude change	Knowledge improves while attitude does not, and the two are reported as one
Protest	The representation, not the belief	The producer of a stigmatising representation	Withdrawal or amendment of the material	Reactance in the audience, and attitude change claimed from a withdrawal
Structural measures	Structural stigma	An institution or a policymaker	The amended rule, budget line or entitlement, read as a document	Never attempted, because it needs access to decision-makers rather than to audiences

GOOD TO REMEMBER

If you are asked to reduce stigma in your own hospital, start with the workforce and with the rules, because those are the two things you can actually change and both act directly on whether a patient is treated well. Contact and education aimed at your own staff are deliverable inside existing teaching time, and the structural audit costs nothing: walk the pathway a psychiatric patient takes through your institution and write down every point at which it differs from the pathway a medical patient takes for no clinical reason. That list is an anti-stigma intervention plan.

MNEMONIC

Meet, Teach, Object, Amend

The four families in the order of increasing durability. Meeting someone changes an audience, teaching changes what an audience knows, objecting removes a representation, and amending a rule changes the disadvantage itself and stays changed. Most programmes stop at the first two, and most of the durable gains are in the last.

Audience	Producer	Institution	No clear advantage
WHAT CONTACT AND EDUCATION ACT ON	WHAT PROTEST ACTS ON	WHAT A STRUCTURAL MEASURE ACTS ON	CONTACT AGAINST EDUCATION, HEAD TO HEAD, PUBLIC STIGMA IN SEVERE MENTAL ILLNESS

Contact and education have not been separated head to head on public stigma towards severe mental illness, so choose between them on cost, audience and feasibility, and remember that the only strategy that reliably outlives the enthusiasm of the people running it is the one that changes a rule.

20 · Mental health literacy and community awareness programmes

A treatment gap is closed one step at a time, and the first step is inside somebody's head. Before a person reaches a service they have to notice that something is wrong, decide that it is the kind of wrong a health system deals with, believe that something can be done about it, and know where to go. **Mental health literacy** is the name for that stock of knowledge and belief in a population, and awareness programmes are the deliberate attempt to raise it. This is a programme class in its own right, with its own audiences, its own delivery vehicles and its own outcomes, and it is not a synonym for anti-stigma work.

The distinction matters because the two are constantly conflated. Anti-stigma work targets attitude and discrimination and is taken up in its own section of this chapter. Literacy work targets recognition, help-seeking and first-response knowledge. They overlap, because a population that believes mental illness is a moral failing will not seek help for it, but they are separable, and a programme that measures one while claiming the other has produced an evaluation that answers the wrong question. No measurement instrument is named in this section; the instrument layer belongs to the section of this chapter that owns stigma measurement.

20.1 What literacy has to contain, derived from the pathway rather than asserted

Rather than reciting a list, it is more useful to derive the components from the pathway a person actually travels, because then each component has an owner and an intervention attached to it.

- **Recognition.** The person, or somebody near them, notices a change and names it as a change. Without this step nothing else happens, and this is the step at which a condition that presents as bodily complaint or as behaviour rather than as reported mood is most often missed.

- **Attribution.** The change is attributed to a health problem rather than to character, misfortune, external agency or the ordinary difficulty of life. This is the step at which explanatory models operate, and it is the step most sensitive to what a community believes about causes.
- **Efficacy belief.** The person believes something can be done. A population that recognises depression and believes it is untreatable will not convert recognition into help-seeking.
- **Route knowledge.** The person knows a specific place to go and what will happen there. "Seek help" is not route knowledge; a named service with a location, a cost and a plausible account of what the first visit involves is.
- **First-response knowledge.** The people around the person know what to do and what not to do in the interval before care is reached, which in this field includes knowing how to respond to talk of self-harm.

Reading the components this way has a practical payoff. It shows that a campaign can raise recognition and change nothing, because the bottleneck was efficacy belief or route knowledge, and it tells a programme designer to find out which step their population is actually stuck at before choosing a message.

RULE **Literacy is only useful up to the capacity of the service it points at.** A successful awareness campaign generates demand. If the district service cannot absorb it, the campaign converts an untreated population into a disappointed one, and the second is harder to reach the next time. Awareness and service capacity are commissioned together, or the awareness work should wait.

20.2 The Indian delivery vehicle that already exists

India does not need to invent a channel for this work, because the district programme already carries one. **Information, education and communication for public awareness generation is a named component of the District Mental Health Programme**, sitting alongside its service, training and other activities. That single fact is worth more in an examination than any number, because it locates the responsibility: public awareness is a programme deliverable with an owner in every district where the programme runs, not an optional add-on that depends on an enthusiastic individual.

Two consequences follow for a resident planning district work. The first is that the mandate already exists, so the question is not whether to do awareness work but how to do it well and how to show it was done. The second is that a component defined as information, education and communication invites the cheapest possible interpretation, which is the production of material. Producing a poster is an activity; changing what a population knows is an outcome; and the distance between the two is the whole difficulty of this topic.

IN INDIA

Because public awareness is a district programme component with a named owner, the decision a resident actually faces is what to do with a mandate that comes with no specified outcome. The defensible course is to choose one bottleneck in the pathway and one audience that can be reached repeatedly through an existing institution, then write down in advance what will be counted and what would count as success. A district that does this produces a small evaluable programme. A district that does not produces material, reports the material, and cannot say at the end of the year whether anybody knows anything they did not know before.

20.3 A worked state example, and what its numbers actually measure

State programmes supply the more instructive examples, because they report what they did. One state programme built around mental health clubs in government medical colleges reported, for a single year of operation, that **37 clubs were established across government medical colleges, conducting 1,389 meetings and awareness activities, between April 2024 and March 2025**.

Now read those two numbers with the discipline this chapter demands. The first counts *clubs established*, which is an institutional structure, and it is a real and useful thing to count because a standing structure inside an institution is what makes a programme survive the departure of the person who started it. The second counts *meetings and awareness activities conducted*, which is an output. Neither counts people, so neither is a reach figure; neither counts knowledge, so neither is a literacy outcome; and neither carries a denominator, so no proportion can be computed from either. What they establish is that a delivery structure existed and was active, which is a necessary condition for an effect and not evidence of one.

The generalisable lesson is that the institution is a good unit for this work. A college, a school, a workplace and a police training centre are all standing institutions with a captive audience, a teaching structure, a calendar and somebody accountable, which is why programmes built on institutions persist and campaigns built on events do not.

37	1,389	Output	Not established
CLUBS ESTABLISHED ACROSS ONE STATE'S GOVERNMENT MEDICAL COLLEGES	MEETINGS AND ACTIVITIES CONDUCTED IN THOSE COLLEGES IN ONE YEAR	WHAT BOTH FIGURES ARE, RATHER THAN REACH OR KNOWLEDGE	CHANGE IN RECOGNITION OR HELP-SEEKING, NATIONALLY OR IN ANY STATE

20.4 Designing a campaign that could work

Five design decisions determine whether an awareness intervention has any chance, and they should be made in this order.

Audience before message. A campaign aimed at everybody is aimed at nobody. The audiences worth choosing are those who are either at high risk, or in repeated contact with people at risk, or in a position to open the door to care. In practice that means adolescents and young adults, frontline health workers, teachers, employers and the police, and each requires a different message.

Bottleneck before content. Establish which pathway step the audience is stuck at. If recognition is intact and route knowledge is absent, a campaign explaining what depression is will change nothing that a card with an address would not have changed better.

Channel by audience, not by fashion. The channel that reaches a college cohort is not the channel that reaches an agricultural community or an older population, and the cheapest channel per contact is rarely the most effective per contact. Where a helpline or a service is named in the message, the channel and the service must be aligned so that the door is open when the message lands.

Language and idiom. A message has to arrive in the language people actually use for distress. Translation of a technical message into a regional language is necessary and not sufficient, because the idiom in which distress is expressed differs from the clinical vocabulary in every language. The cultural material behind this belongs elsewhere in this chapter and in the Consultation-liaison, geriatric and transcultural psychiatry notes; the programme point is simply that a message that does not use the population's own words for suffering will not be recognised as being about them.

Dose and repetition. A single exposure decays. Programmes embedded in a recurring institutional calendar accumulate; single events do not, however well attended they were.

A sixth consideration cuts across all five and is specific to this field. Awareness messages about mental illness can carry unintended harm in a way that messages about, say, hand hygiene cannot: material about suicide can affect a vulnerable reader, material that presents a condition as permanent can depress efficacy belief in exactly the people it hoped to reach, and material that names a diagnosis loosely can teach a population to apply a label rather than to seek an assessment. Every awareness message in this field therefore needs a review step that asks who the most vulnerable reader is and what this text does to them, and that step is cheap, is almost always omitted, and is the sort of thing a psychiatrist attached to a district programme is uniquely qualified to insist on.

PITFALL

Substituting an awareness day for an awareness programme. An annual observance is a communication opportunity, and it is often the only thing a service does. It reaches a self-selected audience once, it has no bottleneck analysis behind it, it produces an attendance figure rather than an outcome, and it recurs annually without accumulating. If a day is all the resource there is, attach it to a standing institutional structure so that it becomes the visible part of something continuous rather than the whole of it.

20.5 Measuring literacy, and what India does not know about itself

Literacy outcomes fall into an ordered set, and knowing the order is most of what an examiner wants. Activities delivered is the weakest, followed by people reached, then knowledge and beliefs in a sampled population, then help-seeking behaviour, then service contact, then outcomes among those who reached care. The rungs above knowledge require the person's behaviour rather

than their report, and the rungs above people reached require a sample and a denominator rather than a tally.

Here the position must be stated honestly. No official national or state programme evaluation measuring a change in illness recognition, help-seeking, first-response knowledge or any other literacy outcome, with the sampled population and denominator stated, was retrieved for India. That was sought through the national health mission, the national institute, and health-department sources for individual states. What is published is what programmes did, not what populations came to know. A resident asked what proportion of Indians can recognise depression, or whether awareness activity has changed help-seeking, should say that no such national figure is established, name what would be needed to establish it, and describe what is published instead.

TRAP **Reporting an activity count as evidence of impact.** Programme reports print what is countable, and what is countable is sessions, posters, participants and events. None of those is a literacy outcome. The correct sentence names the count for what it is, an output, and states separately that the outcome was not measured. Candidates who quote activity totals as achievements are repeating the error the report itself is careful not to make.

There is a second and quieter reason to insist on the ordered set. Programmes are funded on what they can report, so a funder that asks only for activity counts will get a system optimised for activity, and the people running it will not be behaving badly; they will be answering the question they were asked. Changing what is asked for is therefore a more powerful intervention on the quality of awareness work than any exhortation about rigour, and it is a change a clinician sitting on a district or state committee is in a position to propose. Ask for one population-sampled knowledge measure a year, with its denominator stated, and the programme will reorganise itself around producing one.

20.6 How this connects to everything else in the chapter

Literacy work sits upstream of almost every other topic here. It feeds the treatment gap, because recognition and route knowledge are two of the gap's determinants. It feeds suicide prevention, because first-response knowledge in the people around a person at risk is what a gatekeeper programme is trying to install in a workforce, and community awareness is the same intervention aimed at a population. It feeds primary care, because a population that presents earlier presents to a general clinic rather than to a specialist. And it is limited by service capacity, which is why it should never be planned in isolation from the service it points at.

PATHWAY STEP	WHAT THE POPULATION MUST HOLD	INSTITUTION THAT CAN SUPPLY IT	WHAT MEASURING IT REQUIRES
Recognition	The ability to name a change as a change	Schools, colleges, workplaces, frontline health workers	A sampled population and a stated denominator, not an attendance tally
Attribution	The belief that it is a health matter	Community channels in the population's own idiom	The same sample, asked about causes rather than about labels
Efficacy belief	The belief that something can be done	People with lived experience, and clinicians who are visible locally	Belief measured before and after, with an interval long enough to show decay
Route knowledge	A named place, a cost and an expectation of the first visit	The district programme's information component, and any helpline named in the message	Behaviour rather than report, ideally service contact attributable to the campaign
First response	What to do, and what not to do, before care is reached	Trained workforces and community groups around the person at risk	Knowledge in the responder, and where possible what the responder then did

Public awareness is a named component of the district programme, so the mandate exists everywhere the programme runs; what is published nationally is activity rather than knowledge, and no Indian literacy outcome with a stated population and denominator is established.

Psychiatric rehabilitation and community care

21 · Principles and components of psychiatric rehabilitation

Rehabilitation is what a service does about the part of illness that treatment does not reach. Symptoms can remit while a person remains unemployed, unhoused, unmarried, out of education and out of every role that gave their life shape, and no amount of additional medication addresses that. Psychiatric rehabilitation is the organised attempt to restore or build those roles, and read at population scale it is not an add-on to treatment but a distinct arm of the service with its own goals, its own workforce, its own outcomes and its own place in the architecture of a health system.

This section takes rehabilitation cross-diagnostically and at the level of systems: what the goals are, how disability and participation are framed and measured, who does the work, how the components are assembled into a network, and what has to happen for any of it to exist in a district. Rehabilitation as it is selected and delivered for an individual patient with schizophrenia, which is the disorder-specific psychosocial account, is taught in the Schizophrenia: management,

antipsychotics and adverse effects notes and is not restated here. Supported employment, deinstitutionalisation, the community settings and the Indian models each have their own section in this chapter and are named rather than taught here.

21.1 Three ideas that organise the whole field

Almost everything in rehabilitation follows from three constructs, and the reason candidates find the field vague is that they learn its activities without learning these.

- **Recovery** in this literature is not synonymous with remission. It denotes a person living a life they regard as worth living, with or without continuing symptoms, and it is defined by the person rather than by the clinician. That shift in who defines the endpoint is the single most consequential idea in modern rehabilitation, because it makes the goal negotiable rather than prescribed.
- **Disability** is the gap between what a person can do and what their environment demands and permits. It is therefore not a property of the person alone, and it can be reduced by changing the environment as readily as by changing the person, which is what makes it a public-health object rather than only a clinical one.
- **Participation** is the outcome that both of the above are aiming at, and it has a usable definition: participation means joining in community activities. That definition is deliberately mundane, and its mundanity is the point. It is checkable, it is meaningful to the person and their family, and it does not require an instrument to notice.

The international orientation of the field follows the same logic. **The World Health Organization's guidance on community mental health services sets out the case for shifting away from institutional, biomedical models of care and toward person-centred, recovery-oriented and human-rights-based approaches**. Each of those three adjectives corresponds to one of the constructs above, and together they describe not a technique but an orientation that a whole service either has or does not.

RULE **The rehabilitation goal is a role, not a score.** A plan whose stated aim is symptom reduction or an improved rating is a treatment plan wearing a rehabilitation label. A rehabilitation aim names the role to be resumed or acquired, the setting in which it happens, and the supports required to sustain it, and it is agreed with the person whose role it is.

21.2 The disability frame, and why psychiatry borrows it

Psychiatry does not need a private theory of disability, and using the general health one has three advantages: it is cross-diagnostic, it is shared with the rest of medicine and with the disability sector, and it is the frame in which entitlements are written. **The International Classification of Functioning, Disability and Health supplies that framework, and it is explicitly designed to apply at both the individual and the population level**, which is precisely what a chapter about services needs: the same construct that describes one person's limitation aggregates into a description of a district's burden.

Its companion assessment instrument is the **World Health Organization Disability Assessment Schedule, WHODAS 2.0**, and its defining property for our purposes is scope: it is used across all diseases, including mental, neurological and addictive disorders. That cross-diagnostic reach is why a rehabilitation service can use one functioning framework for a mixed caseload rather than a different measure for every diagnosis, and it is why functioning data from a psychiatric service can be compared with, and pooled with, functioning data from the rest of the health system.

The instrument is named here and not reproduced. Its domain structure, its scoring and its administration belong to the chapter that owns assessment instruments, the Psychotherapies, clinical assessment, MSE and nosology notes, and no part of it is printed in this chapter. What a resident needs from it here is the conceptual point: functioning is measurable, it is measurable in the same terms across conditions, and it is a different quantity from symptom severity.

21.3 Community inclusion as the outcome, and as an entitlement

Set against a history in which people with mental illness were removed from society for years at a time, the modern statement of the rehabilitation aim is unusually direct. In India it is not merely a professional aspiration but a legal one: **under the Mental Healthcare Act, 2017, every person with mental illness has the right to live in, be part of, and not be segregated from society**. The architecture of that statute, the machinery of rights, capacity, admission and review that surrounds the provision, belongs to the Mental health legislation and forensic psychiatry notes and is not rehearsed here.

What matters for a service is the direction of the obligation this creates. If community living is an entitlement, then segregation requires justification rather than inclusion requiring permission, and a person occupying an institutional bed for want of anywhere to go is not a clinical fact but a service failure with a legal character. That reframing is what converts rehabilitation from a benevolence into a duty, and it is the argument a resident should be able to make in one sentence.

IN INDIA

Two Indian facts sit together and they generate a concrete decision. Community living is a statutory entitlement, and the national programme's stated objectives include promoting community participation in the development of mental health services and stimulating efforts toward self-help in the community. Together they mean that when a resident writes a rehabilitation plan in a public service, the community component is not discretionary and is not something to be added if resources allow. The operational consequence is that the plan should name the community role, the person or group in the community who will support it, and the district programme staff member responsible, before it names any additional treatment.

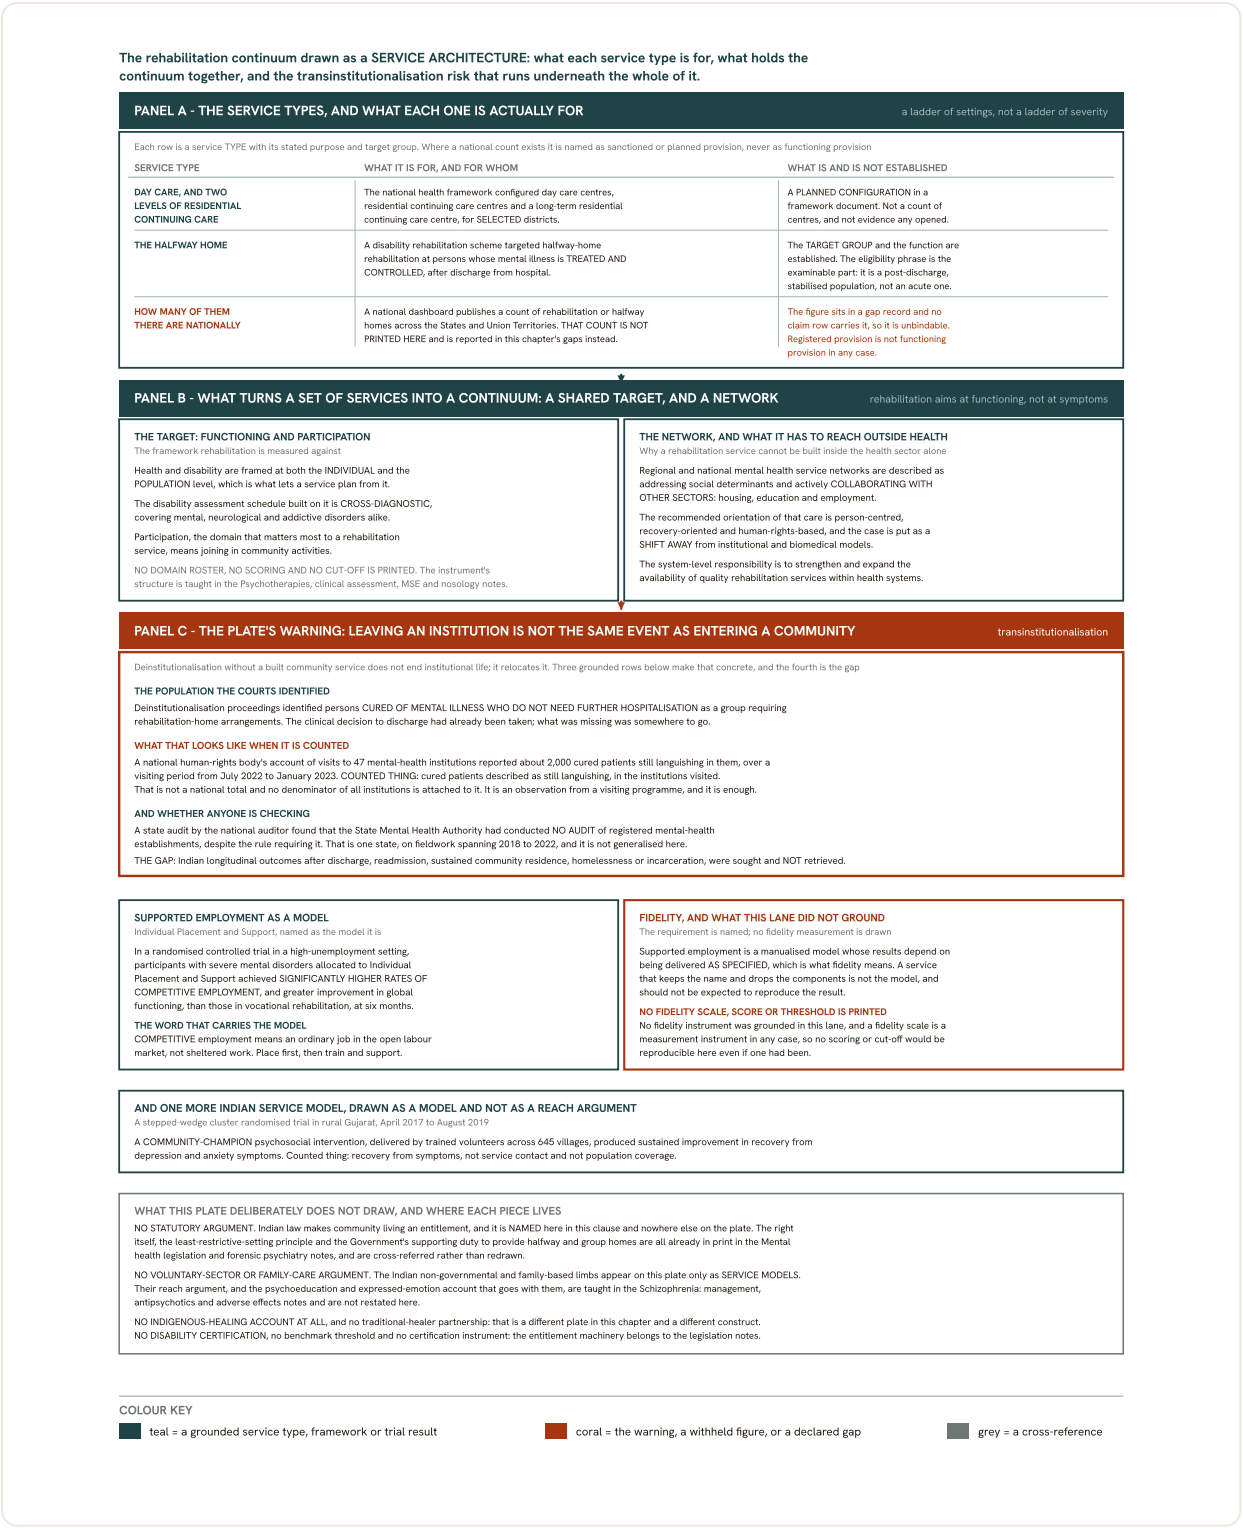

Fig 39.8 The rehabilitation continuum as a service architecture, with transinstitutionalisation as its warning. The national framework configured day care and two levels of residential continuing care for selected districts, and a disability scheme targeted halfway-home rehabilitation at people whose mental illness is treated and controlled after discharge; the national count of such homes sits in a gap record that no claim row carries, so it is not printed. The continuum is held together by a target, participation, meaning joining in community activities, and by service networks that collaborate across housing, education and employment. The warning is concrete: courts identified cured people who no longer needed hospitalisation but had nowhere to go, a human-rights body reported about 2,000 such patients still in the 47 institutions it visited, one state auditor found no audit of registered establishments had been done at all, and Indian post-discharge outcomes were sought and not retrieved. Supported employment is drawn as a model: it achieved significantly higher competitive-employment rates than vocational rehabilitation in a randomised trial, and its fidelity requirement is named without any fidelity instrument being reproduced.

21.4 The components: three ways to close the same gap

If disability is the gap between what a person can do and what the environment demands, then only three kinds of action can close it, and every rehabilitative component in the field is one of the three. This is the most useful classification a resident can carry, because it converts a shapeless list of activities into a decision.

Raise the person's capacity. Skills training in the domains the role requires, whether that is self-care, household management, money, travel, conversation, or the specific competencies of a job or a course. This is the component people think of first, it is the slowest of the three, and it is the only one that transfers with the person when they move.

Supply a support that substitutes for the missing capacity. A person, a structure or a piece of assistance that does what the person currently cannot: a family member who manages medication, a supported setting, a job coach, a case manager, a prompt, an entitlement that replaces lost income. Supports work immediately and stop working when they are withdrawn, which is why the plan has to state whether a support is a bridge or a permanent adjustment.

Lower what the environment demands. Modified hours, an adjusted course load, a changed task, a physical relocation of a service closer to where people live, a form simplified, a rule waived. This is the cheapest of the three and the one clinicians reach for last, because it requires negotiating with somebody outside the health system rather than doing something to a patient.

Most real plans use all three, and the useful discipline is to say which is which, because they have different timescales and different failure modes. A plan built only of skills training will show nothing for months; a plan built only of supports will collapse when the support is withdrawn; and a plan built only of environmental adjustment leaves the person no more able than before if the environment changes again.

21.5 Who does rehabilitation, and what a team has to contain

Rehabilitation is the least doctor-centred part of psychiatry, and the composition of the team is not incidental to it. In India the district programme is built around a multidisciplinary team: **the district team under the programme includes a psychiatrist, a clinical psychologist and a psychiatric social worker**. Those three disciplines map onto three different problems, and understanding the mapping is more useful than memorising the list. The psychiatrist holds diagnosis, medication and risk; the clinical psychologist holds assessment of functioning and psychological intervention; the psychiatric social worker holds the person's relationship with their family, their entitlements and their community, which is where most rehabilitation actually happens.

Two riders follow. First, a team roster is a statement about establishment and not about occupancy: a sanctioned post is not a person, and a district with vacancies in two of the three disciplines has a team on paper only. Second, the roster above is what the programme names and is not asserted here as the complete list of anybody's staffing; occupational therapy, nursing, community health workers, peer workers and vocational staff all have roles in a mature rehabilitation service, and the absence of any of them shapes what that service can offer.

TRAP **Listing rehabilitation activities in place of rehabilitation principles.** Asked about psychiatric rehabilitation, most candidates produce a list of interventions. An examiner is looking for the organising logic first: a person-defined goal expressed as a role, disability understood as the fit between person and environment, participation as the outcome, and a team whose composition follows from the fact that most of the work is social. The activity list is worth marks only once that frame is on the page.

21.6 From a team to a system: networks and other sectors

A team can rehabilitate a person only as far as its own walls. Everything a person needs to occupy a role, somewhere to live, something to do, money, transport and a social world, is held by other sectors, which is why rehabilitation is the part of psychiatry most dependent on institutions that do not report to health. This is not a rhetorical point but the accepted design: comprehensive mental health service networks are described as addressing the key social determinants of health and actively collaborating with other sectors such as housing, education and employment.

The practical form of that collaboration is unglamorous and specific: a named contact in the social welfare office, a working relationship with a disability certification process, a school or college willing to take a student back on modified terms, an employer prepared to make an adjustment, a landlord or a hostel that will accept a tenant. A rehabilitation service is largely a set of such relationships, and the ones that are written down and institutionalised outlive the individuals who built them.

21.7 Getting it to exist: implementation as the real problem

Rehabilitation suffers from a characteristic implementation deficit. It is uncontroversial, it appears in every policy document, and it is the first thing cut when a service is under pressure, because its absence produces no immediate crisis. The international guidance addresses exactly this: the recommendations on rehabilitation in health systems are addressed to member states and other stakeholders in order to strengthen and expand the availability of quality rehabilitation services, which is to say the problem being solved is availability rather than technique.

What has to be true for a district rehabilitation service to exist, in order of how often each is missing: a named person whose job it is; a physical space that is not a ward; a link to at least one non-health sector; a referral route in and a discharge route out; and a record of who is in the service and what they are working toward. Notice that none of those is a treatment, and that a service with all five and no new intervention will do more rehabilitation than a service with a manual and none of them.

21.8 The frameworks compared, and what each is good for

The commonest confusion in this topic is between the constructs, the frameworks and the instruments, so it is worth setting them side by side with what each can and cannot deliver.

WHAT IT IS	WHAT IT FIXES	LEVEL IT OPERATES AT	WHAT IT CANNOT DO
Recovery orientation	Who defines the goal, and therefore what counts as success	The individual, and the culture of a whole service	Be measured directly by any symptom or disability score
The functioning and disability classification	A shared vocabulary for limitation and for the environment's contribution to it	Individual and population, by design	Tell you what to do about any particular limitation
The cross-diagnostic disability assessment schedule	Comparable measurement of functioning across conditions	The individual, aggregable upward	Substitute for a symptom measure, or for the person's own account of their goals
The rights framework in statute	The direction of the obligation: inclusion is the default and segregation needs justifying	The service and the state	Create the community capacity that makes the entitlement usable
Service networks with other sectors	Access to housing, education, employment and income, which sit outside health	The system	Function without named relationships and someone to maintain them

GOOD TO REMEMBER

In an outpatient clinic the whole of this section reduces to one extra question at the end of a review: what does this person do all day, and what would they like to be doing that they currently cannot? A person whose symptoms are controlled and whose answer to that question has not changed in two years is not doing well, whatever the mental state examination records, and that is the moment to write a rehabilitation aim rather than to adjust a dose.

21.9 Evaluating rehabilitation, and the honest position

Rehabilitation is evaluated on roles occupied and sustained rather than on symptoms: living situation, occupation or education, income and entitlements received, social contact, and functioning measured on a cross-diagnostic scale. Two design cautions apply. Outcomes take time, so a study window shorter than the time it takes to acquire a role will find nothing regardless of the intervention. And the environment is part of the outcome, so a service operating in a labour market or a housing market that offers nothing will produce poor role outcomes with excellent practice, which is an argument for reporting the setting alongside the result rather than for despair.

MNEMONIC

Goal, Gap, Team, Sector, Place

The five things a rehabilitation plan has to name. The person's own goal expressed as a role; the gap between what they can do and what the environment demands; the discipline in the team who will hold the work; the sector outside health whose cooperation is needed; and the physical place where it happens. A plan missing any one of them will not survive contact with a district.

Role	**Cross-diagnostic**	**Statutory**	**Availability**
THE UNIT OF A REHABILITATION GOAL, NOT A SYMPTOM SCORE	SCOPE OF THE DISABILITY ASSESSMENT FRAMEWORK USED	STATUS OF COMMUNITY LIVING FOR PEOPLE WITH MENTAL ILLNESS IN INDIA	THE PROBLEM THE INTERNATIONAL GUIDANCE ADDRESSES, NOT TECHNIQUE

Rehabilitation aims at a role the person chooses, works on the gap between the person and their environment, measures functioning on a framework shared with the rest of medicine, and in India rests on a statutory entitlement to live in and not be segregated from society.

22 · Individual Placement and Support (IPS) and supported employment

Work is the rehabilitation outcome patients ask for and services most often decline to organise. Ask a person with a severe mental illness what they want and paid work appears near the top of the list far more often than clinicians expect. Work supplies income, structure, identity, social contact and a reason to be somewhere at a fixed time, all of which are exactly the things illness takes away, and it is the outcome most visible to the family. Supported employment is the service class built to deliver it, and Individual Placement and Support is the model that dominates the field.

This section treats the model as a programme: how a vocational service is designed, what its implementation barriers are, what its fidelity means, how it is evaluated, and what its Indian position actually is. The model as an intervention chosen and delivered for one patient with schizophrenia, and the older distinction between preparing a person before placing them and placing them and then supporting them, are taught in the Schizophrenia: management, antipsychotics and adverse effects notes and are named here rather than re-derived. The principle set and fidelity criteria published in the model's own manual are not reproduced in this chapter.

22.1 Why a health service is in the employment business at all

The objection is worth answering directly, because an examiner may raise it. Employment is not a health service's core competence, employers are not health institutions, and a labour market is not something a district hospital can influence. Three arguments answer it.

- **The barrier is clinical in origin.** The reason many people with severe mental illness are out of work is not a lack of jobs in general but a set of consequences of illness and its treatment,

together with discrimination. Nobody else is positioned to address those, and a generic employment service that does not understand them will fail with this population.

- **The support has to be coordinated with treatment.** Medication timing, appointment scheduling, relapse recognition and the handling of a period of illness while employed all require the clinical team, and a vocational service operating with no line to the clinicians will lose people at the first setback.
- **Work changes the clinical picture.** Income, structure and role are not incidental to outcome, which is why employment is a rehabilitation aim and not a life event that happens after treatment finishes.

RULE **The endpoint is competitive employment, not activity.** **Competitive employment** means an ordinary job in the ordinary labour market, open to anyone, paid at the going rate. Occupational activity within a service, sheltered production and unpaid work experience are different endpoints entirely, and a programme that reports them as employment has changed the outcome definition without saying so.

22.2 The two service logics, and what each demands of a system

Vocational rehabilitation has historically been organised around preparing a person first, through assessment, training and graded work in a protected setting, and placing them once they are judged ready. **Supported employment** inverts the order: the person is helped into an ordinary job early and the support is delivered on the job. The contrast itself is taught in the notes named above; what belongs here is what each logic requires a service to build, because that is what makes one of them feasible in a district and the other not.

A preparation-first system requires physical infrastructure, a sheltered setting, equipment, supervision and a production process, and its unit of investment is a building. A place-and-support system requires almost no infrastructure and a great deal of relationship: employers who will take a referral, a specialist who can spend the day travelling, and a clinical team willing to be interrupted. The first is easier to fund because it is visible and countable; the second is harder to fund and reaches ordinary employment.

The distributional consequence is the one worth stating in an answer. A preparation-first system has an implicit gate, since somebody decides who is ready, and gates exclude the people with the most severe illness. A place-and-support system with an open door reaches those people and accepts that some placements will fail. Which of those a service prefers is a value choice about who the service is for, not a technical one.

22.3 The design decisions that define a supported-employment service

Individual Placement and Support is the best-specified expression of the place-and-support logic. Rather than reciting its published principles, it is more useful to set out the decisions any vocational service has to make, because those decisions are what a resident will be asked about and what a service actually gets wrong.

DESIGN DECISION	THE RESTRICTIVE OPTION	THE SUPPORTED-EMPLOYMENT OPTION	WHAT THE CHOICE COSTS OR BUYS
Who is eligible	Referral after an assessment of readiness	Anyone who says they want to work	An open door reaches severe illness and raises the failure rate; a gate protects the success rate by excluding the people the service exists for
What counts as a job	Sheltered or in-service occupational activity	An ordinary paid job in the open labour market	Sheltered work is easier to arrange and does not produce the income, status or social contact that the outcome is valued for
When the search starts	After a period of preparation and training	Early, with support delivered on the job	Preparation delays and loses people at every step; early search accepts that learning happens in the real setting
Whose preference decides	What the service can arrange	The kind of work the person actually wants	Jobs chosen by the person are held longer; jobs chosen for them are convenient to arrange and quickly lost
Where the employment worker sits	In a separate vocational agency	Inside the clinical team, sharing its meetings and its record	Integration is the expensive part and is repeatedly the part dropped, after which the service is no longer the model it is named for
How long support lasts	Until placement, then discharge	Continuing as long as it is needed, on both sides of the placement	Time-limited support produces placements and not retention; continuing support is a standing cost with no dramatic moment to justify it
Whether income advice is included	Not the service's business	Part of the work, because entitlements interact with earnings	Without it a person can be advised into a job that leaves them worse off, and will reasonably refuse the next offer

Reading the table downward gives the model. Reading it across gives the examination answer, which is that each decision has a defensible restrictive version and that the supported-employment position is a coherent set of choices rather than a slogan.

22.4 The evidence, and how to read a single trial

The comparison that matters is against conventional vocational rehabilitation rather than against nothing. In a randomised controlled trial conducted in a high-unemployment setting, **participants receiving Individual Placement and Support achieved significantly higher rates of competitive employment and showed greater improvements in global functioning than participants receiving vocational rehabilitation**, with those outcomes assessed at six months in people with severe mental disorders who met the trial's eligibility criteria.

Four things in that sentence are load-bearing and a candidate should be able to point to each. The comparator is an active one, so the finding is not merely that doing something beats doing nothing. The primary outcome is competitive employment, which is the endpoint that matters rather than a proxy. A second outcome, global functioning, moved in the same direction, which is the finding that argues against the objection that employment gains come at a cost to the person's mental state. And the setting was one of high unemployment, which matters for the next subtopic.

TRAP **Quoting an employment rate as though it were a property of the model.** Employment rates achieved in vocational trials are functions of the model, of the eligibility criteria and of the labour market the trial ran in, and the last of the three moves the number more than the first. A rate quoted without its labour market is uninterpretable, which is why this section reports the direction of the comparison and prints no employment percentage at all.

22.5 Transportability, which is the real Indian question

Transportability, meaning whether a result obtained in one place will hold in another, is the question this evidence raises most sharply, because every employment outcome is defined against a labour market and the first thing to ask of any vocational evidence is what market it came from. A trial in a high-unemployment setting is informative in a specific way: it tests the model where jobs are scarce, which is a harder test than a tight labour market provides, and it therefore travels better than a result obtained where employers are competing for staff.

The Indian question is not only about the quantity of work but about its form. Where a large share of employment is informal, seasonal, self-organised or family-based, the definition of competitive employment, an ordinary job in the open market at the going rate, describes a smaller part of the working population than it does in the settings where the model was developed and tested. That does not make the model inapplicable; it means the outcome definition has to be examined before the model is imported, and that a service which counts only formal-sector placements will under-record what it achieved. Work within a household or a family enterprise is a real vocational outcome in this setting, and it is taught in the notes cross-referred above rather than here.

The honest position on Indian implementation is that this chapter's sources carry no coverage figure, no service count and no outcome data for supported employment in India. Formal vocational services organised on this model are scarce, and a resident asked about Indian supported employment should say that the model's evidence base is international, that no

national Indian implementation figure is established, and that the transportability question is about the labour market and the outcome definition rather than about the intervention.

22.6 Fidelity, and why the word matters

Fidelity is the degree to which a service as delivered matches the model as specified. It matters in this field more than in most, because supported employment is easy to name and hard to run, and the components that get dropped under pressure are systematically the expensive ones: the integration of the employment worker into the clinical team, the open door, and the continuation of support after placement. A service that has dropped those is still called by the model's name, and its results are then reported as results of the model.

Two consequences follow. For a reader of the literature, an implementation study that reports poor outcomes without reporting fidelity has not shown that the model failed. For a service, fidelity is the thing to measure when outcomes are disappointing, before concluding that the approach does not work locally. Structured fidelity instruments exist for this model and are published by the groups that developed them; none is reproduced here, and a service intending to use one should obtain it from its rights holder.

> PITFALL
>
> Calling a job placement scheme by the model's name because it places people in jobs. The name denotes a specified set of components, and the two that are almost always missing in practice are the employment worker's membership of the clinical team and the continuation of support after the person starts work. A service without those places people and then loses them, which is not the model performing badly but a different service performing as expected.

22.7 Evaluating a vocational service

The endpoints form an ordered set and each answers a different question. Number entering the service answers a reach question. Number placed in competitive employment answers an efficacy question. Time to first placement answers an efficiency question. **Job tenure** and total time worked answer the retention question, which is the one that distinguishes a service from an introduction agency. Earnings answer the question the person actually asked. And functioning and clinical outcome answer the objection that work will destabilise people.

Two cautions apply to all of them. The denominator has to be stated, since a placement rate computed over people who completed a preparation phase is not comparable with one computed over everybody who walked through the door. And the follow-up has to be long enough for retention to be visible, because a placement measured at the moment it happens tells you nothing about whether the person is still there.

There is one further evaluation trap peculiar to this field and it is worth naming. Employment outcomes are highly sensitive to who is counted and when the counting starts, so two services with identical practice can report very different results by defining their cohort differently: everyone referred, everyone who attended once, everyone who set a work goal, or everyone still engaged at the point of analysis. The last of these is the most flattering and the most common,

because it silently removes the people for whom the service did not work. A published vocational result should always be read backwards from the denominator to the referral, and a service reporting its own results should state the referral cohort before anything else.

GOOD TO REMEMBER

Ask about work at every review, in the same routine way as sleep and appetite, and ask what the person wants rather than what they are ready for. In a service with no vocational specialist the useful actions are small and available: agree a work goal in the notes, schedule appointments so they do not collide with a working day, avoid regimens that make morning work impossible where an alternative exists, and speak to the family about the difference between protecting somebody and keeping them idle.

MNEMONIC

Open door, Ordinary job, Own choice, One team, Ongoing support

Five things a supported-employment service either has or has not. No readiness gate, an ordinary paid job in the open market, the work the person chose, the employment worker inside the clinical team, and support that does not stop at placement. When outcomes disappoint, check these before questioning the approach.

Competitive THE ONLY EMPLOYMENT ENDPOINT THAT COUNTS AS THE OUTCOME	**Higher** EMPLOYMENT WITH THE MODEL AGAINST VOCATIONAL REHABILITATION, RANDOMISED COMPARISON	**Retention** WHAT SEPARATES A SERVICE FROM AN INTRODUCTION AGENCY	**Not established** ANY INDIAN COVERAGE OR OUTCOME FIGURE FOR THIS MODEL

Supported employment places the person in an ordinary paid job first and supports them there, its endpoint is competitive employment and its evidence is a randomised comparison against conventional vocational rehabilitation, and what fails in practice is almost always fidelity rather than the model.

23 · Deinstitutionalisation: rationale, outcomes and lessons

A service transition, not an event and not a policy announcement. **Deinstitutionalisation** names the deliberate shift of the centre of gravity of psychiatric care out of large custodial institutions and into general hospitals, community teams and ordinary housing. Every country that has attempted it has discovered the same thing: closing beds is easy, and building the community capacity that has to receive the people is slow, expensive and politically invisible. The distance between those two facts is where the entire teaching content of this topic lives.

The statutory right that mandates community living, and the rights architecture that surrounds it, belong to the Mental health legislation and forensic psychiatry notes and are named here rather than rehearsed. What this section owns is the transition itself: why it was undertaken, what its outcomes were, what has to exist for it to succeed, what happens when the second half is not

built, and what the Indian record actually documents. The community settings that receive people, the day care centre and the halfway home, are configured in their own section of this chapter.

23.1 What drove it, and why the drivers matter

Four forces converged, and it is worth separating them because they pull in different directions and because a service that understands only one of them will make characteristic mistakes.

- **Therapeutic.** Effective treatment shortened the period during which continuous institutional supervision was necessary, so a category of person appeared who no longer required a hospital and had nowhere else organised to be.
- **Ethical and legal.** Long-stay institutions were repeatedly found to produce harm of their own, and the growth of rights-based thinking made indefinite custodial care without justification indefensible rather than merely regrettable.
- **Clinical.** Prolonged institutional living produces its own disabilities, a loss of initiative, of skills and of social contact, which are additional to the illness and are caused by the setting.
- **Economic.** Large institutions are expensive to run, and this is the driver that most often becomes the operative one. That matters, because a transition motivated by cost has a strong incentive to complete the closure and a weak incentive to fund the replacement.

RULE **Deinstitutionalisation is a two-sided programme and only one side is self-executing.** Bed closure happens by administrative decision. Community capacity happens only if somebody funds, staffs and builds it. A programme that treats the second as a consequence of the first has not planned a transition, it has planned a discharge.

23.2 The arc, told as a pattern rather than as a chronology

The international experience repeats a recognisable sequence, and knowing the sequence is more useful than knowing any one country's dates. It begins with a long asylum era in which the institution is the service and admission is effectively indefinite. A critique then accumulates from several directions at once: from clinicians who observe that a portion of the disability they are treating is produced by the setting, from lawyers and rights advocates who object to indefinite detention without review, from the emergence of treatments that make continuous supervision unnecessary for many people, and from finance ministries that notice the running cost of large estates.

Bed reduction then proceeds, usually faster than the community programme that was supposed to accompany it, and the visible consequences appear in other sectors rather than in psychiatry: in homelessness, in criminal justice, in nursing and residential homes, and in the burden carried by families. A later corrective phase follows in which community teams, crisis services, supported housing and assertive follow-up are built, and the systems that build them find that community care is not obviously cheaper than the institutions it replaced, only better, which is a very different argument to make to a treasury.

The clinical construct that justified the whole enterprise deserves its own name. **Institutionalism** is the syndrome produced by prolonged institutional living itself, comprising loss of initiative and of ordinary decision-making, submissiveness to routine, loss of practical and social skills through disuse, and a narrowing of expectation until the person no longer wants what they cannot have. It is additional to the illness, it is caused by the setting, and it is partly reversible, which is why it is an argument for moving people rather than an argument that they cannot be moved.

23.3 What has to exist on the receiving side

The precondition list is short and each item is a place where real programmes have failed.

Somewhere to live. Housing is the precondition, not an adjunct, and it is the one a health department cannot supply on its own. A discharge plan without an address is a transfer of the person to their family or to nowhere.

An income. A person leaving a long stay has usually lost earning capacity, savings and often any claim on family property. Without an income or an entitlement, community living is not sustainable regardless of clinical state.

A team that follows. Continuity of clinical care after discharge, with somebody responsible for finding the person when they do not attend, is what distinguishes community care from discharge. The absence of an **assertive follow-up** function, meaning a service that goes after the person rather than waiting for them, is the commonest technical failure.

Something to do. Occupation and role, addressed elsewhere in this chapter, without which the community placement is a smaller and lonelier institution.

A family or a substitute for one. In a system where families provide most long-term care, the family's willingness and capacity is a service variable and not a private matter, and it has to be assessed rather than assumed.

23.4 Transinstitutionalisation and the other failure modes

Transinstitutionalisation is the term for what happens when the receiving side is not built: people do not enter community life, they move into another institution. The destinations differ by country and by era, and the categories to know are prisons, nursing and old-age homes, custodial or beggar homes, and unregulated private facilities, with homelessness as the outcome when no institution absorbs them at all.

The concept is examinable because it explains why bed-count data can look like success while the population's situation has not improved. A country that halves its psychiatric beds and doubles the psychiatric population of its prisons has not deinstitutionalised anybody; it has changed which ministry is responsible. The corollary for evaluation is that the outcome measure cannot be a psychiatric bed count, and has to be a description of where people actually are.

TRAP **Treating bed reduction as the outcome of deinstitutionalisation.** Bed numbers measure the supply side and are easy to obtain, which is why they get reported. The outcome of interest is where the people are living, whether they are still in contact with services, and whether they have an income and a role. If those cannot be reported, the honest statement is that the programme's inputs are known and its outcomes are not.

23.5 What the Indian record actually documents

India's deinstitutionalisation story is not primarily a story of planned bed closure. It is a story about people who no longer need to be in hospital and are still there, and it has been documented mainly through litigation and inspection rather than through programme evaluation. Three kinds of record exist and each is a different sort of evidence.

The first is judicial. Deinstitutionalisation proceedings before the Supreme Court identified, as a population requiring rehabilitation-home arrangements, persons living with mental illness who have been cured and who do not need further hospitalisation. Note the construction of that category. It is defined administratively, by two negatives, no longer ill in the relevant sense and no longer needing a hospital, and it says nothing about what the person can do or wants. A category defined that way identifies who should not be where they are without identifying where they should go, which is precisely the gap the proceedings were addressing.

The second is inspectorial. **An account by the National Human Rights Commission of visits to 47 mental-health institutions reported about 2,000 cured patients still languishing in institutions**. Read the scope carefully before using the figure. It describes patients in the institutions that were visited, so it is not a national census, it carries no denominator, and no proportion may be computed from it. What it establishes is that the phenomenon exists at institutional scale and has been found by an official body that went and looked.

The third is audit. A performance audit found that a state mental health authority had not conducted the audit of registered mental-health establishments that it was required to conduct. That finding is about the machinery rather than about patients, and it is the most quietly damaging of the three, for the reason set out below.

47	about 2,000	None	Not established
MENTAL-HEALTH INSTITUTIONS VISITED IN THE INSPECTION ACCOUNT	CURED PATIENTS STILL IN THOSE INSTITUTIONS, NOT A NATIONAL CENSUS	VALID DENOMINATOR FOR THAT COUNT, SO NO PROPORTION	WHAT HAPPENS TO PEOPLE AFTER DISCHARGE IN INDIA

23.6 The accountability machinery, and why the audit finding matters

A system that intends to move people out of institutions needs to know what its institutions are doing, which is why regulatory inspection of registered establishments exists as a duty rather than as a good idea. When an audit finds that the required inspection of registered mental-health establishments has not been carried out, the consequence is not merely a procedural lapse. It means that the state's own information about conditions, about length of stay and about who is ready for discharge is not being generated, and a transition cannot be planned on information that is not collected.

This is the general form of a lesson that recurs across this chapter: the failure is usually not at the level of policy, which is generally sound, nor at the level of clinical practice, which is generally willing, but at the level of the machinery that is supposed to observe and report. A resident who can identify the missing observational step in any programme is answering these questions at the right level.

IN INDIA

The operational decision is what to do when you have a patient who is ready for discharge and has nowhere to go. Three things follow from the record above and each is actionable. Record readiness for discharge explicitly in the notes on the day it is reached, because the category of person who no longer needs hospital care is the category the courts and the inspectorate act on, and an undocumented readiness is invisible to both. Involve the social work function early, because the obstacle is an address, an income and a receiving family rather than a treatment. And ask whether your establishment has been inspected by the state authority, because where that machinery is not operating, nothing about your ward's long-stay population is being reported to anybody.

23.7 What India does not know about its own discharges

Here the chapter has to be plain. No official Indian longitudinal or comparative data on what happens to people after discharge from mental-health institutions was retrieved. That includes readmission, sustained community residence, homelessness, incarceration, transfer into custodial or beggar homes, and every other transinstitutionalisation outcome. It was sought from the courts, the health ministry, the human rights commission, the national auditor, the disability empowerment department and state governments.

That absence is not a small one, and it is worth stating what it means rather than merely noting it. Without post-discharge outcome data, nobody can say whether Indian deinstitutionalisation, to the extent that it has happened, has produced community living or transinstitutionalisation. The country has documentation of the problem, judicial direction about it, and no measurement of the result. In a viva, a candidate who says exactly that, and who names transinstitutionalisation as the specific thing that would be measured, has given the strongest available answer.

PITFALL

Assuming that a discharge to family is the same as community living. In a family-based care system the family is the default destination, and for many people it is a good one. But a discharge that transfers the whole burden of supervision, income, occupation and crisis management to a household with no support, no training and no line to the service is a private institution with fewer safeguards than the public one. The question to ask before such a discharge is what the family is being asked to do, and what the service is offering them in return.

23.8 The lessons, stated as design rules

LESSON	WHAT GOES WRONG WHEN IT IS IGNORED	WHAT IT REQUIRES IN PRACTICE
Build the receiving capacity before reducing the sending capacity	People leave with nowhere to go, or do not leave at all and occupy beds that are no longer clinically needed	Housing, income and follow-up commissioned as part of the same programme, not as a later phase
Measure where people are, not how many beds there are	Bed reduction is reported as success while the population moves into other institutions	Post-discharge follow-up with named outcomes, including incarceration and homelessness
Treat readiness for discharge as a documented status	People ready to leave are invisible to the courts, the inspectorate and the planners	Explicit recording, and a register that somebody outside the institution can read
Keep the inspection machinery working	The state stops knowing what its own establishments contain	The statutory authority actually conducting the audits it is required to conduct
Fund the family as a service partner	Discharge becomes an unsupported transfer of custodial responsibility to a household	Carer support, crisis access and a named contact for the family

MNEMONIC

Roof, Rupees, Role, Review

The four things a person needs on the day they leave a long stay. Somewhere to live, an income or entitlement, something to do, and a clinical contact who will notice if they disappear. A discharge plan missing any one of the four is the mechanism by which deinstitutionalisation becomes transinstitutionalisation.

Deinstitutionalisation succeeds or fails on the receiving side, its true outcome measure is where people are living rather than how many beds were closed, and in India the long-stay population has been documented by courts and inspectors while what happens after discharge has never been measured at all.

24 · Community mental health services, day care and halfway homes

Between the ward and the family home there is a ladder, and most Indian districts own only its two ends. A person recovering from a severe illness rarely moves in one step from inpatient care to independent living, and the settings that occupy the middle of that ladder, day care, the halfway home, supported accommodation, longer-term residential care and the community team that visits, exist to make the intermediate steps possible. This section is about how each of those settings is configured: what it is for, who enters it, who staffs it, what a person does there, how they leave, and which arm of government pays for it.

The settings themselves will already be familiar. Their compact definitions, and the place each occupies on the rehabilitation ladder, are taught in the Schizophrenia: management,

antipsychotics and adverse effects notes, and the statutory right to community living and the prohibition on keeping a person in an institution who does not need to be there belong to the Mental health legislation and forensic psychiatry notes. Neither is repeated here. What follows takes the settings as known and asks the service questions about them, which is the part no other chapter carries.

24.1 What it means to configure a setting rather than to define it

A setting is defined by what it is called and configured by five decisions, and it is the five decisions that determine whether it works.

- **Function.** What is the setting actually for, in one sentence: containment, structure, skill acquisition, supervision of treatment, respite for a family, or transition to somewhere else.
- **Entry criteria.** Who is eligible, who decides, and what a person must be able to do before they are accepted.
- **Staffing.** Which disciplines, at what density, present at which hours.
- **Duration and exit.** How long a person stays, what triggers the move on, and where they move to.
- **Funding and governance.** Which arm of government or which body pays, registers and inspects it.

The fourth is the one that separates the settings from each other conceptually, and the fifth is the one that separates them administratively in India, which is why the last two subtopics of this section are about money and counting rather than about clinical content.

RULE **A community setting without a defined exit becomes a small institution.** Every intermediate setting is justified by the step it enables. Where no exit criterion is written and no destination exists, length of stay drifts upward, the population ages in place, and the setting acquires exactly the long-stay character the ladder was built to avoid. Write the exit before the admission.

24.2 The community team, which is the setting without a building

Before any of the physical settings, the ladder needs the service that connects them, and it is the one most often left out of an answer because it has no address. A community mental health team is defined not by where it sits but by where it goes: it holds a caseload of people living at home or in supported settings, sees them where they are rather than where the hospital is, and takes responsibility for noticing when somebody stops attending.

Its four functions are worth naming separately. It supplies *continuity*, so that a person is followed by a service rather than by a series of unconnected appointments. It supplies *outreach*, meaning contact that is initiated by the service, which is the single feature that distinguishes community care from an outpatient clinic and the one that reaches people who default. It supplies *coordination*, holding the relationships with the day-care centre, the residential setting, the family, the employer and the welfare office. And it supplies *crisis access*, without which every deterioration becomes an emergency admission.

In India this function is carried by the district mental health programme's team, and it is worth being clear about the implication. Where that team's posts are vacant or its outreach component is not funded, the entire ladder above and below it becomes a set of disconnected facilities, because there is nobody whose job it is to move a person along it. The physical settings are visible and get built; the connecting function is invisible and gets cut, and its absence is the commonest reason a district with facilities still has no community service.

24.3 Day care, configured

The **day care** centre is the least expensive intermediate setting because it borrows the person's own accommodation. Its function is structure and occupation during the day, together with a regular point of clinical contact, for a person who lives at home. Its natural population is a person whose family can hold the nights and the weekends but cannot supply a day that has any shape to it, which describes a very large share of the severe-illness population in a family-based system.

Its configuration questions are specific. Attendance is usually flexible, so a register that records who is expected and who came is the difference between a service and a room. Transport is the commonest reason for non-attendance and is almost never budgeted. Staffing needs to include somebody who can run an activity programme, not only somebody who can supervise medication. And because the person goes home each evening, the family is a partner in the day care arrangement rather than a bystander, which means the setting can be used deliberately to give a carer predictable hours of relief.

24.4 The halfway home, configured

The **halfway home** is residential and transitional, and both of those words are load-bearing. Residential, because it supplies accommodation and therefore reaches the person for whom home is not currently available or not currently workable. Transitional, because its whole justification is that the person is going somewhere afterwards.

Indian scheme design states the target group explicitly. **The Deendayal Disabled Rehabilitation Scheme of 2009 targeted halfway-home rehabilitation at people whose mental illness is treated and controlled, after their discharge**. Read the eligibility carefully, because it does two things at once. It defines the setting as post-discharge and therefore downstream of treatment, and it defines the population by clinical stability, which means the halfway home is not a place to send an unstable person and not a substitute for admission. A service that uses it as either has misconfigured it.

The configuration questions that decide whether such a home works are the length of stay and the destination. A halfway home with no ceiling on stay and no supported accommodation to move into becomes long-term residential care under another name, which is not a failure of the staff but a failure of the ladder above them.

TRAP **Describing the halfway home as a place for people who are unwell.** The scheme design defines its population as people whose illness is treated and controlled, after discharge. Candidates routinely describe it as an intermediate treatment setting for partially recovered patients, which imports an acute function it was not configured for and confuses it with day care and with continuing residential care in the same answer.

24.5 The continuing-care tier, and how India planned it

Not everybody moves on. A proportion of people with the most severe and persistent illness, particularly those with no family and no income, need residential support that is not transitional, and a ladder that pretends otherwise simply discharges them into homelessness. Indian programme design has recognised this in the structure of its own planning: **the National Health Mission implementation framework for 2012 to 2017 provided for day-care centres, residential continuing-care centres and a long-term residential continuing-care centre in selected districts**.

Three features of that plan are worth teaching. It is tiered, distinguishing day attendance from residential continuing care and again from long-term residential continuing care, which is exactly the ladder logic. It is explicitly limited to *selected* districts, so it was never a universal offer and should not be described as one. And it is a statement of what will be provided, which is a plan rather than an inventory, so nothing about how many such centres came to exist follows from it.

24.6 Two doors, two ministries, one patient

The single most useful administrative fact in this topic is that India's intermediate settings are reachable through two different arms of government, and they have different eligibility logics, different registering authorities and different money. The health route runs through the national and district mental health programmes and treats the setting as a health service. The disability and social welfare route runs through disability schemes and treats the same setting as a rehabilitation facility for a person with a disability, which brings certification, entitlements and a different inspection regime with it.

ROUTE	HOW THE SETTING IS FRAMED	TYPICAL ELIGIBILITY LOGIC	WHAT IT BRINGS WITH IT
Health programme route	A service component of the mental health programme, planned for selected districts as day care and as two tiers of residential continuing care	Clinical need, decided by the treating service	Clinical staffing, a link to the district team, and dependence on programme funding cycles
Disability and social welfare route	A rehabilitation project, with the halfway home as a named model project for people whose illness is treated and controlled after discharge	Post-discharge stability, and often a disability certificate	Grant-based funding to voluntary organisations, certification requirements, and a different inspectorate

The practical consequence for a resident is that the answer to "where can I send this person" depends on which door you knock on, and that the two doors have different waiting times, different paperwork and different reasons for refusing. Knowing that there are two is worth more in a district job than knowing the name of any single facility.

IN INDIA

The decision this section forces is procedural and it is made early or not at all. If a person is likely to need an intermediate residential setting after discharge, start the disability certification and the scheme paperwork while they are still an inpatient, because the social welfare route requires documentation that takes time to assemble and cannot be produced on the day of discharge. Simultaneously ask the district programme what it actually operates locally, since the health route's day-care and continuing-care provision was planned for selected districts rather than for all of them. Doing both in parallel is the only way to have a destination ready when the person is ready.

24.7 What is counted, and what a count of it means

A national dashboard publishes a count of rehabilitation homes and halfway homes across states and union territories, which sounds like the coverage figure this section needs and is not. This chapter cannot print those figures, because no claim row here asserts them, and the honest treatment is to teach what such a count would and would not establish.

A dashboard count is a count of *listed or registered* facilities. It is not a count of facilities that are open, not a count of places available, not a count of people accommodated, and it has no denominator, so no proportion of need met can be computed from it. Two facilities appearing as one row each may differ by an order of magnitude in the number of people they hold. And a national total says nothing about distribution, which is the variable that matters to a patient, because a home in another state is not a destination.

The deeper gap sits underneath the count. Current operative staffing standards and referral criteria for day-care centres and halfway homes, together with any national or state outcome data that would distinguish sanctioned or registered provision from functioning services, were sought across the health ministry and mission, the disability empowerment department and state health and social welfare authorities, and were not retrieved. So the position to state in a viva is this: the settings are named in Indian scheme design, their target populations are defined, a national listing of homes exists, and what they are staffed with, who they must accept and what happens to the people in them is not established.

PITFALL

Quoting a registry total as service capacity. It is the same error as reading a sanctioned district total as coverage, and it recurs across this chapter because registries are the only national data that exist for community services. A listed home may be closed, may be full, may take only one sex, may charge fees, and may be a day's travel away. Before referring, confirm the four things a registry never records: is it open, is there a place, what does it cost, and will it take this person.

Supported accommodation deserves a mention as the rung above the halfway home, because it is the destination that makes a transitional setting transitional. It is ordinary housing with a support component attached, ranging from a warden or visiting worker to a shared flat with staff on call, and its defining feature is that the tenancy rather than the treatment is the organising fact. Where it does not exist, everything below it silts up. This chapter's sources carry no figure for its availability in India, so the honest statement is that the rung is named in policy and its extent is unmeasured.

24.8 Choosing a setting for a particular person

The decision reduces to three questions asked in order. Does the person have somewhere to sleep tonight that is safe and available? If yes, the residential settings are not indicated and the question is what fills the day. If no, is the need transitional or continuing? A transitional need with a plausible destination points to a halfway home; a continuing need with no destination points to the continuing-care tier, and pretending otherwise produces a failed placement. And finally, who is going to keep clinical contact wherever the person goes? A community setting without a named clinical contact is where people are lost to follow-up.

MNEMONIC

Function, Entry, Staffing, Exit, Payer

The five configuration questions, in the order in which they should be asked of any community setting. If you can answer all five for the day-care centre and the halfway home in your own district, you know more about local services than most of the people referring into them.

Selected DISTRICTS THE PLANNED DAY-CARE AND CONTINUING-CARE TIERS WERE FOR	**Post-discharge** TARGET POPULATION FOR THE HALFWAY-HOME MODEL PROJECT	**Two** GOVERNMENT ROUTES INTO THE SAME SETTINGS, HEALTH AND SOCIAL WELFARE	**Not established** STAFFING STANDARDS, REFERRAL CRITERIA AND OUTCOMES FOR EITHER SETTING

Day care borrows the person's own accommodation and supplies the day; the halfway home is residential, transitional and configured for people whose illness is treated and controlled after discharge; and in India both are reachable through a health route and a social welfare route with different eligibility, different money and different inspectors.

25 · Models of care in India: NGOs, family-based care and indigenous resources

Most mental health care in India is delivered by people the health system does not employ. Families, voluntary organisations, community volunteers and traditional practitioners between them carry a far larger share of the load than the district programme does, and a chapter on service architecture that describes only the government machinery has described the smaller part of the system. This section treats those three as *models of care*: configured arrangements with an identifiable provider, a funding basis, a governance structure and, in principle, an evaluable output.

Two boundaries apply before we start. The family as the delivery vehicle for psychoeducation and for work with high expressed emotion, and the voluntary sector named as a force multiplier for community reach in the management of schizophrenia, are both taught in the Schizophrenia: management, antipsychotics and adverse effects notes, and neither is restated here. The design of a formal partnership with traditional and faith-based healers, meaning bidirectional referral, training, safeguards and access, is taught in the section of this chapter that owns traditional healers, and is named here rather than built.

25.1 What makes something a model rather than an activity

A **model of care** is not the same as a thing that helps. Four properties turn an arrangement into a model, and they are the properties that let it be commissioned, replicated and evaluated.

- **A defined provider and a defined role.** Somebody specific does something specific for somebody specific, and it is written down.
- **A funding and governance basis.** Money comes from somewhere on a stated basis, and somebody is accountable for how it is used.
- **A relationship with the formal system.** Referral in, referral out, and an agreed division of what each side does, without which the model is a parallel service rather than a component of one.
- **An output that could be measured.** Not necessarily measured, but of a kind that could be.

Running the three Indian limbs through those four properties is the most useful thing this section does, because it explains immediately why the voluntary sector is the best documented, why family care is the largest and least visible, and why indigenous resources are the hardest of the three to hold to any of it.

RULE **Name the provider, the money and the referral relationship, or you have not described a model.** A great deal of writing about Indian community psychiatry describes admirable activity without any of the three, which is why so little of it can be commissioned by anybody or repeated anywhere else.

25.2 The voluntary sector as a configured model

The **voluntary sector**, meaning non-governmental organisations working outside both the state system and private practice, occupies a specific and predictable position in Indian mental health care. They tend to do the things the public system finds hardest to fund: long-term residential rehabilitation, day activity, vocational work, homeless outreach, carer support, and services for populations that fall between departmental mandates. They are usually geographically concentrated, so their national coverage is thin even where their local quality is high, and they typically depend on a mixture of philanthropic funding, government grants and project money, which means their planning horizon is set by their funding cycle rather than by their patients' needs.

The partnership questions between such an organisation and a district service are concrete and are what a resident actually has to negotiate. Who accepts clinical responsibility for a person in

the organisation's care, and is that written down? What is the referral route in each direction, and what happens outside working hours? Who holds the clinical record, who prescribes, and who reviews? What happens to the people in the service if the grant ends? An arrangement with clear answers is a model; an arrangement without them is a friendship between two institutions, and it does not survive a change of personnel.

This section names no Indian organisation. That is a deliberate omission and worth stating plainly: naming a service is a factual claim about what that organisation does, and this chapter's sources do not carry a description of any individual Indian organisation. A resident preparing for an examination should know the sector's characteristic functions, which are set out above, and should read about specific organisations in their own published accounts rather than from a list learned second-hand.

25.3 The family as India's largest care system

In India the family is not an adjunct to care but the substrate on which everything else rests. Co-residence is common, supervision of medication is routine, transport to appointments is a family undertaking, and the family is usually the first to detect deterioration and the last line of support when nothing else is available. Reading that as a service model rather than as a cultural fact changes what a service is obliged to do about it.

If the family is a provider, then it has the same needs as any other provider. It needs to know what it is treating, which is information rather than instruction. It needs a route of access when things change, because a carer with no way to reach the service will present at an emergency department instead. It needs relief, since supervision without respite is not sustainable across the years these illnesses last. It needs financial support, because carer time is unpaid labour with an opportunity cost that falls disproportionately on women. And it needs somebody to notice its own health, since carer distress is both a consequence of the role and a determinant of whether the person being cared for stays at home.

Carer organisations and family self-help groups are the organised form of this. Their functions are advocacy, mutual support, and in some settings direct service provision, and they change the relationship between families and services from petitioning to negotiating. The techniques of family intervention itself, psychoeducation and the work on expressed emotion, belong to the notes cross-referred above and are not described here; what belongs here is the service obligation that follows from treating the family as part of the workforce.

TRAP **Describing family involvement as an Indian cultural advantage and stopping there.** It is an advantage, and it is also an unfunded transfer of long-term care to households, disproportionately to women, with no training, no relief and no income attached. Both halves belong in the answer. A candidate who writes only the first half has described a resource; a candidate who writes both has described a model with a cost.

25.4 Indigenous and traditional resources as a service model

Indigenous resources, the third limb, are what no other chapter treats as a service model, and they are difficult precisely because the phrase covers at least three different things. There are

traditional systems of medicine with their own texts, training and practitioners. There are religious and faith-based settings to which distressed people and their families go, sometimes in very large numbers. And there are local healers with no formal system at all, who are frequently the first point of contact and, in many districts, the most accessible one.

Treated as a service model, the honest ledger is short and should be stated without either romanticism or contempt. What these resources reliably supply is *access*, because they are local, affordable, culturally intelligible and available without a referral; *explanation*, in an idiom the family already uses; and *social sanction*, since consulting them carries none of the discredit a psychiatric attendance carries. What they do not supply is evidence of therapeutic effect for psychiatric disorder, and this chapter does not print one. The cultural and relational significance of indigenous healing, including the traditional teacher and disciple relationship read as a native model of the therapeutic bond, is taught in the Psychotherapies, clinical assessment, MSE and nosology notes, which places it at the cultural level and explicitly not as evidence-based treatment. This chapter prints no claim stronger than that.

The service consequence is a matter of position rather than of belief. These practitioners are already in the pathway, whether or not any service acknowledges them, so the operative question is not whether they should be, but what a formal service does about the fact. The design of that relationship, referral in both directions, what may safely be shared, what training is offered and what safeguards apply, is the subject of the traditional healers section of this chapter and is not settled here.

25.5 The one Indian community model with a trial behind it

Very few Indian community models have been evaluated with a controlled design, which is precisely why the ones that have been matter disproportionately. A community-champion model deserves attention on those grounds: in a cluster-randomised trial conducted in rural Gujarat, **the Atmiyata intervention had a significant effect on recovery from symptoms of depression and anxiety, with effects sustained at 8-month follow-up**.

What makes this instructive is the provider. The intervention is delivered by volunteer community champions, ordinary community members rather than health workers, which places it at the far end of the workforce spectrum from the specialist service. Three features of the design are worth extracting for any examination answer. The provider is drawn from the community being served, which addresses both access and acceptability at once. The design is cluster-randomised at village level, which is the right unit when the intervention acts on a community rather than on an individual. And the follow-up extends beyond the intervention period, which is what turns a demonstration of effect into a claim about durability.

IN INDIA

The decision this section supports is how to treat the non-governmental providers already working in your district. Treat them as a model rather than as goodwill: ask each one the four questions that make a model, who does what, on what money, with which referral route in each direction, and what they count. Where a volunteer or community-champion layer exists, the Indian evidence supports taking it seriously as a therapeutic component with a durable effect rather than as outreach, which means it deserves supervision, a defined scope and a route to escalate, exactly as a paid worker would.

25.6 What the Indian model literature is missing

The gap in this topic is not a gap in activity but a gap in evidence and in accounting, and it has a characteristic shape. There is no national inventory of voluntary-sector mental health provision, so nobody knows what exists or where. There is no measurement of what family care actually costs the households that supply it. Very few community models have been evaluated against any comparator, and those that have are concentrated in a handful of research settings, which raises the transportability question rather than settling it. And the most common form of publication is a description of a promising programme with no control condition and no follow-up, which is why so much of the field reads as encouraging and proves so little.

Because so much of the literature is descriptive, it is worth carrying a short appraisal routine for any Indian model-of-care paper, and it is the routine an examiner is testing when they ask what you think of a programme. Ask what the comparator was, and treat "before and after in the same people" as the weakest answer available, because a service that recruits people at their worst will improve without doing anything. Ask who was counted, and specifically whether the denominator is everybody offered the model or only those who stayed in it. Ask when the outcome was measured, since an assessment taken at the end of the intervention says nothing about durability. Ask who delivered it and whether that person exists outside the study, because a model delivered by a research team is not a model a district can run. And ask what it cost, since a model whose cost is unreported cannot be compared with anything the state is already funding.

Applying that routine to the Indian field produces a consistent verdict: a small number of models are properly evaluated, a large number are described, and the two groups are not the same models. That is not a criticism of the people running services, who are rarely funded to evaluate anything. It is an argument for building the evaluation question into the design of the next programme rather than attempting to reconstruct it afterwards.

None of that is a reason to dismiss the models. It is a reason to be precise about what is claimed for each, which is what the table below does.

MODEL	WHAT IT RELIABLY SUPPLIES	FUNDING AND GOVERNANCE	WHAT IS ESTABLISHED ABOUT EFFECT
Voluntary sector organisations	Long-term rehabilitation, day activity, vocational work, outreach to populations the public system misses	Philanthropy, grants and project money, with a planning horizon set by the funding cycle	Nothing at national level in this chapter's sources; no national inventory of provision exists
Family-based care	Supervision, accommodation, transport, early detection and the whole of long-term support	Unfunded, borne by households and disproportionately by women	Nothing quantified here; the cost to households is unmeasured
Community champions and volunteers	Local, acceptable, first-line psychosocial contact within the community itself	Programme or research funding, with volunteers rather than salaried staff	A cluster-randomised trial in rural Gujarat found improved recovery from depression and anxiety symptoms, sustained on follow-up
Indigenous and traditional resources	Access, explanation in the family's own idiom, and social sanction	Private, fee-for-service or offering-based, outside any health governance	No effect claim is printed here; the cultural reading is owned by another chapter and is explicitly not an evidence claim

PITFALL

Treating an unevaluated local programme as a model because it is admired. Enthusiasm, longevity and local reputation are not evidence, and a programme that has run for years without ever defining an output is not a model that anybody else can adopt. The kindest and most useful thing a visiting psychiatrist can do for such a programme is to help it define what it would count, because that is what converts it from a good thing into something a state could fund.

MNEMONIC

Provider, Purse, Pathway, Proof

The four questions that turn an arrangement into a model of care. Who does it, who pays for it, how does a person get in and out of it, and what would show that it worked. Ask them of a voluntary organisation, of a family and of a village volunteer alike, and the differences between the three limbs become clear immediately.

Volunteers
PROVIDER IN THE ONE INDIAN COMMUNITY MODEL WITH A CONTROLLED TRIAL HERE

Sustained
RECOVERY EFFECT AT FOLLOW-UP IN THAT TRIAL

Unfunded
BASIS ON WHICH FAMILY CARE IS SUPPLIED

No inventory
NATIONAL RECORD OF VOLUNTARY-SECTOR MENTAL HEALTH PROVISION

A model of care has a provider, a purse, a pathway and a proof; India's three great non-governmental models are the voluntary sector, the family and the indigenous practitioner, and of the three only a community-volunteer intervention carries a controlled Indian trial in this chapter's evidence.

Primary care, integration and service delivery models

26 · Integration of mental health into primary care and the role of medical officers

There will never be enough psychiatrists, and integration is the only answer anybody has that is not arithmetic nonsense. If mental disorder is common and specialists are few, then care has to be delivered by the part of the health system that is already everywhere and already sees everybody, which is primary care. Integration is the deliberate rebuilding of primary care so that it detects, treats, refers and follows up mental, neurological and substance-use conditions as ordinary business rather than as a specialist favour. This section is about how that is designed in India, who does what, and what is known about whether it is happening.

Two internal boundaries keep this section honest. The competencies, training and supervision that make non-specialist delivery possible, together with the decision-support instrument built for it, belong to the section of this chapter on task sharing. The escalation architecture of collaborative and stepped care, meaning who is added to a person's care and when, belongs to the section that owns those models. The national programme's own objectives and evolution belong to the section that owns the national programme, and are named here rather than restated.

26.1 What integration is, and three things it is not

Integration means that a mental health task is performed at the primary level by the staff who are there, using the same record, the same clinic session and the same supply chain as everything else they do. Being clear about what it is not is the faster route to the concept.

- **It is not a specialist clinic held in a primary-care building.** A visiting psychiatrist running a monthly session at a health centre is outreach. It is useful, it increases access, and it leaves the primary-care team's own practice exactly as it was, because nothing is done differently on the other twenty-something working days of the month.
- **It is not a screening programme.** Detection without a treatment response and a follow-up route generates identified and untreated people, which is worse than not looking, because it consumes trust as well as time.
- **It is not the transfer of all mental health care to primary care.** Integration implies a division of labour, and a division of labour implies that some conditions and some phases go upward. A model with no referral criteria has not integrated anything, it has abandoned people at the bottom of the system.

RULE **Integration is a two-way relationship or it is not integration.** Every design in this field has an upward limb, referral of what primary care cannot manage, and a downward limb, return of the person to primary care with a plan the primary-care team can execute. Systems build the upward limb because it is a request and neglect the downward limb because it is a gift. The result is a specialist service that fills with people who could be managed below it.

26.2 The medical officer's workflow, which is the heart of the item

Indian operational guidance is explicit about what the doctor at the primary level is expected to do. **At the primary and urban primary health centre level the medical officer's clinical workflow spans case detection, management, referral and follow-up of mental, neurological and substance-use disorders**. Those four verbs are the item in miniature, and each of them has a distinct requirement attached.

Detection requires that the presenting complaint be recognised for what it is, which in primary care is very often a bodily symptom, a sleep complaint, a request for a tonic, or a family member's description of behaviour rather than a patient's description of mood. It also requires time, which is the scarcest commodity in a busy general clinic.

Management requires a small formulary that is actually stocked, a small set of conditions the officer is expected to treat, and permission to treat them. Where any of the three is missing the workflow stops at detection.

Referral requires a named destination, a route and a reason to believe the person will be seen. A referral into a queue nobody can enter is a form of discharge.

Follow-up requires a record that persists between visits and somebody who notices non-attendance, which together are what the field calls **continuity of care**. This is the step most often absent, and its absence converts a chronic-disease service into a series of unrelated first visits.

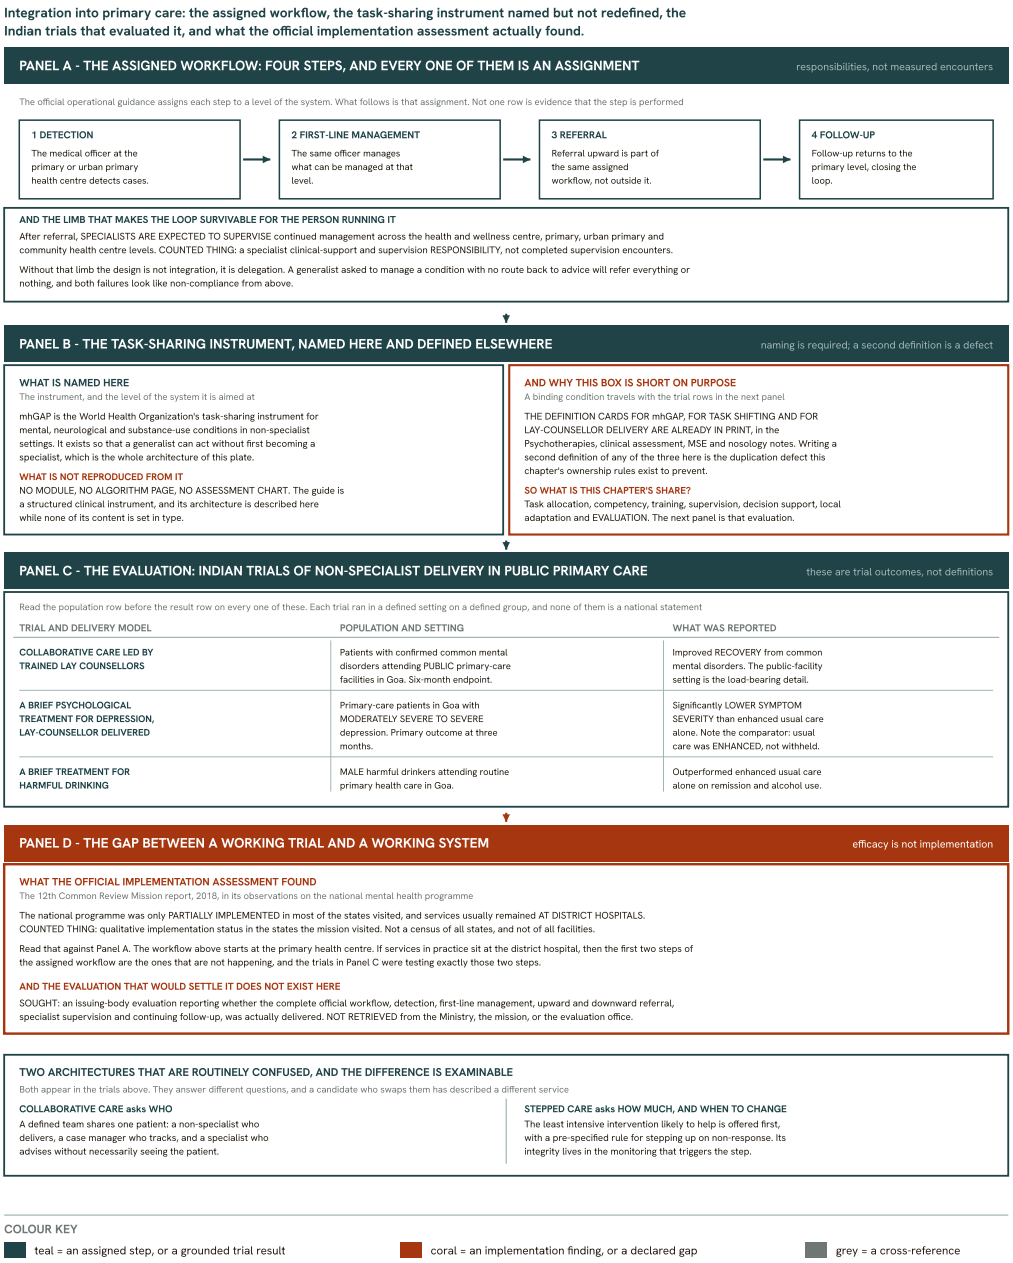

Fig 39.9 Primary-care integration: the assigned workflow, the instrument named, the trials that evaluated it, and the implementation finding that sits against all three. The medical officer at the primary or urban primary health centre is assigned case detection, management, referral and follow-up, and specialists are expected to supply continuing clinical support and supervision after referral, which is what separates integration from delegation. mhGAP is named here as the task-sharing instrument; its definition, and those of task shifting and lay-counsellor delivery, are already in print in the Psychotherapies, clinical assessment, MSE and nosology notes and are not rewritten. The evaluation is Indian and it is real: lay counsellor-led collaborative care improved recovery in public primary-care facilities, a brief lay-delivered treatment lowered depression symptom severity against enhanced usual care, and a counterpart for harmful drinking outperformed enhanced usual care alone. Against that, the official implementation assessment found the programme only partially implemented, with services usually remaining at district hospitals, and no issuing-body evaluation of the complete workflow was retrieved.

26.3 The upward limb, and the return leg that makes it a loop

The Indian programme design for severe illness is specific and worth learning as a sequence. **Within the national and district programme's service delivery, primary health centres refer people with severe mental disorders to the district hospital, and then follow up the treatment plan drawn by the psychiatrist there**. Read the second half of that sentence carefully, because it is the part that gets lost. The primary health centre is not simply a referring agency; it is the place where the specialist's plan is subsequently executed, month after month, which is where the great majority of the person's contact with the health system actually occurs.

Three practical requirements follow from the return leg and each is a common point of failure. The plan has to be written in a form the primary team can act on, which means named drug, dose, duration, what to watch for and when to send the person back. The medicine has to be available at the primary level, since a plan that requires a monthly journey to the district hospital for a supply has not returned the person anywhere. And the route back up has to be open without a fresh referral for a person who deteriorates, because a rigid one-way system punishes the primary team for accepting the patient in the first place.

TRAP **Describing integration as detection plus referral.** This is the commonest incomplete answer in the topic. Detection and referral are the first and third of four verbs in the official workflow, and a description that omits management at the primary level and follow-up after the specialist visit has described a triage service. The examinable content is the loop, not the arrow.

26.4 Supervision, which is what holds the whole design up

Supervision, meaning a continuing relationship in which a non-specialist can bring a real case to a specialist, is the component everything else rests on. A non-specialist asked to manage a condition they were not trained to manage will do it once, badly, and then stop, unless somebody is available to be asked. Indian guidance places that obligation explicitly: **after referral, specialists are expected to provide ongoing clinical support and supervision for the continued management of people with these conditions at the community health centre, primary health centre and health and wellness centre levels**.

Note what this is not. It is not a training event, which is a discrete input; it is a continuing relationship. Note also who it burdens: the same district psychiatrist who is already running the outpatient department is the person expected to supply it, which is why supervision is the component that quietly disappears when a post falls vacant. The design questions that decide whether it survives are mundane and answerable: what is the medium, is it scheduled or on demand, is it case-based or didactic, and is anybody's job description changed to include it. The competency framework and training architecture that sit behind supervision belong to the task-sharing section of this chapter.

IN INDIA

The decision this section supports is what to do with the referral letter you write as a district psychiatrist. Because the primary health centre is expected to follow the plan you draw, the letter is not a discharge summary but an operating instruction for a colleague who has no specialist training and no easy way to ask you a question. Write the drug, the dose, the intended duration, the two adverse effects that would matter, the specific circumstances that should bring the person back to you, and a way to reach you. A plan that assumes the primary team will interpret it is a plan that will be abandoned at the first uncertainty, and the person will simply stop attending.

26.5 What is actually happening, as opposed to what is designed

India has operational guidance, a defined workflow, a referral pathway and a supervision obligation. What it has less of is evidence that any of this is running. The most useful official observation available here is a review-mission finding: **the 2018 Common Review Mission found the national mental health programme implemented only partially by most of the states visited, with services usually available through district hospitals**.

That single sentence contains the central problem of this item. If services are usually available *through district hospitals*, then care has not descended to the primary level in most of the places that were looked at, which is the opposite of integration. Two cautions on scope: the finding describes states and facilities that a review mission visited rather than a census of the country, and it is qualitative, so it supports a direction and not a proportion.

The evaluation that would settle the question does not exist in this chapter's sources. No issuing-body evaluation reporting whether the complete official workflow, detection, first-line management by the medical officer, referral upward and downward, specialist supervision and continuing follow-up, has been implemented in Indian primary-care facilities was retrieved. It was sought from the health ministry, the national health mission, the national health systems resource centre and the government's evaluation office, and what was found was either an earlier review, a document predating the current operational guidance, or a procurement notice for an evaluation rather than its findings.

Four	District hospital	Partial	Not retrieved
VERBS IN THE OFFICIAL PRIMARY-CARE WORKFLOW: DETECT, MANAGE, REFER, FOLLOW UP	WHERE SERVICES WERE USUALLY AVAILABLE IN THE STATES A REVIEW MISSION VISITED	IMPLEMENTATION FOUND IN MOST STATES VISITED, QUALITATIVE AND NOT A CENSUS	ANY EVALUATION OF THE COMPLETE WORKFLOW IN INDIAN PRIMARY CARE

26.6 Where integration breaks, in the order it breaks

The failure points are predictable, and a resident who can name them in sequence can both diagnose a local service and answer the question.

STEP	WHAT HAS TO BE TRUE	HOW IT FAILS	WHAT WOULD SHOW IT
Detection	Time in the consultation, and recognition of presentations that are not complaints of mood	The presentation is treated as the physical complaint it arrived as, and nothing further happens	Recorded diagnoses at the primary level, against expected frequency
Management	A stocked formulary, a defined scope of practice and permission to prescribe within it	Detection without treatment, so the officer stops detecting	Drug availability at the primary level, and prescriptions actually issued there
Referral upward	A named destination that will see the person	Referral into an inaccessible queue, which the family experiences as refusal	Proportion of referrals that result in a specialist contact
Return downward	An executable plan and the medicines to execute it	The person keeps returning to the district hospital for routine review, which silts up the specialist clinic	Proportion of stable people reviewed at the primary level rather than at the hospital
Supervision	A scheduled, case-based relationship with somebody's job description changed to include it	It becomes voluntary, then occasional, then nothing, especially when a post is vacant	Scheduled supervision contacts held, not training events delivered
Follow-up	A persisting record and somebody who notices non-attendance	Every visit becomes a first visit and continuity is lost	Retention in care over a defined period, with the denominator stated

PITFALL

Judging a primary-care mental health service by how many people it detected. Detection is the cheapest number to produce and the easiest to increase, and on its own it says nothing about whether anybody was treated or stayed in treatment. The number that reflects an integrated service is retention: how many of the people started on treatment at the primary level are still in care after a defined period, with the denominator stated. If a service cannot produce that, it does not yet know whether it works.

Reading the table upward rather than downward gives the other examinable lesson. A service that is failing at follow-up cannot be fixed by more training in detection, and a service failing at management because nothing is stocked cannot be fixed by supervision. Each step depends on the ones before it, so the correct first question about any underperforming integrated service is which step is the earliest one that is broken. Programmes that repeat detection training every year while the formulary remains empty are extremely common, and they are not failing through incompetence; they are fixing the step that is easiest to fix.

26.7 The workforce question, and why this section prints no benchmark

The argument for integration is usually opened with a workforce statistic: so many psychiatrists for so many people, against a recommended minimum. This section prints no such benchmark, and the reason is worth teaching because it is a lesson about evidence rather than about workforce.

Several psychiatrist-per-population figures circulate in Indian teaching, they differ from one another, and the recommended minimum they are usually measured against cannot be traced to an issuing body in this chapter's sources. A ratio quoted without a source, a reference year and a stated definition of who counts as a psychiatrist is not a fact; and a minimum attributed to an international body that did not issue it is a false attribution, which is a more serious error than a wrong number because it borrows authority as well as data. The defensible position is to make the argument structurally, which loses nothing: specialists are few and unevenly distributed, mental disorder is common and present in every district, and no plausible expansion of specialist training changes that arithmetic within a working lifetime. That argument does not need a ratio, and it cannot be wrong.

GOOD TO REMEMBER

When a primary-care colleague telephones about a patient, the useful reply is not a diagnosis but a decision they can act on today: what to start or change, what to watch for, when to review, and what should bring the person back to you. Answering at that level takes less of your time than a referral does, keeps the person near home, and is the single most effective piece of integration available to an individual psychiatrist regardless of what the programme is doing.

Integration is a loop, not an arrow: detect, manage, refer upward and take the person back with a plan the primary team can execute, held together by continuing specialist supervision, and Indian review findings indicate that services in most states visited still sat at the district hospital rather than below it.

27 · WHO mhGAP intervention guide and task-shifting

If the specialist workforce cannot grow fast enough, the only remaining variable is who is allowed to do what. Task sharing is the deliberate redistribution of defined clinical tasks to workers with less training, supported by structured decision aids, supervision and a clear escalation route. The World Health Organization's mhGAP Intervention Guide is the instrument built to make that redistribution safe for mental, neurological and substance-use conditions. This section treats both as design problems: how tasks are allocated, what competency means, how training and supervision are constructed, what a decision aid actually does, how much a country may change, and what the evidence shows.

The definitions themselves are owned elsewhere and are named rather than rebuilt. Task-shifting and task sharing as constructs, the mhGAP Intervention Guide as a document, and lay-counsellor-delivered treatment as a category are all defined in the Psychotherapies, clinical

assessment, MSE and nosology notes, which carries them with their evidence base. The primary-care workflow into which any of this is delivered belongs to the section of this chapter on integration, and the escalation architecture of stepped care to the section that owns it. No module, algorithm or assessment chart from the guide is reproduced anywhere in this chapter.

27.1 Task allocation is a design decision, and it is made task by task

The question is never whether a cadre is "capable". It is whether a specific task, defined narrowly enough to be trained and checked, can be performed by a specified worker under specified conditions with an acceptable failure rate. Four properties make a task a good candidate for redistribution, and the same four explain why some tasks resist it.

- **The task is bounded.** It can be described as a procedure with a start, a finish and a small number of decision points, rather than as clinical judgment applied to an undefined situation.
- **The decision rule is explicit.** Somebody can write down what to do in each case that arises, which is precisely what a decision aid is for.
- **The failure is visible.** If the task is done badly, somebody notices, either because the person deteriorates in a recognisable way or because a check exists.
- **An escalation route exists.** The worker can hand the situation upward quickly when it exceeds the boundary, and doing so is treated as correct practice rather than as failure.

Applying those four in order settles most disputes. Delivering a manualised brief psychological treatment for a defined condition scores well on all four. Adjusting an antipsychotic in a person with a complex physical comorbidity scores badly on the first two. Recognising that somebody is unwell and needs to be seen scores well on all four and is therefore the task most widely and most safely redistributed anywhere in the world.

RULE **Task sharing redistributes a task with its supports, or it is simply understaffing.** The package is training plus a structured decision aid plus supervision plus an escalation route. Remove any one of the four and the model becomes a less qualified person doing a harder job alone, which is not what any of the evidence tested.

27.2 Competency rather than cadre

Competency, meaning what a worker can be observed to do rather than what they hold a certificate in, is the organising idea of this whole section. The professional reflex is to ask what qualification somebody holds. The task-sharing question is what they can demonstrably do, which is a different and more useful thing to know. The practical consequence is that programmes specify competencies, then select whoever can acquire them, which is how community health workers, nurses, counsellors without a psychology degree and general medical officers all end up delivering parts of the same programme in different settings.

Selection matters more than it looks. Programmes that recruit for attributes the training cannot supply, literacy sufficient for the materials, standing in the community, the ability to hold a conversation about distress without flinching, and a willingness to be supervised, achieve competency faster than programmes that recruit on formal qualification alone. And competency

has to be assessed rather than assumed: attendance at a training course is a record of presence, and observed performance on the task is a record of competence.

27.3 Training, and why most of it decays

Training in this field fails in a characteristic way. A cascade model, in which a small group is trained centrally and each trains the next tier, loses content at every step; a single workshop produces a measurable rise in knowledge that decays within months; and knowledge gained in a classroom transfers poorly to a clinic without practice under observation.

What survives has a recognisable shape: it is short, repeated rather than single, built around cases rather than around lectures, includes observed practice, and is followed by continuing contact with the trainer. That last element is the bridge from training into supervision, and it is why the two should be commissioned as one thing rather than as a course and a hope.

27.4 Supervision, the component that is always cut first

Supervision in a task-sharing programme is not the periodic review of a subordinate. It is the mechanism by which a bounded task stays bounded: the point at which cases that have drifted outside the worker's remit are identified and moved, at which errors are corrected before they become habits, and at which the worker is retained, because isolated non-specialists doing emotionally demanding work leave.

Its design parameters are few and are worth being able to state: frequency, who supervises, whether it is individual or group, whether it is case-based or general, and whether attendance is protected time or personal generosity. Group case-based supervision at a defined interval, delivered by somebody one step up rather than by the most senior person available, is the arrangement that most often survives contact with a real service, because it is affordable and because it uses the tier immediately above rather than the scarcest tier.

TRAP **Presenting task sharing as a solution to a shortage of specialists.** It redistributes specialist time rather than removing the need for it. Every task-sharing model consumes specialist time in training, in supervision and in receiving escalated cases, and a district with no specialist at all cannot run one properly. The correct framing is that task sharing multiplies the reach of the specialist who exists, not that it substitutes for one who does not.

27.5 What a decision-support instrument does

The **mhGAP** Intervention Guide is the instrument the field is built around, and its function is worth describing precisely because the description is what an examiner wants. Architecturally it is organised by presentation rather than by diagnosis, it converts assessment and management into stepwise sequences a non-specialist can follow, it specifies what must be excluded before proceeding, and it states explicitly at which points the person should be referred or discussed with a specialist. In other words it externalises the parts of clinical reasoning that ordinarily live in a trained clinician's head, so that the worker's judgment is required in fewer places and those places are marked.

Its limits follow from the same design. A presentation-based sequence handles the common and the typical and is not built for the atypical, the comorbid or the treatment-resistant, which is exactly why the referral points are part of the instrument rather than an afterthought. And a guide is not a programme: possessing it changes nothing without training, supervision and a service to escalate into. This chapter names the guide, describes what it does, and reproduces no part of its content.

27.6 Local adaptation, and what may not be changed

Every country adapts, and adaptation is expected rather than tolerated. The distinction to hold is between adapting the *surface* and adapting the *structure*. **Surface adaptation** covers language, the idiom in which symptoms are described, the examples used, the cadre selected, the setting, and alignment with the national formulary and referral map, and all of it improves fidelity to intent. **Structural adaptation**, meaning removing a referral trigger, widening the task boundary, dropping a step because it is inconvenient, or omitting supervision because there is nobody to supply it, changes the intervention into something the evidence does not cover.

The examinable formulation is that adaptation should preserve the safety architecture and change everything else. A programme that has translated the materials, chosen a locally appropriate cadre and aligned the drugs with what the district actually stocks has adapted well. A programme that has kept the materials in their original form and quietly abandoned supervision has adapted badly while appearing faithful.

27.7 The Indian evidence, which is unusually strong

India contributed two of the most-cited randomised evaluations in this field, both testing brief psychological treatments delivered by lay counsellors in routine primary care against enhanced usual care. For depression, **participants receiving the Healthy Activity Program in addition to enhanced usual care had significantly lower symptom severity than those receiving enhanced usual care alone**, in primary-care patients with moderately severe to severe depression. For harmful drinking, **Counselling for Alcohol Problems delivered by lay counsellors in addition to enhanced usual care was better than enhanced usual care alone for harmful drinkers in routine primary health-care settings**.

Four features make this pair worth learning rather than merely citing. The comparator in both is enhanced usual care rather than nothing, so the finding is not that attention beats neglect. The setting is routine primary care rather than a research clinic, which is the setting the result has to generalise to. The provider is a lay counsellor, which is the whole point of the design. And the two conditions are different, one a mood disorder and one a substance-use problem, which suggests the approach is a method rather than a treatment for one condition.

The proper use of these trials in an answer is as evidence about *delivery*. They establish that non-specialists, trained and supervised, can deliver a manualised psychological treatment in an Indian primary-care setting to a standard that outperforms the enhanced usual care they were compared against. They do not establish that any untrained worker can deliver anything, and they say

nothing about what happens to such a programme once the trial's training and supervision structure is withdrawn.

IN INDIA

Because the delivery question has been answered here rather than borrowed, the decision facing an Indian service is not whether non-specialist delivery can work but whether the district can supply the supervision that made it work. That converts the planning question into an arithmetic one a resident can actually do: how many workers, at what supervision frequency, in groups of what size, adds up to how many hours of somebody's week, and whose week is it. A programme that cannot answer that has not been designed, and it will reproduce the trials' structure for as long as its initial enthusiasm lasts.

One further caution belongs with the Indian evidence and is the kind of point that separates a good answer from a fluent one. Trials of this sort recruit, train and supervise their workers to a standard that a research team can guarantee and a district usually cannot, so the trial estimates what the model can do under favourable conditions rather than what it will do under ordinary ones. That is not a criticism of the trials, which were conducted in routine settings precisely to narrow that gap. It is a reminder that the implementation question, whether the supervision structure survives once the researchers leave, is a separate empirical question from the efficacy question, and that this chapter's sources answer the first and not the second.

27.8 The design decisions, assembled

DECISION	THE QUESTION TO ANSWER	THE COMMON FAILURE	WHAT IT COSTS IF YOU GET IT RIGHT
Which task	Is it bounded, rule-governed, checkable, and escalatable	Redistributing judgment rather than a procedure	Time spent writing the boundary down before anybody is trained
Which worker	What competencies are required, and who can acquire them	Selecting on qualification rather than on demonstrable competency	A selection process, and the willingness to reject candidates
What training	Short, repeated, case-based, with observed practice	A single workshop, cascaded through tiers, measured by attendance	Repeated contact rather than one event
What supervision	Frequency, supervisor tier, group or individual, protected or voluntary	Dropped when a post falls vacant, and never restored	A standing claim on the time of the tier above the worker
What decision support	Presentation-based sequences with explicit exclusions and referral points	Distributing the document and calling it implementation	Adaptation work, and alignment with the local formulary
What adaptation	Change the surface, preserve the safety architecture	Preserving the materials and abandoning the supervision	Explicitly recording what was changed and why
What evaluation	Outcome in the person, not activity in the worker	Reporting numbers trained instead of people improved	An outcome measure collected routinely from the start

PITFALL

Counting workers trained as the programme's result. Trained workers are an input, and they decay: people leave, get redeployed, or stop doing the task when nobody asks about it. A programme reporting cumulative numbers trained across several years is reporting a quantity that has no relationship to how many people are delivering the task today. The number that matters is how many trained workers are currently active and supervised, and almost nobody publishes it.

MNEMONIC

Task, Trainee, Training, Tools, Talk-to-someone

The five things a task-sharing programme has to specify: the bounded task, the worker who will do it, the training that produces the competency, the decision-support tools that hold the reasoning, and the supervision and escalation route. The last is the one that disappears, and it is the one all the evidence depended on.

Bounded	Enhanced usual care	Routine primary care	Supervision
THE PROPERTY THAT MAKES A TASK REDISTRIBUTABLE	THE COMPARATOR IN BOTH INDIAN LAY-COUNSELLOR TRIALS	THE SETTING THOSE TRIALS RAN IN, NOT A RESEARCH CLINIC	THE COMPONENT CUT FIRST AND THE ONE THE EVIDENCE RESTED ON

Task sharing redistributes a bounded task together with its training, its decision support, its supervision and its escalation route, and the two Indian lay-counsellor trials that outperformed enhanced usual care in routine primary care are evidence about that whole package rather than about the counsellor alone.

28 · Telepsychiatry: models, telepsychiatry guidelines and Indian regulatory framework

Telepsychiatry earns its marks as a service, not as a gadget. The examinable question is never whether a psychiatrist can be seen on a screen; it is what a health system gains, and what it must build, when the specialist and the patient stop having to be in the same building. That reframing decides everything downstream: who is stationed where, who is permitted to start the encounter, what is counted, and what the counting is allowed to prove. Candidates lose the marks in three predictable places. They describe the modalities of remote consultation, which is a technology answer to a service question. They recite a national helpline total as though it were a number of patients. And they attribute a governance position to an instrument whose current status they have not checked. The professional-conduct frame around remote practice, the consent and confidentiality obligations at a distance, and the identity of the operative regulatory code all belong to the Forensic ethics, consent and legal procedure notes, and are not restated here. What follows is the delivery architecture, the national programme, the monitoring discipline and the equity argument.

28.1 The service problem, stated before any solution

A specialist mental-health workforce is small, unevenly distributed and slow to grow. Every scheme for extending it is a variation on the same manoeuvre: move the scarce expertise, or move the decision that needs it, so that the specialist's time is spent only on what nobody else can do. Referral moves the patient. Outreach moves the specialist. **Task-sharing** moves the task. **Remote consultation** moves the encounter itself, and it is the only one of these that does not consume travel time at either end.

That is the whole economic case, and it explains why the design questions are the ones they are. If the constraint is specialist time, a remote service that simply converts face-to-face appointments into video appointments has bought convenience and no coverage: the same clinician sees the same number of people, and the queue behind them is unchanged. Coverage only rises when the remote link lets someone who is *not* a psychiatrist hold the patient contact while the psychiatrist supplies the decision. A telepsychiatry programme that has not answered who holds the contact has not yet been designed.

RULE **A telepsychiatry programme is judged by the population it can now reach and by whose time it saves, never by the technology it deploys.** Bandwidth, platform and picture quality are preconditions. They are not the intervention, and an appraisal that stops at them has appraised nothing that could change a coverage figure.

28.2 Hub and spoke, and what the architecture is actually doing

The dominant service design for remote specialist care is the **hub-and-spoke model**. A small number of **hubs** concentrate the scarce resource, in this case psychiatrists and the supervisory and record-keeping apparatus around them. A much larger number of **spokes** sit where the population is, staffed by whoever the health system already has at that level. The link between them carries clinical decisions in one direction and clinical information in the other.

Read structurally, the model does three separable things, and a programme can succeed at one while failing at the others. It *concentrates* expertise, so that a psychiatrist is not the rate-limiting step in every district simultaneously. It *distributes* access, so that the distance a patient travels falls to the nearest spoke rather than the nearest specialist. And it *standardises*, because a hub that supervises many spokes tends to impose one assessment format, one prescribing habit and one escalation route across all of them. The third effect is the one most often overlooked and is frequently the largest clinical gain, because it raises the floor of care at the periphery rather than the ceiling at the centre.

The corresponding failure modes are equally separable. A hub with too many spokes becomes a new bottleneck with a longer waiting list. A spoke with no trained staff becomes a video booth, which returns the model to moving the patient. And a link with no agreed **escalation route**, meaning a pre-arranged answer to who attends an acute presentation at the spoke and where the person goes, leaves the periphery holding risk it was never resourced to hold. That is where remote services generate their most serious incidents.

This chapter cannot state the official Indian architecture in the terms its own programme documents use. What was sought was a directly retrieved official passage defining the hub-and-spoke or tiered service structure for Indian telepsychiatry, including the roles of peripheral cells and specialist hubs; the programme and institutional sources approached either failed to open, exceeded retrieval limits or returned server errors, and no such passage was obtained. The reasoning above is service-design reasoning and is offered as such. An answer that describes the generic architecture and then says plainly that the official Indian tiering is not established from a source it has read is a stronger answer than one that supplies a confident tier list.

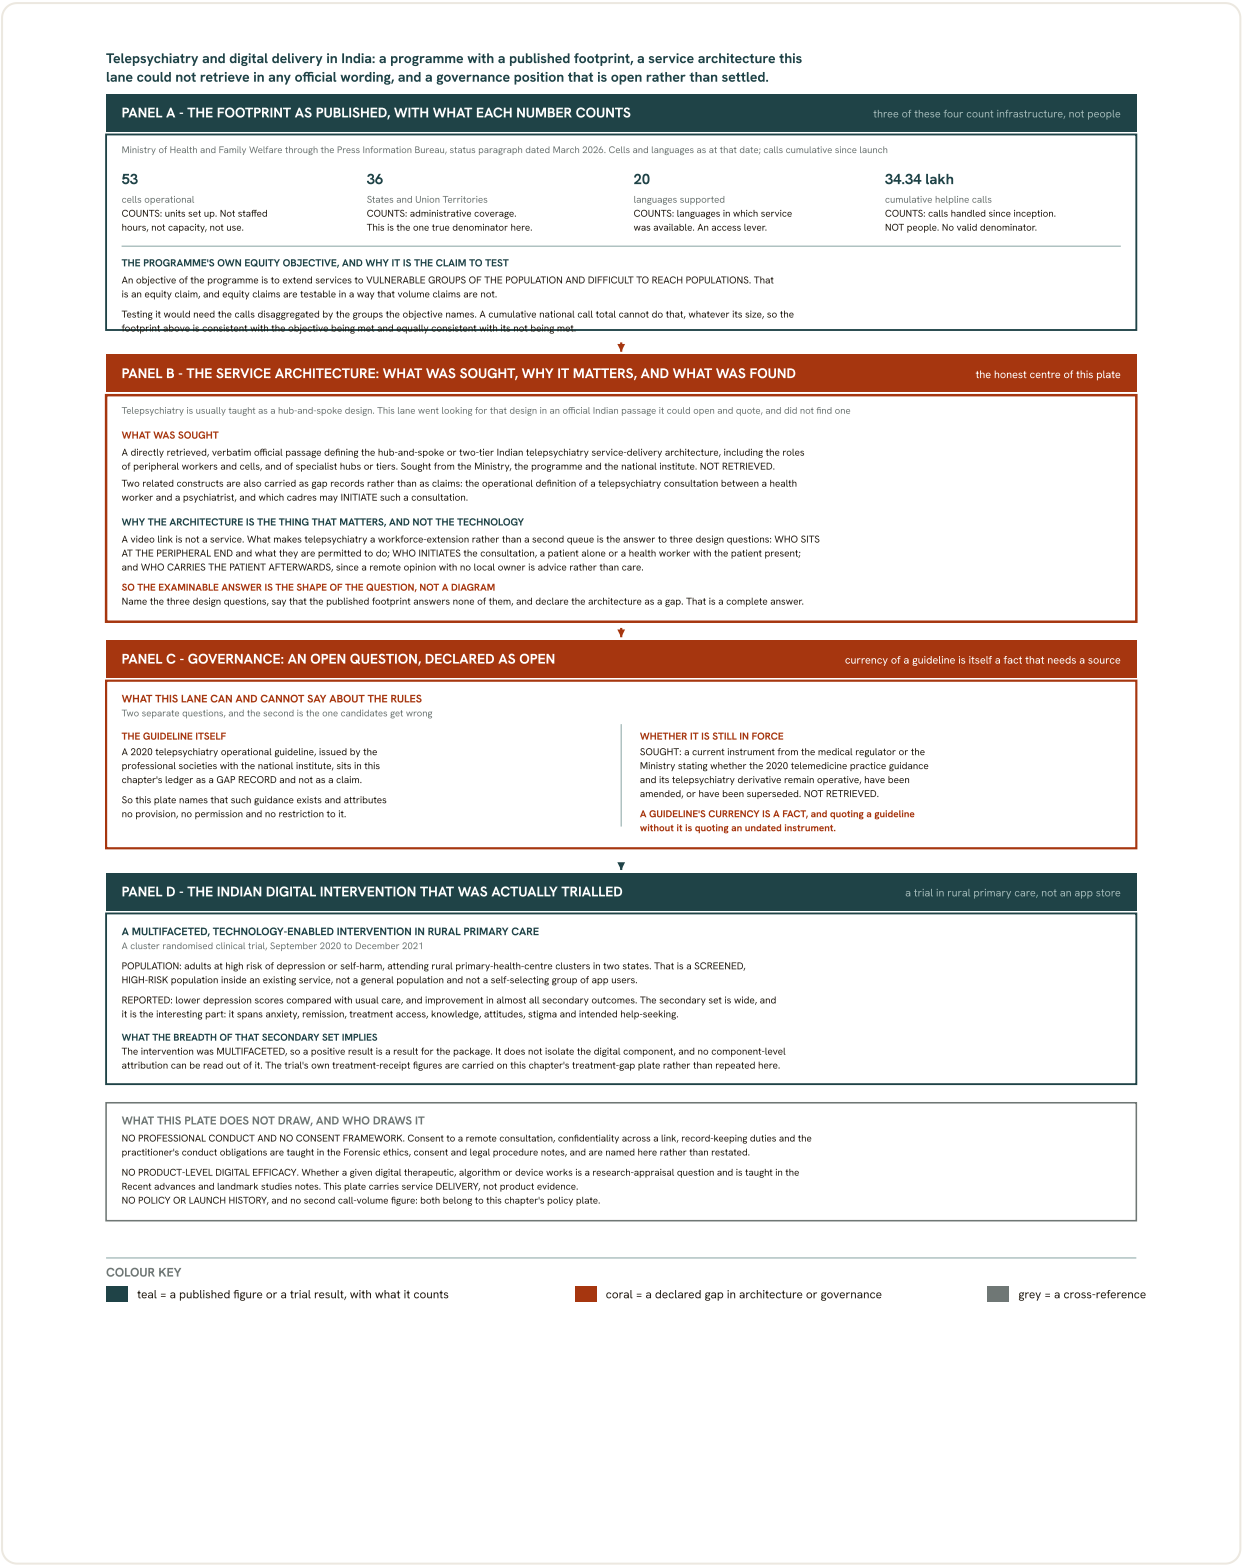

Fig 39.10 Telepsychiatry and digital delivery: a published footprint over an architecture that is a declared gap. The programme reports 53 cells across 36 States and Union Territories with support in 20 languages, and more than 34.34 lakh cumulative helpline calls; three of those four count infrastructure and the fourth counts calls rather than people. Its stated objective is to extend services to vulnerable and difficult-to-reach populations, which the footprint can neither confirm nor refute because it is not disaggregated. The service architecture itself is the honest centre of the plate: a verbatim official passage defining the hub-and-spoke or two-tier design, and the roles of peripheral workers and specialist hubs, was sought and not retrieved, and no current instrument confirming whether the 2020 telemedicine guidance remains operative was retrieved either. The one Indian trial drawn here reported lower depression scores and improvement in almost all secondary outcomes in a high-risk rural primary-care population, for a multifaceted package that does not isolate its digital component.

MNEMONIC

Place, Person, Permission, Proof

The four axes on which any remote mental-health programme is specified, and the order in which they fail. Where are the spokes and where is the hub. Who staffs each end. Who is permitted to initiate the encounter. What is measured well enough to show whether the reach was real.

28.3 The national instance, and what it was set up to do

India's national tele-mental-health service is delivered through **Tele-MANAS**, and its own statement of purpose is the right place to begin, because a programme's declared objectives are what its monitoring should be reporting against. Among those objectives is the explicit commitment to extend services to vulnerable groups of the population and to populations that are difficult to reach. That sentence is worth reading as a design instruction rather than as a preamble: it makes equity of reach a stated aim of the programme, which means underserved reach is a legitimate thing to hold the programme to, not an external criticism of it.

The programme's published national status figures describe its footprint. At its most recent published national status update, reported by the Ministry of Health and Family Welfare, there were **53** operational cells across **36** States and Union Territories, with service available in **20** languages, and **more than 34.34 lakh** calls received and addressed through the helpline since the service began.

53	36	20	more than 34.34 lakh
OPERATIONAL CELLS	STATES AND UNION TERRITORIES COVERED	LANGUAGES OF SERVICE	CALLS ADDRESSED SINCE INCEPTION, NOT PEOPLE

Each of those quantities counts a different thing, and the differences are the examinable content. A cell is a staffed unit, so the cell count is a supply figure. Coverage of States and Union Territories is an administrative reach figure and says nothing about depth within any one of them. The language count is an access figure and is arguably the most under-discussed of the four, because a helpline in a language the caller does not think in is a helpline the caller does not use. The call total is a **cumulative activity figure** and is the one that is misread most often, because activity is not the same object as the **unique users** a coverage claim would need.

28.4 Reading a programme's own numbers without laundering them

A national figure is only a fact when four things travel with it. Who issued it, what period it refers to, which population it describes, and what it is a proportion of. Strip any one and the number becomes a rumour with a decimal point in it. Applied to a helpline total, the fourth question is fatal: a cumulative count of calls has no valid denominator at all. It is not divided by the population, because it is not a count of people; it is not divided by callers, because one caller may call many times; and it cannot be compared with a prevalence, because the two count incommensurable things.

WHAT THE FIGURE IS	WHAT IT CAN SUPPORT	WHAT IT CANNOT SUPPORT
Number of operational cells	A statement about staffed service capacity	Any claim about how much of that capacity was used
States and Union Territories covered	Administrative reach across the country	Depth of reach inside any one of them
Languages of service	A concrete access provision for callers	That every caller reached service in their own language
Cumulative calls addressed	Total activity handled since the service opened	Number of individuals helped, or any rate per population

TRAP **Reading a cumulative helpline call total as a count of people served, and then dividing it by a population to produce a coverage rate.** Candidates do this because the number is large, official and easy to remember, and because every other figure in a public-health answer is a rate. The correct sentence names the count as calls received and addressed since the service began and stops there. If an examiner wants a coverage claim, the honest answer is that the programme publishes activity, not unique users, so a coverage rate cannot be computed from it.

IN INDIA

Because reaching vulnerable and difficult-to-reach populations is a stated objective of the national tele-mental-health programme, a state cell planning its rota has a specific and answerable design question rather than a general aspiration: which of the populations named in that objective is it currently failing to receive, and what in the service is producing the failure. Language of service, hours of operation and the referral destination offered at the end of the call are the three levers that can be moved locally, and the objective makes each of them a monitoring question rather than a courtesy.

28.5 The regulatory frame, and the currency question inside it

Remote practice in India operates inside a national telemedicine framework and a professional-conduct code, and this chapter names them as the governing frame and goes no further. The provisions themselves, the regulation numbers, the sequence by which the newer conduct regulations were notified and their subsequent status, and the identity of the code that is operative today are taught in the Forensic ethics, consent and legal procedure notes, together with consent to the modality, identity verification at both ends, confidentiality at a distance and the situations in which a remote encounter is not enough. Repeating any of that here would produce a second and possibly divergent account of a statutory position, which is the single most damaging thing a service chapter can do to a legal one.

Two regulatory facts a service chapter does need, and cannot supply, are declared here rather than filled in from recollection. The first is the identity, issuing body and year of the dedicated Indian telepsychiatry operational guidance that practitioners commonly refer to; what was sought was that document itself, and it was not established from a source this chapter opened. The second is more consequential and is a genuine live uncertainty: no current national instrument was retrieved that states explicitly whether the standing telemedicine practice

guidance and the telepsychiatry guidance derived from it remain operative, have been amended, or have been superseded. Multiple official routes were attempted and each failed to open or returned unusable content.

The teaching point survives the gap, and is arguably sharpened by it. Guidance for remote practice has changed repeatedly and quickly in every jurisdiction that has issued any, so the currency of the instrument is part of the clinical question and not an administrative footnote. A candidate who names the framework, states that its current standing must be checked against the issuing body rather than assumed, and points to the chapter that owns the conduct code has answered correctly. A candidate who recites a version and a year from memory has asserted the one thing most likely to have moved.

28.6 Who may open the encounter, and why that answer sets the ceiling on coverage

Return to the architecture. The hub extends the workforce only if a non-specialist may hold the patient and initiate the contact with the specialist. Everything about the size of a programme therefore depends on a permission: whether a nurse, an auxiliary nurse midwife, an allied health professional or another cadre of health worker may start a telepsychiatry consultation, and under what supervision. If only a registered medical practitioner may initiate, the spokes must be staffed by doctors and the model inherits the shortage it was built to relieve. If a trained health worker may initiate, the spoke can sit at the level where the population actually presents.

The specific Indian operational position on this is a declared gap in this chapter. Two related propositions were sought and not established from an opened source: an operational definition of telepsychiatry service delivery conducted between a health worker and a psychiatrist, and an operational statement permitting nurses, allied health professionals, auxiliary nurse midwives and other health workers to initiate such a consultation. Both are exactly the kind of proposition a candidate is likely to half-remember from a slide, and both change the shape of a service completely depending on which way they read.

What can be taught safely, and what an examiner is really testing, is the consequence structure. The permission determines the staffing of the spoke. The staffing determines the training burden. The training burden determines how fast the programme can scale and how uniform its quality will be. And the same permission determines the medico-legal question of who is responsible for the patient during and after the link, which is where the conduct code becomes unavoidable and where the reader is sent to the chapter that owns it.

28.7 Governance, monitoring and the evaluation a remote service owes

Remote delivery makes some things easier to measure and some things easier to lose. It is easier to count contacts, because they pass through a system that logs them. It is harder to know what happened afterwards, because the person who would have noticed is at the other end of a link that has closed. Monitoring has to be designed against that asymmetry rather than around the data that happen to accumulate.

A remote mental-health service should be able to state the following about itself, and a service that cannot is being appraised on its activity log alone.

- Who was reached, described by the populations the programme says it exists to reach, and not only by total volume.
- What proportion of contacts ended with a named destination, meaning a specific onward service, review or clinician, rather than advice alone.
- Whether the destination was reached, which requires a follow-up mechanism the link itself does not provide.
- How acute risk identified during a remote contact was escalated, to whom, and with what agreed local response.
- What the spokes needed and did not get, which is the only signal that reliably distinguishes an under-trained spoke from an under-used one.

The Indian reach argument for remote specialist care, including the contribution of the non-governmental sector to extending it, is developed in the Schizophrenia: management, antipsychotics and adverse effects notes, and is not re-derived here.

PITFALL

Designing the escalation route last. A remote service is commissioned around the consultation, and the acute pathway is added afterwards if at all, so the spoke discovers during its first emergency that nobody has agreed who attends, where the person is taken, or which clinician holds responsibility until they arrive. The escalation route is not an appendix to a telepsychiatry protocol; it is the part that determines whether the service can safely accept unfiltered presentations at all.

28.8 Equity, and the way a remote service quietly reproduces the gap it was built to close

Remote delivery is often presented as an equity intervention, and it can be one, but only against an explicit account of who is excluded. Every remote service imposes a set of entry requirements that face-to-face care does not: a device, a connection, sufficient privacy at the patient's end to speak freely, enough literacy or confidence to navigate a call, and a language the service offers. Each of those requirements is unevenly distributed in the same direction as the underlying disadvantage, so an unexamined remote service can expand access fastest among those who already had the most.

This is why the programme's own equity objective matters operationally. If reaching vulnerable and difficult-to-reach populations is a declared aim, then the entry requirements above become the programme's business, and the counter-measures are concrete: service in more languages, a staffed spoke where the person has no private device, hours that fit shift and agricultural work, and a call destination that exists in the caller's own district. None of that follows automatically from putting a service online, and the difference between a remote service that narrows a gap and one that widens it lies almost entirely in whether those counter-measures were built.

Telepsychiatry extends a workforce only when someone other than the specialist may hold the patient; everything else about the model, including its numbers, follows from that permission.

29 · Collaborative and stepped-care models of mental health delivery

Most people with a common mental disorder are already in contact with a health service; almost none of them are in contact with a psychiatrist. Collaborative and stepped care are the design answers to that arithmetic. They are not treatments, and they are not referral pathways with better manners. They are ways of organising a primary-care system so that the decisions requiring specialist judgement reach a specialist while the contact, the follow-up and most of the delivery stay where the patient already is. The marks here sit on structure rather than on content: what the roles are, what triggers a change of treatment, where the joins are, and what the system must measure to know whether any of it worked. Case management and assertive community treatment as service models, with their caseload logic and target populations, belong to the Schizophrenia: management, antipsychotics and adverse effects notes; the general-hospital liaison models and the classic economic argument for funding a liaison service belong to the Consultation-liaison, geriatric and transcultural psychiatry notes, which also records that the Indian cost-effectiveness evidence for such services is what is missing. Neither is restated here.

29.1 Stepped care as a rationing principle, stated honestly

Stepped care organises an intervention set by intensity and offers the least intensive intervention that is likely to work, with an explicit rule for moving up when it does not. Two commitments make it work and both are frequently dropped in practice. The first is that the lowest step must be a real intervention with a real chance of benefit, not a holding position. The second is that the rule for stepping up must be written down before the patient arrives, applied on a schedule, and triggered by an observation rather than by the patient's persistence or the clinician's patience.

It is worth being candid that stepped care is a rationing principle. A system adopts it because it cannot give everybody the most intensive option, and it distributes the scarcest resource by escalating only those who have already failed something cheaper. That is a defensible allocation, and it is defensible precisely to the extent that the escalation actually happens. Where the stepping rule is absent, stepped care degenerates into a queue with a therapeutic vocabulary, and the people who do worst are the ones least able to keep coming back to ask.

A distinction worth fixing early is between the lowest step and no step at all. Watchful waiting, in which a clinician defers treatment and reviews later, is a legitimate clinical decision but it is not the bottom rung of a stepped-care system unless the review is scheduled and somebody owns it. The bottom rung of a working system is an active low-intensity intervention with a named deliverer, a defined content and a defined end point. The difference is not semantic: in the first arrangement the patient returns if they deteriorate, and in the second the service comes back to look.

There is also a stratification logic that stepped care is sometimes confused with. Stratified allocation assigns the patient at the outset to the intensity their presentation appears to warrant, and does not require failure at a lower level first. Stepped care allocates by observed response rather than by initial appearance. Most real programmes are hybrids, and it is worth saying so rather than pretending purity: severity, risk and previous treatment history are used to enter people at a higher step, while response governs movement thereafter. What must not happen is that the hybrid becomes an excuse to hold everybody at the bottom.

RULE **A stepped-care system is defined by its stepping rule, not by its steps.** Any service can list interventions in order of intensity. What makes the arrangement stepped care is a pre-specified observation, taken at a pre-specified interval, that obliges the system to change what it is doing. Without that, the arrangement is a menu.

29.2 Collaborative care, and the three roles that constitute it

Collaborative care is a specific organisational form and not a synonym for good communication. Its defining feature is that a named person, distinct from both the treating primary-care clinician and the specialist, takes responsibility for keeping a defined group of patients under active review. That role is usually called the **care manager**, and the model stands or falls on whether it exists as a funded post rather than as an aspiration attached to somebody's existing job.

Three roles interlock. The primary-care clinician retains clinical responsibility, prescribes and remains the patient's medical home. The care manager holds the register, makes the scheduled contacts, delivers or supports the low-intensity intervention, records the agreed measure and raises the cases that are not improving. The consulting specialist reviews those cases, usually without seeing most of the patients, and advises on the ones that are stuck. The specialist's time is therefore spent on decisions rather than on encounters, which is the whole point: one psychiatrist supervising a caseload through a care manager can influence a population many times larger than the one they could see.

Two structural features are easy to miss and are frequently examined. The first is the **population register**: collaborative care is delivered to an enumerated list of patients, not to whoever returns. A patient who stops attending is a case the register flags, whereas in ordinary care they are simply absent. The second is that the specialist review is **caseload-based** rather than referral-based. The specialist looks systematically at those who are not improving, which inverts the usual selection, where the cases that reach a specialist are the ones somebody remembered to refer.

MNEMONIC

Register, Role, Review, Route

The spine of any collaborative-care arrangement. An enumerated population register. A named care-manager role that is somebody's actual job. A scheduled review carrying an agreed measure. And a route that obliges the system to do something different when the measure does not move.

29.3 Measurement-based escalation, and what a measure is for here

The measurement in measurement-based care is not for diagnosis and not for research. It exists to make deterioration and non-response visible to a system that would otherwise notice neither. That purpose sets its properties: it must be short enough to be repeated at every contact, stable enough that a change means something, and administered by whoever is actually in the room, which in this model is the care manager and not the specialist.

The clinically important discipline is that the measure must be attached in advance to a consequence. A rating repeated at intervals with no pre-agreed action attached is documentation, and documentation absorbs the same clinical time as a decision while producing none. The service therefore has to specify, before the programme opens, what change counts as adequate progress, at which review the question is asked, and what happens on each answer. Naming and describing an instrument is legitimate teaching; this chapter typesets no instrument's items, response options, scoring rule or thresholds anywhere, and a candidate should describe the escalation logic rather than reproduce a cut-off.

Note where this places the burden. The system, not the patient, owns the trigger. In ordinary care the patient who is not improving has to come back and say so, which selects for confidence, proximity and money. In a measurement-based system, the review happens on schedule and the absence of improvement declares itself. That single inversion is where most of the equity gain in these models comes from.

Enumerated, not attending	Scheduled, not requested	Caseload, not referral	Obliged, not offered
WHO THE REGISTER COUNTS	WHEN THE REVIEW HAPPENS	HOW THE SPECIALIST SELECTS CASES	WHAT THE MEASURE TRIGGERS

Every tile in that strip names a default that ordinary care sets the other way, which is a useful way to audit an existing service: ask which of the defaults it has actually inverted.

29.4 The joins, which is where the system leaks

Steps are easy to design and joins are hard to run, so the joins are where an examiner will probe. Each transition between steps is a moment at which responsibility can be dropped rather than handed over, and the failure is usually silent because both sides believe the other is holding the patient.

THE JOIN	WHAT MUST BE AGREED BEFORE A PATIENT REACHES IT	HOW IT FAILS IN PRACTICE
Recognition into the programme	Who may enter a patient on the register, and on what basis	Entry depends on individual clinician interest, so the register reflects enthusiasm rather than need
Low-intensity step to structured intervention	The observation that triggers it and who acts on it	The trigger exists but no capacity was commissioned behind it, so the step is nominal
Structured intervention to specialist decision	Whether the specialist reviews the record or must see the patient	The review defaults to an appointment, and the model reverts to ordinary referral
Any step back down, or discharge	Who resumes routine follow-up and with what safety-netting	Discharge is treated as an ending, and relapse re-enters the system as a new presentation

The number of steps is not standardised and varies between programmes; what is invariant is the structure of the join. An answer that describes a named ladder of steps has described one programme. An answer that describes what must be agreed at each transition has described the model.

29.5 The Indian evidence, and what it licenses

The most directly relevant Indian evidence for this construct comes from public primary-care facilities in Goa, where recovery from common mental disorders improved among the patients attending them when collaborative care was delivered by **a trained lay counsellor**. The finding matters for a specific reason that is easy to state and easy to overstate: the care-manager role was filled by a trained lay counsellor rather than by a mental-health professional, in the public sector, in ordinary facilities.

Read carefully, that result licenses a workforce conclusion and not a universal one. Its population is patients with common mental disorders attending public primary-care facilities, so it says nothing about severe mental illness, about facilities without the supervisory structure the trial supplied, or about a counsellor cadre without the training the trial delivered. The delivery agent is the variable of interest, and the supervision is the condition that makes the delivery agent safe. A programme that copies the cadre and drops the supervision has copied the cheap half.

IN INDIA

Where a district cannot place a mental-health professional in every facility, and most cannot, the practical decision this evidence supports is to build the care-manager role from a trained non-specialist cadre with specialist supervision attached, rather than to hold the model in abeyance until specialist posts are sanctioned. The gain was obtained in ordinary public primary-care facilities with a lay counsellor delivering the collaborative intervention, so the design question for a district programme is what training and what supervisory link it can actually sustain, not whether a psychiatrist can be found for every centre.

29.6 What these models are not, and the errors that follow

Collaborative care is not consultation. In consultation the specialist answers a question about a patient and the arrangement ends there. In collaborative care the specialist joins a standing system with a register, a schedule and a named person holding the caseload, and the relationship persists whether or not any particular question is asked. Liaison practice and the taxonomy of liaison service models belong to the Consultation-liaison, geriatric and transcultural psychiatry notes.

Neither model is case management, and the distinction is examinable. Case management and assertive community treatment are service models for a different population, defined by their caseload logic and their target group, and they are taught with their figures in the Schizophrenia: management, antipsychotics and adverse effects notes. Case management appears here only as a component: the care-manager function inside collaborative care borrows the idea of a named person holding a defined caseload, and borrows nothing else.

TRAP **Describing stepped care as "start with the least intensive treatment", full stop.** Candidates reproduce the first half of the definition because it is the memorable half, and lose the marks that sit on the second. The examinable content is the escalation: what is measured, when it is measured, what threshold obliges a change, and who is responsible for making it. A description without the stepping rule is a description of a waiting list.

PITFALL

Commissioning the register and the care manager but not the step above. A programme that can identify and monitor many more people than the specialist tier can absorb generates a queue of correctly identified, correctly measured, non-improving patients with nowhere to go, and the care manager becomes the person who apologises to them. Capacity at the higher step is a precondition for opening the lower one, not an enhancement to be added later.

29.7 Fidelity, and why a model that worked in a trial stops working as a programme

These are complex interventions, and complex interventions degrade in characteristic ways when they scale. A trial supplies training, supervision, protected time and a research infrastructure that measures whether the protocol was followed. A programme supplies none of those unless somebody commissions them, and the components that are dropped first are always the invisible ones. Supervision is invisible. The register is invisible until it is missing. The scheduled review is visible only to the person who did not receive it.

The practical consequence is that a programme evaluation that reports outcomes without reporting **fidelity** cannot interpret its own result. If outcomes are poor and fidelity was poor, the model was not tested. If outcomes are poor and fidelity was good, the model failed in that setting, which is a genuinely different finding with a genuinely different response. Reporting both is not methodological fussiness; it is the difference between fixing the implementation and abandoning the design.

Three components carry most of the fidelity burden in these models and are worth naming as the things to protect when a budget is cut. The first is supervision of the non-specialist deliverer, because it is what converts a trained cadre into a safe one. The second is the scheduled review, because dropping it converts the register into a list. The third is the capacity at the step above, because escalation that has nowhere to go teaches the whole system to stop escalating. A programme that keeps the counselling sessions and loses all three has kept the visible half of the intervention and discarded the mechanism.

29.8 Evaluation, and the quantities the model has to be able to state

These models are unusually easy to evaluate honestly, because their own machinery generates the necessary denominators. The register defines who was in the programme, so proportions can be computed rather than estimated. A service running collaborative or stepped care should be able to state each of the following, and one that cannot is reporting activity.

- How many people were entered on the register in a stated period, and out of what attending population.
- What proportion received a scheduled review at the intended interval, which is the fidelity measure that matters most.
- What proportion of those not improving at review were actually stepped up, which is the single number that distinguishes the model from a menu.
- What proportion of specialist reviews were caseload-based rather than triggered by an individual referral.
- What happened to those discharged, since a model that improves recovery and loses relapse has moved the problem rather than solved it.

Costing and financing sit outside this construct and are taught in the mental health economics and financing material in these notes; the classic economic argument for funding a liaison service, and the observation that Indian cost-effectiveness evidence in this space is scarce, are already made in the Consultation-liaison, geriatric and transcultural psychiatry notes and are not re-derived or re-declared here.

> Collaborative care is defined by a register, a care manager and caseload-based specialist review; stepped care is defined by the rule that forces the step, not by the list of steps.

Special-setting and disaster mental health

30 · Disaster mental health: psychological first aid, phases and intervention models

A disaster does not produce one clinical problem; it produces a population with a changed distribution of need. Most of the people affected will recover without any formal intervention. A minority will develop diagnosable disorder. A separate and often forgotten group already had severe mental illness before the event and has just lost its supply of medicines, its clinic, its

records and its family carers. A group larger than any of these has been displaced, and **displacement** generates its own morbidity from crowding, lost livelihood and lost privacy rather than from the original event. A last group is the responders. Any response designed around only one of those groups fails all the others, and that is the examinable point: disaster mental health is a service-design question about matching a tiered response to a heterogeneous population, not a question about which therapy to give a survivor. The statutory machinery of disaster management, its tiers and its office-holders, and the professional and ethical frame around emergency work are taught in the Forensic ethics, consent and legal procedure notes and are not restated here. The clinical early-trauma intervention itself, with its action principles, its follow-up rule and its standing cautions about early single-session and pharmacological approaches, is taught in the Anxiety, OCD and trauma-related disorders notes. What follows is the population response and the service that has to deliver it.

30.1 Needs assessment as a method, not as an impression

The first deliverable of a mental-health response is not an intervention, it is a description of who needs what. **Rapid needs assessment** is a method with a defined output, and a response that skips it delivers whatever the responding agency happens to be able to provide, which is a common and expensive failure.

A usable assessment establishes several things that cannot be inferred from the event itself. It establishes the size and composition of the affected population, including how many are displaced and where they now are. It establishes what has been lost from the pre-existing service: which facilities are standing, which staff are contactable, which drug supply lines still run, and whether patient records survived. It establishes what the population itself says it needs, which in the acute period is reliably practical rather than psychological. And it establishes what already exists locally, meaning the community structures, faith networks and lay helpers who will still be present long after any external team has left.

The output of that assessment should be a distribution rather than a headline. A single figure for the proportion of a population needing mental-health care is almost always useless in operations, because it merges people who need information and practical help with people who need medication continued and people who need specialist treatment. The three are met by different tiers with different workforces and different costs.

MNEMONIC

Assess, Tier, Train, Track

The sequence a disaster mental-health programme is built in, and the order in which it is usually cut. Assess before responding. Tier the response so each level of need meets the cheapest workforce that can safely meet it. Train and support the people who will still be there. Track what happened, because a response nobody measured teaches the next response nothing.

30.2 The tiered psychosocial response

The organising structure of every credible disaster mental-health response is a **layered response**, in which the widest layer serves everybody affected and each successive layer serves a smaller group with a more specialised workforce. Read from the base upwards, the layers are these.

The base layer is basic services and security delivered in a way that protects dignity: shelter, food, water, safety, and above all information, because uncertainty about missing relatives and about what happens next is one of the largest sources of distress in the acute period. This layer is not usually thought of as mental-health work and is the layer with the greatest population mental-health effect. Above it sits community and family support: restoring contact between separated people, reactivating community structures, supporting normal routines for children, and enabling collective mourning practices. Above that sits focused, non-specialised support delivered by trained and supervised workers who are not mental-health professionals, aimed at those whose distress is not settling. At the apex sits specialised mental-health care for the minority with severe or persisting disorder, and for those whose pre-existing illness has destabilised.

Three properties of the layered structure carry most of the teaching weight. It is not a triage sequence: the layers operate simultaneously, not one after another. It is inverted in cost and in volume, so the layer serving most people is cheapest and the layer serving fewest is dearest, which is exactly why an unplanned response over-invests at the top. And each layer requires a different workforce, so a plan that names the layers without naming who staffs each one has not been costed.

This chapter cannot attribute the layered framework to an issuing body from a source it has opened, and does not do so. The structure is taught here as service reasoning; a candidate who describes the layers and their workforce implications has the substance, and one who attaches a body and a year from recollection has added the one element most likely to be wrong.

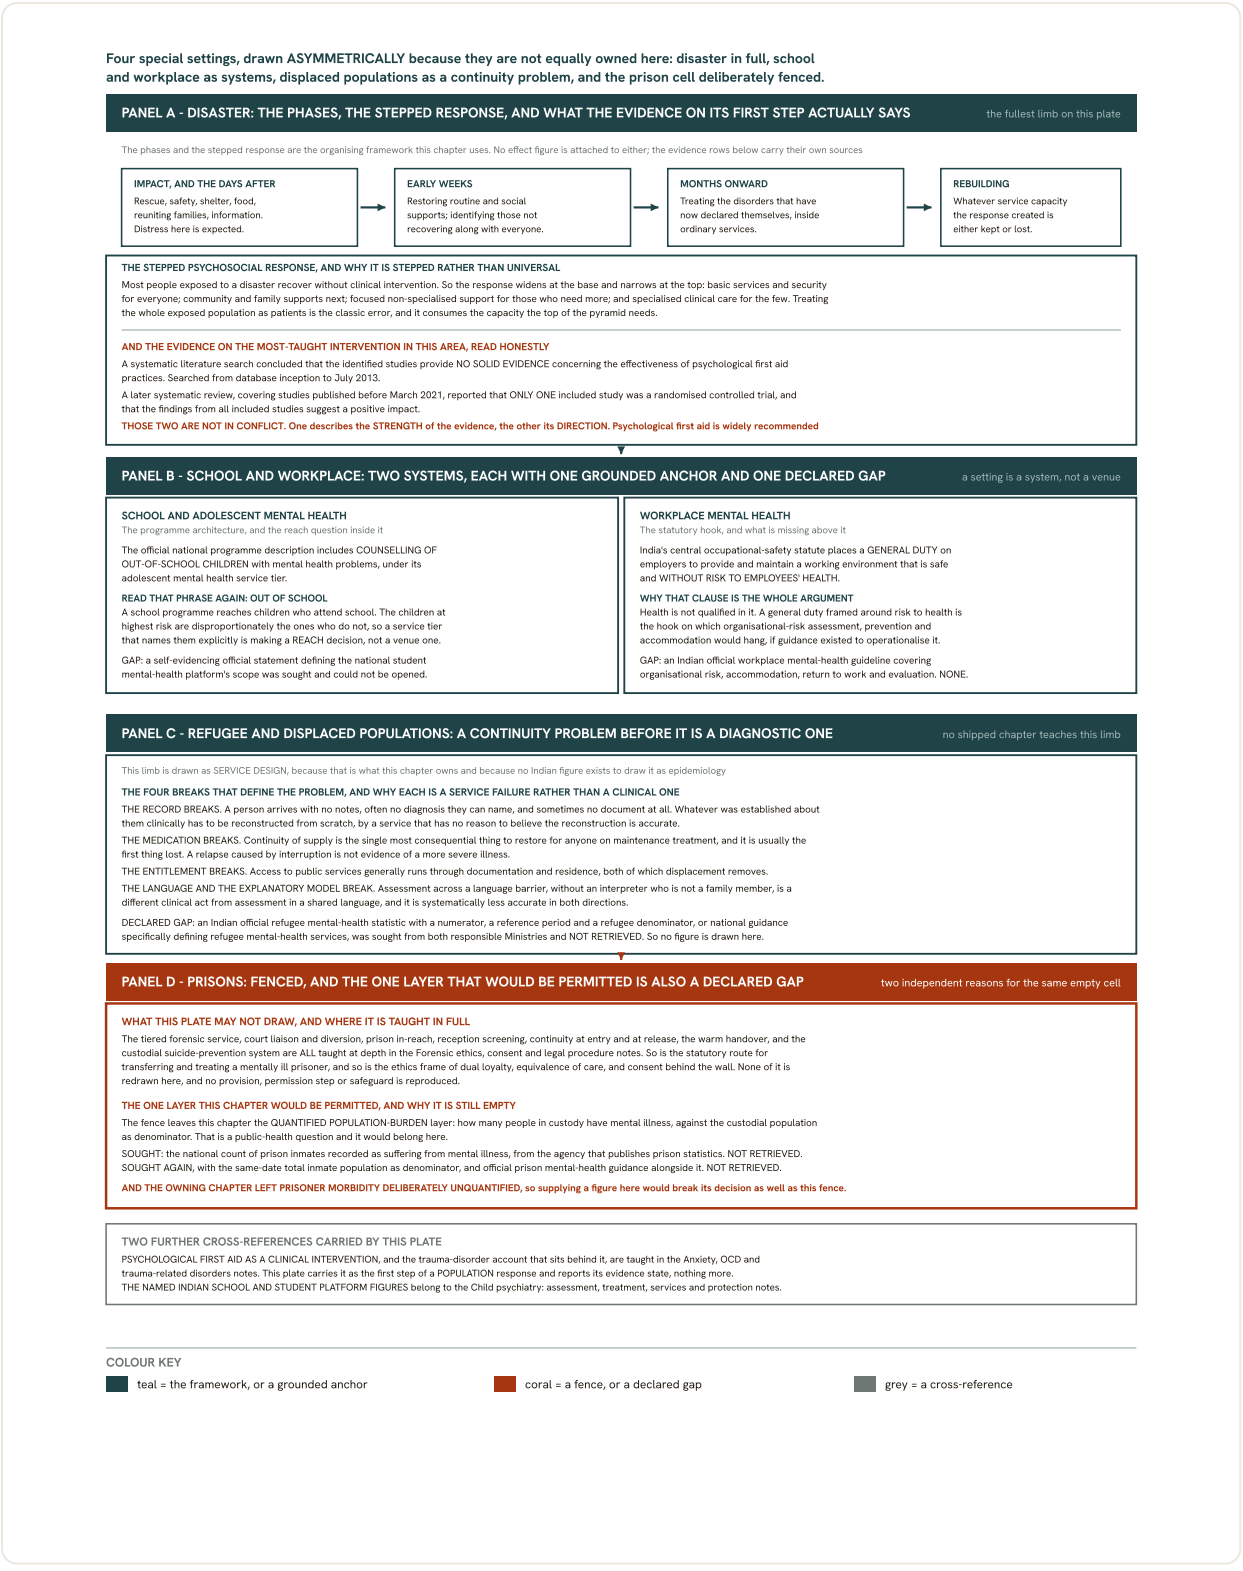

Fig 39.11 Four special settings, drawn to different depths because they are owned to different depths. Disaster carries the phases and the stepped psychosocial response in full, with its first step read honestly: one systematic search found no solid evidence of psychological first aid effectiveness while a later review found only one randomised trial among its included studies and reported that all of them suggest a positive impact, which are statements about strength and about direction rather than a contradiction. School rests on an official service tier that names counselling of out-of-school children, a reach decision rather than a venue one, with the national student platform's scope a declared gap. Workplace rests on a general statutory duty to maintain a working environment without risk to employees' health, with no Indian operational guideline above it. The displaced-population limb is drawn as four breaks in continuity, and no Indian refugee mental-health statistic was retrieved. Prisons are fenced to the Forensic ethics, consent and legal procedure notes, and the one permitted layer is itself a declared gap.

30.3 Where psychological first aid sits, and what it is for

Psychological first aid occupies the focused non-specialised layer. It is a structured, brief, humane response delivered by trained non-specialists to people in acute distress after a critical event, and its purpose is to reduce immediate distress, meet practical needs and connect the person with continuing support. Two boundaries define it more usefully than any description of its content.

The first boundary is that it is not a treatment. It does not target a disorder, it is not indicated by a diagnosis, and completing it is not a therapeutic episode. Its clinical action principles, the rule governing active monitoring and review afterwards, and the standing cautions about what must not be done in the acute phase are taught in the Anxiety, OCD and trauma-related disorders notes, and a candidate should point there rather than reproduce them.

The second boundary is that it is not universal. The people who benefit are those in acute distress, not everyone who was present. A response that pushes an emotional intervention onto every exposed person misallocates the workforce and risks pathologising a normal reaction, and it also crowds out the practical help that the acute period actually demands. The competence being tested when an examiner asks about psychological first aid is usually this discrimination, not the recall of a set of steps.

The delivery implication is the reason the model matters at scale. Because it is deliverable by trained non-specialists, it converts teachers, volunteers, community health workers and relief staff into a usable mental-health workforce for the widest tier of need. That is a workforce multiplication, and it is what makes a population-scale response arithmetically possible at all.

30.4 The evidence base, and how to hold it honestly

This is the part of the topic where candidates most often assert more than the literature supports, and it is worth getting exactly right, because the honest position is more impressive than the confident one.

A systematic search of the literature on this intervention concluded that nothing it identified amounted to solid evidence of effectiveness, which was the basis for its finding that guidelines could not be built on the evidence then available. A later systematic review of the same intervention reported a different but compatible picture: across what it included, randomized evidence was confined to a single trial while the studies as a whole pointed towards benefit.

Recommended widely	**Directionally positive**	**Randomized evidence scarce**	**No solid effectiveness evidence**
STATUS IN DISASTER RESPONSE PRACTICE	SIGNAL ACROSS INCLUDED STUDIES IN THE LATER REVIEW	DESIGN OF THE INCLUDED STUDIES	FINDING OF THE EARLIER SYSTEMATIC SEARCH

Those statements are not in conflict and reading them as a contradiction is the error to avoid. One reports the absence of solid effectiveness evidence; the other reports that the studies that do exist point in a favourable direction while almost none of them are randomized. Both are statements about the evidence base rather than about the intervention, and together they

describe a widely recommended intervention whose recommendation rests substantially on plausibility, consensus and the absence of harm rather than on trial evidence.

RULE **Absence of solid effectiveness evidence is not evidence of ineffectiveness, and it is not permission to assert effectiveness either.** The correct sentence names the intervention, states what the reviews found about the evidence, and gives the reason it is nonetheless recommended: it is low-risk, deliverable at scale by non-specialists, and the alternative on offer in the acute period is frequently nothing at all.

There is a structural reason the evidence is thin, and saying it demonstrates understanding rather than evasion. Randomizing an immediate humane response after a catastrophe is difficult to justify and difficult to execute; the exposed population is displaced and hard to follow; the outcome of interest emerges over a long period; and the intervention is delivered by many different people in many different forms under one name. Those are features of the setting, not failures of the researchers, and they mean the evidence base is unlikely to become deep quickly.

30.5 What changes as the response moves through its phases

A disaster response is not one service running for a long period; it is a sequence of different services with different staffing, and the transitions between them are where continuity is lost. The most important operational fact about the sequence is counter-intuitive: the mental-health workload does not peak when the media attention does. It rises as the acute relief effort demobilises, at precisely the point when external teams withdraw and funding attention moves elsewhere.

PERIOD OF THE RESPONSE	WHAT THE MENTAL-HEALTH SERVICE IS MAINLY DOING	THE CHARACTERISTIC FAILURE
Before any event, as preparedness	Building the plan, the roster and the training so that a response does not have to be invented	No plan exists, so the response is assembled by whoever arrives first
Immediate aftermath	Practical help, information, safety, and restoring supply and records for those already under treatment	Psychological intervention is offered while the practical layer is unmet
Relief and early recovery	Focused non-specialised support, case-finding for persisting distress, and support to responders	External teams deliver in parallel to the local service rather than through it
Later recovery	Specialist treatment for persisting disorder, and handover into the standing service	The external response has already left and the standing service was never strengthened

The service consequence of the last row is the single most useful thing to be able to say about disaster mental health. A response measured by what it delivered during the emergency will look successful and leave nothing behind. A response measured by what the district can do afterwards is a different programme, staffed and budgeted differently from the start.

The first row is the one under a service's own control and the one most often empty. **Preparedness** is the only phase in which decisions can be taken calmly, and it is the phase in which a district can decide, in advance, who leads the mental-health component, which staff are on the roster, what training they will have had, how a drug supply is re-established, where displaced patients will be seen, and what the mutual-aid arrangement with neighbouring districts is. None of those questions gets a good answer in the week after an event, and every one of them determines what the response is able to do.

The transition that matters most is the last one, and it has a name worth using precisely. **Handover** here does not mean transferring a list of patients; it means transferring a functioning arrangement, including who now holds each patient, where the record sits, who supervises the trained non-specialists, and which budget line carries the work from that point. A handover that consists of a summary document is an ending described as a transition.

PITFALL

The parallel service. An external team arrives with its own staff, its own protocol, its own records and its own funding line, works alongside the district service without integrating with it, and departs when the funding ends. Every patient it was holding is then either lost or handed to a service that has never seen them, has no record of the treatment given and was not resourced for the extra load. Working through the existing service is slower at every point and is the only arrangement that leaves capacity behind.

30.6 The responders are an exposed population

The workforce delivering the response is itself part of the affected population, and in a local disaster it is often part of it twice over. Rescue workers, health staff, police, volunteers and administrators are exposed to the event, to its aftermath and to sustained contact with distress, and in a district-level disaster many of them have lost homes and relatives in the same event they are working through.

Responder care is therefore a programme component and not a gesture, and it is designed at the level of the system rather than the individual. The measures that make a difference are structural: rostering that enforces rest rather than relying on individuals to request it; briefing before deployment about what will be seen; a named supervisor with an explicit responsibility for the team's condition; a mechanism to stand somebody down without it being treated as a failure; and access to care that is confidential enough that a local worker will actually use it in a place where everybody knows everybody.

The confidentiality point deserves emphasis because it is where responder programmes most often fail in practice. A support service staffed by the worker's own colleagues, in the worker's own institution, is a service the worker may not use for exactly the problems it exists to address. Designing an access route that sits outside the immediate hierarchy is a service-design decision that costs almost nothing and determines whether the provision is real.

30.7 Special groups the tiered plan has to name explicitly

A layered plan distributes generic need well and handles specific vulnerability badly unless the vulnerable groups are named in the plan itself. Each of the following requires a different arrangement, and each is routinely discovered late.

- People already receiving treatment for severe mental illness, whose immediate need is supply and continuity rather than a new intervention, and whose records may no longer exist.
- Separated and unaccompanied children, for whom reunification and protection are the mental-health intervention and everything else is secondary.
- Older and disabled people, whose access to a distribution point, a shelter or a clinic may be the binding constraint on every other service they need.
- The bereaved, particularly where bodies were not recovered, since the practical and administrative aftermath of an unconfirmed death is itself a prolonged stressor.
- Displaced people living in temporary settlements, where crowding, loss of privacy and loss of livelihood generate new problems that the original event did not.

Naming these groups in the plan does more than allocate resources. It commits somebody to counting them, and a group nobody counts is a group whose needs will be met by whatever is left over.

TRAP **Answering a disaster mental-health question as though the task were to treat post-traumatic stress disorder in survivors.** Candidates go straight to a diagnosis and a therapy, and thereby miss the population structure, the layered response, the people whose established treatment has been interrupted, and the responders. The disorder-level question is a legitimate one and belongs to the chapter that owns acute trauma; the question asked here is what a service does for a population, and the marks are distributed accordingly.

30.8 Evaluation, and what a response should be able to show afterwards

Disaster responses are evaluated less often than almost any other public-health intervention, for understandable reasons and with predictable consequences: each response is improvised, and the improvisation is not recorded, so the next one starts from the same place. Building the evaluation into the plan before the event is the only point at which it is cheap.

What a response should be able to state afterwards is modest and rarely available. How many people were reached at each layer, and out of what estimated affected population. What proportion of those already under treatment for severe mental illness had their treatment continued without interruption, which is the most concrete continuity measure available and the one most likely to reflect real service performance. How many non-specialists were trained, how many were supervised afterwards, and how many were still in post once the response ended. What proportion of responders used the support offered. And what capacity remained in the district when the response closed, compared with what was there before it opened.

That last quantity is the honest measure of a disaster mental-health programme, and it is the one that distinguishes a relief operation from a health-system intervention. An event that leaves a

district with more trained workers, a written plan and a functioning referral route has produced a durable gain. An event that leaves a district with a completed activity report has not.

> The response is layered and simultaneous, psychological first aid is one rung of it delivered by trained non-specialists, and the population that most reliably needs a psychiatrist is the one that already had one before the disaster.

31 · School mental health programmes and adolescent mental health services

The school is the only place where a health system can reach almost an entire age group without anyone having to decide they are unwell. That single property is what makes school mental health a public-health topic rather than a paediatric one, and it is what the marks here are actually about: the school is a delivery platform, and the examinable questions are the ones asked of any platform. Which tier of need is being addressed. Who delivers at each tier. What proportion of the intended population is genuinely reached. Who pays, and for how long. And how anybody would know whether it worked. What a school programme contains, how life-skills teaching is built, how a single session becomes a school culture, and how an identified child is assessed, treated, safeguarded and referred are taught at length in the Child psychiatry: assessment, treatment, services and protection notes, which also carries the Indian delivery platforms with their coverage figures. None of that is reproduced here. What follows is the platform read as a system: tiers, coverage, financing, evaluation, and the adolescents the school platform structurally cannot reach.

31.1 The school as a platform, and what the platform property buys

Every population intervention faces a selection problem. Services delivered in clinics reach the people who present, and presentation is filtered by recognition, permission, money and distance, all of which are unevenly distributed. A **platform intervention** avoids the filter by delivering where the population already is. Schools are the most complete such platform available for young people, and their advantages are structural rather than clinical.

The assembled population is the first advantage: no health-seeking decision is required, so the intervention reaches those who would never have been brought. The second is repeated contact over a long period, which is what any preventive intervention needs and what a clinic almost never has. The third is the presence of a trained adult workforce that already observes the child daily and is capable, with support, of noticing change. The fourth is that the school is itself part of the causal environment, so it can be modified rather than merely used as a venue.

The disadvantages are equally structural and are less often stated. The platform reaches only the enrolled and the attending, so it systematically misses the young people at highest risk. Teachers are not a free workforce and every task added to them displaces another. The school's institutional interest is educational attainment, so a mental-health programme is retained when it is seen to serve that interest and dropped when it is not. And a programme delivered inside a school inherits the school's own hierarchies, so confidentiality is harder to guarantee than in a clinic, which is a matter for the chapter that owns the identified child.

RULE **A school mental-health programme is a platform decision before it is a content decision.** The question that determines its effect is not which curriculum is delivered but which tier of need it is aimed at, who delivers it, and what proportion of the intended age group is actually enrolled, attending and present when it is delivered.

31.2 The prevention tiers applied to a school

The prevention taxonomy is developed as a framework in the prevention material of these notes, and its definitions belong elsewhere again; what belongs here is its application, because the school is the setting in which all its tiers can be seen operating in one building. Applied to a school population, the tiers separate cleanly by whom they are aimed at.

TIER	WHO IT IS AIMED AT IN A SCHOOL	WHO DELIVERS IT, AND WHAT IT COSTS
Universal	Every pupil, irrespective of risk, and the school environment itself	Teachers within the timetable; cheapest per head and dearest in total, because everyone receives it
Selective	Groups with a raised exposure but no identified problem, defined by circumstance rather than by symptom	Trained school staff or a visiting worker; requires a defensible basis for grouping and careful handling of labelling
Indicated	Individual pupils showing early problems that fall short of a disorder	A trained non-specialist with supervision, or a visiting mental-health worker; smallest numbers, highest unit cost
Treatment, which is not prevention	Pupils with an established disorder	The health service, not the school; the school's job here is recognition and a working referral route

The last row is where most school programmes fail, and it is a system failure rather than a content failure. A universal programme in a school raises recognition, and raised recognition generates identified children. If no referral destination exists, the programme has manufactured demand it cannot serve, and the teachers who identified the children carry the consequence. Building the highest tier before opening the widest one is the single most consistent lesson from school programmes in any health system.

MNEMONIC

Enrolled, Attending, Present, Reached

The four filters standing between an intended school population and the population a programme actually serves. Coverage claimed against enrolment is an administrative figure. Coverage claimed against those present when the intervention was delivered is a service figure. The gap between them is where school programme evaluations most often go wrong.

31.3 The Indian delivery platforms, named and located

India does not lack school and adolescent platforms; it has several, they sit in different ministries, and their coverage provisions, training structures and target ages are taught with their figures in the Child psychiatry: assessment, treatment, services and protection notes. This chapter names them so that a reader knows what exists and where the detail lives, and reproduces none of their coverage figures.

- The district mental health programme's school outreach component, which places mental-health work inside schools through the district team and its master-trainer model.
- Rashtriya Kishor Swasthya Karyakram, the national adolescent health programme, which carries adolescent mental health inside a wider adolescent health remit and includes a clinic-based adolescent-friendly service tier.
- The Ayushman Bharat School Health and Wellness Programme, which works through designated teachers delivering scheduled health-promotion sessions within the school timetable.

The system-level observation worth making about that list is the one a candidate can make without any figure at all. The platforms are plural, they sit under different ministries with different reporting lines, and they were designed at different times for different primary purposes. A district therefore does not have one adolescent mental-health programme with a coverage figure; it has several partial provisions whose overlaps and gaps nobody is required to reconcile. Integration across those platforms is the practical Indian problem, and it is an administrative problem rather than a clinical one.

31.4 The adolescents who are not in school

Every advantage of the school platform is conditional on enrolment, and the conditionality is not random. Young people out of school are disproportionately those who are working, married early, disabled, displaced, from the poorest households, or already in difficulty. On any plausible account of risk they are the group with the highest need, and the platform designed to reach adolescents reaches them least.

This is not an oversight in the Indian service description. The **National Mental Health Programme**'s own account of what its district teams deliver on outreach includes the counselling of children who are not in school and who have mental health problems, listed within its adolescent mental health work. The provision is therefore already named at national level, which changes the nature of the question a district faces: it is not whether an out-of-school limb is legitimate, but what contact point it uses.

That contact point is the whole design problem, because there is no assembled population to work with. The available options are all second-best and each carries a different reach and a different cost. Work through the health facility, which returns the selection filter the school platform existed to avoid. Work through the community health worker, which reaches households but adds to an already loaded role. Work through workplaces where adolescents are employed, which reaches the working young but requires an employer's cooperation. Work through

community and religious institutions, which reaches those inside them. Work through a remote or helpline route, which requires a device and a private moment. A district plan that names one of these and resources it has an out-of-school limb; a plan that names none has a school programme and a claim.

IN INDIA

Because the national programme's own outreach description already includes counselling for children outside school who have mental health problems, the practical decision for a district team is not whether to serve this group but which single contact point it will commit to and staff. Choosing one route and running it properly reaches more of this population than distributing the intention across all of them, and it makes the coverage question answerable, because a named route has a denominator that can be counted while a general intention does not.

31.5 Coverage, and the difference between a programme existing and a programme reaching

Coverage is the quantity on which any platform intervention is properly judged, and it is the quantity most often replaced by a proxy. A programme can be sanctioned in a district and absent in its schools. It can be present in a school and delivered to a fraction of classes. It can be delivered to every class and reach only those present on the day. And it can reach everyone present and change nothing, because the tier addressed was not the tier of need.

The honest formulation asks four questions in sequence and refuses to collapse them. What is the intended population, defined by age and by geography rather than by enrolment. What proportion of that population is enrolled and attending, which is an education-system figure the health system must obtain rather than assume. What proportion of those actually received the intervention as designed. And what proportion of those identified as needing the next tier reached it. A programme that can answer only the first two is reporting the education system's performance, not its own.

Districts	Schools	Teachers trained	Adolescents reached
WHAT A SANCTION FIGURE COUNTS	WHAT AN INSTITUTIONAL FIGURE COUNTS	WHAT A TRAINING FIGURE COUNTS	THE ONLY DENOMINATOR THAT ANSWERS COVERAGE

Read that strip from left to right as a descent from what is easy to report towards what a population actually received. Each tile counts a real thing, and only the last one has the population in its denominator. A programme report that stops before the last tile has not answered the coverage question; it has answered an administrative one and left the reader to assume the rest.

TRAP **Quoting the number of schools or districts covered as though it were population coverage.** Districts covered is an administrative reach figure, and its denominator is districts, not children. Schools covered is likewise a figure about institutions. Neither can be converted into a proportion of the adolescent population without the enrolment and attendance data that turn one into the other, and the young people at highest risk sit precisely in the gap between those denominators.

31.6 What an adolescent service tier has to look like to be used

An adolescent service is not a paediatric service with older patients or an adult service with younger ones, and the reasons are about access rather than about diagnosis. Adolescents present late, present through somebody else, and stop attending for reasons that have more to do with the shape of the service than with their symptoms. Designing an **adolescent-friendly service** means removing the specific obstacles that this age group faces, and each of them is a system decision.

Location and hours are the first, because a service open only during school or working hours obliges the young person to explain their absence, which is itself a disclosure. The entry route is the second: a service reached only through a parent excludes the adolescents whose difficulty involves the household, and a service reached only through a psychiatric department attaches a label at the door. Staff attitude is the third and is the one adolescents themselves report as decisive. And a clear statement of what will and will not be shared with a parent or a school is the fourth, since an adolescent who cannot predict where their words will go will manage the risk by saying less. The confidentiality boundary, the limits of the teacher's role and the handling of an identified child are taught in the Child psychiatry: assessment, treatment, services and protection notes and are not restated here.

The last design problem is **transition**. A young person who reaches an adolescent service and remains unwell must eventually move into adult services, and that move is a documented point of disengagement across health systems. Treating transition as an administrative transfer rather than as a planned handover with an overlap period, a named receiving clinician and a shared plan produces a predictable loss of exactly the patients who most needed continuity. A district that builds an adolescent tier without deciding what happens at its upper edge has built a service with an exit and no destination.

31.7 Financing, and why school programmes have a characteristic life cycle

School mental-health programmes fail in a recognisable pattern, and the pattern is financial rather than clinical. A programme is introduced with project or scheme funding that pays for training and for a coordinating post. The training is delivered and counted. The coordinating post ends with the project. The trained teachers are transferred, promoted or retire, and the school reverts. A subsequent evaluation finds no effect and concludes that the intervention does not work, when what happened is that it was never sustained long enough to be tested.

The financing questions that determine whether this happens are worth naming precisely, because they are answerable in advance. Whether the recurring costs, meaning refresher training and supervision, sit on a recurring budget line or a project one. Whether the coordinating role belongs to a post or to a person. Whether the receiving health service at the top tier was funded to take the referrals the programme generates. And whether the education system carries any of the cost, since a programme entirely funded by the health side is a programme the school has no institutional stake in retaining.

PITFALL

Counting teachers trained as the programme's output. Training is an input, it is easy to count, and it is what appears in reports. It tells you nothing about whether anything was delivered afterwards, whether the trained teacher is still in that school, or whether a single child reached a service. A programme reporting only training numbers has reported its expenditure.

31.8 Evaluation, and what this chapter cannot establish

The evaluation of a school mental-health programme should be aimed at the tier it addresses, and mismatched evaluation is the commonest reason a reasonable programme is judged ineffective. A universal intervention should be judged on population-level change and on the school environment, not on the recovery of identified children, of whom it will contain few. An indicated intervention should be judged on the outcome of those identified, and on whether they reached the next tier. Judging a universal programme by clinical outcomes in a handful of identified pupils guarantees a null result whatever the programme did.

Two things this section would ordinarily state are declared as gaps rather than supplied, and both are exactly the kind of fact that feels certain from memory.

The first is the national student mental-health support initiative run from the education side. What was sought was a primary official statement defining its scope for school, college and university students; the official routes approached timed out or returned no retrievable page text, and no such statement was obtained. The construct exists and is named here; its scope, its year and its provisions are not established by anything this chapter has read, and a candidate is better served by saying so than by attributing a remembered description to a ministry.

The second is prevalence. No defensible Indian figure is available here for cyberbullying among school-going children and adolescents, and none is supplied. This matters as method and not only as caution: a prevalence figure measured in one population cannot be transferred to another simply because both consist of school children, and a figure quoted without its survey, its year, its age band and its definition of the behaviour is not a fact about India. The correct answer names the construct, says the Indian figure is not established, and moves to what a service should do about a problem whose size it does not know.

A school programme's effect is set by its tier and its coverage, and its coverage is capped by enrolment, which is precisely why the out-of-school limb is not an afterthought but the part that reaches the highest risk.

32 · Workplace and occupational mental health

Work is where most adults spend most of their waking, non-domestic life, and it is the one setting in which an institution can change a person's exposure by changing its own arrangements. That is why workplace mental health is a public-health topic and not an occupational-medicine footnote: the employer holds levers no clinician holds. It can change how much is demanded, how much control a person has over it, whether support exists, whether the

role is intelligible, and whether the job will still exist next month. A clinician can treat the consequences of all of these and can change none of them. The examinable content sits on that asymmetry, and the commonest failure in an answer is to describe workplace mental health as a set of services offered to employees, which relocates the problem into the worker and leaves the work untouched. What follows is the organisational risk, the prevention structure applied to a workplace, the accommodation and return-to-work system, the manager's role and its limits, and what an Indian programme can and cannot be held to.

32.1 The setting, and the three populations inside it

A workplace, viewed as a health platform, has the same assembled-population advantage as a school and an additional one: the institution has a continuing relationship with the person, a record of their attendance, and a financial interest in their capacity to work. It also has three distinguishable populations, and a programme that does not separate them will be judged against the wrong outcome.

The first population is everybody employed, well and unwell, whose exposure is set by how the work is designed. The second is those with emerging difficulty who are still working, often at reduced effectiveness and usually undisclosed. The third is those absent from work or returning from absence, whose problem is no longer only clinical but also contractual, financial and social. Each requires a different intervention, delivered by a different part of the organisation, and evaluated on a different measure.

Two further groups sit at the edges and are routinely forgotten. Workers in insecure, informal or contract arrangements are exposed to more of the hazards and covered by fewer of the provisions, so a programme built for permanent employees can widen a gap inside its own workforce. And managers, who are asked to carry much of the delivery, are themselves employees with the same exposures.

32.2 The statutory floor, and how far it reaches

India's central occupational-safety statute places a general duty on employers, which is to provide and to keep in place a working environment that is safe and does not put employees' health at risk. The wording of the duty is the load-bearing part, and it is worth reading twice. It concerns the *environment*, not the worker's constitution. It runs to *health*, without a qualifier confining it to physical health. And it obliges the employer to *provide and maintain*, which is a continuing obligation rather than a one-off provision.

A caution about how far that reading may be pressed, and it applies to any statutory duty. The exact strength of a duty, including whatever qualification the statute attaches to it, is the substance of the obligation and not decoration around it; a duty framed absolutely and a duty framed with a practicability qualifier are different claims about what an employer must do. This chapter states the duty and does not reproduce the statutory text, the section locator or the qualifying words, and a candidate arguing a legal point should go to the statute rather than to a summary of it. The disability entitlement frame that sits behind adjustments in employment is taught in the Mental health legislation and forensic psychiatry notes.

RULE **Workplace mental health is a work-design intervention first and a service offering second.** Interventions aimed only at the individual, however good, leave the exposure in place and locate the problem in the person exposed to it. An answer that lists counselling services without addressing how work is organised has described the smaller half of the field.

32.3 Organisational risk, described as properties of work rather than of workers

The **psychosocial hazards** of work are features of how a job is arranged, and they are describable independently of who holds the job. The categories that recur across occupational settings are these, and each has a corresponding organisational remedy that no individual intervention can substitute for.

- Demand: the volume, pace and difficulty of the work relative to the time and resources given for it.
- Control: how much say the worker has over how, when and in what order the work is done.
- Support: whether practical help and supervision are actually available from managers and colleagues.
- Role: whether what the person is responsible for is defined, consistent and free of conflicting instructions.
- Relationships: exposure to bullying, harassment, discrimination and unresolved conflict.
- Change and security: how organisational change is managed, and whether the job itself is precarious.

The important structural claim about these hazards is that they interact rather than add. High demand alongside high control is a demanding job; high demand alongside low control is the arrangement most consistently associated with harm. Effort without corresponding reward, recognition or security behaves similarly. Named theoretical models formalise these interactions and attach evidence to them; this chapter does not name them or their originators, because no claim row here carries them, and a model attributed from memory to the wrong author is exactly the kind of error a viva finds. The categories above are usable without the model names, and an answer that reasons from demand and control to a specific organisational remedy has demonstrated the understanding the model exists to convey.

MNEMONIC

Design, Detect, Adjust, Return

The four functions of a workplace mental-health programme, in the order of their population effect and the reverse of the order in which they are usually built. Design the work so it does less harm. Detect difficulty early and make disclosure survivable. Adjust the job so the person can keep doing it. And build a route back for those who have stopped.

32.4 The prevention tiers applied to a workplace

The prevention taxonomy is developed as a framework in the prevention material of these notes and is applied here rather than restated. Applied to a workplace it separates the interventions by

the level at which they act, and the separation is what makes an evaluation interpretable.

LEVEL AT WHICH IT ACTS	WHAT IT LOOKS LIKE IN A WORKPLACE	WHO HAS TO ACT	HOW IT CHARACTERISTICALLY FAILS
The work itself, before anyone is unwell	Workload and rostering decisions, clarified roles, managed change, an enforced anti-harassment position	Senior management, because these are budget and structure decisions	Delegated to a health or welfare function that cannot change any of them
The whole workforce, as capability	Awareness that reduces the cost of disclosure, and training that makes managers approachable	The organisation, with time released for it	Delivered as a single session and never refreshed, so the culture reverts
Individuals with emerging difficulty	Early conversation, confidential access to help, adjustment before absence occurs	Line managers, supported by an occupational health or counselling route	Access exists but disclosure is unsafe, so nobody uses it until they are absent
Those already absent or impaired	Structured return to work, graded duties, sustained adjustment, continuity with treatment	Manager, occupational health and the treating clinician together	Handled as an attendance problem by a process designed for discipline

The job	**The person**	**Disclosure cost**	**Return route**
WHAT AN ORGANISATIONAL INTERVENTION CHANGES	WHAT AN INDIVIDUAL INTERVENTION CHANGES	WHAT DETERMINES WHETHER EITHER IS USED	WHAT DECIDES IF ABSENCE BECOMES EXIT

32.5 Adjustment, and why it is cheaper than everything downstream

Adjustment means changing the job so that a person with a mental-health difficulty can continue to do it, and its most useful property is that it is usually inexpensive and reversible. The adjustments that matter in mental health are unglamorous and mostly concern time, predictability and load: altered start and finish times so that treatment appointments or medication effects are accommodated; a temporary reduction in the most demanding component of the role rather than in the role as a whole; a quieter or more predictable working location; a phased increase in duties; a named person to check in; and a temporary change in the frequency of supervision so that difficulty is caught before it accumulates.

Two design principles carry most of the effect. The first is that adjustment should be available before absence occurs, not only as a condition of return, because the cheapest point to intervene is while the person is still at work. The second is that an adjustment must have a review date and a person who owns it, or it either lapses silently or becomes permanent by default, and both outcomes damage the arrangement's credibility for the next person who needs one.

IN INDIA

Because the employer's general duty concerns a working environment that is safe and without risk to employee health, and that duty is not written as a duty about physical health alone, the practical decision for an Indian organisation is to locate mental-health provision inside the occupational safety and health management system it already runs rather than beside it as a welfare activity. That placement is not cosmetic: it puts the provision where the statutory duty, the reporting line and the standing safety committee already sit, which is what converts an initiative into an obligation somebody is answerable for.

32.6 Return to work, treated as a system rather than a date

Return to work is where workplace mental health becomes measurable and where most organisations perform worst, because absence is managed by processes designed for a different purpose. The default machinery is **attendance management**, whose logic is verification and escalation, and applying it to a mental-health absence reliably delays return and sometimes prevents it.

A functioning return system has a small number of features and they are all about contact and structure. Contact during absence is maintained by a named person on an agreed basis, since silence is read as abandonment and repeated formal letters are read as threat. A return is planned before it happens, with the returning person present at the planning. Duties are **graded** rather than restored in full on the first day. The adjustments are written down, given a review point, and communicated to whoever needs to know and to nobody else. And the return is reviewed after a period rather than treated as complete on arrival, because relapse in the first weeks back is common and is best met with a further adjustment rather than a further absence.

PITFALL

Requiring full fitness before return. The demand looks prudent and is counterproductive: it converts a person who could do part of the job now into a person doing none of it indefinitely, removes the structure and contact that support recovery, and lengthens absence to the point at which returning at all becomes unlikely. A **capacity-based return**, which asks what the person can do and adjusts around what they cannot, is both safer and faster.

32.7 The manager's role, its limits, and the confidentiality problem

Most workplace mental-health programmes rest on line managers, and most manager training fails by being too ambitious about what a manager is for. A manager is not being trained to assess, diagnose, counsel or treat, and training that implies otherwise produces either an anxious manager who avoids the conversation or a confident one who does something inappropriate.

The manager's job has three parts and stops there. Notice a change in the person's work or presentation. Have a conversation that makes disclosure safe and is about work rather than about diagnosis. And connect the person to a route, whether that is occupational health, a counselling service or their own doctor, while adjusting what can be adjusted meanwhile. Training aimed at

those three does measurably more than training aimed at recognition of disorders, and it is also the version a manager can practise without exceeding their competence.

Confidentiality is the structural problem that determines whether any of this is used. An employee discloses to someone who also decides their appraisal, their duties and possibly their continued employment, and the same information that unlocks an adjustment can be read as evidence of unreliability. The resulting **cost of disclosure**, meaning what the employee reasonably expects to lose by speaking, is the single variable that determines whether any provision in the organisation is used at all. The design answer is to separate what the manager needs to know from what they must not: a manager needs to know what adjustment is required and for how long, and does not need a diagnosis, a treatment or a prognosis. Where an **occupational health function** exists, its correct output to a manager is a statement of capacity and adjustment, not a clinical account. Where a service is delivered by the employer's own staff, the same problem arises inside the service, which is why an access route independent of the reporting line is a design requirement rather than a courtesy.

TRAP **Reporting uptake of an employee counselling service as the outcome of a workplace mental-health programme.** Uptake is an activity figure with no population denominator attached, and it can rise for good reasons or bad ones: a workforce under increasing strain generates more uptake, as does a service that has become easier to reach. It says nothing about exposure, about absence, about return, or about the people who did not disclose. The outcomes that answer the question are absence and return-to-work measures, the proportion of adjustments requested that were granted, and any measure of the psychosocial hazards themselves.

32.8 Evaluation, and what is not established for India

The evaluation problem here is that the easily available measures belong to human resources and the meaningful ones do not exist unless somebody builds them. Absence data are collected everywhere and are a poor single measure, because absence falls both when people get better and when they become too insecure to take leave. A defensible evaluation therefore reads several quantities together: absence and its duration, the proportion of absences that end in return rather than exit, the proportion of requested adjustments granted and sustained to their review point, and a repeated measure of the psychosocial hazards themselves, which is the only quantity that reports on the intervention that matters most.

Two things a section on Indian workplace mental health would ordinarily supply are declared here as gaps. There is no primary-official Indian workplace mental-health guideline available to this chapter addressing organisational risk, prevention, reasonable accommodation, return to work, manager training and programme evaluation. What was sought was exactly such an instrument from the labour and health ministries and their technical bodies; the official sources approached either carried only a bare mention of workplace stress management without any framework, or established a general health duty without an express mental-health framework, or failed to open. The construct is named here without a national instrument behind it, and a candidate who says that plainly is answering correctly.

There is likewise no national coverage figure available: how many Indian workplaces run any mental-health provision, what proportion of the workforce it reaches, and what proportion of that workforce is in the informal arrangements that no such programme touches are all unquantified here. The absence is itself instructive, because a workforce whose majority is informally employed cannot be covered by an employer-based model however good that model is, and a national workplace mental-health strategy that addresses only formal employment addresses a minority of the working population.

> The employer's duty runs to the working environment and to health without qualification, so the first intervention in workplace mental health is always to the design of the work, and every service offered to the worker is downstream of it.

33 · Prison, refugee and other special-population mental health

A special population, in service terms, is not a population with an unusual diagnosis; it is a population whose access to care is controlled by something other than its need. For prisoners that something is custody. For refugees and displaced people it is legal status, documentation and mobility. For others it is the absence of an address, a guardian or an entitlement. The clinical material is largely the same material taught everywhere else in psychiatry; what changes, and what carries the marks, is that the ordinary route to care has been interrupted by an institution or a legal category, so the service has to be redesigned around the interruption. This section teaches the displaced-population limb in full, and for prisons only the population and system questions: what a prison mental-health figure would have to be to mean anything, and how prison mental-health systems differ across countries. Custodial law, prisoner rights, the ethics of practice behind the wall, the design of an in-reach service, continuity at entry and at release, and the custodial suicide-prevention system are taught at depth in the Forensic ethics, consent and legal procedure notes, and none of them is restated here.

33.1 What makes a population special, stated as a rule about access

The useful generalisation is that in each of these populations a third party stands between the person and the service, and that third party's interests are not identical to the patient's. A prison authority is accountable for security. An immigration authority is accountable for status determination. A shelter or an institution is accountable to whoever funds it. None of them is primarily accountable for the person's mental health, and each can, without malice, produce a decision that removes the person from care.

Three consequences follow and they recur across every population in this section. Continuity is fragile, because the person can be moved, released, transferred or deported without reference to their treatment. Consent and confidentiality operate under constraint, because the person's circumstances limit what a refusal can mean and who else has an interest in the information. And ordinary measures of service performance mislead, because the denominator is a population the health service does not control and often cannot count.

RULE **Where a third party controls access, service design is mostly about the joins with that third party and only secondarily about the clinical content.** The question that determines whether a special-population service works is not what treatment it offers but what happens to a patient at the moment the custodian, the authority or the institution makes a decision about them.

33.2 Displacement, read as a sequence of exposures rather than an event

Refugee and displaced-population mental health is often taught as though the trauma were the flight. That framing is incomplete and, for service design, misleading. The exposures are distributed across a sequence, and the parts a receiving service can actually change lie at the end of it.

Before departure sit the conditions that produced the displacement: conflict, persecution, disaster, destitution, and the losses accumulated while deciding to leave. During movement sit the hazards of the journey itself, separation from family, and, for many, exploitation and violence en route. After arrival sit a different set of exposures that are chronic rather than acute: uncertain legal status, prohibition or absence of work, dependence, crowded or temporary accommodation, discrimination, and the sustained absence of information about what will happen next.

The post-arrival exposures are the ones a health service and a policy can modify, and they behave differently from the pre-arrival ones. The events before and during flight are fixed and historical. The conditions after arrival are ongoing and administrative, and prolonged uncertainty about status functions as a continuing stressor rather than a background condition. That distinction is why an intervention aimed only at past trauma, in a person whose present circumstances remain unresolved, so often disappoints: it treats the part of the sequence that has ended and leaves the part that is still happening.

Two further groups belong in this limb and are frequently excluded from it. **Internally displaced people**, who have not crossed a border, are usually more numerous than refugees and are covered by fewer specific provisions. And people whose displacement is old, meaning long-settled populations in **protracted situations**, have a different problem again: their acute needs have passed and their structural disadvantage has become permanent.

33.3 What a service for displaced people actually has to solve

The design problems are concrete and are mostly not clinical. Each of them has a service answer, and a plan that has not answered them will deliver care to whoever happens to arrive able to use it.

- Entitlement: what a person is allowed to receive depends on a legal status that may be undetermined, contested or absent, so the service must decide in advance what it will provide to somebody whose status is unresolved.
- Language: assessment through an untrained **interpreter**, or through a family member, changes what is said and what is recorded, and interpreting capacity is the single most common binding constraint on the quality of a refugee mental-health assessment.

- Documentation: people arrive without records, so treatment history, previous diagnoses and current medication have to be reconstructed, and continuing supply of an existing medicine is frequently the most urgent clinical task.
- Mobility: populations move between camps, cities and countries, so a plan requiring several appointments at one location may be unusable, and a **portable record** held by the patient is worth more than a good record held by the clinic.
- Calibration: distress is expected and is not by itself a disorder, so a service must be able to distinguish the person who needs housing, information and a resolved status from the person who needs treatment, without dismissing the second or medicalising the first.

MNEMONIC

Status, Speech, Supply, Setting

The four things to establish before any assessment of a displaced person is worth recording. What legal status they hold and what it entitles them to. In what language the encounter will actually happen, and through whom. What treatment was already running and whether it can be continued. And what their living conditions now are, since those are the exposure a service can still change.

PITFALL

Building a separate refugee mental-health clinic funded by a project. It is visible, it is fundable, and it produces a parallel service with its own records, staff and closing date, attached to a population that is mobile and whose entitlement to the mainstream service was never resolved. When the project ends, the patients belong to nobody. Strengthening the general service to receive this population is slower, less visible and the only version that survives.

33.4 What is not established about refugee mental health in India

This is a section where a confident figure would be easy to produce and impossible to defend, so the position is stated plainly. No Indian primary-official refugee mental-health statistic is available to this chapter, meaning no figure carrying a numerator, a reference period and a refugee denominator; and no national guidance specifically defining refugee mental-health services was retrieved either. What was sought was exactly that, from the home and health ministries. The official sources reached described camps, relief schemes and legal procedure, and contained no mental-health statistic and no mental-health-specific guidance for this population.

The absence is worth teaching as content rather than passed over, because it explains a real feature of the field. India hosts displaced populations of several origins under several different administrative arrangements, and a person's entitlement can depend on which arrangement they fall under rather than on what they need. Where no single national mental-health provision defines the service, what a displaced person receives is determined locally, by whichever combination of the general health service, a state arrangement and a non-governmental provider happens to exist where they are. A candidate who can say that, and can say that the national figures do not exist, is describing the system accurately. A candidate who quotes a prevalence for

refugee mental disorder in India is quoting something no Indian official source in this chapter's reach has published.

Not established	Not retrieved	Not retrieved	Not available
INDIAN REFUGEE MENTAL-HEALTH STATISTIC WITH A REFUGEE DENOMINATOR	NATIONAL GUIDANCE DEFINING REFUGEE MENTAL-HEALTH SERVICES	NATIONAL COUNT OF INMATES RECORDED AS MENTALLY ILL	SAME-DATE INMATE POPULATION AS A DENOMINATOR

33.5 Prisons, and the boundary of what belongs here

Prison mental health is taught as a service in the Forensic ethics, consent and legal procedure notes, and the boundary is worth stating so a reader does not go looking for it here. That chapter carries the custodial service architecture and the standards it is held to. The statutory route by which a mentally ill prisoner is transferred and treated is named here only as the dependency it is, since a service whose transfer route does not work has no upper tier, and the reader is sent to the Forensic ethics, consent and legal procedure notes for the provision itself. The rights and ethics frame governing care behind the wall is likewise named here only as the standard against which any prison mental-health system is measured, and is taught in the same place.

What remains for a public-health chapter is narrower and genuinely distinct: the question of what a prison mental-health figure would have to be to mean anything, and the comparison of prison mental-health systems across countries. Both are population and system questions rather than service-design questions, and neither is taught elsewhere in these notes.

33.6 The numbers problem, and what an honest prison figure would require

It is well established, and stated in the chapter that owns the custodial service, that psychiatric morbidity in custody runs far above the community rate. Nothing in this section contradicts that direction. What this section does is explain why attaching a number to it is harder than it looks, and that explanation is examinable in its own right.

Start with what is routinely published. Prison administrations publish **administrative counts**, and a count of inmates recorded as mentally ill is a count of recognition and recording, not a count of illness. It depends on who did the recognising, with what training, at what point in the sentence, using what threshold, and on whether recording it had any consequence for the institution. A system with no reception assessment records few cases; a system with an active assessment records many; and the difference between the numbers describes the two systems, not the two populations.

Then note the denominator problem, which is specific and fatal to casual comparison. A prison population is a **flow** as much as a **stock**: the number held on a given date is not the number who passed through in a year, and the two differ most for the remand population, which is also the population with the highest turnover and often the highest morbidity. A numerator collected across a period, divided by a population counted on one date, produces a figure that is not a proportion of anything.

An Indian figure that would satisfy this chapter's standard therefore needs a numerator with a stated case definition and ascertainment method, a same-date or same-period denominator from the same source, and a stated reference period. That figure was sought here from the national prison statistics published under the home ministry by the National Crime Records Bureau, together with the corresponding total inmate population. It was not obtained: the national publication timed out on repeated attempts, and where an official route did serve, it exceeded the retrieval limit so that no verbatim table and row could be quoted. A related route supplied a total inmate population without the mental-illness numerator that would have to sit above it. No figure is printed here, and the correct answer in a viva is that the direction is established, the Indian proportion is not, and the reason is a numerator and denominator problem rather than an absence of interest.

TRAP **Quoting an administrative count of prisoners recorded as mentally ill as though it were a prevalence.** The count is a recognition figure produced by the prison system's own procedures, its denominator is usually a single-date headcount while the numerator accrues over a period, and the case definition is rarely stated. Candidates reach for it because it is the only number available. The stronger answer names the count for what it is, states that morbidity in custody runs far above the community rate, and explains what would have to be true for a real proportion to be computed.

33.7 How prison mental-health systems differ across countries

Comparing systems rather than services is the other thing this section can legitimately do, and the comparison is more instructive than a table of prevalences would be, because the structural choices explain most of the variation in what is delivered.

AXIS ON WHICH SYSTEMS DIFFER	ONE ARRANGEMENT	THE OTHER ARRANGEMENT	WHAT THE CHOICE DETERMINES
Who is accountable for health inside the walls	The prison administration provides health care itself	The health ministry provides it, inside a facility run by another department	Whether clinical standards and staffing follow health-service norms or custodial ones
Who employs the clinicians	Employed by the custodial service	Employed by an external health provider working in the prison	Independence of clinical judgement, and how easily posts can be recruited to
Where the sickest are treated	Within dedicated units inside the custodial estate	By transfer out to health-service facilities	Capacity limits, waiting for transfer, and who carries the risk while waiting
How coverage is reported	Activity counts from the custodial system	Health-service reporting with a defined population	Whether coverage can be compared with the general population at all

The last axis is the one that makes cross-national comparison so difficult, and it is worth saying explicitly. Where prison health is reported through the custodial system, its figures are not

commensurable with the health system's, so international differences in reported prison morbidity partly measure differences in reporting architecture. A comparison that does not say which architecture each country uses has compared reporting systems and called it epidemiology.

33.8 The other populations, and the structure they share

The bank of special populations is longer than these two, and the shared structure introduced at the start is what makes them teachable together rather than as a list. In each case a third party or a legal category stands between the person and ordinary care, and the service response is a set of joins rather than a new treatment.

People without a home have no address, which is the hidden requirement in most systems for registration, appointment letters, follow-up and medicine supply. People in institutions of any kind have their access mediated by the institution's staff, so their care depends on somebody else recognising a need and acting on it. People who have been trafficked or are in exploitative work have their movement controlled by another person, so confidentiality and the ability to attend are both compromised. Migrant workers within a country lose entitlements attached to their place of origin without gaining those attached to their place of work. In every case, the correct question is the same: at which administrative moment does this person fall out of care, and what would have to exist for them not to.

That question generalises, and it is the reason this material belongs in a public-health chapter at all. Special-population psychiatry is not a set of exotic clinical entities; it is the ordinary service, examined at the points where its assumptions about address, identity, entitlement, language and freedom of movement quietly stop being true.

> In every special population the third party who controls access is the design problem, and the figures these populations generate describe the recognition system that produced them before they describe the population itself.

Prevention, economics and digital mental health

34 · Levels of prevention (primary, secondary, tertiary) applied to mental health

A prevention taxonomy is a routing device, and it earns its place only because it stops the same argument being made several times over. Community psychiatry is full of interventions that sound alike and act at completely different points: a public awareness campaign, a training programme for general doctors, a helpline, a restriction on access to a lethal method, a supported employment service. Placed on the prevention axes, each one declares whom it acts on and at what point in the course of illness it acts, and once that is declared the argument about it becomes tractable. That is the work this section does for the rest of the chapter: it states the mapping onto mental health and then routes each application to the topic that owns it, so that no application is explained twice. The definitions of the terms themselves, with their lineage and the caution against reading the axes as one, are taught in the Intellectual disability and autism

spectrum disorder notes. The machinery of screening, meaning the criteria a screening programme must satisfy and the biases that inflate its apparent benefit, belongs to the Research Methods, Biostatistics and Epidemiology notes. Neither is restated here.

34.1 What the taxonomy is for, and the two questions it asks

The prevention vocabulary exists because two entirely different questions can be asked of any preventive intervention, and answering only one of them produces confusion that looks like disagreement.

The first question is temporal: at what point in the natural history of the disorder does this intervention act? Before it exists, once it exists but before it has declared itself, or after it is established and the target is now disability rather than onset? That axis yields primary, secondary and tertiary prevention.

The second question is about the recipient: who is offered this intervention, and on what basis were they selected? Everybody in a population, a subgroup at raised risk, or an individual already showing early signs? That axis yields **universal**, **selective** and **indicated** prevention.

The axes are independent, and that independence is the entire reason both exist. An intervention has a position on each, and knowing one position tells you nothing reliable about the other. Reading them as a single ladder is a well-known error with its own exam trap, and both the definitions and that trap are taught in the Intellectual disability and autism spectrum disorder notes. What this section supplies is the mental-health mapping and the routing that follows from it.

MNEMONIC

Whom, When, What, Whether

The four questions that make a prevention claim assessable. Whom does it act on, and how were they selected. When in the course of the disorder does it act. What does it actually consist of, delivered by whom. And whether anybody measured the outcome it is supposed to change, in the population it was aimed at.

34.2 The temporal axis, mapped onto mental health

Mapping the temporal axis onto psychiatry is less tidy than mapping it onto infectious disease, and the untidiness is itself worth understanding rather than glossing.

Primary prevention in mental health acts on determinants and exposures before any disorder exists. In practice this means the material conditions and the social environment, most of which sit outside the health sector: household poverty, violence in the home, adverse experiences in childhood, alcohol availability, working conditions, and access to lethal means. The awkward feature is that almost none of these is a psychiatric intervention, and almost all of the effective levers belong to other ministries. That is not a reason to demote primary prevention; it is a reason to say plainly that a psychiatric service's primary-prevention role is largely advocacy, intersectoral work and the design of population-level restrictions, not clinical activity.

Secondary prevention acts once the disorder exists but before it has declared itself or done its damage, and its content in mental health is early detection followed by prompt effective treatment. This is where most of a health service's preventive effort actually sits, because the interval between onset and treatment in psychiatry is long and the harm accrues during it. Note the boundary carefully: the machinery of screening as a discipline, the criteria a screening programme must meet and the biases that make an unevaluated programme look successful, are taught in the Research Methods, Biostatistics and Epidemiology notes. The stage-by-stage design of a screening-to-treatment pathway, and the rule that a screen without a named destination is not a service, are worked end to end in the Perinatal/women's mental health and emergency psychiatry notes. What belongs here is only the placement of secondary prevention as a tier, and the mental-health examples of what is looked for and by whom.

Tertiary prevention acts after the disorder is established, and its target is disability, relapse and social exclusion rather than onset. In psychiatry this is the largest of the three limbs by volume of work, because the conditions that dominate a service are long-term and their principal harm is functional. Almost everything a rehabilitation service does sits here, and it is rarely called prevention, which is precisely why it loses arguments about resources to interventions that carry the word.

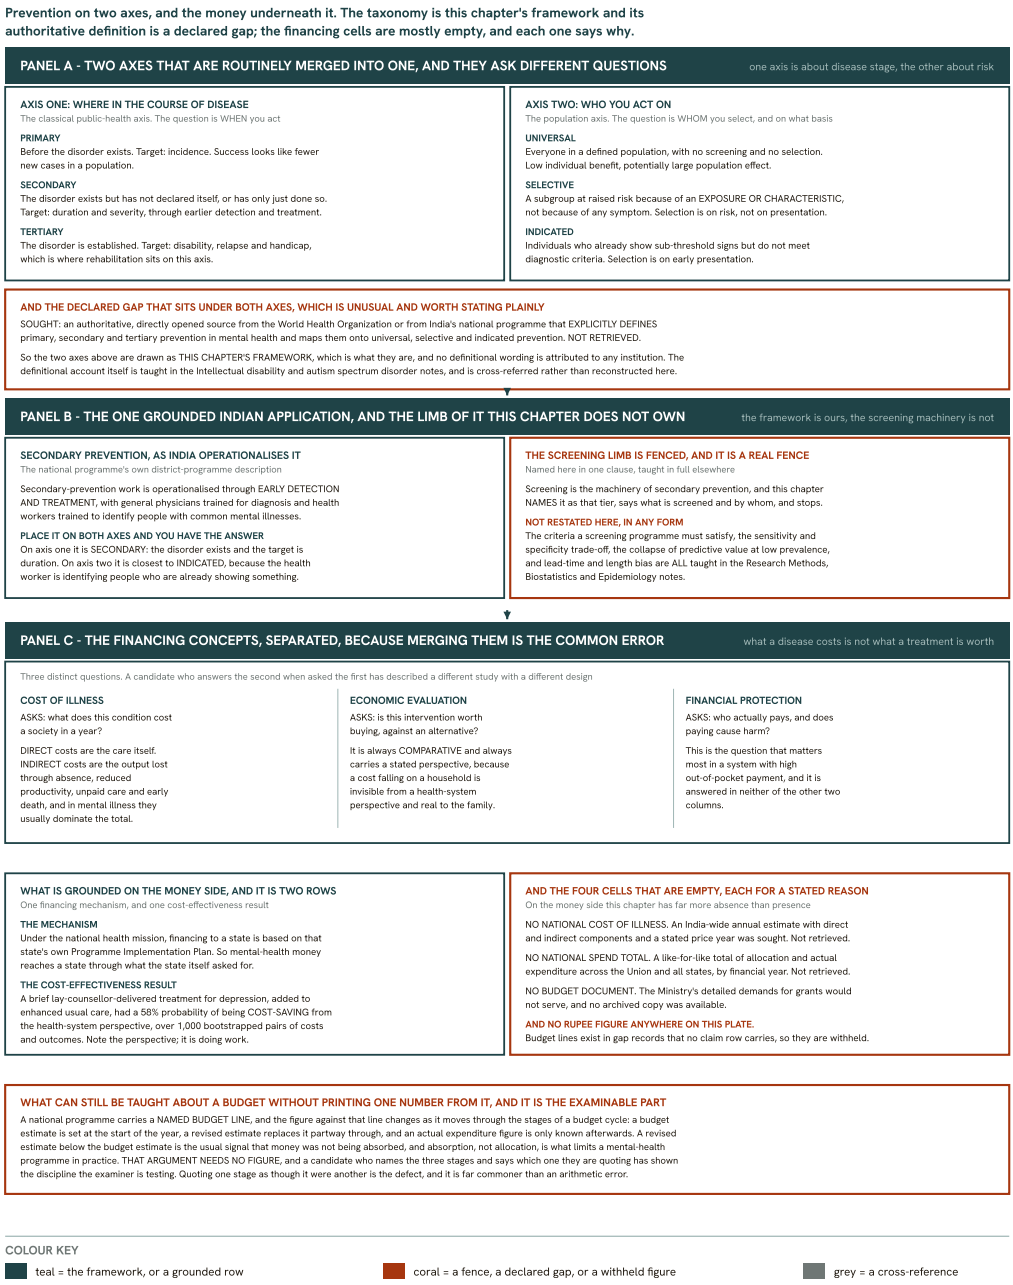

Fig 39.12 **Prevention on two axes, and the financing underneath, with the empty cells labelled.** The two axes ask different questions, disease stage against risk basis, and they are drawn as this chapter's framework because an authoritative source explicitly defining primary, secondary and tertiary prevention in mental health and mapping them onto universal, selective and indicated prevention was sought and not retrieved. The one grounded Indian application is secondary prevention operationalised as early detection and treatment through trained general physicians and identifying health workers; the screening machinery under it is fenced to the Research Methods, Biostatistics and Epidemiology notes. On financing, state money flows through the state's own Programme Implementation Plan, and a brief lay-counsellor-delivered treatment had a 58 per cent probability of being cost-saving from the health-system perspective across 1,000 bootstrapped pairs. No rupee figure appears: no national cost-of-illness estimate and no like-for-like national spend total were retrieved, and the budget lines that exist sit in gap records no claim row carries, so the budget argument is taught through its stages instead.

34.3 The recipient axis, and what it changes about delivery

The second axis is about selection, and its practical value is that it predicts the delivery problem before the intervention is designed. A universal intervention has no selection step at all, so it needs no case-finding apparatus and no consent to being identified as at risk, but it must be cheap per head because everybody receives it and it must be acceptable to people who will not benefit. A selective intervention requires a defensible basis for defining the subgroup, which means either a routinely available marker or a screening step, and it carries a labelling cost that the universal version does not. An indicated intervention requires individual identification, which is the most expensive selection of all and generates the largest ethical obligations, because a person identified as showing early signs is now known to the service and must be offered something.

The examinable consequence is that the cost profile inverts along this axis. Universal interventions have the lowest unit cost and the highest total cost. Indicated interventions have the highest unit cost and reach the fewest people, but concentrate the benefit where risk is highest. Neither is superior in principle, and a programme that has chosen one without stating why has usually chosen by convenience.

Whole population	**Raised-risk subgroup**	**Early signs, identified**	**Established disorder**
WHO A UNIVERSAL INTERVENTION IS OFFERED TO	WHO A SELECTIVE INTERVENTION IS OFFERED TO	WHO AN INDICATED INTERVENTION IS OFFERED TO	WHO SITS OUTSIDE PREVENTION ALTOGETHER

The fourth tile is there deliberately. People with an established disorder are not the recipients of prevention on the second axis at all; they are the recipients of treatment, and of tertiary prevention on the first axis. Keeping that tile in view is what stops a service describing its ordinary clinical work as prevention because the word attracts funding.

34.4 The routing table, which is what this section is for

Every substantial preventive activity in community psychiatry is taught somewhere, and the taxonomy's job is to say where. The table below is the chapter's routing device: it places each application on the axes and names where it is developed, so that the argument is made once, in full, in the right place.

APPLICATION	TEMPORAL TIER	RECIPIENT AXIS	WHERE IT IS DEVELOPED
Restricting access to lethal means	Primary	Universal	The means-restriction and gatekeeper material of these notes, with the population argument in the Somatic-symptom, sexual, impulse-control disorders and suicide notes
Responsible media practice on suicide	Primary	Universal	The means-restriction and gatekeeper material of these notes

APPLICATION	TEMPORAL TIER	RECIPIENT AXIS	WHERE IT IS DEVELOPED
Gatekeeper training for non-clinicians	Secondary	Selective, by role rather than by risk	The means-restriction and gatekeeper material of these notes
A national suicide prevention strategy as a whole	Spans all three	Spans all three	The national suicide prevention material of these notes; the three-tier grid worked through suicide exemplars is in the Somatic-symptom, sexual, impulse-control disorders and suicide notes
Anti-stigma work aimed at the general public	Primary, acting on a determinant of access	Universal	The anti-stigma intervention material of these notes
Mental health literacy and awareness campaigns	Primary and secondary, since recognition shortens delay	Universal	The mental health literacy material of these notes
School-based programmes	Primary, with an indicated limb inside them	All three, in one setting	The school and adolescent material of these notes; the Indian platforms are in the Child psychiatry: assessment, treatment, services and protection notes
Workplace programmes	Primary through tertiary, depending on the component	All three	The workplace material of these notes
Early detection by trained general doctors	Secondary	Indicated, on presentation	This section, and the primary-care integration material of these notes
Screening pathway design in one population	Secondary	Universal or selective, by design	The Perinatal/women's mental health and emergency psychiatry notes
The methodology of screening and its biases	Applies to secondary	Not applicable	The Research Methods, Biostatistics and Epidemiology notes
Rehabilitation, supported employment and community services	Tertiary	Established disorder, so outside the recipient axis	The rehabilitation and community-care material of these notes

RULE **Placing an intervention on the two axes tells you what evidence it needs and what denominator it must report against; it tells you nothing about whether it works.** A tier is a description, not a recommendation. Every row above still has to be argued on its own evidence in the place where it is developed, and the taxonomy's only claim is that the argument belongs in one place.

34.5 How the Indian programme operationalises the secondary tier

The abstraction becomes concrete at exactly one point in the Indian system, and it is worth stating precisely because it is the answer to the most likely viva question on this topic. In **India's National Mental Health Programme**, the secondary tier is operationalised as detecting illness early and treating it, with general physicians trained to diagnose and treat and health workers trained to identify.

Read the structure of that arrangement, because it explains the whole design. The Indian secondary tier is delivered not by an instrument but by a workforce: the detection step is a trained general doctor or health worker recognising a presentation in the course of ordinary contact, and the treatment step follows immediately from the same training. There is no separate screening programme with an invited population and a defined interval; there is an opportunistic detection system riding on existing clinical contact. That is a defensible design in a system with limited specialist capacity, and it has a specific consequence: the capacity of the secondary tier is set by training throughput and by supervision, not by procurement.

IN INDIA

Because the national programme puts its secondary tier in the hands of trained general physicians and identifying health workers rather than in a screening apparatus, a district that wants to strengthen this tier should be counting how many of its general doctors and frontline workers have actually been trained, how recently, and whether anyone supervises them afterwards. Buying or adopting an identification tool changes nothing if the person holding it has no training and no route for a positive finding. Training throughput and supervision are the levers this design exposes, and they are the ones a district can actually pull.

PITFALL

Treating the training as complete once it has been delivered. Detection skill in non-specialists decays without reinforcement, and the trained doctor is transferred, promoted or retires while the programme's records continue to count them. A district reporting cumulative numbers trained is reporting a historical total, not a present capacity, and the gap between those two quantities widens every year the programme runs.

34.6 Tertiary prevention, and why it loses the argument it should win

The largest preventable burden in psychiatry is disability in people who already have a diagnosis, and almost nobody calls the work that reduces it prevention. Relapse prevention, continuity of medication, family support, supported housing, supported employment and the

maintenance of social role are all tertiary prevention, and each prevents a specific, countable harm.

- A readmission that did not happen, which is the outcome most services already record and least often claim.
- A job lost during a relapse, and with it the income and the routine that supported recovery.
- A tenancy or a place in the family home lost while somebody was too unwell to hold it.
- A relationship that ended because nobody supported the family through an episode.
- A contact with the criminal justice system that followed from untreated illness rather than from anything else.

Each item on that list is countable, is already recorded somewhere, and has a cost attached to it in some department's accounts.

The reason this limb is systematically under-argued is partly linguistic and partly budgetary. Linguistically, prevention is heard as meaning stopping something from starting, so activity in people who are already ill is coded as treatment and competes for treatment budgets rather than for prevention ones. Budgetarily, the benefits appear as costs that did not occur, in a budget line different from the one that paid for the service, and often in a different department altogether. A supported housing placement that prevents several admissions saves money in the hospital budget and spends it in the community one, so the service that produced the saving does not receive it.

The counter-argument a candidate should be able to make is that the tertiary tier is the only one whose effect can be demonstrated in a defined denominator over a short period, because the population is already enumerated and the outcomes are already recorded. Where a primary-prevention claim requires a large population and a long follow-up, a tertiary-prevention claim can be tested on a service's own caseload against its own readmission record. The economics of that argument, and the methods for making it, are developed in the mental health economics and financing material of these notes.

34.7 What this chapter cannot establish, and how to answer without it

One thing an authoritative section on this topic would ordinarily supply is declared here as a gap. No authoritative source could be opened that explicitly defines primary, secondary and tertiary prevention in mental health and maps them onto the universal, selective and indicated scheme in a single statement of the taxonomy. What was sought was exactly that: an international agency publication on the prevention of mental disorders, several of its repository records, secondary reproductions of the taxonomy in the indexed literature, and Indian operational guidance for mental health at the primary-care level. The agency records returned access errors, the literature routes returned verification pages rather than article text, and the Indian operational documents supplied promotion, detection, screening and referral examples without labelling the full taxonomy.

The honest consequence is stated rather than concealed: the taxonomy is taught here as the standard framework it is, its definitions are cross-referred to the chapter that carries them, and no issuing body or year is attached to it in this section. A candidate asked to attribute the framework should say which chapter of their own reading carries the definitions and should not attach an agency and a date from memory, because a framework misattributed to a body that did not issue it is a discrediting error in an otherwise correct answer.

TRAP **Treating the tier label as though it were evidence of effect.** Candidates write that an activity is primary prevention and then proceed as though its benefit had been established by the classification. It has not: the tier states when and on whom the intervention acts, and every claim about whether it works is a separate claim requiring its own evidence, its own population and its own outcome. The most common form of this error is asserting that a public awareness activity prevents disorder, when the evidence available concerns knowledge or attitudes and the outcome asserted is incidence.

The two axes answer different questions, when and to whom, and the taxonomy's job in a community psychiatry chapter is to route each application to the place where its evidence is argued in full.

35 · Mental health economics: cost of illness, cost-effectiveness and financing

The argument about what mental health should cost is made whether or not psychiatrists take part in it, and it is settled by people who read budget documents rather than case notes. That is the practical reason this material is examinable: a clinician who cannot say what a service costs, what it saves, who pays and where the money enters the system is unable to argue for it in the only language the argument is conducted in. The topic divides cleanly into a small number of questions that are frequently run together and should not be. What does this illness cost, and to whom. Is this intervention worth its cost compared with the alternative. How does money actually reach a mental-health service. And what happens between an allocation and an expenditure. The classic economic argument for funding a general-hospital liaison service, with its historical figures and the observation that Indian cost-effectiveness evidence for such services is what is missing, is already made in the Consultation-liaison, geriatric and transcultural psychiatry notes and is not repeated or re-declared here. Insurance benefit design, parity and the regulator's mandate belong to the insurance and financial-protection material of these notes.

35.1 Cost of illness, and what the total is and is not

A **cost of illness** study answers a descriptive question: what does this condition consume, across a defined population, over a defined period. It is a burden statement, not an evaluation, and it makes no comparison between courses of action. Its components separate as follows, and the separation matters because different components fall on different payers.

COMPONENT	WHAT IT COUNTS	WHO USUALLY BEARS IT
Direct medical	Consultations, medicines, investigations, admissions, procedures	The health system, the household, or an insurer, in a proportion that varies by country
Direct non-medical	Transport to care, food and lodging for an accompanying relative, informal payments	The household, almost entirely, and it is routinely omitted from health-system costings
Indirect	Lost work and productivity of the patient, and of family members providing care	The household and the wider economy; the largest component for most mental disorders
Intangible	Pain, distress and loss of quality of life not otherwise captured	The patient and family; usually acknowledged and not costed

Two features of a cost of illness total decide whether it can be used at all. The first is the **perspective**: a total computed from the health system's point of view counts what the health system spends, and a total computed from a societal perspective adds the household's costs and the lost production. These give very different numbers for the same disease, and in mental illness the difference is unusually large because the indirect component dominates. A figure quoted without its perspective is uninterpretable.

The second is the counterfactual, and this is where the figure is most often misused. A cost of illness total is not a sum that could be saved. It is what the condition currently consumes, and no intervention removes all of it; some of it would be consumed by whatever the person had instead, and some of it is the cost of the treatment that keeps them well. The only defensible use of the total is to establish scale and to argue that a problem consuming this much deserves attention, and the only way to establish a saving is a comparison between courses of action, which is a different study.

TRAP **Presenting a cost of illness figure as the money a proposed programme would save.** The two answer different questions and the first cannot substitute for the second. A burden total has no comparator, so it cannot support any claim about a difference; and treating the whole burden as recoverable implies an intervention that abolishes the disorder at no cost, which nothing does. If the question is whether a programme is worth funding, the answer requires an economic evaluation and not a burden estimate.

35.2 What India's cost of illness figure is, and why it is not printed here

An examiner may reasonably expect an Indian national figure at this point, and the honest answer is that this chapter does not have one. What was sought was an official India-wide annual cost of illness estimate for mental disorders, with its direct and indirect components separated and a stated price or reference year. The national survey's summary report was consulted, the detailed report's official address returned an error, the ministry's mental-health and programme pages were searched, and indexed-literature and international-agency routes were tried for an Indian economic estimate. No official national estimate meeting that description was obtained.

The absence is worth teaching rather than concealing, and it is not a small one. Without an official national burden estimate, an Indian argument for mental-health investment has to be assembled from international burden estimates, from disability measures whose derivation belongs to the burden material of these notes, and from individual studies with local populations. Each of those is defensible and none of them is what a finance ministry asks for, which is one figure attributable to a national body with a stated year. A candidate who names the construct, says the national estimate is not established, and explains what the argument has to be built from instead has given a better answer than one who quotes a figure whose issuing body they cannot name.

35.3 Economic evaluation, and the four forms it takes

An **economic evaluation** always compares at least two courses of action on both their costs and their consequences. If it compares costs only, it is a costing exercise. If it compares consequences only, it is a clinical study. The forms differ in one respect only, which is how the consequence is valued, and that difference determines what question each can answer.

FORM	HOW THE OUTCOME IS VALUED	THE QUESTION IT ANSWERS	ITS LIMITATION
Cost-minimisation	Not valued; outcomes are assumed equivalent	Which of two equally effective options is cheaper	The equivalence assumption is rarely justified and is often asserted rather than shown
Cost-effectiveness	In natural clinical units, such as symptom-free time or cases detected	What it costs to buy one more unit of this particular outcome	Cannot compare across conditions, because the units differ
Cost-utility	In a combined measure of length and quality of life	What it costs to buy a comparable unit of health, whatever the condition	Depends on how the quality weights were derived and in which population
Cost-benefit	In money, including the health outcome itself	Whether total benefits exceed total costs, in one currency	Requires putting a money value on health, which is contested and rarely done well

The practical significance for mental health is that the middle two dominate, and the choice between them is a choice about who the result must persuade. A **cost-effectiveness** result in natural units speaks to a psychiatrist and to a programme manager who already accept that the condition matters. A cost-utility result is the one that lets mental health compete for a share of a health budget against cardiology and oncology, because it converts the outcome into a currency the whole budget uses. A specialty that only ever produces results in its own units is arguing where nobody else is listening.

35.4 Reading a cost-effectiveness result without being deceived by it

A cost-effectiveness figure carries a set of design choices, each of which can move it substantially, and each of which is a legitimate examination question.

- The perspective, again: a result from the health system's point of view ignores what the household paid to attend, and interventions that shift cost onto families look efficient from inside the system.
- The comparator: an intervention compared with nothing will almost always look good, and the informative comparison is with what the service would otherwise have done.
- The time horizon: benefits that accrue late are missed by a short study, and mental-health interventions with relapse-prevention effects are systematically undervalued by short follow-up.
- Discounting: costs and benefits arriving at different times are not equivalent, and the rate chosen affects any intervention whose costs are immediate and whose benefits are later, which describes most of prevention.
- Uncertainty: a single point estimate hides the range of plausible results, so a defensible evaluation reports how likely the conclusion is to hold rather than asserting it.

An Indian result illustrates the last of these particularly well. In a trial-based economic evaluation conducted in primary health centres in Goa, the programme under evaluation, identified in the trial by the acronym **HAP**, delivered alongside enhanced usual care, had a **58 per cent** chance of being cost-saving from a health system perspective.

Notice the form of that statement, because the form is the teaching. It is not a claim that the programme saved money; it is a statement of how often the intervention came out cheaper across repeated resampling of the paired cost and outcome data. A probability just above the halfway mark is a genuinely useful result and an honest one: it says the intervention is about as likely as not to pay for itself in health-system costs, while delivering its clinical benefit. Reported as a point claim that the programme is cost-saving, the same analysis would be a misrepresentation, and reported as a failure to demonstrate saving it would be a different one.

58 per cent	Not established	Not retrieved	Withheld
CHANCE OF BEING COST-SAVING, HEALTH-SYSTEM PERSPECTIVE, ONE GOA PRIMARY-CARE TRIAL	OFFICIAL INDIA-WIDE ANNUAL COST OF ILLNESS FOR MENTAL DISORDERS	LIKE-FOR-LIKE NATIONAL ALLOCATION AGAINST ACTUAL EXPENDITURE	SCHEME-LEVEL BUDGET LINES NO CLAIM ROW HERE ASSERTS

RULE **A cost or cost-effectiveness figure means nothing without its perspective, its comparator and its time horizon, and a probability of being cost-saving is not a statement that it saved money.** Those four attributes are the whole of the appraisal, and a figure quoted without them is the economic equivalent of a prevalence quoted without its population.

35.5 How money actually reaches a mental-health service

Financing mechanisms are the least glamorous part of this topic and the part that most determines what a district can do. The generic mechanisms are few. General taxation funds a service directly from government revenue. Social or mandatory health insurance funds it from contributions. Voluntary or private insurance funds it from premiums. Out-of-pocket payment funds it from the household at the point of use. External or donor financing funds it from outside

the country. Most systems, India's included, use several at once, and the mix determines who is protected and who is not.

What matters clinically is that these mechanisms differ in when the money is paid relative to when the illness occurs. Pre-paid mechanisms, whether tax or insurance, spread the cost across a population and across time. Out-of-pocket payment concentrates it on the household at the moment it is least able to bear it, which for a chronic mental illness means repeatedly, over years, in a family whose earning capacity the illness has already reduced. That is the whole argument for financial protection, and it is an argument about the timing of payment rather than about its total.

The Indian route by which programme money reaches a state has a specific and consequential shape. Under the **National Health Mission**, money reaches a state against that state's own Programme Implementation Plan. The plan is the state's own proposal of what it intends to do, and the money follows the proposal.

IN INDIA

Because national mission money reaches a state against its own Programme Implementation Plan, the operative lever for anyone trying to fund a mental-health activity in a district is what gets written into that plan before the financial year, not what is argued for afterwards. An activity nobody proposed is an activity nobody funded, and a clinician who wants a post, a training programme or a drug budget has a specific and dated point of entry: the plan-writing cycle. This is the single most actionable piece of financing knowledge in the topic, and it is administrative rather than economic.

35.6 Allocation against expenditure, and the gap between them

A budget line is a permission to spend, not a record of spending, and in mental health the two diverge more than in most programmes. The reasons are structural and are worth knowing because they are what an examiner is testing when they ask why increased allocation has not produced increased service. Money allocated to posts cannot be spent if the posts cannot be recruited to, and specialist mental-health posts are among the hardest to fill. Money allocated late in a financial year cannot be spent before it lapses. Money allocated for capital cannot be moved to recurring costs even when recurring costs are the constraint. And money released against a plan that was written optimistically returns unspent, which then becomes an argument for allocating less next time.

That last mechanism is the important one and it is self-reinforcing. Under-spending is read by a finance authority as evidence of low absorptive capacity, which justifies a smaller allocation, which reduces the capacity further. Breaking that loop requires spending on the things that can actually be delivered, which usually means training, supervision and recurring supply rather than infrastructure, and it requires the plan to be written by somebody who knows what the district can absorb.

PITFALL

Quoting an allocation figure as though it described a service. An allocation is what a document says may be spent; it is not what was released, not what was spent, and not what reached a patient. The chain from allocation to release to expenditure to utilisation loses value at each join, and a claim about service delivery supported only by a budget number has skipped every one of them.

35.7 The financing figures this chapter deliberately does not print

This section is where a chapter is most tempted to supply remembered numbers, and several that would ordinarily appear are declared here as gaps instead. Each is a real construct with a real answer somewhere; none is established by anything this chapter could open and verify, and a figure written from recollection into a financing argument is the kind of error that survives into somebody's answer script.

No like-for-like national total of mental-health allocation and actual expenditure, across the union and all states and union territories with each financial year identified, was obtained. Union budget documents, expenditure documents, the ministry's annual report, the national programme's own page, state plan and record-of-proceedings indexes, and the programme's framework and plan guidelines were all approached. The pieces exist in different documents on different bases and were not reconcilable into one comparable total.

The national programme's own line in the detailed demands for grants could not be reached: the address that would carry it returns an error after a domain migration, a repair attempt returned the same dead address, and no archived snapshot was available. The scheme-level budget lines for the national tele-mental-health programme, across recent actual, budget and revised estimates, and the plan-period allocations to the district programme, are likewise not printed here: those figures exist in budget documents but no claim row in this chapter's ledger asserts them, so they are withheld deliberately rather than reconstructed.

The teaching that survives all of that is the discipline itself, and it is the discipline the whole chapter is built on. An Indian financing figure is a fact only when it carries the document that issued it, the financial year it refers to, whether it is an allocation, a revised estimate or an actual expenditure, and what it is a proportion of. Those four attributes are exactly what makes budget figures so easy to misquote: the same programme in the same year has several different correct numbers attached to it, and quoting the wrong one confidently is indistinguishable, to a reader, from quoting an invented one.

35.8 Financial protection, and what a household actually pays

The last question is what the illness costs the family, and it is the one a clinician meets most directly. Out-of-pocket payment for a chronic mental illness is not a single event but a stream: repeated medicine purchases, repeated travel, repeated days of lost earning for the patient and for whoever accompanies them, and, where the public service is unavailable or unacceptable, private consultation fees. The stream continues during the periods when the person is well, which is exactly when a family is most likely to stop paying it, and non-adherence for cost reasons is often invisible to a clinician who never asks about the transport fare.

The national survey did produce a household expenditure finding for care of a person with a mental disorder, together with an observation about the absence of state or insurance coverage for most families. That finding is a declared gap in this chapter and its figure is not printed, because no claim row here asserts it. The construct is named without its rupee amount, and the reasoning around it stands on its own: an expenditure of this kind, incurred monthly and indefinitely by a household whose earning capacity the illness has reduced, is a financial-protection failure whatever its exact size.

The specific Indian mechanisms of financial protection, meaning the public insurance scheme, the parity requirement for mental illness and the regulator's mandate, are taught in the insurance and financial-protection material of these notes and are not restated here. What belongs to this section is the economic point behind them: financial protection is achieved by moving payment from the point of use to a pre-paid pool, and any scheme is judged on whether the household's payment at the point of use actually falls, not on whether a benefit exists on paper.

> A cost of illness total states scale and can never state a saving; only an economic evaluation with a named perspective, comparator and time horizon can do that, and in India the money reaches a service through the state's own plan.

36 · Digital mental health interventions and apps in the Indian context

The interesting question about a mental-health app in India is almost never whether it works, and almost always whether anybody who needs it can reach it, will keep using it, and has somebody at the other end who acts on what it produces. That is the difference between the product question and the system question, and it is the boundary this section works to. Whether a given digital therapeutic has established efficacy, what trial standards it must meet, how software is classified for regulatory purposes and what it means for such a product to be prescribable are taught in the Recent advances and landmark studies notes. What belongs here is the Indian implementation picture: access and the divide inside it, adoption and adherence, integration with an existing service, equity, governance and programme monitoring. Remote consultation between a patient and a clinician is a service model in its own right and is taught in the telepsychiatry material of these notes; this section covers what the health system does with software rather than what it does with a video link.

36.1 A functional taxonomy, because the technology label explains nothing

Grouping digital tools by their platform, meaning apps against websites against messaging, tells you nothing useful. Grouping them by what function they perform in a service tells you who has to act, what has to exist behind them, and how they fail.

FUNCTION	WHAT IT DOES	WHO MUST ACT FOR IT TO MATTER	HOW IT CHARACTERISTICALLY FAILS
Information and psychoeducation	Explains a condition, a treatment or a service to a public or a patient	Nobody, in the short term; it is a one-way transfer	Written in a register and a language its intended audience does not use
Self-guided intervention	Delivers a structured therapeutic programme with no clinician involved	The user alone, repeatedly, without prompting	Attrition, which is very high without human contact
Guided or blended intervention	Delivers the same programme with a person supporting adherence	A supporter, who need not be a specialist	The support component is dropped first when the budget tightens
Clinician-facing decision and workflow support	Prompts assessment, records outcomes, flags who is not improving	The clinician, and whoever governs the workflow	Added to a workload with no time released, so it is bypassed
Screening and case-finding by a frontline worker	Structures an enquiry the worker is already making	The worker, and the service receiving the positives	Positives are generated with no destination to send them to
Monitoring and follow-up	Collects symptoms, adherence or attendance between contacts	Somebody who reads it and responds	Data accumulate that nobody has been made responsible for

The fourth column is the section in miniature. Every failure listed is organisational rather than technical, and none of them is fixed by a better application. That is why an Indian digital mental-health question is a service question.

RULE **A digital tool is worth what the response behind it is worth.** Software that identifies distress, records a symptom score or flags deterioration changes nothing unless a named person is obliged to act on the output within a defined period. Where no such person exists, the tool has converted a clinical problem into a data problem.

36.2 Access, and the divide inside the population that most needs the service

The **digital divide** is the reason this matters. Digital delivery is routinely presented as an access solution, and it can be, but only against an explicit account of who cannot use it. The entry requirements are specific and each is distributed unevenly in the same direction as the underlying disadvantage.

- A device that the person controls, rather than a household device controlled by somebody else.
- Connectivity that is reliable enough and cheap enough for repeated rather than occasional use.
- The language of the interface, which for a person in distress must be the language they think in and not merely one they can read.

- Enough literacy, and enough familiarity with the conventions of an interface, to navigate it without help.
- Privacy at the moment of use, which is the requirement most often forgotten and the one hardest to meet in a crowded household.

The shared-device problem deserves separate emphasis because it inverts the usual assumption. Where a phone is shared within a household, an application on it is visible to whoever else uses it, and a browsing history, a notification or an installed icon can disclose a person's help-seeking to the very people they may need to keep it from. For a woman in a household where help-seeking is contested, and for an adolescent, a digital route can be less private than a clinic visit rather than more. A service that assumes digital equals confidential has assumed the opposite of what may be true.

> **PITFALL**
>
> Building in one language and adding others later. Language is treated as a translation task to be done after the product works, so the pilot runs in English or in the state's dominant language, the evaluation reports on the population that could use it, and the populations excluded never appear in the denominator. Because the excluded groups are also the underserved ones, the programme's own evaluation will report success while the access gap it was built to close is unchanged.

36.3 The Indian evidence, and what it points to

The strongest Indian signal for digital mental health does not come from a consumer product but from a multifaceted intervention delivered inside a rural primary-care system. In rural primary-health-centre clusters in Haryana and Andhra Pradesh, among adults at high risk of depression or self-harm, those who received the intervention had lower depression scores than those receiving usual care, and nearly every secondary outcome moved in the same direction. The outcomes examined alongside depression included anxiety, remission, access to treatment, knowledge, attitudes, stigma and intended help-seeking.

Two features of that result are worth extracting, because they are what an Indian answer should be built on. The first is that the digital component sat inside a service rather than beside it: the technology supported frontline health workers and primary-care clinicians who were already in contact with the population, which means the entry requirements listed above were largely met by the service and not by the patient. The second is the breadth of the outcome set. An intervention that moves knowledge, attitudes, stigma and intended help-seeking as well as symptoms is acting on the pathway to care and not only on the illness, which is the correct ambition for a population intervention and is not something a standalone self-guided product is designed to do.

IN INDIA

Because the Indian evidence that has actually moved depression scores comes from an intervention delivered through rural primary-care clusters, associated with lower depression scores than usual care, the practical decision for a district is to treat a digital tool as a component bolted into an existing pathway with named workers behind it, not as a service that can be procured and pointed at a population. The corollary is a procurement rule: before adopting any tool, name the worker who will use it, the time released for them to do so, and the clinician who receives what it produces. A tool adopted without those three has been bought rather than implemented.

36.4 Adoption and adherence, which are separate problems

Digital interventions have a characteristic and well-described failure curve, and it has a shape that no other intervention type shares. **Uptake** is easy and cheap, because installing something costs the user almost nothing. **Continued use** collapses quickly, because stopping also costs almost nothing. The result is that the population who complete a self-guided programme is a small and highly selected subset of the population who started it, and it is selected for exactly the characteristics that predict good outcome anyway.

The single most reliable modifier of that curve is human contact. A brief, scheduled contact from a person, who need not be a mental-health specialist and need not deliver any therapy, substantially changes the proportion who continue. That is the entire logic of guided digital intervention, and it also explains why the guided version costs more than the self-guided one and is worth it: the support is not an accessory to the software, it is the component that makes the software reach anybody.

MNEMONIC

Access, Adoption, Adherence, Action

The four gates a digital intervention has to pass, each with its own denominator and its own failure. Who could reach it. Who started it. Who kept going. And who did something with what it produced. A programme reporting only the second gate has reported the easiest number it has.

Who could reach it	Who started	Who continued	Who was acted on
ACCESS, DENOMINATOR IS THE INTENDED POPULATION	ADOPTION, DENOMINATOR IS THOSE WHO COULD REACH IT	ADHERENCE, DENOMINATOR IS THOSE WHO STARTED	ACTION, DENOMINATOR IS THOSE WHO PRODUCED A SIGNAL

36.5 Integration, or why an application is not a service

An application becomes part of a health service at a small number of specific joins, and naming them is the most useful practical content in this topic. Who introduces the tool to the patient, and at which contact. Whether what the tool records enters the clinical record or sits in a separate system nobody opens. Who is responsible for a concerning response, within what period, and by what route. What happens when the person stops using it, since disengagement from a monitoring tool is itself clinical information. And who supports the user when the tool does not work, which in practice is whoever they saw last.

Safety escalation is the join with the highest stakes and the one most often unspecified. A tool that asks about self-harm will receive positive answers, at any hour, from people whose location and identity it may not know. A programme that has not decided in advance what happens then has built a mechanism for collecting disclosures it cannot respond to. The decision is not primarily technical: it is about who is on duty, what they are permitted to do, and what the local escalation route is.

36.6 Governance, data and the questions an Indian programme has to answer for itself

Digital mental-health data are among the most sensitive categories of personal information, and the governance questions are concrete rather than abstract. Where are the data stored and under whose control. Who may access them, and can an employer, an insurer or a family member obtain them. What was the person actually told, and was consent obtained in a language and a form they understood rather than by scrolling past a screen. What happens to the data if the provider is acquired, changes its terms, or closes. And who is accountable when the tool gives advice that turns out to be wrong.

This chapter carries no Indian instrument that settles those questions for mental-health applications, and none is attributed here. That absence should be stated as such rather than filled: a candidate who names the questions, says that a specific national framework for evaluating, endorsing or governing mental-health applications is not something they can attribute, and points to the chapter that carries the regulatory classification of software has answered better than one who names a framework from recollection. The regulatory and product-classification material sits in the Recent advances and landmark studies notes.

One governance point can be made without any instrument, because it follows from the service logic already established. A public programme that recommends a third-party application to a population has taken on responsibility for it, and has done so without any of the assurance machinery it would apply to a medicine or a device. That is a decision worth making explicitly rather than by default, and the minimum discipline is to know who evaluated the tool, against what, and who reviews that judgement when the product changes.

36.7 Monitoring a digital programme, and the measures that flatter it

Digital programmes generate more data about themselves than any other kind of service, and almost all of it measures the wrong thing. Downloads, registrations, page views, sessions and average session duration are all easy to collect, all report on activity, and none has the intended population in its denominator. A programme reporting them is reporting the traffic its own promotion generated.

The measures that answer the question are the four gates named above, each reported against its own denominator, plus the clinical outcome in the population reached. Two further measures are worth insisting on because they are the ones that reveal an equity failure. First, the composition of the reached population compared with the intended one, broken down at least by sex, by rural or urban residence and by language, since a programme can look successful while serving a demographic that was never the target. Second, the proportion of signals generated that received

a response within the intended period, which is the measure that distinguishes a service from a data-collection exercise.

TRAP **Quoting downloads or registrations as evidence of a digital mental-health programme's reach.** A download is an installation event with no denominator, no population and no clinical content. It can be produced by advertising alone, it counts devices rather than people, and it says nothing about whether the application was opened twice. The reach question requires the intended population as a denominator, and the impact question requires an outcome measured in the people who actually used it.

36.8 What this section does not have, and how to answer without it

The figures a resident is most likely to be asked for here are the ones this chapter cannot supply, and the discipline of saying so is worth as much as the figures would be. No official national Indian figure for the reach, uptake or effectiveness of any mental-health application is carried here, and none is invented. No national count of Indian mental-health applications, of their users, or of their clinical outcomes is available to this chapter. No Indian figure for device ownership, connectivity or private access among people with mental illness is held either, which is why the access argument above is made structurally rather than quantified.

Nor is any prevalence figure supplied for online harms among Indian school-going children and adolescents. That figure is frequently quoted, the populations behind the various circulating versions differ, and a figure measured in one country's schoolchildren does not become an Indian figure by being applied to Indian ones. A service designing a response to online harm has to do so without knowing the size of the problem, which is uncomfortable and is the actual position.

There is a further consequence of that position which is worth drawing out, because it is the one a service actually has to act on. Where the size of a problem is unknown, a service cannot size its response to the problem, so it must size the response to what it can sustain and then measure what it meets. That is a different planning logic from the one used for a quantified problem, and it puts the emphasis on building a route that can absorb whatever arrives rather than on estimating demand in advance. Applied to online harm among young people it means an accessible, non-stigmatising point of contact and a workforce trained to receive the presentation, rather than a campaign scaled to a prevalence nobody has established.

What remains, and it is the durable part, is the framework: a digital intervention is characterised by its function rather than its platform, is limited first by access and then by adherence, is worth what the response behind it is worth, and is evaluated on the intended population as a denominator rather than on the traffic it generated. Those propositions hold whichever product is in front of you, and they are what an examiner is testing when they ask about digital mental health in the Indian context.

Access, adoption, adherence and action are separate gates with separate denominators, and the Indian evidence that has moved outcomes came from a tool embedded in a primary-care service rather than from a product handed to a population.

37 · Social determinants of mental health and global mental health movement

Almost every strong predictor of mental ill health in a population is something a psychiatrist cannot prescribe. Income, education, housing, safety at home, work, and the accumulated experience of childhood do more to shape the distribution of disorder in a district than the availability of any treatment does, and they are administered by departments the health service does not control. That is the uncomfortable structure of this topic, and it is what makes it a public-health subject rather than an aetiological one. The examinable content is not a list of hardships; it is the argument that follows from the list, which runs: the causes are largely social, the levers are largely outside health, therefore the health system's role includes evidence, advocacy and intersectoral work, and none of that reduces its obligation to treat the people in front of it. Migration and ethnicity taught as a clinical and epidemiological topic, with its mechanisms, its acculturation framework and its risk estimates, belongs to the Consultation-liaison, geriatric and transcultural psychiatry notes; migration appears here only as one determinant among others, without any of its figures.

37.1 What a social determinant is, and the life-course claim

A **social determinant** is a condition of life that influences health and is itself produced by how a society distributes resources, status and power. Two properties distinguish a determinant from an ordinary risk factor. It is structurally produced, so it is patterned across a population rather than randomly distributed. And it is modifiable by policy rather than by clinical action, which is precisely why it belongs in a chapter about programmes.

The organising proposition for the whole topic is that mental health, and much of the common mental disorder a population carries, is patterned by **the environments people live through**, meaning the social, the economic and the physical together, acting at different stages of a life rather than at one. Every clause of that proposition is doing work. It covers mental health and not only disorder, so the argument is about the distribution of wellbeing and not merely about caseness. It names three kinds of environment, so the determinants are not reducible to income. And the life-course clause is the decisive one: exposures act at different stages, they accumulate, and an exposure in early life can express itself decades later, which means the timing of an intervention matters as much as its content.

MNEMONIC

Cause, Course, Consequence, Contact

The four routes by which a social determinant reaches mental health, and they are separate claims requiring separate evidence. It can raise the chance that disorder occurs. It can worsen the course once it has. It can amplify the social damage the disorder does. And it can obstruct contact with a service, which is the access limb and belongs with the treatment gap material of these notes.

37.2 The determinants, grouped by the lever that would move them

Listing determinants is easy and unilluminating. Grouping them by which sector holds the lever converts the list into a plan, and it is the form an examiner rewards.

DETERMINANT	HOW IT ACTS ON MENTAL HEALTH	WHICH SECTOR HOLDS THE LEVER
Poverty and income insecurity	Chronic stress, debt, inability to sustain treatment, and constrained choice at every decision point	Finance, social protection and employment
Education	Shapes literacy, earning capacity and the ability to navigate services across the whole life course	Education
Adverse experience in childhood	Acts early, accumulates, and expresses itself long after the exposure has ended	Child protection, education, police and social welfare
Violence in the home and gender inequality	Direct exposure, and constrained ability to leave, to earn or to seek help independently	Home affairs, law, and women and child development
Housing and the physical environment	Crowding, insecurity of tenure, noise, heat, sanitation and the absence of private space	Housing, urban development and local government
Work and its conditions	Demand, control, security and reward, and the loss of all of them in unemployment	Labour, and employers
Alcohol and substance availability	Price and access shape consumption, and consumption shapes harm at population scale	Excise, revenue and law enforcement
Discrimination and social exclusion	Chronic exposure to devaluation, and reduced access to every other resource above	Law, education and every service that receives the public

The third column is the point of the table. Not one of these levers sits inside a mental-health budget, and most sit outside health altogether. A district mental-health plan that lists determinants without naming the department that owns each one has produced a description; a plan that names them has produced an addressee.

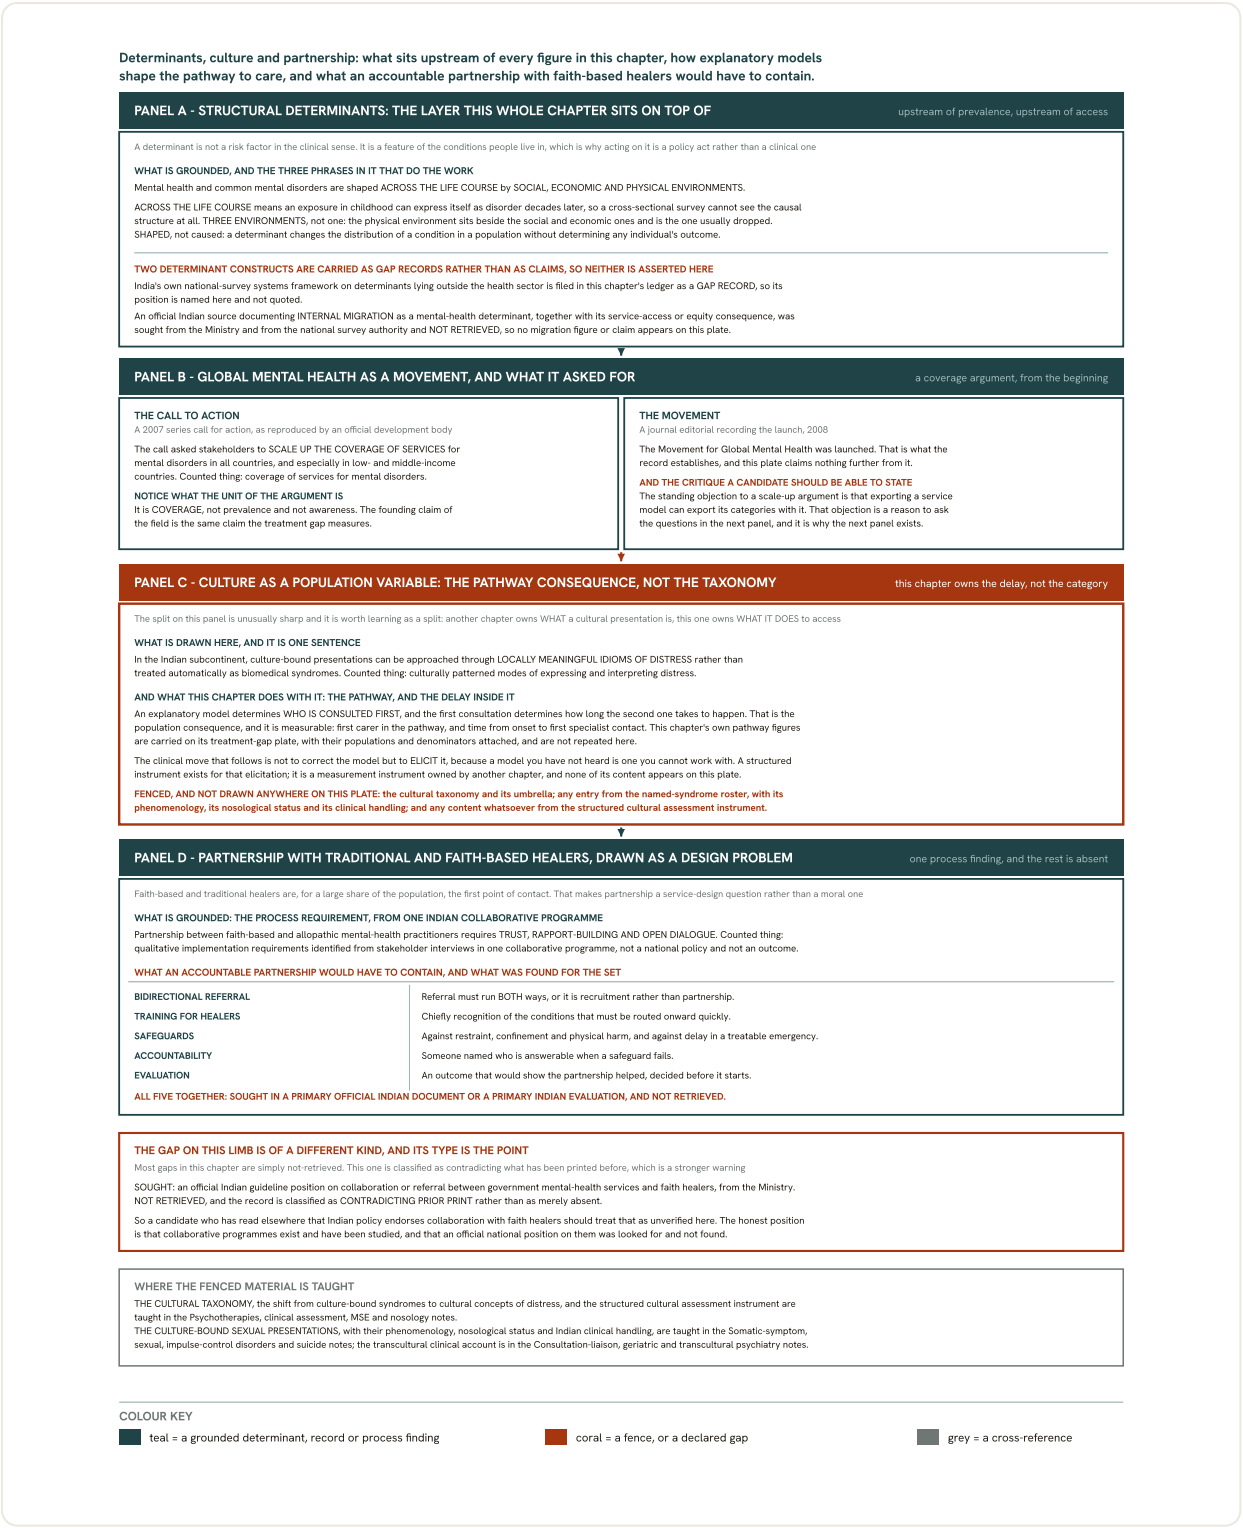

Fig 39.13 Determinants, culture and partnership: the layer upstream of every figure in this chapter, and the two limbs where the evidence runs out. The grounded determinant statement is that mental health and common mental disorders are shaped across the life course by social, economic and physical environments, in which the life-course clause, the three environments and the word shaped are each load-bearing. Global mental health began as a coverage argument: the call to action asked for scale-up of service coverage in all countries, especially low- and middle-income ones, and the Movement for Global Mental Health was launched. Culture is drawn only for its pathway consequence, culture-bound presentations approached through locally meaningful idioms of distress; the taxonomy, the named syndromes and the structured cultural assessment instrument are fenced to their owning chapters. Partnership carries one process finding, that trust, rapport-building and open dialogue are core requirements, while no primary source specifying bidirectional referral, healer training, safeguards, accountability and evaluation together was retrieved and the official Indian position is recorded as contradicting prior print rather than as merely absent.

37.3 The gradient, and what it implies for how a service is targeted

Determinants act as a **gradient** and not as a threshold. It is not the case that disadvantage below some line produces risk and everything above it is equivalent; the relationship runs across the whole range, so a service that concentrates entirely on the worst-off leaves most of the population-attributable burden untouched, because most people are not in the worst-off group.

That produces a design tension every programme in this chapter meets. Targeting the most disadvantaged is efficient per person reached and misses the bulk of cases. Universal provision reaches everyone and dilutes effort where need is lowest. The resolution used in practice is to provide universally while scaling the intensity of provision to need, so that everybody is covered and the most disadvantaged receive more. The principle carries a formal name in the health-inequalities literature, which this section does not attach because no claim row here carries it; the design instruction stands without the label, and a candidate should describe the arrangement rather than name a framework they cannot attribute.

RULE **A determinant is a cause the health system can usually only reach through another sector, and naming the sector is part of naming the determinant.** A statement that poverty causes mental ill health is not yet a public-health proposition. It becomes one when it says which policy instrument, held by which department, would move it, and what the health system's contribution to that argument is.

37.4 The nihilism trap, and the intervention menu that answers it

The commonest misuse of this material is to treat it as a counsel of despair: if the causes are social, clinical work is a distraction, and nothing short of redistribution will help. That inference is wrong in both directions and it is worth being able to dismantle it quickly.

It is wrong about causation, because a determinant raises the probability of disorder in a population without making the disorder in any individual less treatable. It is wrong about action, because the health system has several genuine roles that require no other department's permission. It can produce and publish the evidence that a determinant is acting, which is often the only quantitative case anybody has. It can advocate on the basis of that evidence in the forums where policy is set. It can design its own services so that they do not compound disadvantage, meaning free at the point of use, near where people live, in the language they speak, at hours that do not cost a day's wages. It can deliver interventions that buffer a determinant it cannot remove, such as support to families under strain. And it can treat, properly and without apology, the people the determinants have already made ill.

Set out as a sequence, those roles answer the objection completely, and they are worth being able to recite because they convert a general complaint into a work plan.

- Measure the determinant in the local population, since the health system frequently holds the only routine data on it.
- Publish and advocate, in the forum where the relevant policy is actually decided rather than in a clinical one.

- Remove the barriers the service itself creates, meaning cost, distance, language and appointment hours.
- Deliver the buffering interventions the health system can deliver alone, such as support to families under strain.
- Treat, at the standard the evidence supports, without letting social causation become a reason to expect less.

37.5 Intersectoral action, and what this chapter cannot attribute

Intersectoral action is the practical form of everything above, and it fails in predictable ways. It fails when it is convened without a shared measure, so each department reports its own activity and nobody can say whether anything changed. It fails when the health sector arrives with a request rather than with evidence and an offer. It fails when the benefits accrue to one department and the costs to another, which is the ordinary case. And it fails when it exists only at the level of a committee, with no counterpart at the district level where services actually meet.

An Indian national statement to this effect would be the natural anchor for this section, and it is declared here as a gap rather than supplied. The construct sought was the national survey's own systems framework proposition, that the determinants of mental health lie outside the health sector and that systems for care are incomplete if health-related sectors are not included. That proposition is not established here from a source this chapter opened and verified, so it is named as a construct and not asserted as a finding or attributed to a body. The reasoning above stands on its own as service reasoning; the national attribution does not.

IN INDIA

Because mental health and common mental disorders are shaped by social, economic and physical environments acting at different stages of life, a district mental-health plan that contains only clinical activities has, by construction, left its largest levers unaddressed. The practical decision is to require that the plan name, for each determinant it identifies, the department that holds the lever and the officer who will be approached, so that intersectoral intent becomes a set of addressees rather than a paragraph. A determinant with no named counterpart in another department will not be acted on, and writing it down is what converts the health system's evidence into somebody else's agenda item.

37.6 Migration, taken as one determinant among others

Internal migration belongs in this list because moving, whether across a border or within a country, rearranges almost every other determinant at once: income, housing, language, social network, entitlement and legal standing all change together, usually abruptly. That is why it behaves as a determinant rather than as a single exposure.

The boundary here is strict and is stated so a reader knows where to go. Migration and ethnicity taught as a clinical and epidemiological topic, with the competing mechanisms proposed to explain differences in rates, the framework used to describe adaptation after migration, and the estimates attached to any of it, are taught in the Consultation-liaison, geriatric and transcultural

psychiatry notes. This section prints no risk estimate for migrants in any generation, no Indian migration rate, and no estimate of any protective effect, and it attributes no position on migration to any Indian guideline.

What remains, and it is genuinely this section's, is the Indian internal picture as a service and equity problem. Internal migration within India moves large numbers of people between states and from rural to urban areas, and the service consequence is structural: entitlements, registrations and continuing prescriptions are commonly attached to a place of origin, while the person is now somewhere else. A worker who moves for seasonal or construction work loses continuity of any long-term treatment as a matter of administration rather than of clinical decision, and returns to their district when unwell. Any service designed for a settled population will systematically under-serve them.

The Indian evidence for that argument is declared as a gap. What was sought was an official Indian source documenting internal migration as a mental-health determinant together with its service-access or equity consequence, without reproducing the clinical and epidemiological migration material owned elsewhere. The national survey routes, ministry pages and international agency material approached returned general determinants or mentions of migration among proposed determinants, but no Indian estimate or official statement of the service consequence was retrieved. The structural argument above is therefore offered as reasoning about how entitlement systems work, and no Indian figure is attached to it.

PITFALL

Attaching a risk multiple to migration. The figures that circulate for psychotic illness in migrant populations come from particular host countries, particular migrant groups and particular ascertainment methods, and they are the subject of an active methodological argument taught in the chapter that owns the topic. Importing one into an Indian internal-migration argument compounds two errors at once: it transfers an estimate across populations that differ in almost every relevant respect, and it converts a service and equity argument into an aetiological claim that this chapter has no standing to make.

37.7 The global mental health movement, and what it actually argued

The **global mental health movement** is best understood as an argument rather than an organisation, and its central proposition is straightforward. A large share of the world's burden of mental disorder falls in countries with the fewest specialists, most people with a disorder in those countries receive no treatment, effective interventions exist and can be delivered by non-specialists, therefore the ethical and practical priority is to scale up coverage rather than to wait for specialist workforces to grow.

The movement's defining call, issued in **2007**, asked its readers to increase the coverage of services for mental disorders in every country and above all in low-income and middle-income ones. The wording contains the argument in miniature: what is demanded is *coverage*, which is a population measure with a denominator, and the demand is addressed to every country with a

particular emphasis rather than to poor countries alone. Shortly afterwards the Movement for Global Mental Health was launched as a network to carry that agenda.

2007	Coverage	Non-specialists	Not established here
CALL TO SCALE UP SERVICE COVERAGE, ALL COUNTRIES, ESPECIALLY LOW- AND MIDDLE-INCOME	THE MEASURE THE CALL DEMANDED, NOT SPECIALIST NUMBERS	THE WORKFORCE THE ARGUMENT RESTS ON	ANY INDIAN COVERAGE FIGURE FOR THIS ARGUMENT

The movement has standing objections, and a candidate who can state them fairly is demonstrating more than one who cannot. The first is that exporting a diagnostic and treatment framework developed in one part of the world risks displacing local understandings of distress and local ways of responding to it. The second is that scaling up treatment can absorb the entire agenda and leave the determinants untouched, which is the tension this whole section is about. The third is methodological: an intervention shown to work in one setting is not thereby shown to work in another, and the transportability of evidence is an empirical question rather than an assumption. The fourth is about who sets the agenda, since priorities, funding and publication have historically been concentrated in the countries with the fewest patients.

37.8 What the argument leaves an Indian service with

India occupies an unusual position in this debate, because it is simultaneously one of the settings the movement was arguing about and one of the places that produced the evidence the movement rests on. That gives an Indian clinician a stronger footing than the debate's usual framing allows: the question is not whether an external agenda should be accepted, but which parts of a largely home-grown evidence base a service should implement, and with what adaptation.

Three implications are worth carrying away. Coverage, not capacity, is the measure the argument is conducted in, so a service arguing for resources should be able to state what proportion of its intended population it reaches. Non-specialist delivery with specialist supervision is the mechanism the argument depends on, which is why it recurs in almost every section of this chapter. And the objections above are not reasons to abandon the programme; they are the design constraints it has to satisfy, meaning that a scaled-up service must be culturally intelligible, must be evaluated locally rather than assumed to transfer, and must not be allowed to become the whole of a country's mental-health policy while the determinants that fill it go unaddressed.

TRAP **Treating the social determinants as an alternative to services, or services as an alternative to the determinants.** Candidates pick one and argue against the other, and both arguments are weak. Determinants shape how many people become unwell; services determine what happens to those who do. Neither substitutes for the other, and the examinable position is that a health system owes evidence and advocacy on the first while delivering coverage on the second.

The determinants of mental health are largely produced outside the health sector and reached through other departments, and the global argument that follows is about coverage of a population rather than about the number of specialists a country has.

Culture, global mental health and traditional healing

38 · Cultural psychiatry, idioms of distress, culture-bound syndromes and explanatory models in the Indian context

Culture belongs in a public-health chapter because it decides where a population goes first, how long it stays there, and what it is holding when it finally arrives at a health service. That is a service fact with denominators and waiting times attached, and it is distinct from the cultural encounter at the bedside. The definitions of the cultural constructs, the umbrella that groups them and the classic roster of named syndromes are taught in the Psychotherapies, clinical assessment, MSE and nosology notes; the clinical encounter with a culture-named presentation, the negotiation between two accounts of one complaint and the placement of a cultural formulation inside a working assessment are taught in the Consultation-liaison, geriatric and transcultural psychiatry notes. This section takes none of that. It takes the population consequence: which door a community uses first, what the detour costs, what a general health service has to be able to receive, and what a service must build for any of this to change.

38.1 The pathway, read as a service problem rather than a curiosity

A **pathway to care** is the sequence of people a person consults between first noticing something is wrong and arriving at the service that will eventually treat them. Read at population scale it has three properties that matter to a planner and are invisible in the consulting room.

The first is that psychiatric services are almost never the first stop, and in many communities they are not the second or third either. The first consultation is usually inside the family, then with whoever the community treats as the appropriate authority for that kind of trouble, and then with a general practitioner or a general hospital. That is not a failure of the population; it is a rational sequence given how the problem was understood at the outset.

The second is that each step consumes time and money, and both are spent before any effective treatment starts. The cost is therefore paid twice over: once in the direct expenditure on consultations that did not help, and once in the untreated duration of the illness, which for several conditions is itself associated with worse outcome.

The third, and the one that turns this from description into planning, is that the pathway is modifiable. Where the population goes first is determined by what the community understands the problem to be, and by which doors are physically and socially available. Both can be worked on. A service that treats the pathway as fixed has accepted a delay it could have shortened.

RULE **The pathway to care is a property of the service system as much as of the culture, and it is measurable.** Where a population goes first is determined jointly by what it believes about the problem and by which doors are open, affordable and near. A service can change the second of those directly and the first only slowly, which is why pathway work begins with placing the service where the population already goes.

38.2 The detour, and what it actually costs a service

The **interval between onset and effective treatment** is the quantity that summarises all of this, and it is the number a service should want most and usually does not have. What can be said without any figure is what the delay is composed of, because each component has a different remedy.

STAGE OF THE PATHWAY	WHAT HOLDS THE PERSON THERE	THE LEVER A SERVICE ACTUALLY HAS
Inside the family, before any consultation	The problem is understood as something other than illness, or as something the family should manage	Population-facing explanation in the community's own vocabulary, which is the literacy and awareness work of these notes
With a community or faith-based helper	That helper is the recognised authority for this kind of trouble, is nearby, and is trusted	Partnership and referral arrangements, developed in the traditional and faith-based care material of these notes
With a general practitioner or general hospital	The complaint presented is one the general service can respond to on its own terms	Recognition capacity in general services, which is the primary-care integration work of these notes
Referred but not arrived	Distance, cost, stigma, or a referral with no named destination	Where the service is placed, what it costs, and whether the referral names a person and a date

Notice that only the first row is about belief. The remaining three are about proximity, trust, recognition and the mechanics of referral, all of which are ordinary service-design variables. It is a persistent error to treat the whole of the pathway delay as a cultural problem requiring cultural work, when most of its length is produced by where the service is and how hard it is to enter.

38.3 Idioms and explanatory models as population phenomena

A population does not present its distress in the categories a service uses to classify it. It presents in the vocabulary it already has, which may be bodily, social, moral or spiritual, and which is coherent within the community's own understanding of what has gone wrong. The taxonomy that groups these forms of expression, its definitions and the roster of named presentations that belong to it are taught in the Psychotherapies, clinical assessment, MSE and nosology notes, and the umbrella is named here once as the frame this argument rests on, without reproducing any part of it.

The stance this chapter takes toward those presentations is a service stance, and it has a source. In the Indian subcontinent, culture-bound presentations are more productively received as **locally meaningful idioms of distress** than as biomedical syndromes to be translated automatically at the door. Read as a service instruction rather than as a nosological position, that has concrete consequences.

- The presentation that arrives is data about the population's understanding, not noise to be filtered before the real assessment starts.
- A service that only recognises complaints already framed in its own categories will systematically under-detect, because the population is not obliged to speak in those categories.
- Population-facing communication that ignores the local vocabulary is speaking a language the audience does not use to think about the problem.
- An idiom carries information about severity and about what the person expects to happen next, which is why receiving it accurately affects what can be offered.

Two Indian presentations, dhat and koro, are the standard examples of a complaint whose form is shaped by a shared explanatory model, and they are named here only as that, examples of how a population's understanding routes a person to one door rather than another. Their phenomenology, their nosological status and their clinical handling are taught in the Somatic-symptom, sexual, impulse-control disorders and suicide notes and are not touched here.

IN INDIA

Because culture-bound presentations in this subcontinent are better received as locally meaningful idioms of distress than converted into a biomedical label at the door, an Indian outpatient service should build the recording of the person's own account of the problem into its first contact rather than leave it to whoever has time. The account is what the eventual explanation, the treatment plan and any psychoeducation have to connect to; a service that records only its own formulation has kept the half of the encounter it already understood and discarded the half that determines whether what it offers makes sense to the person receiving it.

38.4 Recognition in general health services, which is where most of it lands

The great majority of culturally framed distress presents to general health services and not to psychiatric ones, which makes **recognition capacity** in those services the single largest determinant of whether it is ever addressed. The design problem is specific: a general practitioner working under time pressure will act on the complaint as presented, and a complaint presented in bodily terms will generate an investigation rather than an enquiry.

The levers here are unremarkable and effective. Training aimed at recognising the common presenting forms in that population rather than at diagnostic subtlety. A short structured enquiry the clinician can actually complete in the time available. A referral destination that is named, near and reachable, since a referral into an abstraction is not a referral. And feedback to the referring clinician about what happened, which is the only mechanism that improves recognition over time and is almost universally absent.

PITFALL

Designing the service around the assumption that the health system is the first door. Outreach, awareness material and referral arrangements are all built as though the population's starting point were a health facility, so they address people who have already found the system. The population that has not is reached by none of them, and it is exactly the population whose pathway is longest. Finding out which door a community actually uses first, in that district, is a prior question and not a research luxury.

38.5 What a service must build for a cultural formulation to be usable at all

It is one thing to accept that a person's own account of their problem should inform their care, and another to run a service in which that happens reliably. The implementation questions are three, and they are the ones a programme has to answer.

The first is who is trained. If eliciting an account is treated as a specialist skill, it will happen only where specialists are, which is the smallest part of the system and the last stop on the pathway. If it is treated as a competence for whoever holds the first clinical contact, it happens where the population is, which requires a short, teachable version and a supervision structure behind it.

The second is at which contact it is applied. Applying it at every contact is unaffordable at scale; applying it at none makes the commitment decorative. The workable answer is to fix it to a defined point, usually the first assessment and any point at which the plan is not working, and to record the outcome where the next clinician will see it.

The third is what it costs in consultation time, and this is the question that decides whether the policy survives contact with a busy outpatient department. An enquiry that adds materially to every consultation in a clinic seeing very large numbers will be abandoned within weeks and will then be reported as having been implemented. The honest planning position is that time is the binding constraint, that the enquiry must be scoped to the time actually available, and that if the time does not exist the service should say so rather than mandate something it cannot deliver.

What such an enquiry is for is modest and specific. **An explanatory-model assessment** is aimed at three things a service otherwise never learns: what the problem means to the person, where they think help might come from, and what they expect a service to do. Each of those is directly actionable, which is why the enquiry is a service investment rather than an ethnographic one: the first tells you what the explanation must connect to, the second tells you who else is already involved, and the third tells you what will be experienced as help. The instrument built on this approach, its structure and its content are taught in the Psychotherapies, clinical assessment, MSE and nosology notes, and where the enquiry belongs inside a working clinical assessment is taught in the Consultation-liaison, geriatric and transcultural psychiatry notes.

MNEMONIC

Place, Partner, Practitioner, Proof

The four decisions that convert a cultural argument into a service change. Place the service where the population's pathway already runs. Partner with whoever holds the door it uses first. Train the practitioner who takes the first clinical contact, not only the specialist at the end. And prove it, by measuring where people came from and how long they took to arrive.

38.6 Measuring a pathway, which almost no service does

The whole of this argument becomes tractable the moment a service records where its patients came from. That is a small addition to a first-assessment record and it produces the only data that can tell a district where its access problem actually is.

First contact	Number of steps	Interval to treatment	Referral source
WHO THE PERSON CONSULTED BEFORE ANY HEALTH SERVICE	HOW MANY HELPERS WERE SEEN BEFORE ARRIVAL	TIME FROM ONSET TO EFFECTIVE TREATMENT, PER PATIENT	WHICH DOOR ACTUALLY DELIVERS PATIENTS TO THIS SERVICE

The last of the four repays a moment's thought, because a service usually believes it already knows the answer and is usually wrong. A department that runs an outreach programme, a helpline and a referral arrangement with a general hospital will assume its patients arrive in some rough proportion across the three. Counted, the distribution is almost always lopsided, and the lopsidedness is the finding: one route is carrying the service and the others are consuming staff time to deliver very few people. That is an actionable result obtainable from a single field on a form.

Those four quantities, collected on a service's own attenders, answer questions no national dataset can. If the first contact is overwhelmingly one kind of helper, the partnership priority is settled. If the number of steps is large but the interval is short, the problem is misdirection rather than delay. If the interval is long, the question becomes which step it accumulated at. And if one referral source supplies most arrivals, the service knows both where to invest and where it is currently invisible.

The important limitation of these measures is that they describe the people who arrived, which makes them a **clinic-attender sample** and not a population one. They say nothing about those who did not, who are the population of interest and are systematically different. Pathway data from a clinic are therefore a starting point for a district question and not an answer to it, and a service that forgets this will optimise for the population it already has.

38.7 What is not established here, and how to answer without it

This section prints no prevalence for any culture-named presentation, and that is a deliberate position rather than an omission. The figures that circulate for such presentations come from clinic samples of very different kinds, use different criteria, and describe populations that are not comparable; a proportion measured among attenders at one specialist service is not a population

rate and cannot be reported as one. The chapter that owns the clinical material makes the same refusal in print, and this chapter does not supply what that one declined to.

Nor does this section carry an Indian national figure for pathway delay, for the proportion of people whose first contact is a non-medical helper, or for the length of the detour. No such national quantity is held here. The consequence for an answer is straightforward and worth practising: describe the structure of the pathway, name the stages and the levers, say that the national quantities are not established, and point out that a service can generate the local versions itself with four fields on its own assessment form. That is a stronger answer than a remembered percentage, and it is also the more useful one, because a district acts on its own numbers and not on a national average.

TRAP **Answering a question about culture and access with a list of named syndromes.** The roster is memorable, it belongs to another part of the syllabus, and reciting it answers a question about nosology rather than the one that was asked. The question here is about where a population goes, why, what that costs, and what a service does about it. A candidate who names the umbrella once, sends the examiner to the chapter that defines it, and then talks about first contact, detour, recognition and referral has answered the question in front of them.

Culture sets which door opens first; the service decides how far away the second one is, and most of a pathway's length is built from distance, cost and recognition rather than from belief.

39 · Traditional healers, faith-based care and integration with mental health services in India

For a large part of the Indian population the first person consulted about a mental-health problem is not a clinician, and no amount of service planning changes that by wishing. The public-health question that follows is narrow and practical: given that a first contact exists which the health system does not control, what arrangement should the health system have with it. That is a design question about partnership, and it is what this section teaches. The clinical encounter with a patient who has been to a healer, the single measured Indian evaluation of a healing site and what it can and cannot bear, the access-against-acceptability distinction and the clinical posture of collaboration without endorsement are taught in the Consultation-liaison, geriatric and transcultural psychiatry notes. Traditional and indigenous resources considered as an Indian service model in their own right are developed elsewhere in these notes. What belongs here is the architecture of a partnership: what it is for, how referral runs in both directions, what training can honestly attempt, what safeguards are non-negotiable, and how the whole arrangement is held to account.

39.1 The premise, stated without sentimentality

Two propositions have to be held together, and most weak answers drop one of them. The first is that faith-based and traditional healing is not an evidence-based treatment for mental disorder; that is the standing position and this chapter makes no stronger claim for it. The second is that a

great many people consult such practitioners first, that this is a coherent choice given how the problem is understood locally, and that they are frequently nearer, cheaper, more available and more socially acceptable than any psychiatric service.

Held together, those two propositions generate the entire design logic. The case for a partnership is not therapeutic. It rests on **access**, meaning that the traditional healer is a point of contact with a population the service does not otherwise reach, and on **harm reduction**, meaning that whatever happens at that contact can be made safer and shorter. A service that argues for partnership on the grounds that healing works has made a claim it cannot support. A service that refuses partnership on the grounds that healing does not work has declined a route to a population that is going there regardless.

RULE **Partnership with traditional and faith-based practitioners is justified by access and by harm reduction, not by therapeutic efficacy.** Keeping that distinction visible is what allows a clinician to collaborate without endorsing, and it is also what stops the arrangement drifting into an implicit claim that the health system does not intend and cannot defend.

39.2 What a partnership is actually for

Stated as design intentions rather than as demonstrated effects, a partnership is built to achieve a small number of specific things, and naming them is what stops the arrangement becoming a gesture.

- Earlier arrival: a person who is going to reach the health service eventually reaches it sooner, because the healer routes them rather than retaining them.
- Reduced harm at the first contact, meaning that whatever practices carry risk are not applied to people with mental illness.
- Continuity: treatment already started is not interrupted while the person is under a healer's care, which is the commonest concrete damage the health system actually sees.
- Reach in the other direction: the healer becomes a route by which information, and sometimes services, reach a population that does not attend clinics.
- Reduced conflict for the patient, who is otherwise required to choose between two authorities and frequently resolves it by concealing one from the other.

The last of those is underrated and is the one clinicians can verify from their own practice. Where the two systems are understood to be in opposition, patients conceal their use of one, which means the psychiatrist does not know what else is being taken or done, and the healer does not know a medicine has been stopped. A working partnership does not require either side to agree with the other; it requires only that the patient can be honest with both.

39.3 Bidirectional referral, and why the second direction is the hard one

Bidirectional referral is the structural core of the arrangement, and its two halves are not equally difficult. Referral in the obvious direction is easy to describe and hard to obtain: the healer identifies a person who needs medical care and sends them. What that requires is not goodwill but three specific things. A recognisable trigger, meaning a short and unambiguous set

of circumstances in which the healer will refer, rather than a request to exercise clinical judgement. A named destination that is reachable, since a referral into an institution is not a referral. And feedback, because a healer who refers somebody and never learns what happened has been given no reason to refer the next one.

The second direction is the one that decides whether the arrangement survives, and it is the one health services find hardest to accept. A partnership in which the health service receives and the healer only sends is not a partnership; it is a recruitment channel, and it will be recognised as such. What the health service can legitimately send in the other direction is not patients for healing but the things the healer's role actually needs: information about mental illness in usable form, a person to ask when uncertain, acknowledgement of the role the healer plays in the community, and in some arrangements a physical presence at the healing site so that people who will not travel to a clinic can be seen.

PITFALL

Designing the referral in one direction and calling it collaboration. The health service writes a protocol that tells healers when to send people to the clinic, delivers a training session about it, and reports a partnership. Nothing flows the other way, no relationship is built, and the arrangement has no value to the person being asked to change their practice. It lasts as long as the project that funded it, and it teaches the healer community that the health system's interest is extractive.

39.4 Training, and what it can honestly attempt

Healer training is the component most often proposed and most often over-specified. It cannot convert a healer into a health worker, and attempting it fails in both directions: the healer's own practice is what gives them standing in the community, and a curriculum that treats it as an obstacle to be corrected will end the relationship.

What training can attempt is narrow and useful. Recognition of a small number of presentations that need medical attention urgently, described in terms the healer already uses rather than in diagnostic categories. Awareness that certain conditions respond to treatment, which is frequently new information and is the single most persuasive content. The specific harms to avoid, stated as practices rather than as principles. And the mechanics of referral, meaning who to contact, how, and what to say.

Two design points follow from experience with any non-specialist cadre and apply with more force here. Training without continuing contact decays, so a single workshop is an event rather than a programme. And training delivered in a register that positions the trainer above the trainee will not be received, whatever its content, which is why who delivers it matters as much as what it contains.

39.5 Safeguards, which are the floor and not a negotiating position

Everything above is conditional on a **safeguarding floor**, and this is the part of the topic where a clinician's obligation is unambiguous. Practices that restrain, confine, deprive of food or water, inflict physical harm, or hold a person against their will are unacceptable irrespective of the

setting in which they occur or the intention behind them, and a partnership that tolerates them is not a partnership but a complicity. That people with mental illness have been chained and confined in domestic, custodial and faith-based settings in India is documented; how widespread or prolonged the practice has been is a separate question that this chapter attaches no figure to, and none should be quoted without its source, its reference year and its denominator. The statutory prohibition on chaining is legislation and is taught with the rest of the mental health law.

The practical safeguarding content of a partnership is therefore a short list of conditions that are stated at the outset rather than discovered later.

ELEMENT OF THE PARTNERSHIP	WHAT IT REQUIRES TO BE REAL	WHAT IT MUST NEVER BECOME
Bidirectional referral	A recognisable trigger, a named reachable destination, and feedback in both directions	A one-way extraction channel with a protocol attached
Training	Recognition, the treatability message, the harms to avoid, and referral mechanics, with continuing contact	An attempt to convert the healer into a health worker, or a single workshop counted as a programme
Safeguards	An explicit floor on restraint, confinement and deprivation, agreed before the arrangement starts	A matter for later negotiation, or something the health service declines to raise for fear of losing access
Accountability	A named person on each side, and an agreed route for raising a concern	A memorandum with no individual answerable for anything in it
Evaluation	Agreed measures collected from the start, including referral counts and what happened to those referred	A report of activities delivered, with no denominator and no outcome

TRAP **Attributing a partnership policy, a referral protocol or a training scheme for faith healers to an Indian national guideline.** This is the specific error to avoid on this topic, because the sentence writes itself and sounds authoritative. No official Indian guideline position on collaboration or referral between government mental-health services and faith healers is established by anything this chapter has opened. Everything in the design above is a proposal with its reasoning attached, and it should be presented as such. A candidate who says that the design is a reasoned proposal rather than a national policy has answered accurately; one who attributes it to a ministry has invented an instrument.

39.6 Accountability, and the difference between a partner and a supplier

A partnership that nobody is answerable for is a document, and documents do not refer patients. Accountability here means something narrower than it does in a formal service contract, because one side is not employed by anybody and cannot be performance-managed. What it can mean, and what is worth insisting on, is that a named person on each side is the point

of contact, that there is an agreed way of raising a concern in either direction, and that concerns raised are actually answered.

The asymmetry of power in the arrangement deserves stating, because it shapes what accountability can realistically look like. The health service arrives with institutional standing, funding and the implicit authority of the state; the healer arrives with community standing and nothing else that a bureaucracy recognises. In that situation an accountability mechanism designed by the health service alone will read as supervision, and supervision is not what was agreed. The workable version is reciprocal: both sides can raise a concern, both sides answer, and the arrangement can be ended by either.

The measures that matter follow from the purposes named earlier and are few. How many people were referred in each direction over a stated period. What proportion of those referred to the health service actually arrived, which is the number that tests whether the destination was real. What happened to them, in outcome terms the healer can understand and will care about. And whether any safeguarding concern arose, how it was raised and what followed. A programme reporting only workshops held and materials distributed has reported its own activity and nothing about the partnership.

39.7 Making it work in practice

The single grounded statement this chapter can make about how such collaboration actually proceeds comes from an Indian programme in Gujarat that brought faith-based and allopathic practitioners together, and it is about process rather than outcome. Collaboration of this kind **requires trust, rapport-building and open dialogue**, and it is challenging.

That is a modest-sounding finding and it is the most operationally useful thing in the section, because it identifies where the cost of the programme actually falls. The expensive component is not the training curriculum, the protocol or the printed material; it is the time somebody spends building a relationship with people who have no obligation to cooperate and some reason to be wary. That time is invisible in a project plan, is the first thing cut when the timeline tightens, and is what the whole arrangement rests on.

IN INDIA

Because collaboration between faith-based and allopathic practitioners requires trust, rapport-building and open dialogue, an Indian district beginning this work should budget the relationship-building period explicitly and assign it to a named person before any protocol is written. Opening with a memorandum, a training calendar or a referral form inverts the sequence: those instruments are the record of an agreement that already exists, and issuing them first is how a partnership becomes a document nobody honours.

MNEMONIC

Two doors, one floor, one ledger

The shape of a defensible partnership. Referral runs through two doors, not one. A safeguarding floor is agreed before anything else and is not negotiable afterwards. And one ledger records what actually happened, meaning who was referred, in which direction, and what became of them.

39.8 What is not established, and how to answer without it

This is a topic on which confident-sounding claims are unusually easy to produce, so the position is stated plainly.

Not established	Not retrieved	Not quantified here	Process, not outcome
OFFICIAL INDIAN GUIDELINE POSITION ON COLLABORATION WITH FAITH HEALERS	INDIAN DOCUMENT SPECIFYING ALL FIVE PARTNERSHIP ELEMENTS	HOW OFTEN OR HOW LONG THE RELIGIOUS PATHWAY IS TRAVELLED	WHAT THE ONE GROUNDED INDIAN STATEMENT DESCRIBES

No official Indian guideline position on collaboration or referral between government mental-health services and faith healers is available to this chapter. What was sought was exactly such a position, in national operational guidance for mental, neurological and substance-use care; it was not established, and the ownership rule for this material is explicit that partnership design and referral must not be attributed to an Indian guideline. The design set out above is therefore a reasoned proposal, and its authority is the reasoning, not a ministry.

No primary official Indian document or primary Indian evaluation specifying all five partnership elements together, meaning bidirectional referral, healer training, safeguards, accountability and evaluation, was retrieved either. Several routes were attempted. The consequence is that the five-element structure above is offered as a design framework assembled from the requirements of the task, not as a transcription of an existing Indian model, and it should be presented that way.

No national quantification of the religious or traditional pathway is supplied here: how often it is used, and for how long before psychiatric contact, is not something this chapter attaches a number to. The single measured Indian evaluation of a healing site, its denominators, its design limitations and the reasons its result cannot be generalised are taught in the Consultation-liaison, geriatric and transcultural psychiatry notes, and its figure is not reproduced here.

What survives all of that is the durable content, and it is what an examiner is testing. A partnership is justified by access and harm reduction rather than by efficacy. It runs in both directions or it does not run. It rests on a safeguarding floor stated before anything else. It is held by named people rather than by a document. And it is evaluated on referrals and what happened to those referred, not on workshops delivered. Those propositions are defensible without a single figure, which is fortunate, because the figures do not exist.

Collaborate for access and for harm reduction, never on a claim of efficacy; agree the safeguarding floor first, make the referral run both ways, and name the people who are answerable for it.

Consolidate and apply

40 · Worked vignettes

A vignette in this territory is never really about the patient in it; it is about the part of the system that patient is standing in. Stems that carry marks here rarely ask for a diagnosis or a drug. They put an ordinary clinical picture in front of the candidate and then plant one further fact: a distance, a vacant post, a medicine that ran out between visits, a family that consulted somebody else first, a figure quoted at a district meeting. That further fact is the **service variable**, and the value of the stem lies entirely in whether the candidate reasons from it or reads past it into a management plan. This closing section introduces no new programme and no new figure. It rehearses the reasoning assembled across this chapter as a reading skill, working each stem from the service variable outwards to the population it belongs to.

The discipline that earns marks is refusing to answer a service question with a clinical one. A woman who cannot collect her medicine because the facility that stocks it is a bus journey away is not asking which agent suits her; she is asking which tier of the system should be holding her follow-up. Where a stem turns on the statute itself, on the wording of a right, on capacity or consent, or on the procedure that follows a death in custody, it has left this territory: those belong to the Mental health legislation and forensic psychiatry notes and to the Forensic ethics, consent and legal procedure notes. Where it turns on how a prevalence was estimated, or on which design would establish it, it belongs to the Research Methods, Biostatistics and Epidemiology notes. What this chapter supplies is the layer between them: who delivers what, to which population, and how you would know whether they are.

40.1 Four questions locate the service variable

Before deciding what a community psychiatry stem is asking, run the same four questions across it. Between them they cover almost every way an examiner can turn an ordinary clinical picture into a problem about a service, and each opens onto a different part of this chapter.

Level	Offer	Access	Denominator
WHICH TIER IS ASKED TO ACT	WHAT THAT TIER ACTUALLY HOLDS	WHO IS NOT ARRIVING	WHAT THE FIGURE COUNTS

Level asks which tier the question is really being put to: the household and the community worker, the primary care facility and its medical officer, the district hospital, or the specialist institution above them. Offer asks what that tier actually holds, in staff, in supply and in training, as against what the reader assumes it holds. Access asks who is not arriving at all, because a service used by the people who were always going to arrive has changed nothing for the people

who were not. Denominator asks what any figure in the stem counts, who issued it, which period it describes and what it is a proportion of. A well-built stem makes one of the four decisive and leaves the other three as scenery.

RULE **The patient is the setting; the service is the question.** If your answer can be written without naming a tier, a provider, a supply, a pathway or a population, you have answered a question about a person while the stem asked about a system. The clinical picture is usually scenery: it tells you what this person needs and almost nothing about who is meant to provide it. The marks sit in naming the level at which the failure sits, saying what that level does and does not provide, and choosing the move that acts there rather than at the bedside.

40.2 The vignette that resolves on the tier that should act

The commonest stem describes a patient stable for a long time who is not stable now, with the prescription unchanged and nothing new in the history except the travelling. She lives in a village; the clinic that knows her is in the district town; the journey takes most of a working day; somebody has to come with her and lose a day of wages; and the medicine she was given runs out before the next appointment falls due. The reading move is to locate the failure on the ladder of care rather than inside the patient, then ask what the tier nearest her actually holds. A relapse produced by a supply that ran out is a distribution problem; one produced by an appointment the household cannot afford to keep is a geography problem; one produced by a family that stopped believing the treatment was working is a continuity problem. None of the three is answered by changing the drug, and the choice of agent, if the stem really wants one, belongs to the Schizophrenia: management, antipsychotics and adverse effects notes.

The answer that earns marks moves the work downwards and keeps the supervision upwards. Follow-up for a person stable on a settled regimen is the kind of task that can sit with a trained general provider working to a structured protocol, while the specialist tier holds the complicated presentations, the treatment failures and the teaching. That redistribution is what **task-shifting** names, and the intervention guide most often examined for it, with the stepped and collaborative arrangements that make it safe, is developed in this chapter's primary care, task-shifting and stepped-care sections. Where distance is the whole of the problem and a trained provider exists but a specialist does not, a scheduled remote consultation moves the scarce person rather than the sick one, and the conditions attached to doing so sit in this chapter's telepsychiatry section. What a candidate should not write is "refer to the psychiatrist" against a stem whose entire point is that the referral is the thing not happening.

PITFALL

Writing "defaulted follow-up" in the notes without ever asking what the visit costs. The entry travels forward as a statement about the patient's motivation, and every later clinician reads it that way. Ask instead how far the journey is, what the fare and the lost wages come to, who has to accompany her, and whether the medicine lasts until the date you have written on the card. A follow-up plan the household cannot afford to keep has been written for the convenience of the clinic, and it will be read as non-adherence for years afterwards.

40.3 The vignette that resolves on what the programme actually provides

A second family holds the patient constant and moves the question to the district. The stem says the district is covered by the national programme, or that a service was sanctioned for it, and then describes somebody who could not get care there: no clinic ran that month, the psychiatric posts are vacant, the medicines on the district list were not in the store, or the outreach that appears in the annual report has never reached that block. The reading move is to separate **sanctioned coverage** from **functional coverage**. A sanction is an administrative event: an approval, a budget line and a set of posts on paper. Function is a service actually delivered to a population over a stated period, which needs the posts filled, the supply arriving, the staff trained and the activity recorded. The two are counted by different instruments, and the first is far easier to count, which is why it is the figure that travels.

The answer therefore asks what the sanction bought and which of its parts is missing, because the missing part names the level that has to act. Vacant posts are a recruitment and cadre question for the state; empty shelves are a procurement question; untrained staff are a training question; and a clinic that runs while nobody attends is an access question, which is a different vignette again. Naming the missing input is most of the answer, and it is also the honest thing to say about coverage figures in general: what gets published is what the system can count. The components a sanction is meant to buy are set out in this chapter's district-programme section, and the route the money takes to reach them in its financing section.

TRAP **Reading a district count as a service count.** A total of districts approved for a programme is a statement about administrative decisions, not about clinics that opened, and it is quoted as though it described a population served. The same error runs through every coverage figure here: facilities equipped is not facilities functioning, posts sanctioned is not posts filled, and a programme present in a district is not a programme present in every block of it. When a stem offers a coverage figure, the examinable move is to say what it counts before saying what it shows.

40.4 The vignette that resolves on what the figure is a count of

A national number inside a stem is an invitation to interrogate it, not a fact to reason from. The stem quotes something the candidate has heard in a seminar: the proportion of people with a mental disorder who are not in treatment, the calls a national helpline has answered, the density of psychiatrists in the population, the share of the health budget reaching mental health. Then it asks for a conclusion. The reading move is to attach four fields to the figure before using it: who issued it, which period it describes, which population it was measured in, and what it is a proportion of. A figure carrying all four is evidence. A figure carrying none is a rumour with a decimal point in it, and any conclusion drawn from it inherits that weakness.

Two of the traps are structural rather than careless. A cumulative count of contacts with a service, such as the calls a helpline has answered since it opened, counts events and not people: one person in distress may call many times, and no arithmetic on the published total recovers how many individuals it stands for, or how many of them reached care afterwards. And a count with no **valid denominator** cannot be turned into a rate, however inviting the comparison. A national

tally of deaths within an occupational group has no trustworthy count of the people in that occupation to sit beneath it, so a rate built from the two puts an uncertain numerator over an unknown one and reads as precision. The honest sentence names what was counted, says what the denominator would have to be, and stops there. Ask also when the measurement was made, because a household survey describes the period it sampled and not the year in which you are reading it. Where the stem is really asking how such a quantity should be measured, or which design would establish it, that reasoning belongs to the Research Methods, Biostatistics and Epidemiology notes.

The third trap is the one that puts contradictory figures into print. One survey can report the proportion untreated among people with common mental disorders, a second proportion among people with severe mental illness, and a further breakdown for one named condition, and those values are not interchangeable because the populations are not. Each carries a different consequence for which tier should act, since a gap concentrated in severe illness points at the district and specialist tiers while a gap concentrated in common disorders points at primary care. The figures themselves, with the survey that issued them and the populations they describe, sit in this chapter's survey and treatment-gap sections; the disorder-by-disorder breakdown and its epidemiological meaning belong to the Research Methods, Biostatistics and Epidemiology notes.

TRAP **Quoting a survey's figure against a population it did not measure.** One national survey yields several treatment-gap values, one for each population it defined, and the commonest error here is to carry away a single remembered number and attach it to whichever disorder a stem names. The number is then correctly quoted and false at once, which is the hardest kind of error to see, because nothing about the sentence looks wrong. Carry the population with the figure, or carry neither.

40.5 The vignette that resolves on where the pathway to care broke

A third family gives a long history before the first psychiatric contact. A young man has been unwell for years; the family took him first to a healer at a shrine, then to a general practitioner who gave him something for sleep, then to a physician who investigated him thoroughly, and only after all of that to a psychiatric service. The stem is not asking whether the healer did harm, and it is not asking for a formulation of the family's explanatory model at the bedside: that assessment, with the idioms in which distress is described, belongs to the Consultation-liaison, geriatric and transcultural psychiatry notes. It is asking where the **pathway to care** could have been shortened, and by whom.

Read the pathway as a sequence of contacts, each of them a person who could have redirected it. The answer names the point at which recognition failed, the provider standing at that point, and the intervention that acts there: awareness in the community, so that a family reads the problem as one a health service treats; recognition training for whoever the population meets first; a working relationship with the practitioners outside the health system whom a population consults before it consults a clinician; and a service near enough for a referral to be kept. Stigma belongs in this vignette as a service fact rather than an attitude, because it decides who presents,

how late, to whom, and under what description. The strategies, the models of engagement and the evidence for each are set out in this chapter's stigma, literacy and traditional-healing sections.

GOOD TO REMEMBER

Ask every new patient and family two questions before the history proper: who did you see first, and what were you told. The answers give you the route this population actually travels, the contact at which somebody could have redirected it, and the explanation the family is still carrying into your consultation. Collected across a clinic year, those two answers are the closest thing a district service has to a map of its own catchment, and they cost nothing but the asking.

40.6 The vignette that resolves on the population rather than the person

A fourth family describes a death, or a cluster of deaths, and the temptation is to answer with an assessment. A farmer in a district of failed rains and heavy debt has died by suicide using a pesticide kept in the house, and the health administration asks what the service should do. An individual risk assessment is a correct answer to a different question, and the evaluation of risk in the person in front of you belongs to the Somatic-symptom, sexual, impulse-control disorders and suicide notes. What this stem asks is which population lever its facts point at, and they point at several at once: a means kept in every house in the village, an economic shock the health system did not cause and cannot undo, the people the man met before he met any clinician, and a local press that will report the death tomorrow.

The reading move is to separate a **population-level intervention** from a clinical one by asking who receives it. A clinical intervention is delivered to a person already identified; a population intervention is delivered to everyone in a defined group whether or not any individual in it has been identified, which is exactly why it can reach people no service has ever seen. Restricting access to a lethal means, preparing the non-clinicians a distressed person actually meets, agreeing how a death is reported, and acting on the debt and distress that brought the person to the act are all interventions of the second kind. Which one the stem wants is decided by the fact it planted, and this chapter's suicide prevention sections carry what each involves and what the evidence for it is; a vignette answer names the lever and the tier that pulls it, and does not claim a size of effect for it. The same move works on an event that strikes a whole community at once, where an answer built on assessing everybody present individually has answered at a level the event does not permit, and the staged population response sits in this chapter's disaster section.

40.7 The vignette that resolves on what receives the patient

The last family reverses the direction. A man has spent many years in a long-stay institution, his symptoms are settled, the team records that he is fit for discharge, and no family can be traced. Answering with a discharge prescription answers a clinical question that has already been settled; the open question is what receives him. Where people are moved out of institutions faster than the structures they move into are built, the result is **transinstitutionalisation**: the same person held in another closed setting, a custodial one, a shelter or a household with no rehabilitation in it, while the population looks deinstitutionalised because a bed count fell. The rationale, the

outcomes and the lessons drawn from that history are developed in this chapter's deinstitutionalisation section.

So the answer inventories the receiving structures by function: somewhere to live with the support this person needs, something to do in the day, a route towards work where that is realistic, a clinical service that will follow him up without a journey he cannot make, and an entitlement that does not depend on relatives nobody can find. Each is a different service with a different provider, and the provider is often not the state; this chapter's section on Indian models of care sets out the part played by non-governmental organisations, by families and by indigenous resources, and a good answer names who would actually have to be asked. The certification and the statutory entitlement that follow a disability assessment are not this chapter's to state and belong to the Mental health legislation and forensic psychiatry notes.

40.8 Look-alike stems and the answering spine

Consolidation is easiest in pairs. The table sets out the stems most often confused in this territory, against the fact that separates them and the axis the reasoning lands on.

TWO STEMS THAT LOOK ALIKE	THE FACT THAT SEPARATES THEM	THE AXIS IT LANDS ON
A patient relapsing on an unchanged prescription, against one relapsing because the supply ran out	Whether the stem describes a change in the illness or a break in delivery	Level
A district counted as covered, against a district where a clinic actually runs	Whether the figure records an approval or a service delivered over a stated period	Offer
A helpline's total of calls, against the number of people it has reached	Whether the count is of events or of individuals	Denominator
A gap figure for common mental disorders, against one for severe mental illness	Which population the survey measured before any proportion was calculated	Denominator
A long delay before first psychiatric contact, against a family that refused care	Whether anyone met earlier in the sequence recognised the problem and could redirect it	Access
A death that asks for a risk assessment, against one that asks for a population response	Whether the stem names an identified person or a defined group	Level

MNEMONIC

Level, Offer, Access, Denominator

The four service variables spell LOAD, which is what a population puts on a system and what a system is built to carry. **L**evel, the tier the question is being put to. **O**ffer, what that tier actually holds in staff, supply and training. **A**ccess, who is not arriving, and why. **D**enominator, what a figure counts, who issued it, when, and out of what. Each opens a different part of this chapter, and a stem is usually built on exactly one.

With the axis identified, an answer that earns marks follows five moves in order.

- Name the level at which the failure sits, before naming any intervention.
- Say what that level actually provides, and which of its inputs is missing.
- Name who is not reaching the service, and at which contact the pathway broke.
- Attach the issuing body, the period, the population and the denominator to any figure you use, or say plainly that the figure does not carry them.
- Say what you would not do, and why the obvious clinical answer leaves the service variable untouched.

That last move is where public health becomes visible to an examiner. A candidate who answers that the patient should be restarted on medication and reviewed monthly has answered a question about one person, and the answer would read the same in any country and any decade. One who answers that the follow-up belongs at the tier the patient can reach, that the district's problem is a vacant post rather than an absent programme, that the figure quoted describes a different population, and that the people worth worrying about are the ones who never arrived, has answered a question about a service. Every vignette in this territory rewards the second answer.

Find the service variable - level, offer, access or denominator - and answer with the tier that has to act and the population it has to reach, never with the next step in a management plan.

41 · Consolidation and quick review

Nothing in this chapter is about a single consultation. Every section here starts with a population carrying more illness than the service in front of it is reaching, and asks what to do about the difference: a national programme built for districts that had no psychiatric service at all, a survey that counted illness the clinics never saw, a suicide prevention lever aimed at people who will never present, a primary care worker asked to do what no specialist is available to do, and a school, a prison or a camp holding people no clinic will ever see. The individual encounter belongs elsewhere. What belongs here is everybody who never reaches one.

Call that difference the **need-to-service distance**: the gap between what a population needs and what its service actually delivers to it. This closing section teaches no new programme and no new figure, because each is taught in the section that owns it. What remains is to state the

argument those sections were arranged to make, and to convert it into something producible from a blank page with the book shut. The argument is that community psychiatry is the management of that distance, and that the reasoning is the same every time: measure the distance honestly, name who is responsible for closing it, choose the intervention that reaches the people who are not reaching care, and find out whether it did. Questions here are set in exactly that shape, which is why an answer built as a list of programme names scores so poorly against one built as a plan.

41.1 One argument, tested against every population here

Read as a list of territories this material is enormous and disconnected: programmes and policy, surveys and burden, suicide prevention, stigma, rehabilitation, integration into primary care, disasters and special settings, prevention and financing and digital services, culture and traditional healing. Read as one argument it is a single claim tested across all of them. The claim is that each section describes a distance between a population and a service, that the distances differ only in what produced them, and that the same four moves answer every one.

They recur because there are only so many ways a person with a treatable illness fails to end up in treatment. The illness is not recognised as illness. It is recognised, and reaching help is shaming, or is better answered somewhere the family already trusts. It is recognised and acceptable, and there is no service within reach or nobody in it trained to treat. It is affordable to nobody in the household once travel and lost earnings are counted. Contact is made once and never repeated, so what was received was never adequate to the illness. And in some populations the person sits somewhere no service goes at all. Every section here is one of those situations wearing a programme's name, which is why the reasoning does not change as you move through them.

RULE **A service is adequate or inadequate only against a stated population, never on its own description.** The service's own account tells you what it offers; the population tells you what share of the need that offer reaches. An answer that lists a programme's components and stops has described the offer and said nothing about the distance, which is the only thing the programme exists to change.

41.2 Need side or delivery side: the question that opens every answer

Before anything is planned or measured, the distance has to be sorted into one of two kinds, because the two are closed differently and are confused constantly. A **need-side distance** means the population is not arriving: the illness is not recognised, help-seeking is unacceptable, the first person consulted is not a mental health service, or coming costs more than the household will pay. A **delivery-side distance** means the population arrives and the service cannot deliver: no trained worker, no medicine on the shelf, no follow-up, no route onward for the person who does not improve. Both are present in almost every district and neither excludes the other, but at any one moment one of them is binding, and effort spent on the other moves nothing.

The distinction decides the intervention. A need-side distance is answered on the population's own ground: awareness and literacy work, contact with people who have been unwell, respectful arrangements with the practitioners and healers a family consults first, removing cost at the point

of use, and taking the service to the school, the workplace, the prison or the camp. A delivery-side distance is answered inside the health system: training and supervising the workers already posted, moving a bounded task to a worker who can safely do it, securing medicine supply, opening a remote link to a specialist who cannot be posted locally, and arranging the route by which somebody who is not improving is escalated. Candidates who cannot separate the two propose more specialists for a population that was never going to come, and awareness work for a population already waiting outside a clinic with an empty pharmacy.

It also decides what to measure. A population survey measures need and says nothing about what any service did; a service record measures what the service did and says nothing about the people who never came. Only a figure with a service numerator over a population denominator measures the distance itself, which is why **coverage** is the most useful and least available number in this whole area.

41.3 The four moves, and why they run in that order

Once the distance is named and sorted, one sequence organises the answer whichever section it came from. It is a revision scaffold and a planning discipline rather than an official procedure, and it yields in one situation: where a population is in immediate danger, act first and measure afterwards, which is the standing position in the first response to a disaster. Outside that the order matters, because each move is close to meaningless unless the one before it has been made.

- Measure the distance, and measure it honestly. State who issued the figure, what period it refers to, which population it describes, and what it is a proportion of. A figure missing any of the four is not a measurement, it is a quotation. Where it does not exist, say so, and name what would have to be counted to produce it.
- Name who is responsible for closing it. Every distance here sits at a level that can act: a household, a village-level worker, a primary care team, a district unit, a state, a national programme, an employer, a school, an insurer, a court. An intervention proposed without a level that owns it is a suggestion, and it does not survive the meeting it is proposed in.
- Choose the intervention that reaches the people who are not reaching care. Interventions differ far more in whom they touch than in how well they work in those they touch, so selecting on effect alone selects, reliably, whatever works beautifully in the people already coming.
- Find out whether it worked, and design that before it starts. What was the distance before, what is it now, in the same population and against the same denominator. Deciding this at the end leaves only whatever the programme happened to record, which is almost always what it did rather than whom it reached.

Reversing any two produces a failure recognisable in a real service. Choosing the intervention before measuring the distance is how a district acquires the service its planners find most familiar rather than the one its population lacks. Choosing it before naming the owner produces the pilot that works and never scales, because nobody whose job it was ever ran it. And measuring, naming and delivering without ever evaluating is the commonest of the three: it is how a programme

accumulates a shelf of **activity returns** and cannot answer, when finally asked, whether the distance it was built to close has moved.

Distance	Duty	Door	Difference
MEASURED WITH ITS OWN DENOMINATOR	THE LEVEL THAT OWNS CLOSING IT	THE ROUTE THAT REACHES THE ABSENT	THE SAME MEASURE, TAKEN AGAIN

41.4 A frame that names every distance

Because the distances recur and the four moves do not change, one retrieval frame serves the whole chapter. Hold it as a set of prompts rather than as a set of topics: under pressure the failure is rarely that a candidate cannot name a barrier, it is that they answer on the barrier the question made obvious and never scan for the others.

MNEMONIC

Distance, Duty, Door, Difference

The four moves of every answer in this area, in the only order that works. **Distance**: measure the gap between what the population needs and what the service delivers, carrying the body that issued the figure, the period it refers to, the population it describes and the denominator underneath it, and declare it missing when it is missing. **Duty**: name the level that owns closing it, because an intervention with no owner has no route to delivery. **Door**: choose the intervention by whom it reaches, not by how well it works in those already attending. **Difference**: measure the same distance again, in the same population and against the same denominator, and treat a count of what the service did as no answer at all. The same four, asked in the same order, of a national programme, a district unit, a school, a prison or a helpline.

Each distance is taught in full in the section that owns it, with its own evidence and its own figures. The frame below is a retrieval index rather than a teaching table, and it gives every row the same three columns deliberately, because the argument is that the columns do not change.

THE DISTANCE	WHICH SIDE IT SITS ON	WHAT CLOSES IT, AND WHAT WOULD SHOW IT CLOSED
The illness is not recognised as illness	Need side, before any decision to seek help	Awareness and literacy work, and recognition training for whoever is consulted first. Shown by a change in who arrives, not by a count of people who attended a talk
Help is not sought, or is sought elsewhere first	Need side, and decisive where it operates	Contact-based work, change to the rules that disadvantage, and working arrangements with the healers seen before any psychiatrist. Shown by who arrives and how late, not by an attitude score
Care is unaffordable once fee, travel and lost earnings are added	Need side, and the one most often left out of a plan	Cost removed at the point of use, financing that follows the patient, care delivered nearer to people. Shown by uptake among the poorest, not by a scheme existing
No service within reach, or nobody in it trained to treat	Delivery side	Integration into general and primary care, task-sharing with supervision, secure medicine supply, remote links to a specialist. Shown by people treated, not by workers trained
Contact is made once and never repeated	Delivery side, and the most expensive to repair	Follow-up that is somebody's named job, a register of who is due, and a route that escalates when nothing improves. Shown by retention, not by first attendances
The person sits where no service goes: institution, prison, camp, shift, classroom	Both sides at once, which is why these populations are reached last	A service designed for the setting, with the setting's own authority attached. Shown by the population inside the setting, not by the district total

41.5 The measurement layer, and what each figure is for

Numbers are this chapter's connective tissue and its commonest source of error, and the error is almost never arithmetic. Each figure is best held as a **measurement proxy**: a countable thing standing in for something that matters and cannot be counted directly. What a figure is a proxy for tells you what a healthy-looking value fails to prove, which is what is being tested whenever a question hands you a national number.

WHAT IS COUNTED	WHAT IT IS A PROXY FOR	WHAT A GOOD VALUE FAILS TO PROVE
Prevalence in a population survey	How much illness exists, in the population and period surveyed	Anything at all about services. A survey counts people, whether or not one of them ever reached care
Units sanctioned, approved or established	An administrative decision that a service ought to exist	That any of them opened, was staffed or saw a patient. A sanctioned unit is an intention, not a service
Activity: clinics held, workers trained, calls answered	Effort expended, which is the easiest thing any programme can count	That anybody was reached who was not already being reached. Contacts are not people, and one person contacting twice is counted twice
Coverage: those treated over those with the condition	The distance itself, and the only figure measuring it directly	That treatment was adequate. Who counts as treated depends entirely on the adequacy rule applied
Outcome in those treated, such as recovery or remission	Whether the treatment works in the people who received it	That coverage moved. An intervention can produce excellent outcomes in everyone it reaches and leave the distance where it was
Money allocated, released or spent	Stated priority, and separately the capacity to convert money into service	That the service exists. These are three different figures, and only the third attaches to something that happened

Held this way the numbers stop being a list to memorise and become a set of questions, and the drill worth doing is the reverse one. Take a figure of the kind a question will hand you and, before commenting on its size, produce its population, its period, its issuing body and its denominator. Where one of those cannot be supplied, naming the missing field is a stronger answer than a confident number.

41.6 When closing the distance is not the aim

Two situations sit outside the argument as stated, and applying the frame mechanically to either is wrong in a way that is easy to hear. The first is the **population lever**, the intervention that never touches care-seeking at all. Restricting access to a lethal method, changing how a death is reported, designing work so that it does less harm, amending a rule that disadvantages people with mental illness: none of these depends on anybody recognising an illness, deciding to seek help or reaching a service. They act on everybody at once, they are usually delivered by somebody outside health, and their effect appears in no service record. The question to ask of them is not who was reached but whether the exposure changed, and the level responsible is often a ministry, a regulator or an employer rather than a health service.

The second is the distance that cannot be measured with the counts available. Some of the most quoted figures in this field have no valid denominator: a cumulative total of contacts with a service is not a count of people, and a count of deaths in an occupational group has no matched population figure to sit over. The honest position is that the numerator is real, the denominator does not exist in matchable form, and no rate may be built from the pair. Saying so is not a failure to answer. Building the rate anyway is the failure, and it is the one that gets quoted onward by everybody who hears it.

41.7 The two ways candidates lose these marks

Two failures account for most of what is lost here. The first is **catalogue answering**: reciting programmes, components and structures without once saying what distance any of them addresses or how anyone would know it had closed. It reads as prepared, it fills a page, and it answers an administrative question nobody asked. The second is quoting a national figure without the population it belongs to, which is worse than it looks, because a correctly transcribed number attached to the wrong group is a false statement and no arithmetic check will catch it.

TRAP **Answering a service question with more specialists.** Asked how to improve care for a district, a population or a special setting, candidates reach almost reflexively for more psychiatrists and more clinics, which is a delivery-side answer given without checking which side the distance is on. Where the population is not arriving, capacity added at the clinic door changes nothing and shows up in no measure. An answer that names the side first, then the level responsible, then the intervention, then the measure that would show it worked, has earned most of what is available whatever it eventually proposes.

PITFALL

Reading a busy service as a reached population. A unit that is full, whose staff are exhausted and whose returns look excellent, tells you what happens to the people who arrived and nothing whatever about those who did not. The two move independently, and the busiest services are often the ones with the least idea of their own catchment. The habit worth keeping is to ask, of any service you work in, what share of the people in its area with the condition it treats has ever reached it. Where nobody can answer, that is the finding.

41.8 Where this chapter stops, and what to carry in

An answer is judged as much by what it declines to teach as by what it covers. Consolidating this material means consolidating its edges, because several neighbouring chapters treat the same programmes, populations and deaths from a different angle. Each of the following is worth rehearsing as a handover: named where it touches the question, passed to its owner in a sentence, and left there.

- The provisions of mental health legislation, the advance directive, the nominated representative, the review machinery and the decriminalisation of attempted suicide belong to the Mental health legislation and forensic psychiatry notes. What is kept here is the service consequence: who arrives, what the service records, and what capacity the change assumes.

- Professional conduct, consent, capacity at the bedside, custodial and court procedure and the statutory arrangements for disaster response belong to the Forensic ethics, consent and legal procedure notes.
- Incidence, prevalence, study design, sampling and the derivation of any rate belong to the Research Methods, Biostatistics and Epidemiology notes. This chapter uses those measures as instruments and never derives them.
- The assessment and management of suicide risk in the person in front of you belongs to the Somatic-symptom, sexual, impulse-control disorders and suicide notes. What is kept here is the population lever.
- Cultural formulation at the bedside, idioms of distress, the named culture-bound presentations and the assessment of somebody who has consulted a faith healer belong to the Consultation-liaison, geriatric and transcultural psychiatry notes. What is kept here is the pathway and the partnership.

GOOD TO REMEMBER

Before writing a line of any service proposal, put the four moves down as four headings and fill them in that order. The discipline shows in the fourth: deciding what measurement would demonstrate a change usually forces a change in the intervention itself, because attractive proposals often turn out to move nothing anybody can count. Choosing the measure last, once the plan is fixed, is how a service ends up with years of returns and no evidence.

Carried into the examination, all of it collapses to a sequence that survives when the detail fails. Name the population and the distance. Say which side is binding. Name the level responsible for closing it. Choose the intervention on whom it reaches. State the measure that would show the distance had moved, and say plainly where that measure does not exist. Consolidation buys not more facts but faster access to the ones already learned, so that under pressure the answer arrives as a method rather than as a half-remembered list of programme names.

Community psychiatry is the management of the distance between what a population needs and what its service delivers: measure the distance with its denominator, name the level responsible for closing it, choose the intervention by whom it reaches rather than by how well it works in those already attending, and then measure the same distance again.

PART XI

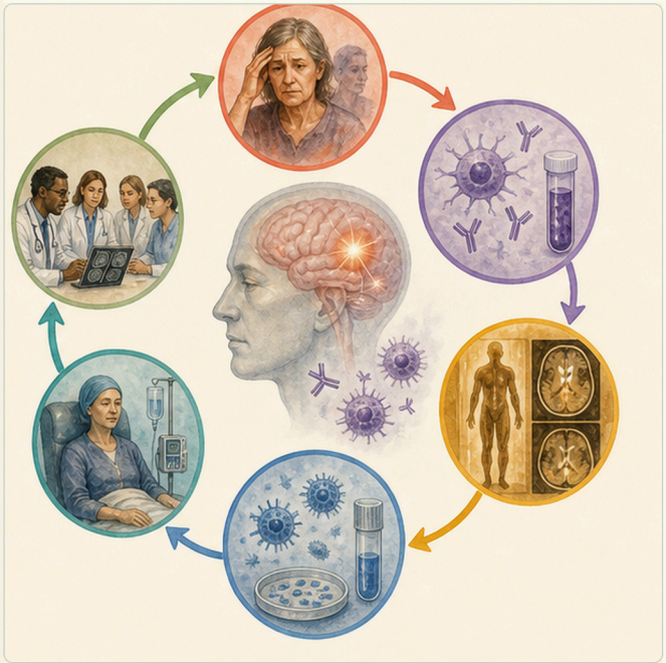
VISUAL 11.3



Palliative psychiatry separates overlapping distress

- Depression
- Demoralisation
- Delirium
- Existential distress
- Symptom care
- Shared goals

Palliative psychiatry distinguishes depression, demoralisation, delirium and existential distress while aligning symptom care with the patient's goals.

Source lock: day-40.final.html#sec-t06

VISUAL 11.4

Systemic disease can signal brain inflammation

- Neuropsychiatric red flags
- Immune evidence
- Malignancy search
- Exclude infection
- Immunotherapy
- Coordinate specialties

Autoimmune, inflammatory and paraneoplastic syndromes are approached through red flags, staged exclusion, immune evidence and coordinated treatment.

PAPER IV

Medical and systemic-disease psychiatry

Four bands . one complete notes document

Cardiac, respiratory and critical-illness psychiatry

1 · The organ interface: what this chapter owns, and what it deliberately points to

At the interface with medicine the psychiatrist is rarely asked what the diagnosis is, and is almost always asked which of three things is producing the picture. The medical illness may be generating the psychiatric symptoms directly. The treatment given for that illness may be generating them. Or the patient may have a psychiatric disorder of their own, arriving in a body that happens to be unwell. Those three answers oblige three different actions, and this chapter is built to make the choice between them quicker and more defensible. This orientation installs that **triage**, adds the fourth question the triage forces, which is who teaches a construct once it has been placed, and draws the map of what follows.

One feature of this chapter should be stated at the outset rather than discovered halfway through. It is deliberately short for the number of constructs it names, because several of them are named here and taught elsewhere in the series. That is a design decision with a defence, and the defence is set out below in full, because a reader who does not understand why a chapter points will read the pointing as a shortfall.

1.1 The three-way question, and what each answer obliges you to do

The first limb is the illness acting on the brain. A systemic disease can produce psychiatric symptoms through mechanisms that require no psychological step at all: inflammation reaching the central nervous system, an immune response raised against a tumour that also recognises neural tissue, hypoxia and carbon dioxide retention, the accumulated products of failing kidneys, endocrine derangement, small-vessel injury, a surge of circulating catecholamines. When this limb is the answer, the psychiatric task is largely to establish it and to hand the patient back for treatment of the disease, because no psychiatric intervention will hold while the process continues.

The second limb is the treatment acting on the brain. Modern medical treatment is potent and it is neuroactive, and the psychiatric consequences of it are not rare accidents but predictable properties of certain agents and certain procedures. Immunosuppression, cytotoxic treatment, interferon, corticosteroids, anaesthesia and surgery itself, oxygen and ventilatory support and implanted devices all change the mental state, each with its own syndrome and its own interval. When this limb is the answer, the decisive evidence usually sits in the drug chart and the procedure record rather than in the mental state examination, and the action is a conversation with the treating team about the exposure.

The third limb is a psychiatric disorder in its own right, occurring in a person who is medically unwell. This limb has two internal shapes that behave alike for management purposes. The

disorder may be one the patient would have developed anyway, whose timing merely coincides with the admission. Or it may be a response to the illness, to what the illness has taken, and to what it will take next. Both need treating as psychiatric conditions, and both are vulnerable to the same argument, which is that a person in this situation would reasonably feel that way. When this limb is the answer, the psychiatric task is the largest and the least likely to be delegated.

Two properties of the triage matter more than the categories themselves. The limbs are not exclusive, and in a medically unwell patient more than one is usually operating at once, so the working question is not which limb is true but which limb is doing the most damage now and which, if missed, is dangerous. And the limbs are answered by different evidence: the first by the disease course and its physiology, the second by exposure and timing, the third by the patient's history, baseline and account of themselves.

Illness	Treatment	Independent disorder	Owner
READ FROM THE DISEASE COURSE	READ FROM EXPOSURE AND TIMING	READ FROM BASELINE AND HISTORY	WHO TEACHES WHAT YOU HAND ON

RULE **State which limb you are in, and say what evidence put you there.** An answer at this interface that names a psychiatric syndrome without placing it against illness, treatment or independent disorder has skipped the step the chapter examines. The examiner's follow-up is almost always the same question in different words: what else could be producing this, and what would separate them?

1.2 The examination technique the triage runs on

The triage is decided by history far more often than by investigation, and by a small number of manoeuvres that are cheap and frequently skipped. Learning them as a fixed order is worth more than learning any single association in this chapter, because the order transfers to every section in it.

Establish the baseline first, from someone other than the patient. What was this person like a month ago, at work, at home, in conversation? A medically unwell patient is observed by staff who never met the well version, so the comparison that would make the change visible does not exist on the ward unless a psychiatrist goes and gets it. Without a baseline, a description of the present state is the only thing available, and a present state cannot establish a change.

Then establish **tempo**. Every psychiatric illness has a characteristic time signature, and the useful reading is the mismatch: a presentation moving faster than the condition it resembles, or continuing to move while adequate treatment is being given, or following a slope rather than an episode. Tempo costs nothing but a careful timeline with corroboration, and it is the reading most often left vague.

Then lay two timelines side by side. The first is the medical course, with its events dated: the acute episode, the operation, the transfer, the deterioration. The second is the drug chart, read for start dates rather than for the current list. Laying the psychiatric change against those two timelines is the single highest-yield act at this interface, and it is what separates the first limb

from the second. A change that begins with the illness and tracks its severity points one way. A change that begins after an agent was introduced, and in the interval characteristic of that agent, points the other.

Ask what was stopped as well as what was started. An admission removes access to alcohol, to nicotine and to whatever else the patient used at home, at a predictable hour, and it frequently interrupts the patient's own long-term psychotropic treatment on the ward round of a team that does not prescribe it. A withdrawal syndrome or an abrupt discontinuation, declaring itself on a medical ward, is read by people looking for a medical explanation as a complication of the illness.

Attend to consciousness and attention before anything else in the mental state. A fluctuating disturbance of attention and awareness changes the entire answer and moves the problem into territory this chapter does not teach, and the whole of that assessment, including any bedside instrument, rating scale or drug choice for it, belongs to the stroke, traumatic brain injury, delirium and focal brain syndromes notes. Recognising the shape and handing it on is the examinable act here.

TRAP **Settling for understandable.** The commonest error at this interface is not a wrong diagnosis but an abandoned one: the low mood is judged a reasonable response to a serious illness, and the assessment stops. Comprehensibility is not a diagnostic exclusion and would not be accepted for any other comorbidity. It costs more than usual here, because the psychiatric state is often what removes the patient from the treatment, the rehabilitation and the adherence that would change the medical trajectory.

1.3 Why a chapter that points beats a chapter that teaches everything thinly

The alternative to routing a topic away is not depth, it is a thin second copy, and a thin copy is worse than an absence because it does not feel like one. A paragraph read on a topic taught properly elsewhere leaves the reader recognising every term, able to defend none of them, and unable to tell which of their own facts are the thin ones. A half-learned fact sits in memory looking exactly like a fact learned well. It survives the first question and fails the follow-up, which is where the marks are, and it fails at the bedside for the same reason.

An explicit omission behaves differently. A reader who has been told that a construct is taught in a named chapter knows precisely what they do not yet have, and can act on it. A reader who met a thin paragraph knows nothing of the kind. That difference is also what makes routing checkable rather than merely tidy: whether a chapter mentioned a topic is a weak test that a chapter can pass while leaving its reader unable to answer anything, whereas whether the reader can name the owner is a test with a right answer.

There is a second argument from the reader's side, and in the last weeks before an examination it is the stronger one. Revision time is fixed, and a chapter that duplicates an adjacent chapter spends that time twice on one topic and not at all on the topics only it can teach. The material this chapter alone carries, which is the systemic and inflammatory disease that presents psychiatrically before anyone knows it is present, is exactly the material that goes unrevised when a chapter pads itself out to look complete. Shortness here buys depth where depth is scarce.

A third argument concerns the text rather than the reader, and this chapter's routing section makes it in full: two accounts of one topic, written by different hands, drift apart, and one owner with one account is the only arrangement in which two pages of the same book cannot disagree.

The fourth argument is the one that matters clinically, and it is why the routing question is not bookkeeping. Liaison work is **routing**. A referral arrives from another team, written by someone unsure what to ask, and the psychiatrist's first act is to decide whose question it is: the treating team's, the psychiatrist's, or a third specialty's altogether. A resident who has practised deciding where a construct belongs has been practising the actual skill, and one who has memorised a paragraph about each has not. The map that follows is therefore content, not furniture.

RULE **A declared gap is a correct answer, and a supplied specific is not.** Where this chapter does not hold a figure, a threshold or a management sequence, it says so and names the kind of source such a statement would rest on. In an examination the equivalent move is to state the direction confidently, state that the magnitude is not something you can quote, and go on. That answer is stronger than a number produced from recollection, which is unverifiable and frequently wrong.

The map of routed constructs is drawn once, on the plate below, and the routing section that follows gives each one an exact address and a single boundary sentence stating what this chapter withholds about it.

1.4 The map of the chapter, and the question each section answers

The chapter is organised into four bands. The first covers cardiac, respiratory and critical-illness psychiatry. The second covers renal, transplant and perioperative psychiatry. The third covers oncology, palliative and paraneoplastic psychiatry. The fourth covers autoimmune, rheumatological and inflammatory systemic disease. A section carrying the psychiatric care of the severely burned patient sits alongside them, and a routing section carries the constructs taught elsewhere. Each section below is named by the question it answers, because a question is easier to hold in mind than a title and it is what an examiner is actually setting.

SECTION	THE QUESTION IT ANSWERS	LIMB OF THE TRIAGE IT MOSTLY TRAINS
Heart failure, arrhythmia and cardiac devices	Which of the somatic symptoms belong to the failing circulation, how do rhythm presentations separate from panic, and what does an implanted device do to a person and a household?	Illness, and independent disorder
Obstructive airways disease, asthma and chronic respiratory failure	Is this breathlessness or is it panic, and which behavioural levers change the trajectory?	Illness, and independent disorder
The stress-heart interface	Can an acute psychological event produce a structural cardiac lesion, and why is the presentation mistaken for a coronary event?	The arrow reversed, running from the psychological event to the organ
Transplant psychiatry and immunosuppressant neurotoxicity	What must a pre-transplant psychiatric opinion contain, and which new neuropsychiatric states belong to the drugs that keep the graft?	Treatment
Perioperative psychiatry and postoperative neurocognition	In what order do the perioperative questions arrive, and which cognitive construct is being named after the operation?	Treatment
Cancer-drug neuropsychiatry	Which agent, which syndrome, and over what interval does that syndrome appear and get looked for?	Treatment
Paraneoplastic neuropsychiatric syndromes	When should a psychiatric presentation start a directed search for a malignancy nobody has found yet?	Illness, before the illness is known
Neuropsychiatric lupus	Does the syndrome in front of you belong to the disease at all, and how is that attribution reasoned when no test settles it?	Illness, with attribution as the whole difficulty
Neurosarcoidosis, cerebral vasculitis and antiphospholipid syndrome	How do you answer on a rare systemic cause without inventing a phenotype for it?	Illness, and evidential discipline
Coeliac disease, inflammatory bowel disease and the gut-brain axis	What do the association and bidirectionality findings actually state, and what will their design bear?	Illness, and independent disorder

SECTION	THE QUESTION IT ANSWERS	LIMB OF THE TRIAGE IT MOSTLY TRAINS
Burns psychiatry	What is the psychiatric task at each stage of the burn timeline, and what question does the injury itself raise about what preceded it?	Independent disorder, and response to injury
Organ-interface routing	Who teaches the constructs this chapter names and does not teach, and what exactly is withheld here?	The fourth question

Read the third column across and the lens becomes visible in the shape of the chapter. The sections on paraneoplastic syndromes, lupus and the rare systemic autoimmune causes are extended training in the first limb, and specifically in its hardest form, where the illness has not yet been identified and the psychiatrist is the person who must raise the possibility. The sections on transplantation, the perioperative period and cancer drugs are training in the second limb, where the answer is in the exposure and the interval rather than in the mental state. The cardiac, respiratory, bowel-disease and burns sections spend most of their length on the third limb, on psychiatric disorder in a person who is genuinely and often permanently unwell, and on the reasoning that keeps it treatable rather than merely understandable.

One section sits outside the scheme on purpose. The stress-heart interface runs the arrow the other way, from an acute psychological event to a demonstrable cardiac lesion, and it is in the chapter because it is the clearest available demonstration that the traffic at this interface is not one-directional. Holding that section next to the triage is useful precisely because it is the exception.

1.5 What this chapter does not teach, and where each of those lives

Five boundaries are enforced throughout, and knowing them in advance saves a reader from searching this chapter for material it has deliberately excluded.

- Prescribing at the interface, meaning organ-adjusted dosing, interaction rankings and the choice of agent in cardiac, hepatic, renal or transplant disease, belongs to the psychopharmacology notes. This chapter teaches everything that precedes a prescription and adds no second version of the prescription itself.
- The assessment and management of the acute confusional state belongs to the stroke, traumatic brain injury, delirium and focal brain syndromes notes, including every bedside instrument, rating scale and drug choice for it. Several sections here reach that boundary, at the end of life, after an operation, in critical illness and in the early burn injury, and each marks the hand-off rather than crossing it.
- Capacity belongs to the mental health legislation notes. This chapter says only that capacity is decision-specific and time-specific, which is enough to reason with, and it states no statutory test.

- The generic immune-brain framework, the workup of autoimmune encephalitis and the neuropsychiatry of interferon-beta belong to the neurology and psychiatry interface notes. What this chapter owns on the immune side is the disease-specific presentation and the decision to suspect, not the general model and not the investigative protocol.
- The constructs defined by a clinical setting rather than by an organ, being the coronary care unit, the intensive care unit, the dialysis unit, the oncology ward and the palliative care unit, belong to the consultation-liaison, geriatric and transcultural psychiatry notes, and the psychiatric disturbance that follows a corticosteroid belongs to the endocrine and metabolic psychiatry notes. Those two owners take the constructs this chapter routes, and the routing section names each one with its boundary.

None of this is a shortfall being managed politely. What those constructs share is a referral pathway and a liaison relationship, not a pathophysiology, so they belong with the chapter that teaches liaison work. The one that follows a drug follows the drug. The classification is working, and stating it out loud is the difference between a boundary and an omission.

1.6 How to use this chapter in the weeks before the examination

Read the routing plate before anything else, so that the constructs this chapter will not teach are settled and stop feeling missing. Then read each section for its discriminators rather than for its lists, because every section here is built around a small number of separations that decide the answer, and the lists around them are recognisable at the paper and not defensible under questioning.

Practise the triage out loud on whichever medical patient you happen to be asked about, and practise it as a four-step answer rather than as three categories. The four cues below are a teaching scaffold for that sequence rather than a validated instrument, and the sequence itself is the answer structure this whole chapter installs. It works on a construct you have never met, which is more than can be said for a memorised list.

MNEMONIC

Limb, Evidence, Shift, Owner

Limb: which of the three the picture mostly sits in, the illness acting on the brain, the treatment acting on the brain, or a psychiatric disorder in its own right in a person who is unwell. **Evidence**: what placed it there, which is the disease course and its physiology for the first limb, exposure and timing for the second, and the patient's baseline, history and account of themselves for the third. **Shift**: what would move you to another limb, said out loud, because the limbs are not exclusive and the working question is which one is doing the most damage now. **Owner**: which chapter takes whatever you have just handed on, named rather than rebuilt from memory.

IN INDIA

No India-specific epidemiology is held for this orientation and none has been invented. The Indian point here is one of service structure. In most Indian general hospitals the psychiatrist arrives at the medical bedside on request, usually late, usually to a referral question written by a team under pressure, and often without the previous notes, the collateral history or the drug chart's start dates to hand. Every manoeuvre in the triage above depends on information the referring team holds and the referral letter rarely contains, so the practical skill is asking for it explicitly and early rather than working from the mental state alone. That is also the argument for reading the consultation-liaison material before a liaison posting begins.

GOOD TO REMEMBER

Three questions at the bedside and one afterwards. Is the disease doing this? Is the treatment doing this? Is this a psychiatric disorder in a person who is unwell? And then, before writing: whose chapter answers the part I am handing on?

This chapter teaches a triage and a map, and it teaches them together, because at the medicine interface deciding where a problem belongs is most of deciding what to do about it.

2 · Depression and anxiety after myocardial infarction and in coronary artery disease: prognosis and safe antidepressant choice

Six of the topics in this chapter are addresses rather than lessons, and saying so plainly is the most useful thing this section can do. Depression and anxiety after myocardial infarction and in coronary artery disease, intensive care psychiatry and the psychological sequelae of critical illness, psychiatric assessment in end-stage renal disease and on dialysis, depression and demoralisation in cancer, palliative care psychiatry, and steroid-induced psychiatric disturbance are each named in this chapter and taught in none of it. Each has an owner elsewhere in the series. This section hands the reader that owner, states what is withheld here, and explains why withholding it is honest rather than lazy.

2.1 Why a routed chapter is more honest than a complete-looking one

The alternative to routing is not depth. It is another thin copy. A chapter that gives every adjacent topic a paragraph produces a reader who recognises every term on the paper, can defend none, and cannot tell which of their facts are the thin ones. That is the harm, and it is not obvious: a half-taught fact does not feel half-taught. It sits in memory looking like a fact learned properly, and it fails at the point of use rather than the point of reading.

The second harm is duplication, and it is invisible while writing. Two accounts of one topic, written by different hands against different sources, do not stay identical. They drift, and a reader who has met both cannot tell which is authoritative. One owner and one account is the only arrangement in which two pages of the same book cannot disagree.

The third point is about how completeness gets checked, which is why routing must be declared out loud rather than practised quietly. Asking whether a chapter mentions a topic is an existence check, and a chapter can pass it while leaving the reader unable to answer anything. Asking whether the reader can name the owner is the better test, because it is checkable. A **routed construct** turns an implicit omission into an explicit one, and an explicit omission can be acted on. Silence cannot.

A fourth reason is particular to this chapter. Five of the routed topics are not defined by an organ at all. They are defined by a setting: the coronary care unit, the intensive care unit, the dialysis unit, the oncology ward, the palliative care unit. What they share is a referral pathway and a liaison relationship, not a pathophysiology, so they belong together in the chapter that teaches liaison work. The remaining topic is defined by a drug and follows the drug. Routing here is the classification working correctly, not a shortfall being managed politely.

RULE **Each routed construct gets one exact cross-reference and one boundary sentence here, and nothing else.** This section supplies no incidence, no prognosis, no management sequence and no dose for any of them, and that restriction is its design, not its limitation. A sentence here that supplied one would be the second copy this arrangement exists to prevent.

2.2 The routing plate, and how to read it

The plate below is this section's content, and each row holds three things.

- The construct, worded as the examination will name it.
- The chapter that owns it, which is what the reader is meant to leave with.
- The single sentence stating what this chapter will not say about it, so that the omission is explicit rather than silent.

The rows are addresses with a warning label attached; they will not survive being revised from.

The owning-chapter column is repetitive, because most of these are liaison presentations pointing at the same place. Some rows carry a split, because a construct can have its assessment owned by one chapter and a single limb owned by another, and the plate says so.

Fig 40.1 The routing map, which is the whole visible content of the organ-interface routing section. Six of this chapter's constructs have owners in earlier chapters, and drawing that once is what makes a short chapter honest rather than evasive. Read the shape before the words: five rows converge on a single destination panel, so the reader sees at a glance that consultation-liaison psychiatry, not this chapter, holds post-infarction mood, critical-illness sequelae, dialysis, cancer and palliative care. The sixth row breaks away because steroid psychiatry belongs to the endocrine and metabolic chapter, and that break is the only thing the second colour means. What each row prints in amber is the entire permitted output: a naming sentence, the exact cross-reference, and a full stop. From memory you should be able to say, for any of the six, which chapter owns it and that this one adds no figure, no threshold and no ladder of its own.

2.3 What this section cannot establish, and how to answer without it

Two things a fuller account would supply are declared here as gaps, because a **declared gap** is a correct answer and an invented figure is not.

The first concerns anxiety rather than depression after infarction. A statement of its prognostic effect would rest on a meta-analysis in the cardiology literature, identified for this series but not opened in quotable form. The consequence is stated rather than concealed: this chapter attaches no prognostic figure to post-infarct anxiety, and a candidate should attach none from memory. What can still be said is that anxiety and depression after infarction are separate constructs on separate evidence, and that an answer treating them as interchangeable makes a claim it cannot support.

The second concerns the desire for hastened death in advanced illness. No current guideline recommendation, and no primary intervention study, could be opened for this series with text usable on its own terms on assessing or managing it; such a claim would rest on an oncology

clinical-practice guideline group, or on investigators of primary palliative-care psychotherapy trials. The absence of a quotable recommendation licenses no inaction: a statement of that kind is met as a communication carrying meaning rather than a symptom to be corrected, and decision-making capacity, which is decision-specific and time-specific, is doctrine owned by the Mental health legislation and forensic psychiatry notes. What is withheld here is a protocol, not the obligation to respond.

2.4 The rows in words, with the boundary stated for each

Depression and anxiety after myocardial infarction and in coronary artery disease is owned by the Consultation-liaison, geriatric and transcultural psychiatry notes, and the choice of antidepressant in established cardiac disease is owned by the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes. This chapter states neither the size of the prognostic effect nor the name of any preferred agent.

3 · ICU psychiatry, post-intensive-care syndrome and psychological sequelae of critical illness

Intensive care psychiatry and the psychological sequelae of critical illness are owned by the Consultation-liaison, geriatric and transcultural psychiatry notes, and delirium in the critically ill patient is owned by the Stroke, TBI, delirium and focal brain syndromes notes. The route follows from the shape of the construct, since post-intensive care syndrome encompasses physical, cognitive, and psychological impairments that persist in patients after discharge from an intensive care unit. Only one of those domains is psychiatric, so a chapter organised by organ could own only a slice of it. Its assessment, its course and its treatment appear here in no form.

4 · Psychiatric assessment and management in end-stage renal disease and on dialysis

Psychiatric assessment and management in end-stage renal disease and on dialysis is owned by the Consultation-liaison, geriatric and transcultural psychiatry notes, and dose adjustment in renal impairment is owned by the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes. The routing follows the service design rather than the diagnosis, since psychological support and interventions should be delivered within the kidney care setting. That makes it a liaison topic before a nephrology one, and no screening approach, treatment sequence or dosing rule appears here.

5 · Depression, demoralisation and adjustment in cancer: screening and treatment

Depression, demoralisation and adjustment in cancer is owned by the Consultation-liaison, geriatric and transcultural psychiatry notes. That chapter carries the distinction between demoralisation and depressive disorder, and the treatment sequence; this chapter carries neither, so a candidate revising how demoralisation differs from depression should not look here. A screening question or brief instrument for depression in advanced disease is stated by neither chapter, and that is a gap in the series rather than a section you have failed to find, so supply none from memory.

6 · Palliative care psychiatry: delirium at end of life, desire for hastened death and existential distress

Palliative care psychiatry is owned by the Consultation-liaison, geriatric and transcultural psychiatry notes, with delirium as a syndrome owned by the Stroke, TBI, delirium and focal brain syndromes notes and the doctrine of capacity owned by the Mental health legislation and forensic psychiatry notes. This chapter says only that capacity is decision-specific and time-specific, and states no approach to sedation, existential distress or a request for hastened death. What changes about delirium once treatment intent has changed, including how far to investigate and how antipsychotic choice differs in the final phase, is stated by neither owner and is a gap in the series rather than a section you have failed to find.

7 · Steroid-induced psychiatric disturbance: mania, depression, psychosis and management

Steroid-induced psychiatric disturbance is owned by the Endocrine and metabolic psychiatry notes. It is the row that follows a drug rather than a setting, so its dose relationship, its onset window and its management sequence all sit in that chapter and none is stated here. The chemotherapy and interferon section of this chapter carries no steroid limb either, by owner ruling, so there is exactly one place to look.

TRAP **Revising from the routing line as though it were an abstract.** A cross-reference is an address, written to be too short to revise from. The failure mode is a candidate who says depression after infarction matters to prognosis but cannot say what it does to it, or who knows corticosteroids cause psychiatric disturbance but cannot say when. Both collapse on the follow-up.

IN INDIA

No India-specific row is held for this section, and none has been invented. The Indian point is one of study order rather than epidemiology. Each of these constructs is by definition a liaison presentation: the patient is admitted under another team, and the psychiatrist arrives on request, often late and with a referral question written by somebody unsure what to ask. The chapters that own them also carry the referral, capacity and communication material, so read them before a liaison posting starts.

GOOD TO REMEMBER

At the bedside the question is not what you remember but which chapter answers the referral in front of you. Cardiac ward, intensive care, dialysis unit, oncology ward and palliative care unit all route to the liaison chapter. A psychiatric disturbance that began after a corticosteroid was started routes to the endocrine and metabolic chapter. Knowing that split in advance beats a half-remembered paragraph about any of them.

These constructs are named here, routed here and taught nowhere in this chapter, so that each is taught once, in full, where it is owned.

8 · Psychiatric aspects of heart failure, arrhythmia and cardiac devices

The failing heart produces most of the somatic symptoms a depression scale counts, so cardiac psychiatry is decided by history and by stage of illness rather than by a symptom total. Drug treatment is deliberately absent: prognosis and antidepressant choice in cardiac disease are taught with depression and anxiety after myocardial infarction and in coronary artery disease, and organ-adjusted dosing with the psychopharmacology notes. What is examinable here precedes any prescription.

8.1 The overlap that defeats a symptom count

Advanced heart failure and a depressive episode share almost the entire somatic side of the syndrome. Breathlessness on exertion, fatigue, disturbed sleep, poor appetite, weight change, psychomotor slowing and loss of sexual interest each follow from a failing circulation, from the treatment burden it imposes, or from a mood disorder, and none of them separates the possibilities alone. A scale that counts them inflates where accuracy matters most; a clinician who discounts them all misses the depression that is present.

Weight the **cognitive and affective items** and interrogate the somatic ones instead of scoring them. Anhedonia in activities that make no physical demand is the most useful single question on a cardiology ward: a person too breathless to walk to the gate can still say whether the radio or a visitor gives any pleasure. Guilt, worthlessness, hopelessness out of proportion to the prognosis actually given, and the thought that others would be better off without them are produced by mood.

Timing is the strongest discriminator on history. If breathlessness and oedema improved with cardiac treatment while mood, interest and outlook stayed flat, the mood state has separated from the haemodynamic state and is behaving as an illness in its own right. If low mood arrived with a decompensation and lifted as it settled, an adjustment reaction reads better. Nocturnal waking divides the same way: waking breathless and needing to sit upright points at the circulation, while waking in the early hours, alert, with the day at its worst on rising, points at mood.

In adults with confirmed heart failure, **people with heart failure and depressive symptoms had poor health-related quality of life**, so the depressive syndrome tracks with how the person actually lives rather than with a score alone. That finding carries a direction and a population and no magnitude, so its use is to justify looking, and to justify treating what is found.

RULE **Attribute by timing and by course, never by the symptom itself.** Any single somatic symptom in heart failure is uninformative. What discriminates is whether it moved with the cardiac state or independently of it, and only a sequential history answers that. Put the cardiac events, the treatment changes and the mood changes on one timeline and the attribution usually declares itself.

8.2 Stage of illness as the organising question

Heart failure is not one psychiatric situation, and the commonest error in a viva is to describe it as though it were. The task, the assessment priority and the realistic intervention all change with the stage.

STAGE	THE PSYCHOLOGICAL TASK	WHAT THE ASSESSMENT MUST REACH
New diagnosis	Absorbing a prognosis and a changed identity, often while still physically well	What they were told, what they believe it means, and who else heard it
Stable on treatment	A daily regimen, fluid and salt restriction, weighing, symptom diaries	Adherence, the cost of the regimen, and whether the effort has become hopeless rather than tiresome
Recurrent decompensation	Repeated admission, unpredictability, lost confidence in the body	Demoralisation, fear of dying in an episode, sleep, the carer's own state
Advanced illness	Anticipated dying, dependence, the meaning of continued treatment	Depression as distinct from a considered response to a real prognosis

The hand-offs are explicit. Demoralisation as a construct, and the screening and treatment of depression and adjustment in a life-limiting diagnosis, are taught in the organ-interface routing section, which also owns palliative care psychiatry and the desire for hastened death. Delirium in the decompensated or dying cardiac patient belongs to the stroke, traumatic brain injury and focal brain syndromes notes, including the bedside instruments.

Cognition is examined rarely and matters constantly. Where attention and processing speed are slowed in advanced disease, a crowded regimen and a consent conversation are at risk, and the risk peaks during a decompensation. Since **heart failure with depressive symptoms ran with poor health-related quality of life**, the stage review is a functional review as much as a diagnostic one.

8.3 Arrhythmia in the psychiatric clinic, and the separation from panic

Arrhythmia reaches psychiatry along several routes: a paroxysmal rhythm disturbance already called panic, an anxiety syndrome that grew out of a documented arrhythmia, a rhythm disturbance and an anxiety disorder present together, and the causes shared by each, which include alcohol, stimulants, thyroid disease and sleep deprivation. The separation is made on history.

Onset and offset carry most of the information. A paroxysmal rhythm disturbance tends to start and stop abruptly, sometimes with a trigger such as a change of posture, and the racing heart precedes the fear. A panic attack builds to a peak over minutes and settles more gradually, fear and bodily symptoms rise together, and catastrophic thinking about the heart is present at the peak. Episodes that wake a person from sleep, that carry syncope, or that occur on exertion rather than at rest shift the balance towards a cardiac cause.

TRAP **Diagnosing panic disorder in a patient whose rhythm has never been recorded during an episode.** They overlap almost completely at the level of reported symptoms, and the label is sticky: once panic is written, every later episode is read through it and the rhythm is never captured. The requirement is an ambulatory or event recording during a typical attack, and the formulation should state whether one exists.

The reverse error is commoner in cardiology. A person with a documented rhythm disturbance and an anxiety disorder is often told the palpitations are anxiety, which is heard as an accusation and produces exactly the hypervigilant self-monitoring that amplifies the next episode. The workable formulation is that the rhythm is real, the fear is real, and each raises the salience of the other.

8.4 Rhythm procedures and the peri-procedural window

Atrial fibrillation is an episodic, bodily felt and unpredictable illness, and unpredictability is the property that generates anticipatory anxiety in any organ system. The load in the group referred for rhythm procedures is substantial: **depressive and anxiety disorders are highly prevalent among patients with atrial fibrillation (AF) undergoing pulmonary vein isolation (PVI)**.

Because **depressive and anxiety disorders are highly prevalent in the group referred for pulmonary vein isolation**, screening belongs before the procedure rather than after a disappointing result. A person anxious before ablation who remains symptomatic after it is easily written off as a treatment failure when the rhythm record is clean. Naming it in advance changes how a residual symptom is read: as an expected part of recovery rather than as proof the procedure failed.

Symptom-rhythm concordance is the idea underneath this. Do the symptoms the patient reports coincide with the rhythm the record shows? Concordance supports a rhythm intervention; discordance says something other than the rhythm is generating the experience, usually interoceptive vigilance, which responds to psychological work rather than to further ablation.

8.5 Living with an implanted defibrillator

An implanted defibrillator is unlike any other treatment a psychiatrist meets, because its therapeutic action is an aversive event delivered without warning from inside the body. The psychopathology follows from that: the therapy hurts, its timing is unpredictable, and it cannot be escaped by leaving the situation. A sudden painful event paired with whatever the person happened to be doing is all ordinary conditioning needs.

Shock-related anxiety is anticipatory: continuous apprehension about the next discharge, with hypervigilant monitoring of the pulse, the chest and any sensation that preceded a previous one. **Avoidance** is the disabling part and the part most often missed, because the person rarely volunteers it. Exertion, sexual activity and driving are avoided in case they provoke the device, being alone in case a discharge occurs with nobody present, and public places because a discharge witnessed by strangers humiliates as well as frightens. After repeated discharges in a short period, intrusive recollection, hyperarousal and phobic avoidance can take a post-traumatic form. Some

patients describe a **phantom shock**, the vivid experience of a discharge the device record shows did not happen.

The household is part of the presentation. Partners commonly witness the discharge, and witnessing what looks like a resuscitation produces its own distress, its own hypervigilance and its own protective restriction of the patient's activity, so a couple can arrive at a shared avoidance that neither of them has named. Hence the recommendation that **psychological assessment, monitoring, and therapy should be offered to ICD patients and their partners as part of routine care**. Each noun does work: assessment at implantation and after any discharge, monitoring because a person well at the device clinic one month may be housebound the next, therapy because detection alone is not a service, and partners because the couple is the unit of care.

RULE **Ask what the person has stopped doing since the device was implanted.** Anxiety is reported readily and avoidance is volunteered almost never, yet avoidance is what removes exercise capacity, work, driving, intimacy and social life. Put the question to the patient and to the partner separately.

TRAP **Reading shock anxiety as simple reassurance-seeking and answering it with reassurance.** Reassurance relieves for minutes and teaches the person that the fear requires an external answer, so the checking increases. The device is genuinely capable of firing, so honest information plus a rehearsed plan for what to do when it fires converts an unbounded threat into an event with a script.

8.6 The device at the end of life, and the deactivation conversation

As cardiac disease advances, the shock function can fire during the dying process, with no prospect of restoring a life the person is already leaving. Deactivating the shock therapy is therefore a planned conversation, held while the person is well enough to hold it and recorded where the treating teams can find it. Psychiatry is asked in for three reasons: capacity, whether depression is colouring the decision, and how to hold the discussion with a family who may hear deactivation as abandonment.

Capacity here is decision-specific and time-specific, so the question is whether this person can make this decision now, and the answer can change with the delirium, the hypoxia or the sedation of an acute episode. The doctrine and the statutory test belong to the mental health legislation notes. What psychiatry adds is the mood assessment underneath: a wish to stop a burdensome therapy late in an illness can be a considered choice, whereas the same wish carried on pervasive hopelessness and a conviction of being a burden requires that the depression be treated and the question asked again.

Families frequently hear deactivation as switching the device off altogether, or as an act that causes the death. What deactivation covers is for the cardiology and device team to answer explicitly, in the family's own language; the psychiatric contribution is to ensure the question is asked and the answer understood.

8.7 Non-drug management, and who does what

Everything here is deliverable without a prescription, which matters where the cardiac regimen is already crowded.

- A written plan for what to do if a discharge occurs or an episode starts: rest, position, who to telephone, when to attend, and when the device record will be checked.
- A graded return to activity, agreed with the cardiologist in writing and shared with the partner. Avoidance is reversed by activity that has been sanctioned; encouragement without sanction moves the conflict into the household.
- Cognitive-behavioural work aimed at the maintaining cycle: catastrophic interpretation of a bodily sensation, checking, avoidance, and the relief that reinforces it. Interoceptive exposure needs explicit cardiology agreement first.
- Paced breathing and applied relaxation, taught as skills for the episode rather than offered as a cure.
- Couple-inclusive sessions as standard rather than as an extra, since **psychological assessment, monitoring and therapy are recommended for defibrillator patients and their partners as part of routine care**.
- Coordination with cardiac rehabilitation where it exists, and with the device clinic in every case, including a question about remote monitoring: it reassures some patients and feeds the vigilance of others.

Sleep is where the cardiac and psychiatric arms of the plan meet. Orthopnoea, nocturia from the regimen, fear of dying in sleep and anticipatory fear of a night-time discharge each fragment the night and each has a different remedy, and asking what wakes the person, and what they do next, separates them faster than any sleep questionnaire.

What belongs elsewhere, named: antidepressant choice, prognostic effect and cardiac safety sit with depression and anxiety after myocardial infarction and in coronary artery disease; organ-adjusted dosing with the psychopharmacology notes; the acutely stress-precipitated cardiomyopathy that mimics infarction with the stress-heart interface section; delirium with the stroke, traumatic brain injury and focal brain syndromes notes; palliative care psychiatry with the organ-interface routing section.

Timing, not the symptom WHAT DECIDES ATTRIBUTION	**Stage, not the label** WHAT ORGANISES THE ASSESSMENT	**Recorded, not assumed** WHAT THE PANIC LABEL NEEDS FIRST	**Avoidance, and the partner** WHAT THE DEVICE INTERVIEW MUST REACH

Each tile carries a decision rather than a fact, and not one of them can be settled from the symptom in front of you: attribution comes from the timeline, priority from the stage, the panic label from a recording, and the device interview from the partner as well as the patient.

IN INDIA

Device therapy is largely an out-of-pocket purchase, the device clinic may be a day's travel away, and the family rather than the individual usually carries the decision and the follow-up. The couple-inclusive element of the recommendation is therefore easier to deliver here than in services built around the individual patient, while longitudinal monitoring is harder, because the person is seen when they can travel rather than when they are due. A written plan the family can act on at home does more work here than a scheduled review. What this section does not hold is worth stating: no Indian prevalence figure for depression in heart failure, no Indian count of implanted devices, no Indian cost figure for defibrillator therapy.

GOOD TO REMEMBER

A short set of questions does most of the ward work: what has changed since the last cardiac event and in what order, what the person has stopped doing since then, and who else was in the room when the prognosis or the device was explained. Attribution, avoidance, and the partner who is carrying the other part of the distress.

The plate lays the limbs of the assessment side by side: the shared somatic symptoms with the questions that separate them, the arrhythmia presentations and where each routes, the psychopathology of living with a device, and the non-drug management that follows. Prescribing is absent from it by design.

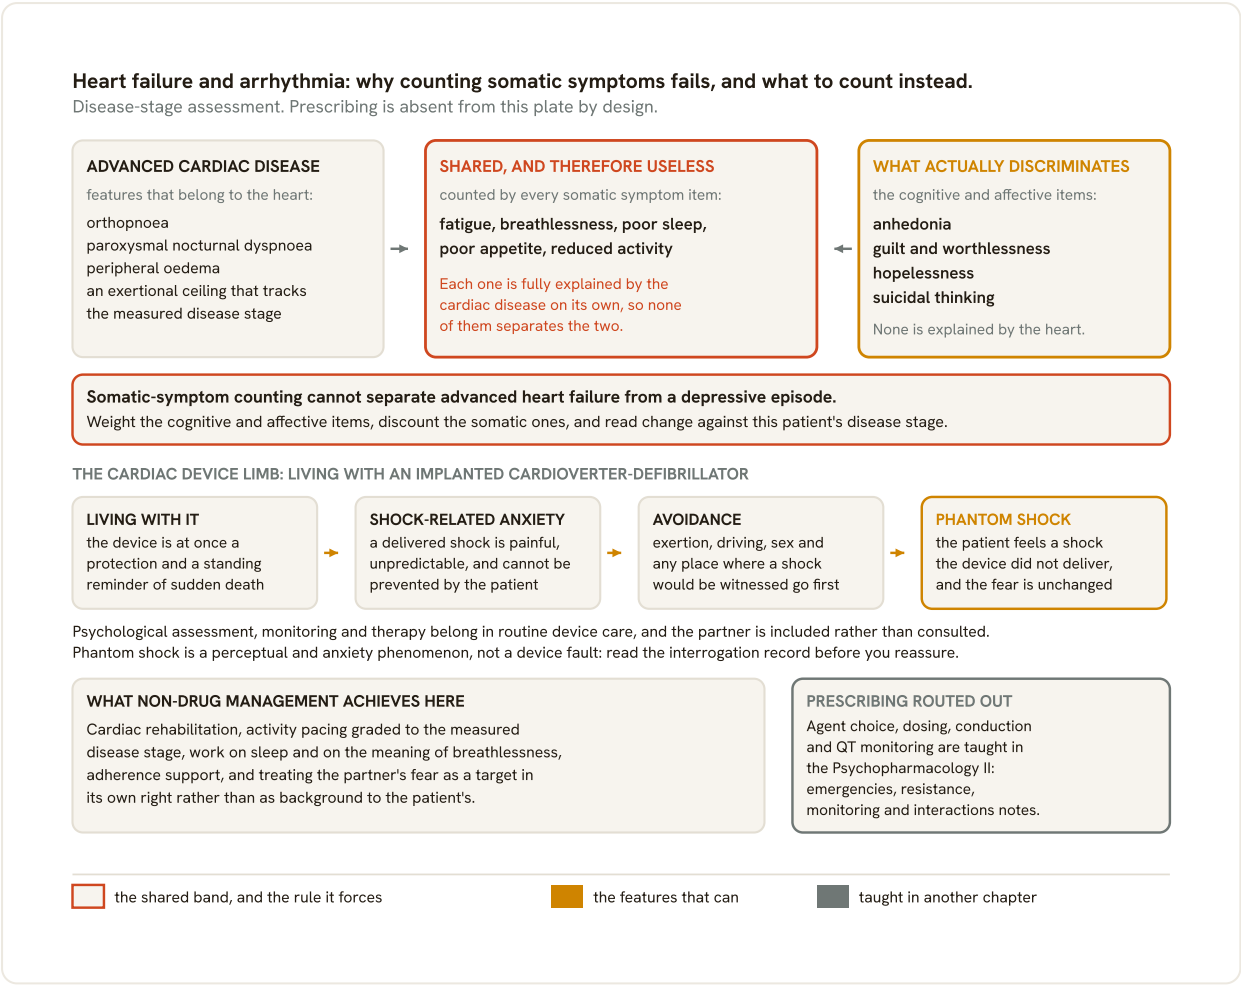

Fig 40.2 Disease-stage assessment in heart failure and arrhythmia, built around the symptom-overlap problem. The centre panel holds the five features a somatic symptom count would score, and every one of them is fully produced by advanced cardiac disease on its own, which is why an instrument weighted toward somatic items inflates in this population and a candidate who counts them reaches the wrong answer confidently. The discrimination lives in the right-hand panel, in items the heart does not generate. The device limb runs on its own logic: the implanted cardioverter-defibrillator protects and threatens at the same time, a delivered shock is painful and cannot be prevented by the patient, avoidance follows, and phantom shock closes the loop by producing the fear without the event. Prescribing is deliberately absent. From memory you should be able to name the five shared features, the four discriminating ones, and the four steps of the device limb, and say why the first list cannot settle the diagnosis.

> Attribute by timing and course, ask what the person has stopped doing since the device was implanted, and treat the couple, since psychological assessment, monitoring and therapy should be offered to defibrillator patients and their partners as part of routine care.

9 · Psychiatric aspects of COPD, asthma and chronic respiratory failure

Breathlessness and panic recruit the same body, and the patient living through either one cannot reliably tell you which of them started. Respiratory psychiatry is examined on that ambiguity and on what a clinician does about it at the bedside. This section installs four things: a working discrimination between the dyspnoea of obstructive airways disease and the dyspnoea of a panic attack; the two specialty-guideline positions this chapter can anchor to a respiratory source; the behavioural levers that move outcome, which are referral to rehabilitation and inhaler adherence; and an honest declaration about chronic respiratory failure, where a specialty

statement was sought and not obtained. Cardiac material is not taught here. Heart failure, arrhythmia and cardiac devices have their own section, and the psychiatric sequelae of critical illness, including post-intensive-care syndrome, sit in the merged organ-interface routing section.

9.1 The discrimination this section exists for

A patient who is breathless, frightened, tachycardic, tremulous and unable to complete a sentence has produced a presentation that two very different processes can generate. Airflow limitation produces breathlessness, and breathlessness produces fear; fear produces hyperventilation, and hyperventilation produces breathlessness. The loop closes in both directions, which is why the question is rarely which one the patient has, and almost always which one is driving the episode in front of you.

Several features shift the probability without settling it. The temporal shape is the most useful single discriminator: a panic attack crescendos and then subsides over a bounded period, whereas an exacerbation of airways disease climbs and stays. The relation to exertion matters, because bronchoconstriction and deconditioning both load onto effort while a panic attack characteristically arrives at rest and out of context. Objective airflow limitation, audible wheeze, a fall in oxygen saturation and a response to a reliever inhaler point one way; circumoral and peripheral paraesthesiae, carpopedal spasm and the light-headedness of hypocapnia point the other, since an obstructed patient usually cannot blow off enough carbon dioxide to produce them. The content of the thought is informative and is often the most accessible part of the history: the catastrophic cognition in panic is about dying or losing control now, and it recurs in the same form.

None of this licenses a clean split, and the examinable position is that it does not need to. A patient with obstructive lung disease who develops recurrent panic attacks has both conditions, each worsening the other, and treating only one leaves the disability where it was. **Anxiety sensitivity**, the tendency to read bodily sensations as dangerous, is the variable that couples them, and it is the one a psychiatrist can treat.

RULE **The dangerous direction of error is treating airflow limitation as anxiety, not the reverse.** Calling a panic attack an exacerbation costs an unnecessary course of treatment. Calling an exacerbation a panic attack can cost a life. Where the two cannot be separated in the room, treat the airway first, interrogate the psychiatry afterwards, and record why.

9.2 Why mood and anxiety cluster in obstructive lung disease, and what they cost

The association is not a coincidence of two common conditions sharing a population, and a candidate who says only that will be pressed. Several distinct pathways converge, and naming them separately earns the marks.

The behavioural pathway is the strongest and the most modifiable. Breathlessness on exertion is aversive, so the patient reduces exertion; reduced exertion produces deconditioning, and deconditioning lowers the threshold at which the next effort produces breathlessness. The spiral narrows the patient's world by degrees and delivers the ingredients of depression, which are loss

of activity, loss of role and loss of contact. From the anxiety side it is avoidance learning: exertion is paired with a frightening sensation, and the patient stops.

Beyond that sit contributions this chapter can name but does not quantify. Tobacco use is a shared risk factor for the lung disease and for several psychiatric conditions, and it means a proportion of these patients carry a nicotine dependence any plan must address. Chronic hypoxaemia and hypercapnia affect attention, processing speed and daytime alertness, and disrupted nocturnal breathing fragments sleep, which independently degrades mood. Systemic corticosteroid exposure is common here and carries its own psychiatric consequences; that construct is owned elsewhere and is named only as a hand-off. Finally, the disease is progressive, visible and frightening with a foreseeable trajectory, and demoralisation in that setting is a reasonable response as well as a clinical problem.

The cost is not only distress. Comorbid mood and anxiety symptoms track with poorer adherence, more frequent presentation to acute services and worse functional status at any given level of measured airflow limitation. No prevalence figure, effect estimate or readmission proportion is held by any claim row available here, so none is stated: carry the direction, and say openly that the magnitude was not obtained.

TRAP **Deciding that low mood in advanced lung disease is understandable, and therefore leaving it alone.** Comprehensibility is not a diagnostic exclusion, and this reasoning would not be accepted for any other comorbidity. It matters more than usual here because the depressive component is what removes the patient from the activity, the rehabilitation and the adherence that would change the trajectory. An understandable depression and a treatable depression are the same depression.

9.3 Pulmonary rehabilitation, and the referral statement to memorise

Pulmonary rehabilitation is a structured programme of supervised exercise training combined with education and self-management support for patients with chronic respiratory disease. It belongs in a psychiatry chapter because it acts on the behavioural spiral above: it is the intervention most likely to reverse the deconditioning, avoidance and social withdrawal carrying much of the psychiatric burden here.

The single most examinable statement this section owns concerns who gets referred. The specialty guideline position is that **coexistent symptoms of anxiety and/or depression in patients with COPD should not preclude referral to pulmonary rehabilitation**. That sentence is worth learning in its shape as well as its content, because it is written as a prohibition on exclusion rather than as an encouragement to refer.

It is written that way because the pressure in real services runs the other way. A patient who appears low, unmotivated or unlikely to complete a course is exactly the patient a stretched programme is tempted to screen out, and the screening is usually informal, done by the referrer, on a judgement about probable engagement rather than by any stated criterion. The guideline blocks that move, and the logic is worth stating in a viva: the psychiatric symptoms are in

substantial part a product of the very deactivation the programme treats, so using them to withhold it removes the intervention from the group with most to gain.

Two boundaries keep the statement honest. It concerns referral and not completion, so supporting attendance, which is where anxious and depressed patients genuinely fall away, remains a clinical task. And no effect size, completion rate or symptom change accompanies the recommendation in the row this chapter holds, so no magnitude is claimed. What a candidate can say without qualification is that coexistent anxiety and depressive symptoms are not a reason to withhold referral to pulmonary rehabilitation, and that the psychiatrist's contribution is often to say so to the referring team.

RULE **Psychiatric comorbidity is an indication to support the referral, not a filter applied before it.** When a respiratory team asks whether a low or anxious patient is suitable for rehabilitation, the guideline-anchored answer is that coexistent symptoms of anxiety and/or depression should not preclude referral. The useful follow-up question is not whether to refer, but what must be arranged so the patient reaches the second session.

9.4 Adherence and technique, which is the behavioural half of disease control

Inhaled treatment is the one therapeutic area where a psychiatrist's ordinary skills change a respiratory outcome, because almost every failure of inhaled treatment is behavioural rather than pharmacological. Two distinctions organise the assessment. The first is between **unintentional non-adherence**, where the patient intends to take the treatment and does not manage it, and **intentional non-adherence**, where the patient has decided against it. The second is between not taking the drug and not delivering it, since a patient with poor inhaler technique is fully adherent and receiving very little.

Psychiatric symptoms map onto these categories specifically rather than generally. Depressive symptoms produce forgetting, loss of routine and the hopeless reasoning that treatment will not help anyway. Anxiety produces overuse of the reliever inhaler and a dependence on it that masks deteriorating control and intermittently reinforces using it again. Beliefs about harm, particularly the fear that inhaled steroid preparations are dangerous or habit-forming, produce quiet intentional non-adherence the patient will not volunteer. Cognitive impairment and manual difficulty produce technique failure independent of all of this.

FAILURE MODE	WHAT IT LOOKS LIKE IN CLINIC	WHAT ACTUALLY CHANGES IT
Technique failure	Correct prescription, exhausted canister, poor control, patient reports full adherence	Watching the patient use the device, then re-teaching or changing the device
Forgetting and lost routine	Erratic use, worse in the morning, tracks with mood and with disorganised days	Anchoring the dose to an existing fixed daily act, plus treating the mood state
Reliever overuse	Frequent reliever use, escalating anxiety, preventer untouched	Naming the cycle explicitly, then treating the anxiety alongside the airway
Belief-driven refusal	Articulate reasons, often about steroids, offered only when asked directly	Eliciting the belief without correcting it first, then addressing the specific fear

The instruction that follows is single and easy to examine: ask the patient to demonstrate, do not ask the patient to report. A demonstration takes less time than the conversation about escalating treatment that follows from assuming the technique was adequate.

Dyspnoea against panic: six discriminators, and the band where they genuinely overlap.
Neither outer column settles the question alone. The middle column is the reason it stays hard.

FEATURE	DYSPNOEA OF COPD OR ASTHMA	WHERE THEY OVERLAP	PANIC ATTACK
ONSET	over minutes to hours, from a baseline that was already limited	both begin with breathlessness and fear, in the same body	abrupt, peaking within minutes from an unremarkable baseline
TRIGGER	exertion, cold air, allergen, infection or a missed preventer	exertion can start either, and fear can follow either	often at rest and out of context, or cued by fear of an attack
TIME COURSE	climbs, and stays up until the airway is treated	a long attack and a short exacerbation look alike	crescendos, then subsides over a bounded period
WHAT RELIEVES IT	a reliever inhaler, and treating the airway itself	reliever overuse eases both for a while, and masks both	slowed breathing and time: the attack is self-limiting
WHAT THE PATIENT DOES	drops exertion, then drops the activities that needed it	avoidance narrows the life the same way from either cause	escapes the situation, carries the inhaler as a safety object
WHAT THE OBSERVER SEES	wheeze, accessory muscle use, falling oxygen saturation	tachypnoea, tachycardia, tremor and visible fear in both	circumoral and peripheral paraesthesiae, carpopedal spasm

The dangerous direction of error is treating airflow limitation as anxiety, never the reverse.
Where the two cannot be separated in the room, treat the airway first, interrogate the psychiatry after, and record why.

LEVER ONE: PULMONARY REHABILITATION
Coexistent symptoms of anxiety and/or depression in patients with COPD should not preclude referral to pulmonary rehabilitation. It is written as a prohibition on exclusion, not an encouragement.

LEVER TWO: INHALER ADHERENCE AND TECHNIQUE
Separate not taking the drug from not delivering it, and unintentional from intentional non-adherence. Then ask the patient to demonstrate the device rather than to report on it.

ROUTED OUT Steroid-induced psychiatric disturbance is taught in the Endocrine and metabolic psychiatry notes.
ROUTED OUT Agent choice, dosing and monitoring are taught in the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes. This plate names no agent and prints no dose.

Fig 40.3 Separating the dyspnoea of obstructive airways disease from a panic attack, with the overlap drawn rather than glossed. The two outer columns are the features that shift probability, read across six axes rather than argued one at a time. The coral column is the honest part: breathlessness and fear recruit the same body, the loop closes in both directions, and a patient with obstructive lung disease who also has panic attacks has both conditions, each worsening the other. That is why the examinable question is almost never which one the patient has but which is driving this episode and in what proportion. The two levers below are where a psychiatrist changes a respiratory outcome, and both are behavioural rather than pharmacological. From memory you should be able to run the six axes in either direction, state the asymmetry of risk in the rule box, and give the referral sentence and the demonstration instruction verbatim.

9.5 Asthma in adolescence, and the association that has to be stated carefully

Asthma carries a second and separate examinable position, and it is age-specific. The specialty guideline records that **asthma in adolescence is associated with an increased likelihood of major depression, panic attacks and anxiety disorder**. Three things about that sentence are worth holding. It names adolescence rather than asthma at any age. It names three outcomes rather than a general elevation in distress. And it states an association, so a candidate who converts it into a causal claim in either direction has overstated the source.

The direction genuinely is uncertain and saying so is the stronger answer. A chronic, visible, sometimes frightening condition that constrains sport, sleep and social life at the stage where all three matter most is a plausible cause of low mood. Anxiety, equally, worsens the perception of breathlessness and the behaviours that control it. Shared factors sit underneath both, including disrupted sleep, corticosteroid exposure and family stress.

The consequence for practice is concrete. Because adolescent asthma is associated with an increased likelihood of major depression, panic attacks and anxiety disorder, mood and panic symptoms are worth asking about routinely in this group rather than waiting for them to be raised, and mood and anxiety are candidate contributors to poor asthma control rather than a separate matter for later. The overlap with panic is awkward because both under-perception and over-perception of airflow limitation occur: the adolescent reporting severe symptoms may be obstructed, panicking, or both, and the one reporting little may be seriously obstructed.

TRAP **Labelling an adolescent's attack as panic and thereby delaying respiratory treatment.** The association above makes panic more likely in this group, which is exactly why the label becomes available and exactly why it is dangerous. An adolescent with asthma presenting with an acute frightening episode is treated for the airway on clinical grounds, and the psychiatric formulation is completed once the episode has settled. Offering reassurance as the first move in an acute presentation answers the question badly, however well the comorbidity is discussed afterwards.

9.6 Chronic respiratory failure, and the gap this chapter declares

The third condition in the section's title is the one for which no guideline statement was obtained, and the honest position has to be stated rather than papered over. A specialty-guideline statement specifically linking chronic respiratory failure with psychiatric sequelae, with psychiatric assessment, or with psychiatric management was sought for this chapter from the respiratory bodies whose statements would carry such a recommendation, being the national thoracic guideline body and the international obstructive lung disease initiative. It was not obtained in a form this chapter can bind. That absence describes what this chapter opened. It is not evidence that no such statement exists, and it must not be converted into a claim that the specialty is silent.

What a candidate does without it is reason from general principles and say that this is what they are doing. Chronic hypercapnia produces daytime somnolence, headache, impaired attention and, as it advances, confusion, any of which can present first as an apparent psychiatric change. Nocturnal hypoventilation fragments sleep, which degrades mood independently. Long-term oxygen therapy and domiciliary ventilation impose visible dependence on a machine and reorganise family life around the equipment. The loss of control is the psychological core, and interventions that return any control to the patient tend to help.

Two boundaries apply. Acute confusional states here are assessed and managed under the delirium material in the stroke, traumatic brain injury and focal brain syndromes notes, and no bedside delirium instrument, rating scale or antipsychotic choice is taught in this section. And a patient declining domiciliary ventilation raises a capacity question; capacity is decision-specific and time-specific, and everything beyond that, including the statutory test, belongs to the mental health legislation notes.

IN INDIA

No figure for the availability, distribution or coverage of pulmonary rehabilitation programmes in India is held by any claim row available to this chapter, so none is offered. What can be said is what the referral position implies for a service that has a programme and for one that does not. Where a programme exists, coexistent anxiety and depressive symptoms are not grounds to withhold referral to pulmonary rehabilitation, and a psychiatrist asked to assess a low patient before referral has a guideline-anchored answer for the respiratory team. Where no programme exists, which is the position across much of the country outside larger centres, the deliverable residue is still the active ingredient: a graded, written, supervised increase in activity that a physiotherapy service, a nursing team or an informed family member can sustain, with education about the breathlessness cycle. The gap in a district service is usually the structure and the supervision, not the exercise.

9.7 What this section hands off, and does not teach

Corticosteroid-induced psychiatric disturbance is common in this population and is owned elsewhere. It is named here as a differential whenever mood, sleep or mental state changes after a course of systemic steroid; the mania, depression, psychosis and management content sits with the corticosteroid owner in the endocrine and metabolic material and on the chapter's routing plate.

Prescribing in respiratory disease routes to the psychopharmacology notes without exception. Sedative burden and respiratory depressant risk are why a psychiatrist is cautious here, and the drug-by-drug reasoning, the comparative rankings and every dose belong there, so none is restated. The same applies to the effect of tobacco smoke on the metabolism of certain psychotropics: it is named as a hand-off, and neither its direction nor its magnitude is stated here.

Non-pharmacological treatment of the anxiety component follows ordinary principles with one adaptation. Interventions that deliberately provoke the feared bodily sensation require care when the airways are genuinely obstructed, because the sensation is not false. The workable version treats the interpretation and the avoidance rather than trying to show the sensation is harmless, and it runs alongside optimised inhaled treatment.

GOOD TO REMEMBER

On the ward, three moves cover most of the value a psychiatrist adds to a breathless patient. Watch the inhaler being used before believing anything about adherence. Ask what the patient thinks is happening during an attack, because the answer separates the catastrophic cognition of panic from the accurate fear of someone obstructed before. And ask whether the patient has been referred for rehabilitation, because anxiety and depressive symptoms are not a reason to preclude that referral and a psychiatric opinion is often what is used to justify not making it.

9.8 The answer, assembled

An examiner asking about psychiatric aspects of respiratory disease wants a structure rather than a list. The following sequence carries this section.

- State the discrimination first: breathlessness and panic share a physiology, the loop runs both ways, and the common answer in this population is both rather than either.
- Give the safe rule of error: treat the airway first when the two cannot be separated, because the costly mistake is calling obstruction anxiety.
- Explain the behavioural spiral of breathlessness, avoidance and deconditioning, since it accounts for much of the presentation and is what treatment targets.
- Deliver the referral position verbatim: coexistent symptoms of anxiety and/or depression in patients with COPD should not preclude referral to pulmonary rehabilitation.
- Deliver the asthma position with its age qualifier and its association wording: asthma in adolescence is associated with an increased likelihood of major depression, panic attacks and anxiety disorder, and say the direction was not established.
- Cover adherence and technique as a behavioural target, and demonstrate rather than ask.
- Declare the chronic respiratory failure gap openly: reason from hypercapnia, sleep, dependence and loss of control, and say that a specialty statement binding psychiatric management to chronic respiratory failure was sought and not obtained.

Both, not either	**Refer, not exclude**	**Watched, not reported**	**Declared, not inferred**
WHAT DYSPNOEA PLUS PANIC USUALLY MEANS	WHAT COEXISTENT LOW MOOD CHANGES	HOW INHALER ADHERENCE IS ASSESSED	WHAT TO SAY ON RESPIRATORY FAILURE

Each tile names a default that ordinary practice sets the other way, which makes the strip an audit of one's own clinic behaviour rather than a summary of the text.

PITFALL

Answering this item as a general essay on the psychological impact of chronic illness. The material is true and it earns very little, because it could have been written about any organ. What makes an answer respiratory is the dyspnoea and panic discrimination, the referral position on rehabilitation, the age-specific asthma association and the behavioural analysis of inhaled treatment.

Breathlessness and panic are usually both present; treat the airway first, refer for rehabilitation regardless of coexistent anxiety or depression, watch the inhaler being used, and ask every adolescent with asthma about mood and panic.

10 · Takotsubo cardiomyopathy and the stress-heart interface

Takotsubo syndrome is the plainest demonstration in medicine that an acute psychological event can produce a structural cardiac lesion, which is why it belongs in a psychiatry paper and not only in a cardiology one. An emotional or physical stressor is followed, usually within hours, by chest pain, breathlessness or collapse, by an electrocardiogram reading as an evolving anterior infarct, by rising biomarkers of myocyte injury, and by a left ventricle gone akinetic over

a territory larger than any single coronary artery supplies. The arteries are then found unobstructed, and the wall-motion abnormality resolves, which infarcted muscle never does. This section teaches the syndrome by mechanism rather than by table: the epidemiological specifics a resident would ordinarily quote are absent from this build's rows, and are declared rather than supplied from memory.

Several neighbouring topics are named here and taught elsewhere, and knowing the boundary is itself examinable. Depression and anxiety after myocardial infarction, and safe antidepressant choice in established coronary disease, belong to the organ-interface routing section. Heart failure, arrhythmia and implanted cardiac devices have their own section. Delirium on the coronary care unit sits with the notes that own delirium, and the psychological sequelae of critical illness with intensive-care psychiatry. Organ-adjusted dosing is a psychopharmacology question. What remains is the mechanism, the differential and the liaison contribution.

10.1 The shape of the syndrome, and why a psychiatrist is called at all

The syndrome is defined by a pattern rather than by any single test, and each element carries weight. There is an acute regional abnormality of left ventricular contraction, extending beyond the distribution of one coronary artery, which makes an occlusive explanation implausible on anatomical grounds alone. There is no culprit obstruction able to account for it. And there is recovery, so the ventricle akinetic on admission contracts normally later. Transience is not a happy outcome appended to the definition, it is part of the definition, and why the diagnosis is partly retrospective.

The name describes the shape the ventricle takes at end systole in the commonest form, a rounded akinetic apex above a narrow hypercontractile base, resembling a narrow-necked pot. That image encodes the paradox the mechanism has to explain: the segment furthest from the base fails while the base works harder than usual.

A psychiatrist is called into this picture for a small number of reasons, and knowing them in advance determines what a useful consultation note contains. The antecedent was psychological and somebody wants it characterised. A psychotropic drug, a substance or a withdrawal state is suspected. The patient is distressed or agitated on a cardiac unit. Or the team, having found clean arteries, is uncertain what to tell the patient and what to arrange on discharge. Each is answerable. Reciting a cardiology description back to a cardiologist is not.

10.2 The catecholamine-surge account, taken in the order the account itself runs

The dominant mechanistic account is a **catecholamine surge** acting on myocardium, and it is best learned as a chain, because each link is separately testable and separately arguable.

The chain begins centrally. A stressor is appraised as threatening, or the body is placed under acute physiological load, and the central autonomic network drives the sympatho-adrenal axis. The adrenal medulla releases adrenaline into the circulation; cardiac sympathetic terminals release noradrenaline into the myocardial interstitium. These are separate deliveries with different distributions, which matters later: circulating adrenaline reaches the whole ventricle, whereas neural noradrenaline concentrates wherever innervation is densest.

The next link is the effect of that load on the myocyte. High catecholamine exposure drives calcium entry and calcium overload, and calcium-overloaded myocytes contract in a disordered, sustained way. The histological correlate described in this setting is **contraction band necrosis**, a pattern distinct from the coagulative necrosis of coronary occlusion, accompanied by oxidative stress, mitochondrial dysfunction and falling cellular energy supply. This is a toxic injury, not an ischaemic one, and the distinction is why the muscle can recover.

A parallel link is vascular. Catecholamine excess is associated with epicardial coronary spasm and, more importantly here, with **microvascular dysfunction**: impaired dilatation of the small vessels that determine actual myocardial perfusion. Perfusion can therefore fall while the large arteries remain widely patent, which reconciles a genuinely injured myocardium with a normal angiogram.

The most interesting link, and the one that best explains why the apex, is receptor level. Adrenoceptor density is described as higher towards the apex while sympathetic innervation is sparser there, leaving the apex disproportionately exposed to circulating adrenaline. The subtype predominating apically can also switch its intracellular coupling: at ordinary concentrations it signals through the stimulatory G protein and increases contraction, and at the concentrations reached in a surge it couples instead to the inhibitory G protein, reducing contraction. On this account the apex is not merely overwhelmed, it is actively switched off, and the switch is protective, sparing the myocyte a lethal calcium load at the cost of regional akinesia.

The final link is **myocardial stunning**. Stunned myocardium is alive but not contracting: the cells persist, the contractile apparatus is temporarily disabled, and function returns when the insult is withdrawn. Stunning is why a ventricle that looks infarcted on admission can look normal later, and it is the single concept that makes the whole syndrome coherent.

RULE **Learn the chain, not the label.** Central appraisal, sympatho-adrenal outflow, adrenal and neural catecholamine delivery, calcium overload with contraction band necrosis, microvascular impairment, apical receptor coupling switch, regional stunning, then recovery. A candidate who can walk that chain can answer any question asked about this syndrome, including those on variants and differential diagnosis, because each attacks a specific link.

10.3 What the account explains well, and where it strains

Good teaching of a mechanism includes its limits, and this one has clear limits. The apical receptor argument explains the commonest morphology elegantly. It explains it too well, because the syndrome also occurs with the akinetic segment midventricular, basal with a hypercontractile apex, and focal. A gradient anchored at the apex predicts apical disease; it predicts basal disease poorly. The honest reading is that the receptor gradient is one contributor within a more general catecholamine-mediated regional vulnerability, and that regional variation reflects unresolved individual differences in innervation, receptor distribution and microvascular reactivity.

The account also under-determines who develops the syndrome. Acute catecholamine surges are common in human life and this presentation is not, so a susceptibility term is required: something about vascular reactivity, hormonal environment, autonomic set point or genetic

variation separating the person who stuns from the far larger number who do not. Naming that term, and saying it is unresolved, is a better answer than asserting a single cause.

This is where a conventional account would supply a demographic profile, since the demographic skew of this syndrome is the specific most often reproduced about it. That figure is exactly what this build cannot supply: the rows available here carry no distribution by sex, no age distribution, and no proportion of acute coronary presentations accounted for by the syndrome. What can be taught instead is what such a figure would require: a consecutive unselected series taken for angiography with suspected acute coronary syndrome, an explicit diagnostic definition applied prospectively, and a stated catchment and period, so that numerator and denominator each mean something. Any figure quoted without those is a number without a population.

TRAP **Treating the receptor gradient as the whole explanation.** It is an attractive and memorable argument, and it accounts for the classical morphology only. Candidates who commit to it are then unable to explain the basal and midventricular variants, and an examiner who asks about variants is usually asking precisely this question.

10.4 Why the presentation is mistaken for an acute coronary syndrome

It is mistaken for an acute coronary syndrome because at first contact it is genuinely indistinguishable from one, which is a property of the syndrome rather than a failure of the clinician. The symptom is the same: chest pain, breathlessness, syncope or shock. The electrocardiogram carries ischaemic change in a territory, commonly ST-segment elevation anteriorly, later T-wave inversion and prolongation of the corrected QT interval. The biomarkers rise, because myocytes really are injured. The ventricle really is akinetic. Every element that ordinarily signals an occluded artery is present, and the artery is not occluded.

What separates them is therefore investigation and time, not acumen at the bedside. Angiography shows no culprit lesion. Imaging shows a wall-motion abnormality crossing coronary territories. Follow-up imaging shows recovery. None of that is available in the first minutes, which is why the correct initial management is the acute coronary syndrome pathway, and why a psychiatrist confident at the bedside that this is stress-related is confident about something they cannot yet know.

The psychiatric traps here run in opposite directions and each is serious. The first is re-labelling: the angiogram is reported clean, the word psychological enters the notes, and the presentation is reinterpreted as anxiety, panic or somatisation. Unobstructed arteries are compatible with a severely injured ventricle, with pulmonary oedema, arrhythmia and haemodynamic collapse: a clean angiogram is not a normal heart. The second is the mirror image: a recognisable emotional antecedent leads the team to a stress explanation while an atherothrombotic occlusion is in progress. A psychological trigger has no power to exclude an occlusion.

TRAP **Reading a clean angiogram as a psychiatric diagnosis.** The angiogram excludes an obstruction; it excludes nothing else. The commonest way this syndrome is mismanaged on a psychiatric liaison list is that the cardiac finding is treated as ruled out and the patient is handed over as an anxiety presentation, at which point nobody is monitoring a ventricle that is still stunned.

10.5 The psychiatric antecedents, and what can honestly be said about them

Antecedents fall into recognisable classes, and the classification here is conceptual rather than quantitative. Emotional antecedents include bereavement, acute interpersonal conflict, fear, grave news, an assault on status or reputation, and acute panic. Physical antecedents include surgery, acute severe illness, sepsis, seizure, respiratory failure and metabolic disturbance, engaging the same sympatho-adrenal pathway with no psychological content. A proportion of cases have no identifiable antecedent of either kind, which matters, because demanding one before entertaining the diagnosis will miss those patients.

A subtler point is valence. The mechanism is driven by arousal and catecholamine load, and arousal is not the exclusive property of aversive emotion, so intensely positive events have also been described as antecedents. This follows from the chain above and is not an anomaly needing separate explanation. What proportion of antecedents is emotional against physical, and what proportion is aversive against pleasurable, are quantitative questions with no grounded answer here.

Comorbidity is a different question from causation, and here this section does hold a grounded statement. **Psychiatric disorders, depression and anxiety among them, are common in patients with this syndrome**, and that is worth stating precisely for what it is: a statement of co-occurrence in the affected population. It establishes that the psychiatrist has a population-level reason to be involved rather than an incidental one.

What it leaves open is the direction of the relationship, and an examiner rewards a candidate who says so. Depression and anxiety may be an antecedent vulnerability, plausibly through sustained autonomic and hypothalamic-pituitary-adrenal dysregulation that alters the response to a surge. They may be a consequence, since surviving a frightening cardiac event with an uncertain explanation generates fear and low mood. They may reflect a shared substrate, with autonomic dysregulation producing each. Co-occurrence is compatible with all of those, and the proportion affected, with any temporal ordering, is a specific this build does not carry.

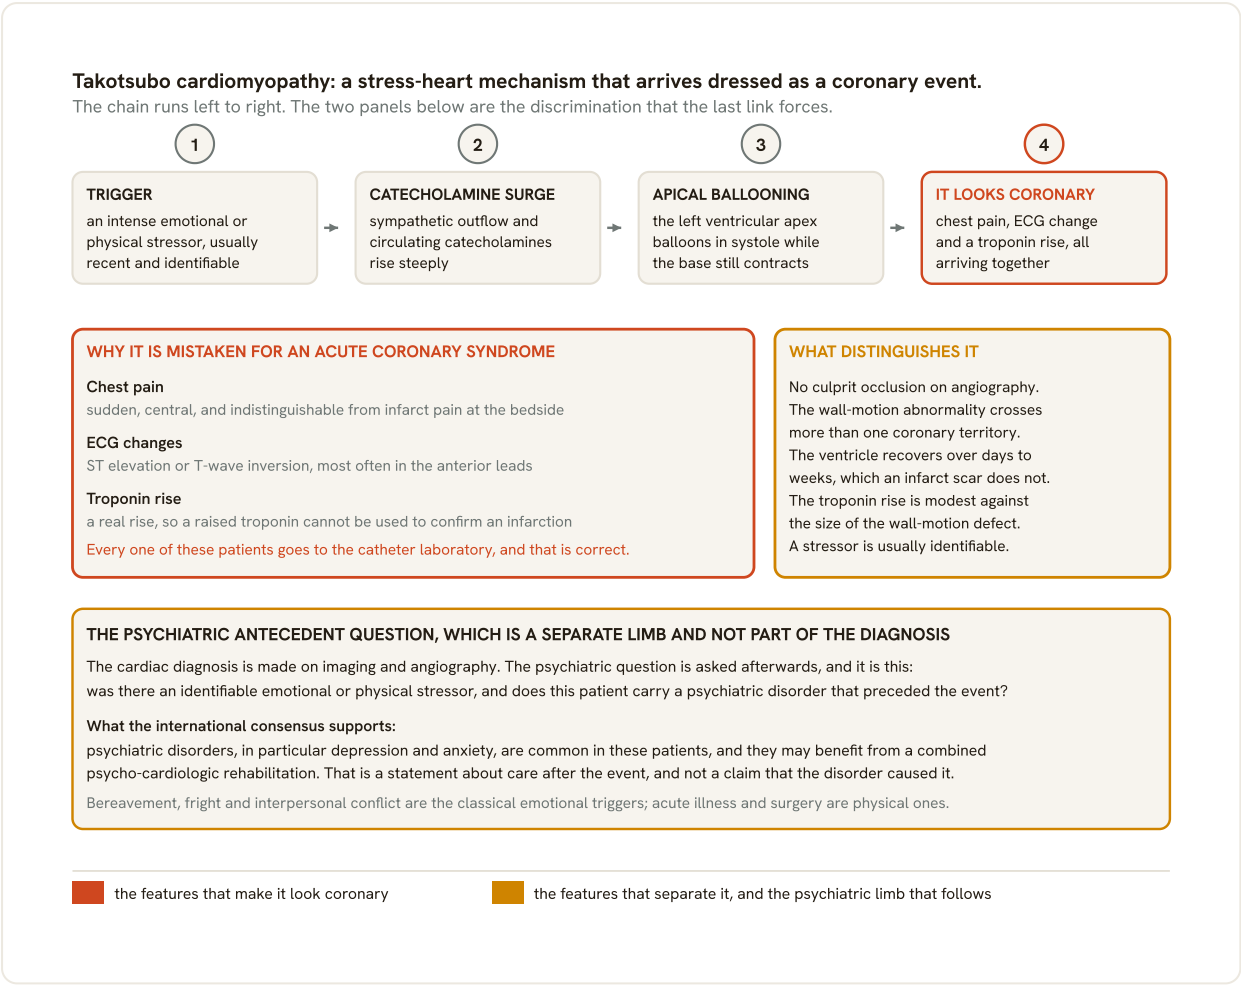

Fig 40.4 The stress-heart interface as a four-link chain, with the mimicry and the discrimination drawn side by side. The mechanism is the examinable spine: a trigger, a catecholamine surge, an apex that balloons in systole while the base still contracts, and a presentation that carries all three cardinal features of an acute coronary syndrome at once. That is why the mistake is not carelessness, and why the correct first move is still the catheter laboratory. What separates the two is the pattern rather than any single test: the wall-motion abnormality does not respect a coronary territory, no culprit occlusion is found, and the ventricle recovers in a way an infarct scar does not. The psychiatric limb is deliberately drawn apart from the diagnosis, because it is asked after the cardiac question is settled. From memory you should be able to give the four links in order, the three mimicking features, at least three discriminating ones, and the reason the antecedent question is a separate limb rather than a diagnostic criterion.

10.6 The differential of the surge, which is largely a psychiatric differential

Because the mechanism is catecholamine load, the differential of the antecedent is a list of states psychiatrists meet constantly, and this is where the liaison psychiatrist supplies information nobody else can obtain.

- **Exogenous catecholamine or sympathomimetic load.** Adrenaline given therapeutically, local anaesthetic containing adrenaline, and sympathomimetic substance use including stimulants and cocaine. The substance history establishes these.
- **Withdrawal states.** Alcohol and sedative-hypnotic withdrawal produce sustained autonomic arousal, and opioid withdrawal a lesser but real adrenergic load. A withdrawal syndrome is an endogenous catecholamine infusion the patient is unaware of receiving.
- **Iatrogenic surges in psychiatric treatment.** Electroconvulsive therapy produces a transient, deliberate and monitored autonomic surge, a recognised context in which this presentation

has been described. Management of that surge belongs to the treatment's own protocol.

- **Hyperadrenergic psychiatric emergencies.** Neuroleptic malignant syndrome, serotonin toxicity and catatonia with autonomic instability sustain adrenergic arousal for hours or days, a longer exposure than a discrete emotional trigger delivers.
- **Acute severe panic and acute stress reactions.** These are most likely to be dismissed as merely psychological on a medical ward, and the mechanism gives a reason to take them seriously as physiological events.
- **Organic causes with psychiatric presentations.** Phaeochromocytoma delivers precisely the surge the mechanism requires and may present with paroxysmal anxiety. Subarachnoid haemorrhage produces neurogenic stunned myocardium by an overlapping pathway, and prolonged seizure activity does the same. Each can reach a psychiatrist first.

Psychotropic drugs with cardiac effects, including corrected QT interval prolongation and the cardiovascular effects of stimulants, are a psychopharmacology topic, cross-referred rather than restated. Their relevance here is that the medication list is part of the surge history.

FIGURE CONVENTIONALLY QUOTED	WHAT WOULD HAVE TO BE MEASURED	WHAT THIS BUILD HOLDS
Frequency among suspected acute coronary presentations	Consecutive unselected patients angiographed for suspected acute coronary syndrome, prospective definition, stated catchment and period	Not grounded here
Sex and age distribution	Composition of a consecutive diagnosed series, read against the composition of the source population	Not grounded here
Emotional against physical antecedents	Antecedent classified prospectively by stated criteria in every case, including cases with none identified	Not grounded here
Time to recovery of wall motion	Protocol-defined repeat imaging at fixed intervals, with a stated definition of normalisation	Not grounded here
In-hospital complications and mortality	Pre-specified complication set, admission to discharge, on a consecutive series	Not grounded here
Recurrence	Cumulative recurrence over a stated follow-up period, with defined ascertainment	Not grounded here
Depression and anxiety in this population	Case ascertainment by a stated diagnostic method, at a stated point after the acute event	**Qualitative statement of commonness only**

10.7 What the psychiatrist on the liaison call actually contributes

The consultation has a small number of jobs, and doing them well is the difference between a note that changes management and a note that restates the referral.

The first is to characterise the antecedent properly. A cardiology record says stress. A psychiatric record says what happened, at what hour, with whom, what it meant to this person, and how long the arousal lasted before the chest pain began. That timed narrative is the only evidence anyone will have about the trigger, it can be obtained on the day and rarely afterwards, and no other member of the team is trained to take it.

The second is to establish the exogenous and withdrawal load, using the differential above. This is a diagnostic contribution, because a withdrawal syndrome or a stimulant exposure changes what the cardiac team monitors and treats.

The third is to separate acute distress proportionate to a frightening event from a psychiatric disorder requiring treatment. The responses differ, and conflating them either medicalises normal fear or misses treatable illness.

The fourth is explanation, and it is underrated. The patient has been told they had something resembling a heart attack and also that their arteries are clean, and those messages conflict unless somebody supplies the mechanism reconciling them. A coherent, non-technical account of a surge, a stunned muscle and a recovering ventricle does real therapeutic work, replacing an incoherent threat with a comprehensible one.

The fifth is treatment and follow-up. **Where depression or anxiety is present, it is treatable in its own right, and a combined psycho-cardiologic rehabilitation approach is the model these patients might benefit from.** The obstacle is structural: a patient discharged with a normal angiogram is likely to leave with follow-up from neither service, and arranging it before discharge is the most useful line in the consultation note. Choice of agent in cardiac disease is a psychopharmacology matter and is handed over. Where consent arises, the operating principle is that capacity is decision-specific and time-specific, and the doctrine belongs to the mental health legislation notes.

RULE **Write the timed antecedent narrative on the day you are called.** Everything else in the consultation can be reconstructed later from records and from the patient. The hour-by-hour account of what happened before onset degrades within days, and it is the one datum that makes the case interpretable to anyone reading the notes afterwards.

IN INDIA

This build located no Indian series, registry entry, service description or cost datum for this syndrome, and none is supplied. What can be said structurally, without inventing a figure, is that recognition depends on early angiography, on repeat ventricular imaging to demonstrate recovery, and on a liaison service that receives the referral before discharge, and that the availability of each varies widely across Indian settings. A resident asked about the Indian picture is on firmer ground naming those dependencies and the absent data than quoting a prevalence figure with no Indian denominator.

GOOD TO REMEMBER

On the ward, hold these points. A clean angiogram excludes an obstruction and excludes nothing else. A psychological trigger never excludes a coronary occlusion. And the muscle is stunned rather than dead, which is why the story ends in recovery, and why the psychiatric work of characterising the antecedent, treating comorbid illness and arranging follow-up is done during an admission everyone else treats as resolved.

MNEMONIC

Surge, Switch, Stun, Settle

Surge is the catecholamine load from adrenal and neural sources. Switch is the apical receptor coupling change from stimulatory to inhibitory. Stun is living but non-contractile myocardium. Settle is the recovery that makes the diagnosis retrospective. The psychiatric work attaches at the start, on the antecedent, and at the end, on comorbidity and follow-up.

Beyond one territory	Stunned	Common	Timed narrative
THE WALL-MOTION FEATURE THAT MAKES OCCLUSION IMPLAUSIBLE	NOT INFARCTED, WHICH IS WHY IT RECOVERS	DEPRESSION AND ANXIETY IN THIS POPULATION, STATED QUALITATIVELY	THE DATUM ONLY THE PSYCHIATRIST CAN OBTAIN

A surge of catecholamines stuns living myocardium, the presentation copies an acute coronary syndrome exactly because the muscle really is injured, and the diagnosis is completed by recovery rather than by the angiogram. Take the timed antecedent on the day, look for exogenous and withdrawal catecholamine load, treat the comorbid depression and anxiety, and arrange the follow-up a normal angiogram will otherwise cancel.

Renal, transplant and perioperative psychiatry

11 · Pre-transplant psychiatric evaluation and post-transplant neuropsychiatry of immunosuppressants (steroids, tacrolimus, ciclosporin)

A transplant psychiatric opinion is read by a committee allocating a scarce organ, which makes it the one psychiatric assessment whose reasoning has to be legible to people outside

psychiatry. The topic splits cleanly and the sides are examined differently. Before transplantation, the question is what the psychosocial assessment must contain and how its conclusion should be written. Afterwards, it is which neuropsychiatric syndromes the immunosuppressants produce, and how to keep that possibility open while a recipient with several plausible causes of a new confusional state is worked up. The routing is strict, and one part of it is a gap rather than a destination. The general machinery by which a co-prescribed agent alters exposure, the inhibitor and inducer ladders and the cytochrome pathways, belongs to the psychopharmacology notes; that chapter names no immunosuppressant, so the interaction rankings and dose changes specific to these drugs are stated nowhere in this series and must not be reconstructed from memory. The confusional state itself belongs to the stroke, traumatic brain injury, delirium and focal brain syndromes notes. The steroid-induced psychiatric syndrome is routed on the plate below and taught in the endocrine and metabolic notes, while dialysis and the intensive-care sequelae around a transplant admission sit in the organ-interface routing section.

11.1 Where the opinion's form is owned, and what this section adds

Two limbs of this assessment are owned elsewhere and are named here rather than taught. How the opinion itself should be written, and the dual agency the interview runs under, belong to the Consultation-liaison, geriatric and transcultural psychiatry notes; so does the separate assessment of a living donor, where the question is whether the offer is voluntary and free of inducement, and where the psychiatrist works for the donor alone. The statutory framework governing donor authorisation belongs to the mental health and medical legislation notes. What this section adds is the limb those chapters do not carry: what the psychosocial assessment must contain, and how a capacity finding made during organ failure should be scoped, dated and re-asked.

11.2 The psychosocial assessment, and the limb this packet grounds

Guidance on evaluating candidates for kidney transplantation specifies the content of the psychosocial assessment, and the limb concerning psychiatry is stated explicitly. The elements of that assessment should include **a mental-status examination**, together with cognitive evaluation to ensure valid decision-making capacity and the ability to provide informed consent for transplantation.

Read that carefully, because the source is narrower than the way the topic is usually taught. It attaches the requirement to the psychosocial assessment as such, and attaches no timing qualifier of its own. This fragment therefore states it at that scope, and treats "pre-transplant" as a description of the setting in which the assessment is customarily performed rather than as part of what the guidance recommends.

The cognitive limb is the one candidates under-weight and the one most likely to change the answer. Organ failure impairs cognition by several routes at once, and the assessment often happens at the point of greatest impairment: uraemia, hepatic encephalopathy, hypoxia, poor cerebral perfusion and disrupted sleep. A patient examined in that state may appear unable to hold a decision they could hold comfortably once dialysis, oxygenation or ammonia handling

improved. So date the finding, name the reversible contributors, and set a point at which the question is asked again.

That licenses the one doctrinal point this section may state. Capacity is **decision-specific and time-specific**: a person may hold capacity for one decision and lack it for another on the same afternoon, and may regain it as their physiology improves. The statutory test, and the machinery that follows a finding of incapacity, are taught in the mental health legislation notes and named here rather than reproduced.

TRAP **Recording a capacity finding as a property of the patient rather than of a decision at a time.** In a population whose cognition tracks a treatable metabolic state hour by hour, writing "lacks capacity" as though it were a diagnosis removes a patient from consideration on a measurement taken at their worst, and the harm is invisible in the notes.

11.3 The rest of the interview, and where its evidence lives

Beyond the capacity limb, the assessment covers ground this packet does not ground with a source, so the honest move is to teach the structure of the interview rather than thresholds nobody here can cite. The domains a unit expects an opinion to address are the psychiatric history and current mental state; substance use and what any stated abstinence rests on; the adherence record; the caring arrangements after discharge; the patient's own account of the regimen and its permanence; and the financial arrangements that will keep immunosuppression running once the admission ends.

One interviewing discipline deserves stating outright, because it is where weak assessments go wrong. Ask about behaviour already on the record in preference to intention offered in the room. The record can be checked: dialysis attendance, missed appointments, prescription collection, what happened the last time a regimen became inconvenient. Why a stated intention is the weaker evidence here, given who the opinion is written for, is argued in the Consultation-liaison, geriatric and transcultural psychiatry notes. That is a point about where evidence lives, and this packet holds no figure licensing any claim that a given behaviour predicts a graft outcome.

Mental state and cognition	Record, not intention	Decision and time specific	Dated, then re-asked
WHAT THE ASSESSMENT MUST CONTAIN	WHERE ADHERENCE EVIDENCE LIVES	HOW CAPACITY IS SCOPED	WHAT A COGNITIVE FINDING IS

11.4 Tacrolimus, and the shape of calcineurin-inhibitor neurotoxicity

The calcineurin inhibitors are what make post-transplant care a psychiatric topic rather than a purely medical one. Their neurotoxicity is prominent enough in the labelling to belong on the differential of every neuropsychiatric presentation in a recipient. The tacrolimus prescribing information states the shape directly: tacrolimus may cause a spectrum of neurotoxicities, and the most severe of these include **posterior reversible encephalopathy syndrome (PRES), delirium, seizure and coma**.

Treat the word spectrum as the examinable part. A label describing a spectrum and then naming only its severe end is telling you a milder end exists while leaving it undefined. This packet holds

no row describing that milder end, so this fragment names the severe end the source names and goes no further.

What the statement licenses is a low threshold, and not a diagnosis. A recipient on tacrolimus who develops a seizure, a fluctuating confusional state or a depressed level of consciousness has a drug on the differential from the first minute, alongside infection, metabolic derangement, graft dysfunction and cerebrovascular events. The observation raising the drug's rank is temporal: whether the change followed an alteration in the regimen, a change of formulation, or the addition of another agent. Which agents do that, in which direction, and what dose response is then required are prescribing questions owned by the psychopharmacology notes.

Note the boundary inside that list: delirium appears as a manifestation of the drug's toxicity, which puts the drug into the delirium differential without putting delirium assessment into this section.

11.5 Ciclosporin, and a signal the label attaches to a combination

Ciclosporin is the other calcineurin inhibitor in routine use, and its labelling carries a neurotoxicity statement structured differently from the tacrolimus one, which is why it is worth learning separately. The statement is conditional on a co-prescription: convulsions have been reported in adult and paediatric patients receiving ciclosporin, particularly in combination with high-dose methylprednisolone.

Several features of that sentence repay attention.

- The signal is attached to a combination. A convulsion in the days after pulsed corticosteroid for suspected rejection is a combination event, and the history must establish what else was given and in what order, rather than settling on whichever agent the patient has taken longest.
- The labelling names adult and paediatric patients alike, so the statement spans the age range and a child or adolescent recipient attracts the same consideration.
- The wording reports occurrence rather than a rate. It licenses vigilance and a position on the differential; it licenses no statement about how often this happens.
- The named partner is a corticosteroid, so the same episode sits inside the corticosteroid material routed below. Naming the combination is this section's job; the steroid syndrome is not.

The plate below arranges the direct neuropsychiatric toxicity of the immunosuppressants by agent class rather than by syndrome, which is the arrangement answering the ward question: you know what the patient is taking and you want to know what it can do. The calcineurin inhibitors and the mTOR inhibitors are marked as interaction-sensitive, and that mark is a pointer rather than a teaching, since the interaction rankings and dose changes they oblige sit in the psychopharmacology notes. This packet holds no row describing an mTOR-inhibitor neuropsychiatric syndrome, so the prose asserts nothing about that class.

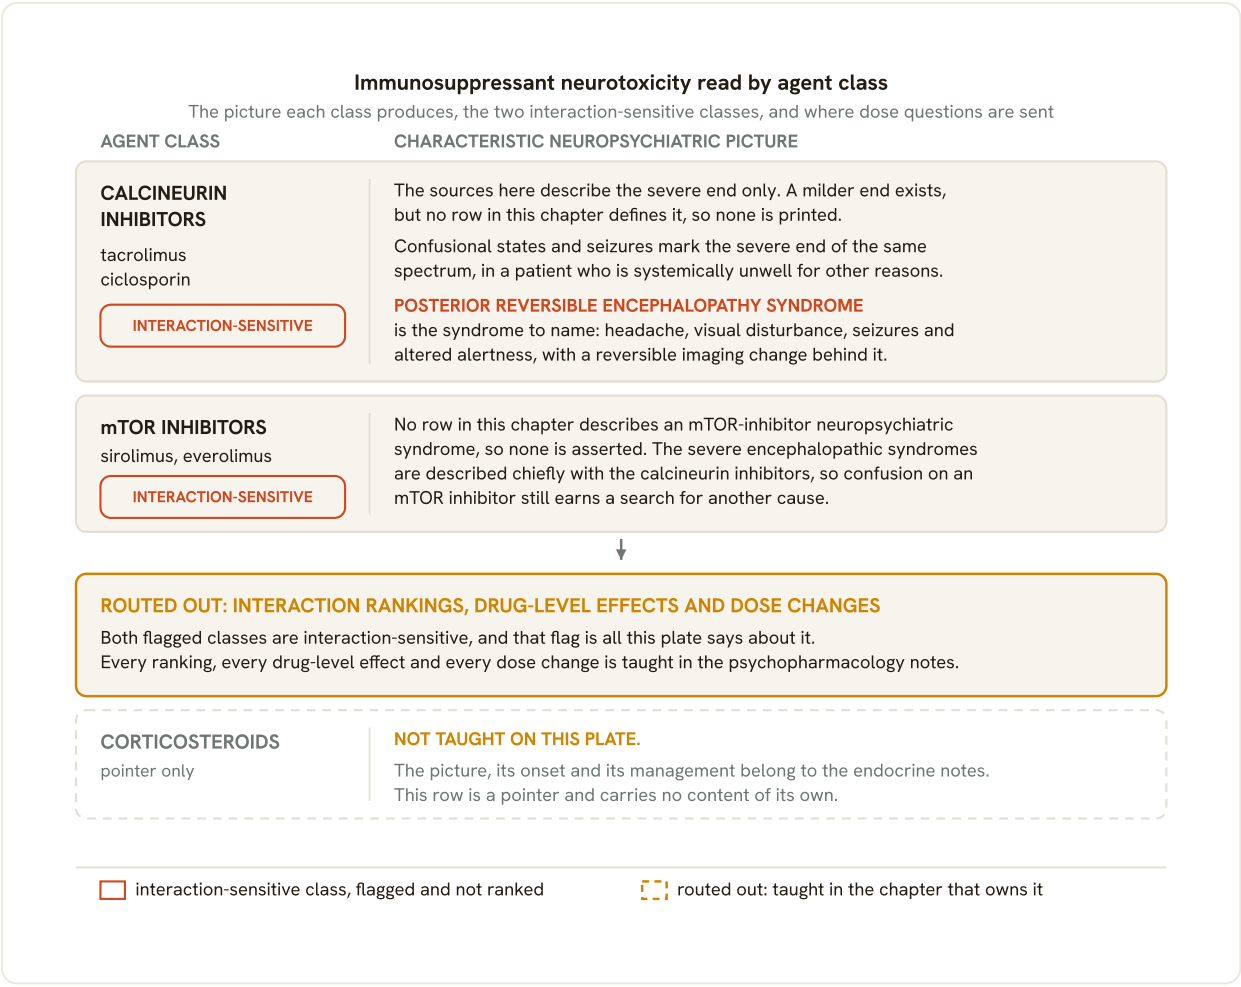

Fig 40.5 Direct neuropsychiatric toxicity of the immunosuppressants, read by agent class rather than by symptom. The calcineurin inhibitors carry the fullest picture: confusional states and seizures at the severe end, and posterior reversible encephalopathy syndrome as a named syndrome rather than a loose description of a confused transplant recipient. The milder end of that spectrum is left undefined here, deliberately, because no source in this chapter's evidence defines it, and naming a spectrum while supplying only one end of it from memory is how a plate acquires content its text does not hold. Nothing is asserted about an mTOR-inhibitor neuropsychiatric syndrome either, for the same reason; what the plate does say is that the severe encephalopathic syndromes are described chiefly with the calcineurin inhibitors, so confusion in a patient taking an mTOR inhibitor still earns a search for another cause before the drug is blamed. Three limbs are deliberately absent from the plate. Interaction rankings, drug-level effects and every dose change are taught in the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes; the corticosteroid picture is taught in the Endocrine and metabolic psychiatry notes; and the form of the pre-transplant opinion, together with the separate living-donor interview, belongs to the Consultation-liaison, geriatric and transcultural psychiatry notes. What that chapter records as a declared gap, the contents of the psychosocial assessment, is taught here. No Indian incidence figure is printed here, because the record was not located. From memory you should be able to name the class, give its severe picture, say the one syndrome out loud, and say which limbs this plate deliberately does not carry.

11.6 Corticosteroids, named here and taught elsewhere

Corticosteroids belong to the transplant regimen and therefore to this chapter, but the psychiatric syndrome they produce is owned elsewhere, so this section states the toxicity at label level and routes the clinical construct. Behavioural and mood changes sit among the common adverse reactions listed for corticosteroids, and that is the level at which this fragment may state them.

Steroid-induced psychiatric disturbance itself, meaning the mania, depression and psychosis that follow corticosteroid exposure and the management of each, belongs to the organ-interface

routing section of this chapter and to the endocrine and metabolic notes. An examiner asking about it in a recipient is asking a question whose answer is the same as in any other steroid-exposed patient: the transplant setting adds a co-prescribed calcineurin inhibitor and an immunosuppressed host, and adds no separate steroid syndrome.

11.7 The recipient with new neuropsychiatric signs, and the order of the questions

The characteristic difficulty after transplantation is that several sufficient causes are present at once, so the examinable skill is sequencing rather than selection. An immunosuppressed patient may be septic while barely febrile, metabolically deranged from graft dysfunction, hyponatraemic, hypoxic, and established on a calcineurin inhibitor and a corticosteroid at once, while carrying the psychological load of an operation they may have waited years for. An answer that names the drug and stops has selected the interesting cause rather than the first one.

The sequence that survives scrutiny puts reversible and dangerous causes first, keeps the immunosuppressant permanently on the list rather than at the end of it, and treats the psychological formulation as concurrent rather than as a diagnosis of exclusion. A recipient's distress about the donor, the graft, or a life reorganised around a regimen is real whether or not a metabolic cause is found, and deferring it until everything else is excluded means it is never addressed.

WHAT YOU OBSERVE	WHAT IT OBLIGES YOU TO ASK	WHERE IT IS TAUGHT
Fluctuating confusion or altered arousal	What is the medical cause, and what is the current regimen	Stroke, traumatic brain injury, delirium and focal brain syndromes notes
Seizure on a calcineurin inhibitor	What else was given, in what order, and when relative to the event	Label level here; prescribing in the psychopharmacology notes
Mania, depression or psychosis after corticosteroid exposure	Which agent, over what course, and what is the earlier psychiatric history	Organ-interface routing section; endocrine and metabolic notes
Doubt about a listing decision or an ongoing consent	Which decision, at what time, and what is reversible now	The requirement here; the statutory test in the legislation notes
Low mood on dialysis while awaiting a graft	What is the renal context, and what treatment is safe in it	Organ-interface routing section, which owns dialysis

Read the middle column rather than the first. Observation-to-diagnosis pairs fail on a stem where the observation has several sufficient causes; observation-to-question survives it, because the question stays the same whichever cause is operating.

11.8 The Indian setting, and what the assessment has to ask in it

Indian practice shapes this assessment more than any refinement of technique. Where the graft comes from a living relative, the psychiatrist acquires a second person to assess, with a different question and a different loyalty, inside a family in which pressure on a potential donor may be entirely unspoken. And because maintenance immunosuppression is a lifelong recurring cost, the sustainability of the regimen is a clinical variable rather than an administrative one.

IN INDIA

Ask the funding question in plain words, at the assessment and again before discharge: who will pay for immunosuppression once the admission is forgotten, and what happens if the recipient was the household's earner. Ask the travel question the same way, since a review schedule assuming a nearby clinic quietly excludes families who cannot make the journey. Where the donor is a relative, hold the separate donor interview the Consultation-liaison, geriatric and transcultural psychiatry notes describe, and record what was asked about voluntariness rather than only the conclusion. This packet holds no Indian figure for transplant volumes, living-donor proportion, drug cost, or psychiatric morbidity in Indian cohorts, so this box states the questions and states no magnitude.

GOOD TO REMEMBER

A short set of sentences carries most of the marks. The psychosocial assessment should include a mental-status examination and cognitive evaluation of decision-making capacity and the ability to provide informed consent for transplantation. Tacrolimus produces a spectrum of neurotoxicity whose severe end includes PRES, delirium, seizure and coma. Convulsions have been reported with ciclosporin, particularly in combination with high-dose methylprednisolone, and behavioural and mood changes are listed among the common corticosteroid adverse reactions.

PITFALL

Attributing a post-transplant seizure to ciclosporin alone. The labelled signal is conditional on a combination with high-dose methylprednisolone, so an answer naming the calcineurin inhibitor and omitting the corticosteroid has reported part of the statement and has stopped taking the history where it was about to become informative. The reverse error costs the same marks.

The pre-transplant side this section owns is the content of the psychosocial assessment, a mental-status examination and a dated cognitive evaluation of capacity, with the opinion's own form owned elsewhere; the post-transplant side is a permanently open differential in which tacrolimus carries a spectrum reaching PRES, delirium, seizure and coma, ciclosporin carries a convulsion signal tied to high-dose methylprednisolone, and corticosteroids are named here and taught elsewhere.

12 · Perioperative psychiatric management, capacity for surgery and postoperative cognitive dysfunction

Surgery reliably produces a new psychiatric presentation in patients who had none the week before. Perioperative psychiatry is best learned as a sequence, because the questions arrive in a fixed order and each has a different owner. Before the operation the question is optimisation and measurement. At consent it is capacity. Afterwards it is which cognitive construct is being named. This section installs that sequence and makes the hand-offs a candidate is expected to make rather than answer: delirium assessment and management, taught with the stroke, brain injury and focal syndrome material, and capacity doctrine with its statutory test, taught with the mental health legislation material.

12.1 The perioperative sequence, and who owns each question

A psychiatrist meets a surgical patient in a small number of recognisable ways, and naming them is the fastest route to a structured answer. The first is the planned preoperative review of a patient with established psychiatric illness, asking whether the illness or its treatment changes the operation or the recovery. The second is the urgent review at consent, where the team is unsure whether the patient can make the decision in front of them. The third, by far the commonest, is the postoperative call about a patient who was lucid on admission and is now confused or agitated. The fourth, most often missed, is the late review months afterwards, where the complaint is not confusion but persisting difficulty with memory or work.

Those shapes belong to different literatures and different chapters, and an examiner wants them separated before the answer starts. The characteristic failure is a single undifferentiated account of postoperative confusion, which loses marks in both directions: it imports delirium teaching into a question about cognitive trajectory, and trajectory language into a question about a disturbed patient on the ward tonight. So fix ownership first. The acute confusional presentation is the delirium chapter's, entire; consent and its statutory machinery are the legislation chapter's; agent, dose and organ-adjusted prescribing are the psychopharmacology chapter's. The plate below traces the pathway from preoperative review, through the operation, to the postoperative neurocognitive outcome, marking each exit where it occurs.

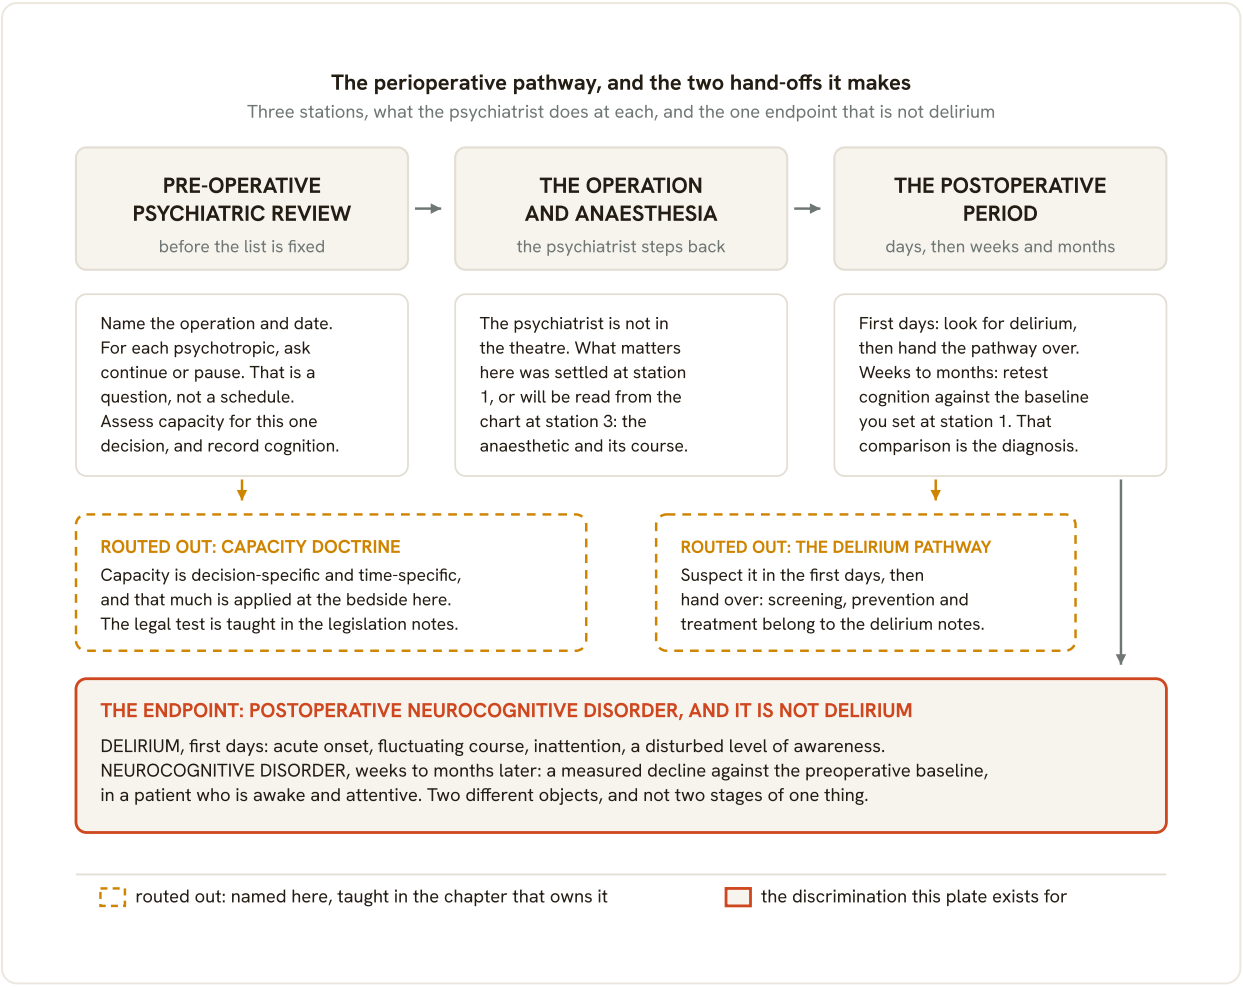

Fig 40.6 The perioperative pathway drawn left to right, with the psychiatrist's task at each station and the two hand-offs marked as branches off the rail. Station 1 is where the work is actually done: medication decisions are framed as questions rather than as a schedule, capacity is assessed for this one decision at this one time, and the cognitive baseline is recorded, because without that baseline the endpoint at station 3 cannot be measured at all. The capacity branch routes to the Mental health legislation and forensic psychiatry notes, which hold the legal test, and consent to the surgical decision is set out in the Forensic ethics, consent and legal procedure notes; the delirium branch routes to the Stroke, TBI, delirium and focal brain syndromes notes, which hold screening, prevention and treatment. The endpoint is postoperative neurocognitive disorder, and a nomenclature working group has recommended perioperative neurocognitive disorders as the overarching term for cognitive impairment identified in the preoperative or postoperative period. From memory you should be able to state what the psychiatrist does at each station, name both hand-offs, and separate delirium from postoperative neurocognitive disorder on onset, attention and course.

12.2 The name of the thing, and why the name was changed

The older vocabulary here was built by researchers rather than clinicians, and it showed. Terms for cognitive change after anaesthesia and surgery accumulated separately, each defined by whichever measurement a study happened to use, so a single patient could be described in incompatible ways depending on which literature the describer had read.

A nomenclature consensus working group addressed this by proposing a single umbrella. **The working group recommends that perioperative neurocognitive disorders be used as an overarching term for cognitive impairment identified in the preoperative or postoperative period.** Read that formulation slowly, because it does more than rename an old idea.

Notice what kind of statement it is: a recommendation about terminology, issued by a working group, and it should be presented as such. An answer promoting it into a diagnostic category with

criteria and thresholds has claimed more than the recommendation says. Notice next where the umbrella reaches. It covers impairment identified in the preoperative period as well as the postoperative period, which is the counter-intuitive limb and the examinable one. That decision converts preoperative cognitive assessment from a chore attached to the construct into part of the construct itself.

RULE **The umbrella reaches backwards, not only forwards.** The overarching term covers cognitive impairment identified before the operation as well as after it. A candidate who describes it as a class of postoperative complication has described half of it, and has lost the reason preoperative assessment belongs in the same discussion.

12.3 The preoperative psychiatric review, and what it is actually for

A preoperative review earns its place by settling a short list of questions where the surgical and anaesthetic teams will find the answers. The first is continuity of psychotropic treatment across the fasting window and any period in which the patient cannot swallow. The review does not choose the agent, which belongs with every dose and interaction ranking to the psychopharmacology material, but it must state, for each agent, whether it continues, is withheld or is given by another route, and which team owns that decision. A plan recording only that the patient takes long-term medication has settled nothing.

The second is withdrawal. An elective admission removes access to alcohol, to nicotine and to anything else the patient used at home, at a predictable hour. A withdrawal syndrome declaring itself on a surgical ward is read, by people looking for a surgical explanation, as postoperative confusion. Establishing what the patient used before admission is preoperative work, and recording it where the postoperative team will see it is the same job.

The third is the illness features that change postoperative risk without changing the operation: patients who communicate pain poorly, who do not seek help when something is wrong, who become agitated in unfamiliar surroundings, or whose treatment history makes an interruption expensive. Each is a practical problem invisible to a clerking that asks about organs. Pre-transplant psychiatric evaluation shares this shape with a different content and a different threshold, and is taught by the transplant section of this chapter.

12.4 The preoperative cognitive baseline, and why it is not optional

The most useful contribution a preoperative review makes to the postoperative period is a measurement taken before the operation. **Older patients should have preoperative cognitive assessment using established screening or diagnostic tools.** The recommendation names a class of instrument rather than a particular one, and this section follows it exactly. Naming a specific instrument here would need a source that attaches a property to it, and none is held, so supplying one from recollection is the error this chapter exists to prevent.

The reasoning is worth stating, because it is what makes the recommendation defensible rather than merely official. Postoperative cognitive change is a change, and a change is a relation between two observations; one postoperative observation cannot establish it. Without a

preoperative measure the team compares the patient against an impression of the patient, formed by relatives under stress and reported after the event.

There is a quieter second yield. Impairment found at the preoperative assessment is informative before any operation happens: it marks a patient whose recovery needs more support, it bears on how the consent conversation is conducted, and it frequently identifies impairment nobody had recognised.

TRAP **Reporting a low postoperative score as a postoperative deficit.** Candidates do this because a score looks like evidence and because the postoperative score is the one they have. Without a preoperative measure it establishes the patient's current level and nothing about change, and a patient with unrecognised pre-existing impairment generates the same result. The examinable point is not the score, it is the comparison the score was supposed to enter.

12.5 Capacity for surgery, and the part of it that belongs here

Almost all of capacity doctrine sits elsewhere. The statutory test and its limbs, the presumption the law starts from, the safeguards and the procedure that follows a finding of incapacity are taught with the mental health legislation material, and none of it is restated here or cited by provision. One property does belong in this section, because the perioperative period is where it does most of its work. **Capacity is described as decision-specific and time-specific.**

Decision-specific means the question is never whether the patient has capacity as a standing attribute, but whether this patient can make this decision. A patient may be unable to manage a complex financial arrangement and entirely able to decide about an operation, and the reverse holds equally. An opinion recorded for one purpose therefore does not answer a different question asked later.

Time-specific means the answer attaches to a moment rather than to a person, and the perioperative period supplies an unusual density of moments in which it can move: pain, disturbed sleep, premedication and the hours immediately after anaesthesia all sit inside the window in which consent is sought. An opinion formed on the morning ward round is not transferable to a consent conversation held that evening. What the psychiatrist supplies is a description of the patient's functional abilities for the specified decision at the specified time, in the terms the legislation sets out; the decision itself belongs to the treating team.

PITFALL

Recording a global verdict. A note stating that the patient lacks capacity, with no decision named and no time attached, is unusable by the team receiving it and indefensible if it is later examined. It also travels: written once, it is quoted for months, across decisions it was never about. Name the decision, name the time, confine the opinion to both.

12.6 Postoperative neurocognitive disorder distinguished from delirium

The two constructs are distinguished by what kind of thing each one is, not by comparing symptom lists. Delirium names an acute disturbance of attention and awareness with a characteristically fluctuating course. It is a condition in its own right, with its own screening

instruments, precipitant list and management, all taught with the stroke, traumatic brain injury and focal brain syndrome material and none of it repeated here. Postoperative neurocognitive disorder names something structurally different: a change in cognitive performance relative to a preoperative baseline, established by comparison rather than by observation at the bedside.

That difference in kind produces every other difference an examiner will want. One is recognised by looking at the patient now; the other cannot be, because a single observation carries no baseline. One fluctuates, which is why repeated observation detects it; the other is a persisting shift, which comparison rather than repetition finds. One declares itself on the ward; the other declares itself after discharge, and reaches a clinician only if somebody thinks to ask.

THE QUESTION	DELIRIUM	POSTOPERATIVE NEUROCOGNITIVE DISORDER
What the term names	An acute disturbance of attention and awareness	A change in cognitive performance against a preoperative baseline
How it is established	Observation of the patient's current state	Comparison of a later measure against an earlier one
Characteristic course	Fluctuating, often worse at night	Persisting, without the same fluctuation
Where it declares itself	On the ward, to the clinical team	After discharge, to the patient and family
Who teaches assessment and management	The stroke, brain injury and focal syndrome material	This section for the construct; psychopharmacology for any agent

RULE **Delirium is observed; a perioperative neurocognitive disorder is computed.** One is a state visible in the room, and the whole of its assessment lives in the chapter that owns it. The other is a difference between two measurements, which is why a service that never takes the first measurement can never make the diagnosis, however carefully it examines the patient afterwards.

The recommendation governing the acute limb is stated here only as a boundary. **Postoperative delirium screening should use a validated delirium score.** Which score, how it is administered and what follows a positive result are the delirium chapter's, and a candidate who reproduces an instrument here has answered another chapter's question while believing they were thorough. The perioperative point is narrower: screening is systematic and instrumented rather than impressionistic, which is a statement about how a surgical service is organised.

The constructs are not alternatives to choose between, and the same patient may pass through both, in sequence, after one operation. Whether an episode of postoperative delirium predicts the later cognitive trajectory is a question no source held for this section answers, and it is recorded below as a gap rather than taught.

MNEMONIC

Measure before, ask at, name after

Measure cognition before the operation, because a change needs an earlier observation. Ask the capacity question at the decision and at the moment. Name the construct afterwards, because delirium and a perioperative neurocognitive disorder are different kinds of thing with different owners.

12.7 Answering the postoperative call without importing the wrong chapter

The postoperative call is where most candidates meet this material, and the discipline that rescues an answer is to establish the shape of the problem before naming it. Establish whether a preoperative cognitive measure exists, because that determines what can be concluded at all. Establish the timeline, separating a disturbance that arrived over hours from a difficulty the family has watched for weeks. Establish whether the disturbance is of arousal and attention now, or of performance over time. Establish what else on the chart could produce it, since a surgical patient carries pain, immobility, infection risk and an interrupted medication list at once.

A postoperative note worth reading later states each of the following.

- Whether a preoperative cognitive assessment exists, where it is recorded, and what it showed.
- The timeline of the change, expressed against the operation rather than against the referral.
- Which construct is being described, and which is being excluded.
- The medication position: what was withheld, what was resumed, what is outstanding.
- Who reviews the patient after discharge, since the trajectory question cannot be answered on the ward.

Routing follows the same discipline. Psychological sequelae of a critical-illness stay, and delirium at the end of life, are taught by the organ-interface section of this chapter. Every question about agent, dose and organ failure belongs to the psychopharmacology material. Naming the destination answers that part of a question completely.

Before it, and after it	Measured, not recalled	This decision, this moment	Observed, or computed
WHAT THE UMBRELLA TERM COVERS	WHAT A LATER SCORE IS COMPARED WITH	HOW THE CAPACITY OPINION IS SCOPED	WHICH CONSTRUCT IS BEING NAMED

Every tile scopes something rather than reporting it: the reach of the term, the comparison a later score must enter, the boundaries of a capacity opinion, and which of the two constructs is in play.

12.8 The Indian perioperative reality, and what it changes

The perioperative recommendations held here come from a European perioperative safety guide, and the nomenclature recommendation from an international consensus working group. No Indian perioperative cognitive-assessment standard, and no Indian figure for how often preoperative cognitive assessment is performed, is held by any source behind this section. That absence is stated rather than filled, and it should be stated in an answer too.

What transfers is clear enough to reason about. The preoperative cognitive baseline is among the cheapest recommendations in perioperative medicine: a brief structured assessment, a person to administer it, and a place in the record the postoperative team will find. The barrier in most Indian surgical services is not cost but ownership, because preoperative clerking belongs to the surgical and anaesthetic teams, and the cognitive item is the first dropped when the list is long. Language and literacy add a second consideration: an instrument administered in a language the patient does not use, or whose items assume schooling the patient did not have, produces a low score that is a finding about the instrument rather than the patient.

IN INDIA

The practical move for an Indian unit is to attach the cognitive item to the anaesthetic preoperative assessment, where older surgical patients are already seen and documented, rather than to build a separate psychiatric pathway that depends on a referral being made. The psychiatric contribution is then to specify which instrument the unit uses, in which languages, administered by whom and recorded where, and to accept that a brief assessment applied consistently beats an ideal one done occasionally. No Indian coverage or outcome figure for such a pathway is held here.

GOOD TO REMEMBER

When the surgical team telephones about a confused postoperative patient, the first question is not what is wrong but whether anybody measured them before. If yes, a genuine comparison is available and a trajectory question can be answered. If no, say so plainly in the note, manage the acute presentation through the chapter that owns it, and arrange the review after discharge.

Delirium is seen at the bedside and belongs to another chapter; a perioperative neurocognitive disorder is a comparison against a preoperative baseline, which is why the measurement taken before the operation is this section's whole practical yield.

Oncology, palliative and paraneoplastic psychiatry

13 · Psychiatric effects of corticosteroids, chemotherapy and interferon (steroid psychosis, chemobrain)

The examinable content in cancer-drug neuropsychiatry is not a list of side-effects but a mapping: which agent, which syndrome, and over what interval that syndrome appears and is looked for. A candidate who has memorised that cytotoxic chemotherapy is associated with cognitive complaints, and that interferon-alpha is associated with depression, has learned the two least discriminating facts available. Marks sit on the rest: where in the course a syndrome belongs, what else produces the same picture at that point, whether the complaint has an objective correlate, and what the evidence licenses in advance rather than in response. This section installs that mapping for two agent families and deliberately routes a third away.

13.1 The boundaries this section keeps

Three boundaries govern what follows. Each exists because the material sits in full elsewhere in these notes, and a second version written here would drift from the first without anyone noticing.

The corticosteroid limb of this topic is not taught here. Systemic corticosteroids and steroid-induced psychiatric disturbance are routed on the chapter's opening plate to the endocrine and metabolic psychiatry material, and the merged organ-interface routing section of these notes carries the clinical construct. This section names steroids and goes no further with them.

Organ-adjusted prescribing is elsewhere too. Doses, dose adjustments and interaction rankings between psychotropics and cytotoxic agents belong to the psychopharmacology notes, and no figure of that kind appears below. The commonest way a candidate loses control of this topic is to answer a question about syndrome recognition with a half-remembered interaction table.

The third boundary is interferon. **Interferon-alpha** is taught here. **Interferon-beta** is taught in the Neuropsychiatry of systemic and neurological disease notes. That is a boundary rather than an accident of filing, and a later subtopic gives the reason.

RULE **Name the agent, name the syndrome, name the interval.** An answer that pairs an agent with a syndrome and stops has given half of what a ward needs. The interval tells the clinician when to look and which explanations compete at that moment.

13.2 Cancer-related cognitive impairment, and why the patient's word is the wrong construct

Patients say **chemobrain**. The construct a clinician should hold is **cancer-related cognitive impairment**, and the change of name is not fastidiousness. A term that asserts its own cause stops the clinician looking, and the value of this topic lies in what is still worth looking for after the complaint has been taken seriously.

The presenting complaint is characteristically about effortful cognition rather than frank forgetting: holding several things in mind, sustaining attention through a task, retrieving an available word, working at the old speed. Patients describe the change against their own baseline rather than any norm, which is both why the complaint is genuine and why it is hard to demonstrate.

Note what the study design in the next subtopic concedes before a single result is read. Its comparison groups are patients with the same cancers, not healthy volunteers. A design that needs disease controls is admitting that the disease, its investigations, its surgery, its other treatments and the fatigue around all of them are candidate causes of the same complaint. The cytotoxic agent is one contributor inside a bundle, and the patient's word names the one easiest to blame.

That study measured cognition with self-reported and performance-based cognitive measures, and it is worth registering that it used both. A complaint and a test result are different observations: the first cannot tell you whether performance has changed, and the second cannot tell you whether the person's life has changed.

13.3 The longitudinal evidence, read for exactly what it licenses

The anchor for the time course here is a longitudinal study of patients receiving chemotherapy for two tumour types, each type carrying its own control group. **225 participants** were assessed. The breast-cancer stratum held **41 patients and 36 controls**; the lymphoma stratum held **73 patients and 75 controls**. The reported conclusion is that, compared with controls, patients with breast cancer and lymphoma showed persistent cognitive worsening still present at **1 year** after treatment.

Read the boundary of that sentence carefully, because it is where the marks are. It is a group-level comparison: it describes two treated groups against two disease-matched groups and predicts nothing about the individual in front of you. It covers two tumour types, so it says nothing about regimens used for other cancers. The strata are modest, and the lymphoma stratum is the larger, so generalise more slowly from the smaller.

TRAP **Converting an observation window into a prognosis.** A finding reported up to a stated point after treatment describes how far the looking reached, not where the problem ended. Candidates translate it into reassurance, that it settles within the year, or into catastrophe, that it is permanent. The evidence supports neither, only that worsening was still detectable at the end of the window examined.

The consequence of persistence is a scheduling consequence. If the complaint outlasts the treatment, the point at which oncology hands the patient back is the point at which nobody is reviewing cognition, and it is exactly then that the patient is trying to return to work. A service that reviews cognition only while chemotherapy runs has arranged to stop looking just before the problem becomes disabling.

13.4 Assessing the complaint without reaching for an instrument

The task is not to confirm the patient's attribution. It is to characterise the complaint, subtract everything treatable that produces the same picture, and decide whether anything acute or evolving sits underneath it. The order matters: the treatable contributors are common and the acute ones are dangerous, and both are missed by a clinician who has already accepted the diagnosis the patient offered.

THE QUESTION TO ASK	WHY IT DISCRIMINATES	WHERE THE ANSWER ROUTES
Did the difficulty predate the first cycle?	Separates a complaint attributed to treatment from one already present at diagnosis	Keeps the differential open instead of closing it on the drug
Is the picture stable across the day, or fluctuating with clouded attention?	Fluctuating inattention is an acute-state question, not a chronic-impairment one	The stroke, traumatic brain injury, delirium and focal brain syndromes notes
Is mood, sleep, pain or fatigue carrying the complaint?	Effortful cognition fails when drive and sleep fail, and those are addressable now	The depression, demoralisation and adjustment material in the merged organ-interface routing section
Is the picture static, or evolving between reviews?	An evolving encephalopathy is a different class of problem from a stable deficit	The paraneoplastic neuropsychiatric syndromes section; the workup sits in the neurology-psychiatry interface notes
Does the complaint have an objective correlate on testing?	Self-report and performance are separate observations answering different questions	Decides whether the conversation is about workplace accommodation or further assessment

Two further routings belong in the same breath. Capacity, where a treatment decision turns on it, is decision-specific and time-specific, and the statutory test is taught in the mental health legislation notes. Where the complaint sits alongside a request to stop treatment, the palliative and existential material in the merged organ-interface routing section owns that conversation.

GOOD TO REMEMBER

The most useful thing a liaison psychiatrist adds here is a timeline. Ask when the difficulty began relative to diagnosis, to surgery, to the first cycle and to the end of treatment, and ask which task first went wrong. A complaint that predates any cytotoxic agent, one that fluctuates within a day, and one still worsening after treatment finished are three different problems wearing the same words.

13.5 Interferon-alpha, and the one thing this section can state as evidence

A spelling point first, because it costs marks in reading rather than in writing. The oncological preparation is written **interferon alfa** in drug nomenclature and in much of the trial literature, and interferon-alpha in general prose. They are the same agent.

The evidence this section can state concerns prevention rather than treatment. In patients with malignant melanoma who were eligible for high-dose interferon alfa therapy, pretreatment with paroxetine appears to be an effective strategy for minimising depression induced by interferon alfa. That was tested in a randomised comparison in which **40 patients were randomised, 20 to paroxetine and 20 to placebo**, with symptoms consistent with major depression during interferon alfa therapy as the outcome of interest.

Retain the qualification exactly as the source states it. Pretreatment appears to be an effective strategy, which is weaker than a claim that it prevents the syndrome, and an answer that upgrades

it has misreported the source. The population is equally load-bearing: melanoma, high-dose interferon alfa, one antidepressant, and pretreatment given before the interferon rather than treatment started once mood has changed. None of those boundaries transfers on its own to another cancer, another interferon, another antidepressant or a reactive prescription.

One thing can be inferred honestly from the design, and it carries the time course. A placebo-controlled prevention trial is only designable if the syndrome it prevents is expected often enough, and soon enough after therapy starts, to be counted inside the treatment course. The trial's shape therefore tells you that interferon-alfa depression is foreseeable and time-linked rather than idiosyncratic. That is an inference about the design, and this section publishes no rate.

RULE **Prophylaxis is a different claim from treatment, and a population is part of a claim.** The bound evidence supports pre-emptive antidepressant cover in a specified oncology population starting a specified interferon regimen. It says nothing about what to do once the mood syndrome has declared itself, and it does not extend to everyone about to receive an interferon. Quoting a prevention result as a treatment result is an invisible error unless you state the population every time you state the finding.

13.6 Interferon-alpha is not interferon-beta, and the separation is clinical

These are distinct preparations, given to distinct populations for distinct reasons, and their psychiatric literatures are separate. Interferon-alpha reaches the psychiatrist through oncology and through infectious disease, in courses that are intensive and time-limited. Interferon-beta reaches the psychiatrist through a chronic neurological illness carrying its own mood burden independently of any drug, which is why the Neuropsychiatry of systemic and neurological disease notes hold it and this section does not.

The separation matters for three reasons an examiner can ask about directly. First, the background rate of psychiatric disorder differs between the populations, so a figure pooled across both would describe no real patient and mislead in both directions at once. Second, the confounders differ: in the alpha setting the competing explanation is the cancer or the infection and its treatment, in the beta setting the neurological illness itself. Third, the clinical decision differs. In the alpha setting the live question is whether to cover a foreseeable, time-linked mood syndrome before a defined course begins; in the beta setting it is embedded in long-term management of a chronic disease, and taken up where that disease is taught.

TRAP **Answering "the neuropsychiatric effects of interferon" as a single topic.** A stem that says interferon without saying which preparation is testing whether the candidate knows the distinction exists. The answer that scores separates alpha from beta, states which one it will discuss, and says why pooling them would be uninformative. The answer that fails treats the word as one drug and produces a paragraph true of nobody.

13.7 Agent to syndrome to time course, which is what the plate carries

The plate below is the compressed form of everything above, built on three columns rather than two. The first names the agent family. The second names the syndrome, in the vocabulary a

clinician would use in a note. The third, which does the work, places that syndrome on the treatment timeline: before treatment, during the course, at handover, and after treatment has finished. Read the third column first when revising, because it converts a list of associations into something usable at the bedside.

Two features of the plate are deliberate rather than accidental. The corticosteroid limb is absent, because steroids are routed on the chapter's opening plate to the material that owns them. And interferon-alpha and interferon-beta are drawn apart rather than sharing a row, for the reasons given above.

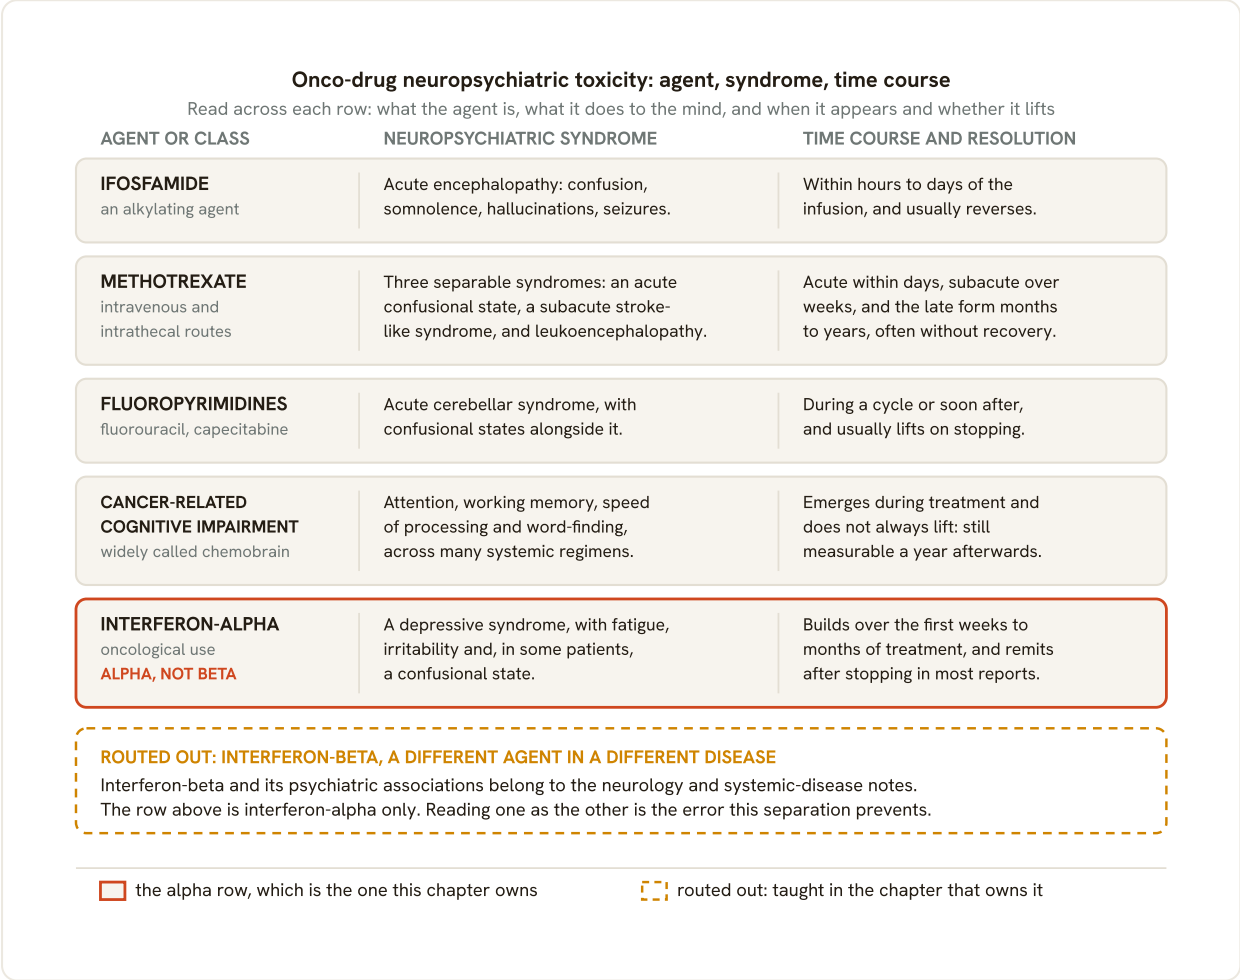

Fig 40.7 Chemotherapy and interferon neuropsychiatric toxicity read as agent, then syndrome, then time course, because at the bedside it is the time course that usually settles the differential. The acute encephalopathies declare themselves within hours to days and usually reverse on withdrawal, which is why ifosfamide, the fluoropyrimidines and the acute methotrexate syndrome sit together; methotrexate is the agent that also carries a subacute stroke-like syndrome and a late leukoencephalopathy that may never recover. Cancer-related cognitive impairment, widely called chemobrain, is the slow limb: it emerges during treatment, spares alertness, and has been measured as still present a year after treatment ends. Interferon-alpha produces a depressive syndrome that builds over the first weeks to months of treatment. The plate separates interferon-alpha from interferon-beta deliberately, because they are different agents used in different diseases and beta belongs to the Neuropsychiatry of systemic and neurological disease notes; the third drug group named in this topic is carried by the routing plate earlier in this chapter and by the Endocrine and metabolic psychiatry notes, so it is not drawn here at all. From memory you should be able to place any of these agents on the three columns and say whether the syndrome is expected to lift.

IN INDIA

No Indian figure for the frequency of cancer-related cognitive impairment, and none for interferon-alfa depression in Indian oncology practice, was located for this section, and none is asserted. What transfers is the structure. Where oncology and psychiatry sit in different institutions and follow-up is episodic, the practical question is not which cognitive instrument to buy but who reviews the patient once the oncology course closes, and when. Since the bound evidence describes a complaint still present after treatment ended, a service with no review point after discharge from oncology has designed itself to miss the window that matters most.

13.8 The shape of an answer that scores

A written answer here is graded on discrimination rather than length, and the discriminating content is ordered.

- Separate the agent families at the outset. Name the corticosteroid limb only to route it, and separate interferon-alpha from interferon-beta before saying anything about either.
- Use the construct rather than the patient's word, and say why the patient's word closes the differential prematurely.
- State every finding with its population attached. A finding without its population is not a shorter answer, it is a weaker and different one.
- Place each syndrome on the treatment timeline, and keep the observation window distinct from the prognosis.
- Route the neighbouring problems by name: delirium, paraneoplastic syndromes, depression and adjustment in cancer, capacity, and organ-adjusted prescribing.
- Say what is not known. The honest gaps here are large, and a candidate who names them is more convincing than one who fills them.

PITFALL

Treating the cognitive complaint as the end of the assessment because the patient has a plausible reason for it. A patient receiving chemotherapy has an explanation available for almost any neuropsychiatric presentation, and that availability is what makes delirium, an evolving encephalopathy and an untreated depression easy to miss. The plausible cause is the one to test last, not the one to accept first.

Agent, syndrome, interval
THE THREE THINGS AN ANSWER MUST NAME

Cancer-related cognitive impairment
THE CONSTRUCT THAT REPLACES THE PATIENT'S WORD

Prevention, not treatment
WHAT THE PRETREATMENT FINDING LICENSES

Alpha is not beta
THE SEPARATION A ONE-WORD STEM IS TESTING

Interferon-alpha is separated from interferon-beta and corticosteroids are routed away; the cognitive syndrome is cancer-related, not chemotherapy-proven; and every finding is stated with its population and its observation window attached.

14 · Paraneoplastic neuropsychiatric syndromes and onconeural antibodies: when to suspect occult malignancy

A paraneoplastic neuropsychiatric syndrome is a psychiatric presentation driven by the immune response to a tumour that has not yet been found. The final clause carries the whole examinable weight. This is not a complication of a cancer already sitting in the case notes; it is the event that makes someone go looking for the cancer in the first place. This section installs the reasoning that converts an ordinary-looking psychiatric presentation into a directed search for occult malignancy: what the term **paraneoplastic** actually claims, why the psychiatric clinic meets these patients ahead of the oncology clinic, what raises suspicion, what a psychiatrist owns and what is handed on, and which antibody has been reported to point where.

14.1 What the term claims, and the sequence that defines it

The prefix does the work. **Para** plus **neoplastic** names a disorder that accompanies a neoplasm while being made of something else. The damaged tissue is nervous tissue, and what damages it is an immune response the tumour provoked. The word **onconeural** names why such a response reaches the brain at all: the antigen belongs to the tumour and to neural tissue alike, so an attack aimed at one compartment lands in the other. Everything examinable here follows from that idea, including why the syndrome can be severe while the tumour stays small enough to have escaped detection.

The defining feature, for examination purposes, is a sequence rather than a severity. **The neurological or psychiatric syndrome comes first, and the malignancy is detected afterwards.** The task-force report that grounds this section states it plainly: **paraneoplastic neurological syndromes almost invariably predate detection of the malignancy**. Hold that sentence in mind through everything that follows, because it is what separates this topic from every other cancer topic on the day, and it is the reason the topic belongs to a psychiatry paper at all.

It is worth being precise about what the label has to displace before it is earned, because a neuropsychiatric picture in someone who turns out to have cancer has several ordinary explanations. It may be a direct effect of tumour mass or of secondary deposits. It may be metabolic or endocrine derangement produced by the tumour. It may be treatment: the cytotoxic agents, the interferon and the corticosteroids, each taught in its own place, in the sibling section on chemotherapy and interferon effects and in the routing section that owns steroid-induced disturbance. It may be adjustment, demoralisation or depression in someone absorbing a serious illness, which the routing section on cancer owns. Cross-refer each by name; this section restates none of their content.

Notice the asymmetry the sequence creates. In the ordinary cancer psychiatry of a known malignancy, those rival explanations are all available on the ward round, because the tumour, the metabolic panel and the drug chart are already in front of you. In the paraneoplastic case they are unavailable at presentation, because nobody has yet established that there is a tumour. The

clinician holds a syndrome and a history, and the question of malignancy has to be raised rather than handed over.

RULE **The defining feature is the sequence, not the severity.** **A paraneoplastic syndrome characteristically declares itself before the malignancy is detected**, which is why the phrase in the bank item is "when to suspect occult malignancy" and why an answer that describes a florid syndrome in a known cancer patient has answered a different question.

14.2 Why the psychiatric clinic meets these patients first

There are honest structural reasons why this presentation lands with a psychiatrist, and a candidate who can state them is well placed to answer the item. The first is the sequence itself. Because **the syndrome usually arrives before the malignancy has been detected**, the first clinician to see the patient is whichever clinician the presenting complaint routes them to. Where that complaint is behavioural, meaning altered mood, altered personality, psychosis, failing memory, reversed sleep, agitation or apathy, that clinician is a psychiatrist. The referral letter says nothing about cancer, because at that point there is nothing about cancer to say.

The second reason is that psychiatric formulations are generous, and their generosity is usually a strength. A subacute behavioural change in an adult can be absorbed comfortably into a first episode of psychosis, a late-onset depressive episode, a mood disorder cycling faster than usual, a dissociative presentation or a functional cognitive disorder. Each is internally coherent and each generates a plausible treatment plan. None of them obliges the clinician to ask what else could be producing this picture, so the question of occult malignancy is one the reasoning process will never raise unless the clinician raises it deliberately.

The third reason is what the examination is actually testing. The bank item asks when to suspect, and suspicion is a skill with a location in time: it belongs at first contact, alongside the initial formulation, and it loses value the longer it is deferred. A suspicion raised after several failed treatment trials is a lesser clinical act than the same suspicion raised at intake, because in the interval the syndrome has progressed while **the malignancy has continued to sit undetected**.

TRAP **Treating the difficulty as a laboratory problem.** Candidates picture the failure as a missed antibody result, so they write about panels and assays. The failure that actually happens is upstream and cheaper to fix: the question of an underlying tumour was never opened, so nothing was ever sent. An answer that begins with the test has skipped the step the item is examining.

14.3 Reading the presentation: tempo, company and fit

Suspicion is a discipline rather than a mood, and it should not be taught as vigilance in general. It is built from a small set of readings that a competent psychiatric history already produces, and the work is to read them deliberately rather than to hope they announce themselves.

The first reading is **tempo**. Psychiatric illnesses have characteristic time signatures, and a clinician who has taken many histories knows them implicitly. What matters here is the mismatch: a presentation that moves faster than the illness it resembles, that keeps moving while treatment is being delivered adequately, and whose trajectory is a slope rather than an episode.

Tempo costs nothing to record, requiring only a careful timeline with collateral corroboration, and it is the reading most often left vague in a psychiatric clerking.

The second reading is **company**, meaning what the psychiatric syndrome has arrived with. Psychiatric syndromes keep characteristic company, and neurological company is different company. When a behavioural presentation is accompanied by features belonging to the nervous system rather than to the mind, the formulation has acquired something it cannot metabolise, and that is informative in itself. The plate below sets out the clusters that carry this weight, and it is the right place to learn them, because they are the content of the source criteria rather than of this author's recollection.

The third reading is **fit**: whether this person fits the illness being diagnosed, and whether a general history has been taken at all. Psychiatric clerking has a known habit of collecting an exhaustive developmental history alongside a thin systemic one, so constitutional features, general medical risk and the ordinary questions an internist would ask are frequently missing. A history that never asked them cannot be reassuring, and the difference between a negative finding and an unasked question is one this chapter returns to repeatedly.

The plate that follows carries the working set: the onconeural antibody group, the tempo and sign clusters that raise suspicion, and the boundary against the autoimmune-encephalitis workup taught elsewhere. Read the plate as the operational list, and this prose as the reasoning that tells you when to reach for it.

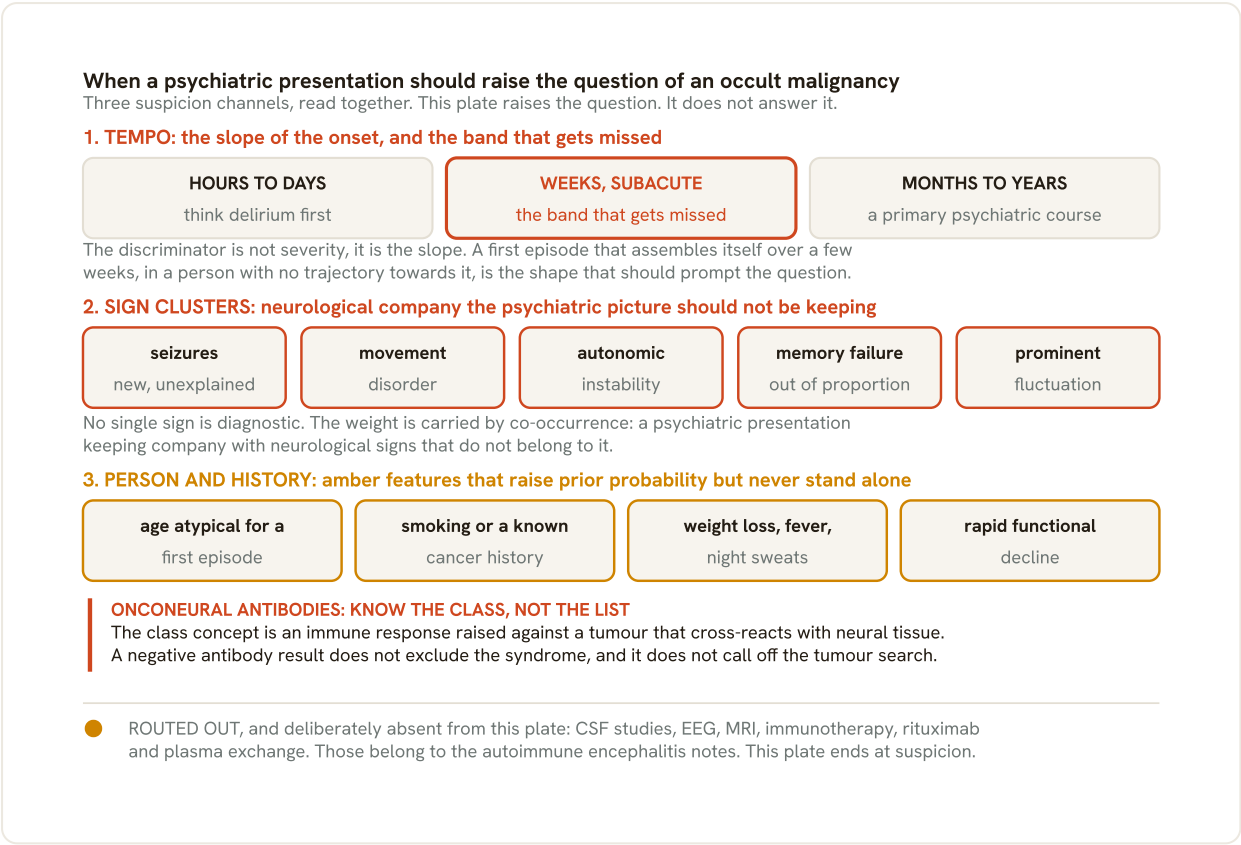

Fig 40.8 The three suspicion channels for an occult malignancy presenting psychiatrically. The plate is deliberately a suspicion instrument and stops there, because the workup and its immunotherapies belong to the autoimmune encephalitis notes and are cross-referenced out rather than duplicated. What it adds to the prose is the tempo rail, which puts the subacute band between two safer neighbours and shows why that band is the one that gets missed: a presentation over hours to days is read as delirium and gets investigated, a presentation over months to years is read as primary psychiatric and gets followed, and the few-week presentation falls between two reflexes. The onconeural antibody idea is carried as a class rather than a list because that is how it is examined and how it behaves, and because a negative result narrows nothing. From memory you should be able to state the tempo band that should worry you, name the sign clusters that a psychiatric picture should not be keeping company with, and say what a negative antibody result does and does not permit you to conclude.

14.4 The boundary: suspicion is yours, the workup is not

This section owns paraneoplastic suspicion. It does not own the autoimmune-encephalitis workup. Cerebrospinal fluid examination, electroencephalography, magnetic resonance imaging, first-line immunotherapy, rituximab, plasma exchange and intravenous immunoglobulin are taught in the Neuropsychiatry of systemic and neurological disease notes, and this text restates no parameter of any of them. The boundary is named explicitly because it is the one an author is most tempted to cross: the workup has protocols and sequences and feels like the substance of the topic, and it is the substance of a different topic with a different owner.

The split is clinical rather than merely editorial. The investigations and the immunotherapy form one coherent body of knowledge, learned and examined together. Suspicion is a separate skill, exercised by a different clinician at an earlier moment, and it is the skill this bank item names.

What the psychiatrist owns is worth stating positively, and it is short enough to hold as a list.

- The timeline, recorded precisely enough that tempo can be read off it later by a clinician who was not in the room.

- The collateral history, often the only source of that tempo.
- The general and systemic history that psychiatric clerking tends to abbreviate.
- The referral itself: one that says "for neurology opinion" transmits only the patient, while one that states the tempo, the company and the explicit reason a tumour is being considered transmits the reasoning.

THE QUESTION IN FRONT OF YOU	WHERE IT IS ANSWERED
Could this psychiatric presentation be driven by a tumour nobody has found yet?	This section.
What do the cerebrospinal fluid, the electroencephalogram and the scan show, and what immunotherapy follows?	Neurology-psychiatry interface notes, autoimmune encephalitis. Never taught here.
Is this delirium, and how is it assessed and managed?	Stroke, traumatic brain injury, delirium and focal brain syndromes notes.
Does this patient have capacity, and what is the statutory test?	Mental health legislation notes. Capacity is decision-specific and time-specific; the test is taught there.
How is the psychotropic adjusted for hepatic or renal impairment?	Psychopharmacology notes. This chapter adds no further version of a dose adjustment.
Is the disturbance caused by the cytotoxic agent, by interferon, or by the corticosteroid?	The sibling section on chemotherapy and interferon effects, and the routing section owning steroid-induced disturbance.
Is this neuropsychiatric lupus, neurosarcoidosis, central nervous system vasculitis or antiphospholipid syndrome?	The sibling sections owning each of those.
Is this depression, demoralisation or adjustment in someone already known to have cancer?	The routing section on cancer.

14.5 The screening imperative, and the guides it names

Once suspicion exists, the criteria are direct about what follows. **Cancer screening should be promptly undertaken when a paraneoplastic neurologic syndrome is suspected, and should be guided by the type of phenotype or antibody.** That single sentence is the operational core of this section, and it repays reading in parts.

The first operative word is **promptly**. It fixes a position in the sequence: the screen belongs at the point of suspicion rather than at the point of diagnostic certainty. The claim carries urgency and carries no interval, so this text supplies none, and a candidate who wants a period in days or weeks should take it from the criteria rather than from a note that would be inventing it.

The second operative phrase is **guided by the type of phenotype or antibody**. The instinct under pressure is to describe a broad sweep, imaging everything and hoping something appears. The criteria describe a search with a direction, where the clinical phenotype narrows the field of plausible primaries and the antibody, when available, narrows it further. An answer that reproduces the urgency while dropping the guidance has reproduced the easier part.

One inference is worth stating, because it is reasoning rather than recollection. If **the syndrome characteristically presents before the malignancy is detected**, the screen is being run in a body where the tumour has so far evaded detection. A first look that finds nothing has therefore not settled the question the way a first look normally settles one, and the posture that follows is continued attention rather than closure.

RULE **Prompt and guided, in that order and with equal weight. The criteria couple the timing of cancer screening to the suspicion of a paraneoplastic neurologic syndrome, and couple its direction to the phenotype or the antibody.** Reproduce the pairing. An answer carrying only urgency describes panic; an answer carrying only direction describes a screen that may arrive too late to matter.

Now the honest limit of this section, narrowed to what the ledger actually withholds. The antibody pairings are cited and taught in the subtopic below, so they have left the list of absences. What is still missing is the machinery around the screen: no row names which imaging modality corresponds to which phenotype, no row gives an interval for repeating a screen that found nothing, and no row states how long surveillance continues. Those three are what a candidate will want next, and they are owed to the source criteria rather than to this note.

14.6 Onconeural antibodies: the risk tier, the phenotype and the reported pairings

The term **onconeural antibody** names an antibody directed against an antigen shared by tumour tissue and nervous tissue. That definition is why the antibody is diagnostically useful at all: because the antigen belongs to each compartment, a serological finding points at a body region that has yet to be searched. Take the term seriously as vocabulary, because it carries the logic of the whole section in a single word.

The antibody earns its place here for the reason the criteria give: **the cancer screen is guided by the type of phenotype or antibody**. The antibody is a laboratory result while the syndrome is a clinical entity, so the result informs the search rather than constituting the diagnosis. And it sits alongside the phenotype in the claim as written rather than replacing it, so a clinician who has a phenotype and awaits a result already holds one of the guides the criteria name.

The criteria then sort the antibodies by the cancer risk each one carries, and that sorting is what makes the guidance operational. **The first group holds the high-risk antibodies, defined as those associated with an underlying cancer in more than 70 per cent of the patients who carry them.** A structural fact travels with the group: **most high-risk antibodies target intracellular antigens**. Put the two together and an inference follows. An antibody raised against an antigen sitting inside the cell is poorly placed to be doing the damage by binding it, so the finding is best used as a pointer towards a hidden tumour rather than as an account of mechanism.

One phenotype belongs to psychiatry more than to any other specialty. **Paraneoplastic limbic encephalitis is characterised by personality change, irritability, depression, seizures, memory loss and sometimes dementia.** Read that list as a psychiatric referral rather than a neurological one. Personality change, irritability and depression are what a psychiatric service is

built to receive; the seizure and the memory failure are what eventually move the formulation, often long after a psychiatric label has been applied and acted upon.

The reported pairings follow, with the evidence grade placed second so that it is read before the pairing it qualifies, and with the two rows that rest on more than one patient placed first. Read the second column before the third. A single reported case establishes that a pairing has been observed in a human being, and nothing beyond it: no frequency, no claim that this tumour is the one the antibody usually points to, and no entitlement to the word "classical".

ANTIBODY	WHAT THE CITED ROW IS	SYNDROME REPORTED WITH IT	TUMOUR REPORTED WITH IT
CRMP5	**The commonest associated diagnoses in a 24-patient cohort.**	**Peripheral neuropathy and cerebellar ataxia**	**Lung cancer**
Anti-Ma2	**Described as a specific marker for that pairing.**	**Limbic and brainstem encephalitis**	**Testicular germ-cell tumour, mainly in adult males**
Anti-Hu	**A single reported case.**	**Adie's pupil with sensorimotor polyneuropathy**	**Primary mediastinal small-cell carcinoma**
Anti-Yo	**A single reported case, arising years after the tumour was resected.**	**Cerebellar degeneration**	**Ovarian cancer**
Anti-Ri	**A single reported case.**	**Opsoclonus-myoclonus**	**Breast carcinoma, in a male patient**
Anti-amphiphysin	**A single reported case.**	**Stiff-limb syndrome**	**Invasive ductal carcinoma of the breast**

The second column is where marks are won and lost, which is why it now sits where the eye reaches it first. Four of these six rows rest on one patient each, and several of those reports were published precisely because they were unusual: an opsoclonus-myoclonus syndrome in a man, a cerebellar syndrome declaring itself years after the ovarian tumour was resected, a mediastinal rather than a pulmonary small-cell primary. A report selected for its rarity is the worst available basis for a statement about what is typical, and an answer that flattens this table into a list of classical associations has manufactured a confidence its own sources never carried.

The criteria also grade how much confidence the label deserves. **The PNS-Care score is a composite model for assigning diagnostic likelihood in a patient with a suspected paraneoplastic neurological syndrome**, and it answers in bands: **definite at 8 or above, probable at 6 to 7, possible at 4 to 5, and a score of 3 or less classed as something other than a paraneoplastic syndrome**. Learn the bands, and learn that a graded answer exists. The items the score weighs are absent from this fragment's ledger, so they are left to the criteria.

Syndrome, then tumour	Prompt and guided	Pointer, not diagnosis	Observed, not typical
THE SEQUENCE THAT DEFINES THE TERM	HOW THE CANCER SCREEN IS RUN	WHAT AN ONCONEURAL ANTIBODY IS FOR	WHAT A SINGLE-CASE PAIRING ROW ESTABLISHES

The four tiles carry the spine of the section: a sequence, a manner of screening, a use for the laboratory result, and a limit on what the pairing table licenses.

IN INDIA

The screening imperative assumes an onconeural antibody panel can be requested, paid for and reported within a useful period, and in much of Indian practice each assumption deserves checking before the plan is written. Panels are sent out to referral laboratories from most district and many teaching hospital settings, the cost is usually met out of pocket, and turnaround runs to the time a courier and a batch run take. The practical consequence is that **the phenotype is frequently the guide available first, with the antibody arriving later to refine the search**, which makes a carefully documented clinical picture more valuable here than where serology returns quickly. The Indian record on availability, pricing and reporting intervals for these panels was never located within this fragment's ledger, so it is described qualitatively rather than quantified.

GOOD TO REMEMBER

On the ward this reduces to a single habit. When a psychiatric presentation moves at the wrong speed, keeps company with neurological features, and sits in a person whose general history was never properly taken, write the timeline down and say the word "paraneoplastic" out loud in the referral. **The syndrome characteristically arrives before the malignancy is found**, so the psychiatrist is often the clinician best positioned to raise the question at the moment it is most useful. What follows, the fluid, the imaging, the electrophysiology and the immunotherapy, belongs to colleagues and to another section. Raising the question well is the part that is yours.

The syndrome almost always arrives before the malignancy is found, so the psychiatrist's part is suspicion at first contact: read tempo, company and fit, write the timeline down, say the word in the referral, and let the cancer screen be prompt and guided while the workup belongs to somebody else.

Autoimmune and inflammatory systemic disease, and burn injury

15 · Neuropsychiatric systemic lupus erythematosus: manifestations, diagnosis and management

The examinable difficulty in neuropsychiatric lupus is not the list of syndromes, it is deciding whether the syndrome in front of you belongs to the disease at all. Lupus reaches the nervous system often enough to produce almost any neurological or psychiatric presentation, and the same patient can also be septic, uraemic, hypertensive, taking drugs with central effects, and

frightened by an illness that has already taken things from them. This section installs the topic in the order the decisions are made: what the term covers, how the manifestations reach a psychiatrist, how attribution is reasoned when no test settles it, and what treatment looks like afterwards.

Several things this presentation touches are owned elsewhere and are named here rather than rebuilt. Delirium assessment and management, including the bedside instruments and the drug choice for an agitated delirious patient, belong to the stroke, traumatic brain injury, delirium and focal brain syndromes notes. Organ-adjusted prescribing belongs to the psychopharmacology notes, and the workup of autoimmune encephalitis to the neurology and psychiatry interface notes. Corticosteroid-induced psychiatric disturbance is taught by the routing section of this chapter that owns it and by the endocrine and metabolic notes, which matters here because the drug class used to treat this disease is itself a recognised cause of psychiatric disturbance. The antiphospholipid syndrome is owned by the sibling section that carries it alongside neurosarcoidosis and central nervous system vasculitis.

15.1 What the term is asked to cover, and why its breadth is the problem

Neuropsychiatric systemic lupus erythematosus, conventionally shortened to **NPSLE**, is a collective label for the neurological and psychiatric manifestations occurring in a person who has lupus. It is a container, not a diagnosis of the kind a psychiatrist is used to making. Standard usage sorts its contents into central nervous system events, peripheral nervous system events and psychiatric syndromes, and those groups share almost nothing at the level of mechanism, severity, investigation or treatment.

That breadth is the source of every difficulty that follows. A label covering both a mild headache and a catatonic psychosis cannot have one test, one mechanism or one treatment, and any sentence beginning "NPSLE is treated with" is suspect before its predicate arrives. The useful move is to handle the label as a question in parts: which syndrome, by which mechanism, in a patient whose disease is at what level of activity, with which alternative explanations excluded.

RULE **Name the syndrome, then the mechanism, then the attribution, then the treatment.** These are separate determinations and each can be right while the next is wrong. A candidate who says "this is neuropsychiatric lupus" has named a container. One who says "this is an acute confusional state, in a patient with active disease, in whom infection and metabolic causes have been excluded, treated as an inflammatory manifestation" can be examined on any of the four.

15.2 How the manifestations reach a psychiatrist

Grouping the manifestations by the route through which they arrive is more useful than grouping them by anatomy, because the route determines what you are being asked to do.

- **Diffuse presentations**, which psychiatry is most often called about: an acute confusional state, mood disturbance of either polarity, psychosis, cognitive impairment across attention, memory and executive function, and anxiety. Here the referral question is usually not "is this lupus" but "is this psychiatric".

- **Focal central events**: seizures, stroke-like episodes, movement disorder, myelopathy, aseptic meningitis, cranial neuropathy and a demyelinating syndrome. These reach neurology or medicine first, and psychiatry is called for the behavioural consequences, for capacity, or because the presentation was read as functional.
- **Peripheral events**: polyneuropathy, mononeuropathy, plexopathy, autonomic disturbance and a neuromuscular junction disorder. These rarely present to psychiatry directly, and their relevance is that pain and disability from them drive mood.

The classes are nomenclature rather than mechanism: they say where the disturbance sits and nothing about why. This chapter also holds no row giving the frequency of any manifestation in any population, so nothing here is called the commonest and no ordering by frequency is printed. Frequency statements circulate widely in this topic and disagree with one another, for the reason the next subtopic makes clear.

15.3 Attribution, which is the actual core of the topic

Everything listed above can be produced by lupus, and every one of them can be produced by something else in a person who happens to have lupus. Diagnosis is therefore **attribution**: a reasoned judgement that this syndrome, in this patient, at this time, belongs to the disease. It is reasoned rather than measured, because **there is no diagnostic gold standard by which the neuropsychiatric syndromes of lupus can be diagnosed**. That fact is the axis of the topic and belongs early in any answer.

Three consequences follow, each worth a sentence. Published frequency estimates disagree, because without a gold standard every study defines its own numerator: a series counting headache and mild mood symptoms and a series counting only severe syndromes are not measuring the same thing, and their percentages are not comparable even when both are correctly reported. No investigation is confirmatory, so every result is evidence to be weighed rather than an answer. And attribution is revisable, since a judgement made on admission may be overturned by the culture result, by the course, or by the response to treatment.

The reasoning runs on a small number of axes worth naming. The first is the temporal relation to disease activity elsewhere: a syndrome appearing while the disease is active in other organs is easier to attribute than one appearing in quiescent disease. The second is the presence or absence of a competing explanation, which the next subtopic takes up because it does the most work. The third is the character of the syndrome, since a course, phenomenology or examination finding atypical for a primary psychiatric disorder points towards a systemic cause. The fourth is response to treatment, and it is retrospective, which is why the attribution has to be made and acted on before the evidence for it is complete.

TRAP **Treating a positive antibody as an attribution.** Serology establishes that the patient has the disease. It does not establish that the syndrome in front of you was produced by it, and a patient with unambiguous lupus can have an unrelated psychiatric illness, an infection or a drug effect. Skipping the attribution step is also how a treatable cause is missed while immunosuppression is escalated.

15.4 What has to be excluded before the disease is credited

Because attribution rests so heavily on the absence of a competing explanation, the exclusion list is the substance of the assessment rather than preliminary housekeeping. Infection comes first and stays first in a patient immunosuppressed by both the disease and its treatment, and it includes meningitis, encephalitis, and the encephalopathy of systemic sepsis without central infection. Metabolic causes follow: uraemia, sodium and glucose disturbance, hepatic and thyroid disturbance. Hypertensive encephalopathy belongs in anyone with renal disease and a new confusional or seizure presentation.

Drug causes are the largest single trap here, because the treatment of the disease and the cause of the psychiatric syndrome can be the same agent. That construct is taught by the routing section of this chapter that owns it; what belongs here is the boundary. A new psychiatric syndrome beginning after a change in immunosuppressive treatment, in a patient whose disease activity elsewhere has improved, pulls in the opposite direction from an attribution to the disease. The distinction changes treatment completely, since one path escalates immunosuppression and the other reduces it.

Primary psychiatric illness stays on the list throughout, supported by a psychiatric history predating the lupus, a family history, and a typical course. So does the ordinary burden of a relapsing systemic illness with a visible skin component and a treatment with visible adverse effects: demoralisation and adjustment disorder in that setting are a person responding to their circumstances rather than the disease reaching the brain, and are treated as such.

Finally, lupus is one member of a family of systemic diseases that reach the nervous system, and the discriminating features are what separate them at the bedside. The plate accompanying this section sets lupus beside the other systemic autoimmune presentations this chapter teaches, neurosarcoidosis, central nervous system vasculitis, the antiphospholipid syndrome, coeliac disease and inflammatory bowel disease, each with its discriminating feature. Each is taught in full by the sibling section that owns it and is named here only to place lupus in its family.

Six systemic autoimmune conditions on one comparator, because the task is telling them apart
One row each. The middle column is the only one that separates them from each other.

CONDITION	THE DISCRIMINATOR, in one feature	WHAT BRINGS IT TO PSYCHIATRIC NOTICE
Neuropsychiatric lupus	multisystem: skin, joints, kidney and blood counts, all in the one patient	psychosis or a mood episode arising inside an already declared illness
Neurosarcoidosis	cranial neuropathy, with basal meningeal or pituitary involvement	apathy and personality change, with hypersomnia and endocrine mood shift
Primary CNS vasculitis	confined to the CNS, with headache and stepwise deficits on a bland screen	no psychiatric presentation is claimed here: a declared gap, see the text
Antiphospholipid syndrome	thrombosis and pregnancy loss are the carrying features, often recurrent	cognitive complaints in a young adult with a thrombotic or obstetric history
Coeliac disease	gluten-driven enteropathy, and the deficiency load does much of the work	depression and apathy that persist after the mood treatment is optimised
Inflammatory bowel disease	relapsing bowel disease, and the burden tracks disease activity	depression and anxiety that flare with the bowel, plus steroid-driven change

READ DOWN THE MIDDLE COLUMN: that is the only column that closes the differential.
Low mood and cognitive change run across these rows, so that column raises the question but cannot answer it.

● ROUTED OUT: the serological and imaging workup for each of these six, and their immunosuppressive treatment, are not taught on this plate. What is taught here is telling the six apart.

Fig 40.9 Six systemic autoimmune conditions laid on a single comparator so that they can be told apart rather than revised one at a time. The plate exists because the right-hand column is nearly identical down all six rows, and that is the teaching point: depression, anxiety and cognitive change are the common currency of systemic inflammation, so the presentation that brings the patient to psychiatric attention almost never identifies which condition it is. The middle column carries the whole differential, and each entry is chosen to be true of that row and false of the other five. One right-hand cell is deliberately empty of a clinical picture: no source explicitly linking primary central nervous system vasculitis to a psychiatric manifestation was located for this chapter, so the gap is printed rather than filled from a neighbouring condition, and the accompanying text says what to do with it. Note the two structural families the table exposes, that the first four reach the brain directly through inflammation, vasculopathy or thrombosis, while the last two reach it indirectly through nutrition, disease activity and treatment exposure. From memory you should be able to give the single discriminating feature for each of the six, and say why the psychiatric column can raise the question but never settle it.

15.5 Investigation, and what each result can and cannot settle

The investigation logic follows from the absence of a gold standard: every test is chosen for what it excludes or supports, and none to confirm. Serology and disease activity markers establish that lupus is present and give some sense of activity elsewhere, which feeds the temporal axis and nothing more. Structural imaging looks for a focal lesion, for ischaemic change and for an alternative structural explanation, and a normal scan is entirely compatible with a severe diffuse syndrome, which is the most misread result in this topic.

Lumbar puncture here is done principally to exclude infection, and its findings in the disease itself are non-specific. Electroencephalography supports or refutes a seizure explanation for an episodic disturbance and characterises an encephalopathy without attributing it. Neuropsychological assessment characterises a cognitive deficit, which is valuable for

rehabilitation and for tracking change, and does not attribute it. Where autoimmune encephalitis is genuinely in question, that workup belongs to the neurology and psychiatry interface notes.

This chapter holds no row carrying an antibody to syndrome association, an imaging finding to syndrome association, or the performance of any investigation in this population, so none is asserted. That is a real gap rather than a stylistic omission, and the antibody associations should be read from a primary source and held separately from what is taught here.

RULE **No investigation closes the question, because no diagnostic gold standard exists for these syndromes.** Order tests to exclude the competing explanations and to characterise the syndrome, and expect to make the attribution on the balance of what you have. An answer promising a confirmatory test is wrong on the central fact of the topic.

15.6 Treatment, and the recommendation this section carries

Once a syndrome has been attributed to the disease, treatment has three limbs, chosen by mechanism rather than by phenomenology. The **inflammatory limb** is immunosuppression, applied when the syndrome is judged to arise from active disease. The **thrombotic limb** is antithrombotic treatment, applied when the mechanism is judged to be vascular occlusion; the antiphospholipid syndrome that most often drives it is owned by the sibling section, so this section names the limb and stops. The **symptomatic limb** is psychiatric and neurological treatment of the syndrome itself, running alongside either of the others rather than after them.

The guideline recommendation this section carries is precise about its population and about its comparison, and both matter more than the drug names. In adult patients with lupus-related severe, acute neuropsychiatric manifestations, the guidance is to **use GCs plus CYC over GCs alone or GCs plus RTX**. The abbreviations are the guideline's own and stand for glucocorticoids, cyclophosphamide and rituximab.

Read the population before using the recommendation, because it carries restrictions a candidate quoting it loosely will drop. It concerns adults, so it says nothing about children. It concerns severe manifestations, so it says nothing about the many mild ones this container also holds. It concerns acute manifestations, so it says nothing about chronic or slowly progressive syndromes, and a chronic cognitive syndrome is precisely what psychiatry is most likely to be asked about. Quoted as though it applied to everyone with this label, it becomes an error of scope.

What this section does not carry is equally worth stating: no dose, no route, no duration, no schedule, no maintenance strategy, no comparison for the mild or chronic presentation, and no statement about what to do when the first choice fails. Organ-adjusted prescribing for renal involvement belongs to the psychopharmacology notes, and remembered regimens in this topic diverge sharply between sources.

15.7 The psychiatric limb, and the boundaries around it

Psychiatric treatment of an attributed syndrome runs alongside the immunosuppression and is not deferred until it works. An acute confusional state is managed as an acute confusional state, by the pathway taught in the delirium notes, while the cause is treated. A psychotic or affective

syndrome is treated symptomatically with two standing cautions in view: renal and haematological involvement constrain the choice of agent, quantified in the psychopharmacology notes rather than here, and the possibility that treatment of the disease is contributing keeps the drug review open.

Two further boundaries belong in an answer. Capacity is assessed as it is anywhere else, and the only things this section says about it are that it is decision-specific and time-specific, which matter unusually often in a fluctuating encephalopathy; the doctrine and the statutory test belong to the mental health legislation notes. Adherence deserves explicit attention, because the psychiatric syndrome sits on top of a demanding medical regimen, and a cognitive syndrome never named will be recorded as non-compliance.

The rehabilitative and psychological work is most often omitted and has the longest reach. A cognitive deficit that has been characterised can be worked with, at home and at work, whether or not it is reversible, and the demoralisation that follows a burdensome illness responds to being named and addressed rather than to being reclassified as a manifestation of the disease.

15.8 Answering the question

The question is almost always some form of "a patient with known lupus presents with a psychiatric syndrome, discuss". Each row below is a decision rather than a heading, so an answer that walks the rows is reasoning aloud rather than reciting.

DECISION	WHAT MOVES IT	WHAT CANNOT SETTLE IT	WHERE THE DETAIL IS TAUGHT
Which syndrome is this	Phenomenology, course, examination, cognitive profile	Serology, which speaks to the disease and not the syndrome	Here
Is it attributable to the disease	Timing against disease activity, absence of a competing explanation, atypical features	Any single investigation, since no confirmatory test exists	Here
Is it infection, metabolic or hypertensive	Cultures, biochemistry, blood pressure, imaging, lumbar puncture	The presence of lupus, which raises infection risk	Here, and the delirium notes
Is it the treatment rather than the disease	Onset after a treatment change, disease quiescent elsewhere, the drug review	Severity, which is uninformative about cause	The routing section owning the corticosteroid construct
Inflammatory or thrombotic mechanism	Focal against diffuse presentation, vascular imaging, antibody profile	Response to a treatment not yet given	Here for the limbs, the sibling section for the antiphospholipid syndrome
What is given, and how is it prescribed	Severity and acuity of the manifestation, and the age group	A remembered dose or regimen	Here for the recommendation, psychopharmacology for prescribing

IN INDIA

No Indian row was located for this item, and the shortfall is declared rather than filled: no Indian cohort, no Indian frequency estimate, no Indian figure for the cost or availability of either named agent, and no Indian guideline statement on this manifestation. The recommendation this section does carry comes from a Latin American clinical practice guideline, so its transferability to an Indian public hospital is a judgement rather than a given, and a candidate who names that is on stronger ground than one who quotes it as though it were local. What is safe to say in an Indian answer is structural: infection carries the most weight of the exclusions where the background burden of chronic infection is high, immunosuppression is decided jointly with rheumatology, and the rehabilitative limb is the one most likely to be dropped where follow-up is difficult.

PITFALL

Answering as though attribution were a formality on the way to treatment. An answer spent on immunosuppression has skipped the contested part, and also the part that protects the patient, since the competing explanations are commoner and more immediately reversible than the manifestation being reached for. Spend the answer where the difficulty is.

GOOD TO REMEMBER

Called to a ward for a patient with lupus and a new psychiatric presentation, give the medical team your view on whether the disease has reached the brain as a judgement rather than a finding, and record what would change it. An attribution offered in that form can be revised without anybody losing face; one asserted as a finding is very hard to withdraw.

MNEMONIC

Syndrome, Sepsis, Salts, Script, Then Attribute

Characterise the syndrome, exclude sepsis and infection generally, check the salts and the rest of the metabolic screen, read the script for drugs that could be doing it, and attribute to the disease last. Everything before the last step is faster, commoner and more reversible than what comes after it.

No gold standard	Attribution	GCs plus CYC
FOR DIAGNOSING THE NEUROPSYCHIATRIC SYNDROMES OF LUPUS	WHAT DIAGNOSIS ACTUALLY CONSISTS OF HERE	PREFERRED OVER GCS ALONE OR GCS PLUS RTX, ADULTS, SEVERE ACUTE MANIFESTATIONS

There is no test that confirms neuropsychiatric lupus, so diagnosis is an attribution built from timing, exclusion and the character of the syndrome, and the exclusions that matter most are infection, metabolic disturbance and the treatment itself. Treatment then splits by mechanism into an inflammatory limb, a thrombotic limb and a symptomatic limb, and the one recommendation this section carries applies to adults with severe, acute manifestations and to nobody else.

16 · Neurosarcoidosis, CNS vasculitis and antiphospholipid syndrome with psychiatric features

Neurosarcoidosis, primary vasculitis of the central nervous system and antiphospholipid syndrome are filed together as rare systemic causes of psychiatric presentation, and that filing is very nearly the only thing they share. Each arrives in psychiatry by a different route, each is settled by a different kind of evidence, and for one of them the psychiatric literature this text could locate is thin enough that saying so is the correct answer rather than an embarrassment. This section installs what is actually sourced for neurosarcoidosis, what is actually sourced for antiphospholipid syndrome, and a worked method for answering on primary central nervous system vasculitis without inventing a phenotype for it. The rare causes are examinable for exactly this reason: they are where a candidate's discipline about evidence becomes visible inside a single paragraph.

16.1 Three names, three different examination problems

The grouping is administrative. A syllabus has to put the uncommon systemic causes somewhere, and the shared shelf tempts a tired candidate into one undifferentiated answer about inflammation reaching the brain. That answer earns very little. The examiner assumes you accept that systemic autoimmune disease can affect the mind, and is asking something else: whether you can tell these conditions apart with a patient in front of you, and whether you know which parts of the answer are yours to give.

It helps to sort them on a single axis: where the discriminating information sits. For **neurosarcoidosis**, the sourced material puts discriminating information inside the mental state itself, because the described presenting picture assembles features that a purely functional psychosis would not usually assemble in the same person at the same time. For **antiphospholipid syndrome**, the sourced material does the opposite: the reported psychiatric syndromes are the ordinary syndromes of general adult psychiatry, so the mental state is precisely where the discrimination is not. For **primary central nervous system vasculitis**, the discriminating information sits in a specialty literature that this text could not quote, and that changes the shape of an honest answer without making the condition irrelevant.

Those are different problems and they take different answers. The first is a recognition problem: can you notice, in a mental state you are already examining, a combination that sends you outside psychiatry. The second is an attribution problem: with a systemic diagnosis on the file and an ordinary psychiatric syndrome in front of you, how much may you claim about the relation between them. The third is an evidence problem: what do you say when the psychiatric claim you would like to make is one your sources will not carry. A candidate who answers all three with one paragraph about immune-mediated brain injury has told the examiner that the differences are invisible to them. The generic immune-to-brain framework belongs elsewhere in this volume and is deliberately not rebuilt here.

16.2 Neurosarcoidosis: a picture that can arrive before the diagnosis

The sourced statement for neurosarcoidosis is a statement about presentation. Reported neuropsychiatric manifestations include **confusion, dysfunction in orientation or memory, hallucinations, delusions and catatonia**, and these are described as manifestations that can be the presenting features of the condition. Read the load-bearing word carefully. Presenting means the psychiatric picture can be the first thing anyone sees, which in turn means the referral may reach a psychiatrist while the systemic diagnosis is still unmade, unsuspected and absent from the file you are handed.

That is the examinable point, and it is about sequence rather than rarity. Were the systemic diagnosis always established first, this condition would be a footnote in liaison practice, because the medical team would carry it. Because the neuropsychiatric picture can come first, the recognition burden lands on psychiatry, during an ordinary assessment of what looks like a first episode of psychosis.

The discriminating feature is the combination rather than any single item. The sourced list runs across layers that psychiatric nosology usually keeps apart: a confusional and cognitive layer (**confusion, dysfunction in orientation or memory**), a psychotic layer (hallucinations and delusions), and a motor and behavioural layer in the form of catatonia. A patient in whom orientation and memory are disturbed, psychotic phenomena are present, and catatonic signs are observable has a picture crossing those layers at once. Crossing them is the signal, and the response is a decision to widen the question beyond the psychiatry room rather than a diagnosis made inside it.

Be equally precise about what the source does not license. The material behind that list is a report of a single presentation, and its framing describes these manifestations as rare. A statement of that kind establishes possibility. It does not establish frequency, it does not rank the features against one another, and it supplies no proportion of patients in whom any of them occurs. So there is no percentage in this section, and a candidate who supplies one has supplied it from memory. The marks here are for recognising the pattern and routing the patient, never for a prevalence figure.

RULE **A presenting feature is not a common feature.** The sourced claim about neurosarcoidosis licenses recognition: you keep the condition available when a picture crosses cognitive, psychotic and catatonic layers together. It licenses no statement about how often that happens, and none that this presentation is typical of the disease. State the possibility, then say what you would do about it.

16.3 What psychiatry contributes when neurosarcoidosis is the question

Once the question is open, the psychiatrist's contribution is a description good enough for someone else to act on. Record phenomenology in the patient's own words rather than in summary labels, because the summary label is what a later reader will doubt. Record catatonic phenomena as observed signs with the manoeuvres that elicited them, so that a neurologist reading your entry can see what you saw. Date the cognitive change against the psychiatric history: a disturbance of orientation and memory that arrived with the psychotic phenomena

reads very differently from one that has been present for years, and only the psychiatric assessment is positioned to establish that ordering.

The rest of the pathway belongs to other owners, and naming them accurately is part of a complete answer. Imaging and cerebrospinal fluid evaluation of a suspected inflammatory brain process, with immunotherapy decisions, sits with the neurology and psychiatry interface material. Assessment and management of delirium as a syndrome, including its bedside instruments, sits with the delirium and focal brain syndromes material. Corticosteroid-related psychiatric disturbance, relevant once systemic treatment begins, is owned by its own routing section and by the endocrine and metabolic material. Adjustment of psychotropic prescribing for organ impairment sits with the psychopharmacology material. Capacity, if it arises, is decision-specific and time-specific, and the statutory test belongs to the mental health legislation material.

Routing is not evasion. An answer that names the right owner for each limb of the work shows the examiner how you manage a shared patient, and in particular that you know how each team assumes the other has already done the thinking.

TRAP **Recording catatonia as a diagnosis rather than as a set of signs.** Once catatonia is entered as a conclusion, the file behaves as though the question has been answered, and the systemic question quietly stops being asked. Candidates fall into this because catatonia feels like an endpoint: it is a named syndrome, it has a management pathway, and naming it produces the relief of having decided something. Written as observed signs instead, it stays what it is, which is a finding that still needs an explanation.

16.4 Primary central nervous system vasculitis: a declared gap, and how to answer it

Here this text has to say something uncomfortable and say it precisely. What was sought was a self-contained quotation from a primary study, a guideline or a systematic review that explicitly links primary central nervous system vasculitis to a psychiatric manifestation. No such quotation was located for this fragment. That is the gap, stated with its exact boundaries, and the boundaries matter: the search was for an explicit link to a psychiatric manifestation, quotable on its own, in a source of that standing.

Note what the gap is not. It is not a finding that the condition has no psychiatric presentation, and converting it into that claim would be a worse error than the one it replaces, because a categorical negative asserts far more than a failed search can support. Absence of a located quotation is a fact about this text's sources. It is not a fact about the disease.

Say also whose claim it would be. A statement linking this condition to a specific psychiatric syndrome would rest on the authors of peer-reviewed clinical studies of the condition and on the neurology and rheumatology specialty literature, where cohorts of these patients are described. Psychiatry cannot assume it by analogy with the conditions on either side of it in this section. The specialty that follows these patients owns the phenotype, and the honest position is to defer to it by name rather than fill the space.

Clinically the gap changes little about what you do and a great deal about what you write. The condition stays available as an inflammatory cerebrovascular possibility in a patient whose

presentation has crossed into neurological territory, and its evaluation sits with neurology as the neurosarcoidosis workup does. What changes is that you refrain from attaching a named psychiatric syndrome to it in a case note, a referral letter or an examination answer, because you would be attributing on authority you lack. You describe the presentation, record why the possibility is open, and let the specialty that can settle it settle it.

This is worth practising as a sentence, because candidates who have never said it aloud tend to bluff instead. A usable form runs: the psychiatric phenotype of this condition is not something I can state from a specific source, the neurology and rheumatology literature holds it, and my contribution is the described presentation and the referral. That answer is short, it is true, and it displays the judgement that separates a safe registrar from an unsafe one. An invented list of psychiatric features, delivered fluently, is the failure mode this discipline exists to prevent.

TRAP **Filling the vasculitis gap with borrowed lupus material.** Neuropsychiatric systemic lupus erythematosus has a rich catalogue of manifestations, it is taught in its own section of this chapter, and it sits close enough in a candidate's mind that its phenotype slides across to fill an empty space. It is a borrowed answer about a different disease, and an examiner who knows the vasculitis literature is thin will hear the borrowing at once. Name the lupus material as the neighbouring topic it is, and leave its content where it belongs.

16.5 Antiphospholipid syndrome: a psychiatric range that reads like general psychiatry

The sourced position for antiphospholipid syndrome is that a range of psychiatric disorders has been reported in these patients, and the reported range includes **psychosis, mania, depression, bipolar disorders and schizophrenia**. Read that list as a whole before reading any item in it. Taken together, **psychosis, mania, depression, bipolar disorders and schizophrenia** are close to a roster of general adult psychiatry. That is the discriminating feature of this condition, and it is a negative one in a useful sense: there is no distinctive mental state signature here to look for.

The consequence follows directly. If the reported psychiatric range is indistinguishable by name from primary psychiatric illness, the mental state examination cannot be the instrument that raises the possibility, and the discrimination has to come from elsewhere in the record. The syndrome is named for an antibody, which tells you that serology and the general medical history are where the question is settled, and that the settling belongs to the rheumatology and haematology literature. This text carries no sourced criteria for the condition, so it prints none, and a candidate who prints a criteria set from memory is doing the thing this method exists to stop.

Be careful with the verb as well. The sourced claim is that these disorders have been reported in patients with the condition. Reported in is an observation of co-occurrence in a described population, rather than a causal claim about the antibody producing the syndrome, and it carries no proportion. So a psychiatrist assessing a patient who already holds this systemic diagnosis has reason to keep the association in view while treating aetiology as unsettled. The material behind the claim is a narrative review drawing on a long publication window: a reasonable authority for the statement that a range has been reported, and a poor one for anything quantitative. There is no figure in this section either.

What this leaves you with is a clinical posture rather than an algorithm. In a patient with the systemic diagnosis on file who develops a new psychiatric syndrome, each of the easy errors is a real one. Treating the psychiatric presentation as unrelated by default discards information the record already holds. Attributing it to the systemic condition by default converts a reported association into a diagnosis and ends an assessment that had barely begun. The defensible position lies between them: keep the systemic diagnosis as a live question in the formulation, put that question in writing, and manage the psychiatric presentation on its own terms while it stays open.

RULE **Reported in is not caused by.** This distinction carries more marks across the chapter than any single disease fact, because almost every systemic association in liaison psychiatry is reported at the level of co-occurrence. Say what your source says, with the verb your source uses, then say separately what you would do clinically. An answer that keeps the moves apart reads as trained. An answer that fuses them reads as memorised.

16.6 Telling them apart in one pass

The plate for this section places the disease-specific presentations beside one another, including the neighbouring topics this section deliberately leaves to their owners: neuropsychiatric lupus, and coeliac disease and inflammatory bowel disease with the gut-brain axis. Use it as a recall grid in revision, working across the row for each condition and asking what makes that condition itself rather than the one above it. The table below does something complementary: it records where each condition in this section stands in evidence, which governs how firmly you may speak.

CONDITION	WHAT THIS TEXT CAN STATE	WHERE THE REMAINDER IS HELD
Neurosarcoidosis	That **confusion, dysfunction in orientation or memory, hallucinations, delusions and catatonia** can be presenting features, so psychiatry may see the patient first	Frequency, imaging and cerebrospinal fluid evaluation, and immunotherapy: neurology and the interface material
Primary central nervous system vasculitis	A declared gap: no self-contained quotation explicitly linking it to a psychiatric manifestation was located for this fragment	The psychiatric phenotype, if described: authors of peer-reviewed clinical studies and the neurology and rheumatology literature
Antiphospholipid syndrome	That a range of psychiatric disorders has been reported, including **psychosis, mania, depression, bipolar disorders and schizophrenia**	Diagnostic criteria, serology and proportions: the rheumatology and haematology literature

16.7 Answering on the rare causes without over-claiming

A complete answer here has a recognisable shape, worth rehearsing because the content is thin enough that structure carries the marks. Five moves carry it.

- Name the three conditions separately, and refuse the single undifferentiated paragraph about inflammation reaching the brain that the shared shelf invites.
- Neurosarcoidosis: give the discriminating feature as a presenting picture crossing cognitive, psychotic and catatonic layers together, and say that the response is to widen the question rather than to make the diagnosis in the psychiatry room.
- Antiphospholipid syndrome: give the discriminating feature as a reported psychiatric range that reads like general adult psychiatry, so the discrimination lives outside the mental state, in the record and the serology.
- Primary central nervous system vasculitis: give the discriminating feature as a psychiatric literature this text could not quote, held by the specialties that follow these patients, and name it as theirs rather than filling the space.
- Mark explicitly which parts of your answer rest on a source and which rest on clinical reasoning, then route the workup to its owner.

Recognition	**Attribution**	**Evidence**	**Reported, not caused**
THE NEUROSARCOIDOSIS PROBLEM	THE ANTIPHOSPHOLIPID PROBLEM	THE VASCULITIS PROBLEM	THE VERB THAT CARRIES THE MARKS

The first three tiles are the three problems this section separates, one to each condition, and a candidate who can say which of the three a question is asking has already done most of the discriminating. The fourth is the verb discipline that runs underneath all three.

The shape survives contact with a question you were not expecting, which is its real value. The neighbouring topics in this chapter, paraneoplastic neuropsychiatric syndromes, neuropsychiatric lupus, immunosuppressant neurotoxicity after transplantation, and the gut-brain topics, are owned elsewhere in this volume and each carries its own sourced material. Name them as neighbours when a question invites the comparison, and resist teaching them inside an answer about these conditions. Examiners read borrowed content as padding, and padding is expensive in a viva.

IN INDIA

No Indian series or Indian guidance on the psychiatric presentation of these conditions was located for this fragment, and that is a limit of this text rather than a claim about Indian practice or the Indian literature. What travels regardless of setting is the referral, and it is worth writing well. Specialist assessment may be separated in time from the presentation you witnessed, so the phenomenology, the catatonic signs with their eliciting manoeuvres, and the dating of cognitive change against the psychiatric history are things only your entry preserves. Where rheumatology, neurology or immunology assessment means travel and delay for the family, the referral letter is what keeps the question alive until they are seen.

GOOD TO REMEMBER

Ask the systemic question at the moment a psychiatric picture stops behaving like one, rather than at the end when everything else has failed. For neurosarcoidosis the trigger is a presentation crossing cognitive, psychotic and catatonic layers together. For antiphospholipid syndrome it comes from the record rather than the mental state, because the reported syndromes are the ordinary ones. For primary central nervous system vasculitis it is the neurological unease that would prompt any inflammatory cerebrovascular referral, and your written answer stops short of naming a psychiatric syndrome for it. Describe fully, attribute cautiously, route to the specialty that can settle it.

Three conditions, three different problems: neurosarcoidosis is a recognition problem, antiphospholipid syndrome an attribution problem, primary central nervous system vasculitis an evidence problem, so describe fully, attribute cautiously, and route each to the specialty that can settle it.

17 · Coeliac disease, inflammatory bowel disease and the gut-brain axis in psychiatry

Two bowel diseases reach the psychiatry examination for opposite reasons: coeliac disease for what it is associated with, and inflammatory bowel disease for how it behaves over time. Both are usually taught under the single heading of the gut-brain axis, and that heading does them a disservice, because it places an epidemiological observation and a mechanistic theory in the same sentence and lends them the same confidence. This section separates them: what the comorbidity evidence in coeliac disease states and what its design will bear, what the bidirectionality evidence in inflammatory bowel disease states and what it will not bear, what each finding changes in front of a patient, and where the mechanistic account stops being evidence and becomes a story that is merely satisfying. The examinable skill here is discrimination, not enthusiasm.

Several neighbouring topics are named here and left to the sections that own them. Neuropsychiatric systemic lupus erythematosus, neurosarcoidosis, central nervous system vasculitis and antiphospholipid syndrome each have their own home in this chapter, and their manifestations are not repeated here. The general immune-brain vocabulary of inflammatory signalling and sickness behaviour belongs to the earlier notes that own it and is used here only as a name. Steroid-induced psychiatric disturbance is owned by the routing section of this chapter and appears below only as a confound to be excluded before anything else is concluded. Delirium assessment belongs to the notes on stroke, traumatic brain injury and focal brain syndromes. Organ-adjusted prescribing, including any adjustment for malabsorption, belongs to the psychopharmacology notes, so no dose, no interaction ranking and no drug choice is stated in this section.

17.1 Three different claims wearing one name

The phrase **gut-brain axis** is used to make at least three claims that differ sharply in how well they are supported, and most of the confusion in this topic comes from sliding between them

inside a single answer.

- A **co-occurrence claim**: people carrying the bowel diagnosis carry more psychiatric morbidity than some comparison group. This is a question about counts in two populations, and it is the easiest of the three to test.
- A **covariation claim**: within a single person, the state of the bowel and the state of the mind move together over time, and each may carry information about the other's future. This needs longitudinal data and is harder to establish.
- A **mechanistic claim**: a specified biological pathway carries the influence in one direction or both. This is the claim the informal literature makes most often and the one it supports least well.

The two diseases in this section illustrate the first two claims respectively. Neither of the findings taught below is a mechanistic claim, and keeping that straight is most of the work an examiner is testing.

17.2 Coeliac disease: the comorbidity signal, and the shape of it

The finding to carry into the examination comes from a systematic review that compared people with the diagnosis against healthy controls. It **identified a significant increased risk for autism spectrum disorder, attention deficit hyperactivity disorder, depression, anxiety and eating disorders in patients with coeliac disease compared with healthy controls**. That sentence rewards slow reading, because each of its parts constrains what may afterwards be done with it.

The comparator is **healthy controls**, and that one phrase governs the whole interpretation. A comparison against healthy people cannot separate what belongs to coeliac disease specifically from what accompanies having any chronic diagnosis at all: a restrictive treatment, a lifetime of appointments, a label, and the ordinary demoralisation of managing a condition that never resolves. A candidate who says the finding demonstrates a disease-specific psychiatric vulnerability has reported a comparison that was never made. The defensible formulation is that psychiatric morbidity is raised relative to people without the disease, and that the design does not tell us whether it is raised relative to people carrying a different chronic illness of similar burden.

The outcome list is broad rather than narrow. It **spans neurodevelopmental, affective, anxiety and eating-disorder categories** rather than picking out a single syndrome, and breadth of that kind fits a general elevation of psychiatric morbidity better than it fits a specific lesion producing a specific disorder. That does not make the finding uninteresting. It makes it a reason to take a full psychiatric history in this population rather than a reason to go looking for one particular condition.

The design is a synthesis of observational comparisons. It establishes that the categories co-occur more often than expected, and it establishes nothing at all about which of them came first. The

rival explanations that survive a design of that kind are set out below, and reciting them is the cheapest mark available in this topic.

TRAP **Converting an association list into a causal list.** The review reports raised risk across several diagnostic categories against healthy controls. Candidates routinely restate this as the bowel disease causing the psychiatric disorders, then reason forward to a treatment implication that no observational synthesis can support. The finding tells you whom to assess carefully. It does not tell you what to attribute, and it does not tell you what to treat first.

17.3 What the coeliac finding actually changes in the room

Two situations arise, and they call for different work. In the first, the bowel diagnosis is already made and the person is referred with a psychiatric presentation. Here the finding does one useful thing: it removes any temptation to treat the psychiatric picture as an obvious reaction to illness that needs no further characterisation. Because the associated categories **include neurodevelopmental as well as affective and anxiety conditions**, a history that stops at mood in the last few months is too short. The developmental history, the school history and the pattern of attention and social functioning across the lifespan belong in the assessment, and they are the parts most often skipped when a medical diagnosis is already on the front of the file.

The entry in that list which most changes a consultation is **eating disorders**, because the management of coeliac disease is itself dietary exclusion. A medically required restriction and a symptomatic restriction occupy the same behavioural territory, and each can conceal the other. A person whose intake has narrowed far beyond what the bowel disease requires may be presented by the family, and even by the treating team, as unusually adherent. The clinically useful question is not whether the person avoids particular foods, which the treatment already dictates, but what the avoidance is for, what happens when it is breached, whether weight and shape have entered the reasoning, and whether the restriction has spread past the medical boundary into foods it never covered. That distinction is doable in the consultation and is where the psychiatric contribution is greatest.

In the second situation the bowel diagnosis has not been made and the temptation is to reason towards it from the psychiatric presentation. Here the section declares a limit rather than manufacturing guidance. No evidence row available to it grounds a screening rule, a case-finding threshold, an at-risk group worth testing or any performance figure for a diagnostic test, so none is printed. What survives without a row is procedural, and it is enough for most examinations: gastrointestinal symptoms, unexplained weight loss and unexplained nutritional deficiency belong to the referring physician, and the right move is a clear referral question rather than a test ordered from the psychiatry clinic.

17.4 Inflammatory bowel disease: two arrows, and the modal verb that carries them

For inflammatory bowel disease the claim to hold is different in kind. A systematic review and meta-analysis concluded that **bidirectional effects of the brain-gut axis are present in inflammatory bowel disease and may influence both the natural history of the disease and psychological health**. This is a covariation claim, not a co-occurrence claim, and it is the more

clinically interesting of the two because it concerns what happens next rather than what is present now.

Unpacked, **bidirectionality** is two arrows, and the conclusion adds a qualifier. The first arrow runs from the bowel to the mind: the state of the disease bears on psychological health. The second runs from the mind to the bowel: psychological state bears on the natural history of the disease. A complete answer names both, because naming only the first reduces psychiatric symptoms to an understandable reaction and leaves the psychiatrist with nothing to offer except sympathy, while naming only the second overstates what any single service can influence.

The qualifier matters as much as the arrows. The conclusion is that these effects **may influence** disease course and psychological health. It is a statement that bidirectional effects are present and that influence is possible. It is not a magnitude, it is not a treatment claim, and it is emphatically not a finding that treating a mood disorder alters the course of the bowel disease. That last step is the one candidates take without noticing, usually in the final sentence of an otherwise careful answer, and it converts a defensible position into an unsupported one.

TRAP **Promoting a bidirectional association into a therapeutic promise.** "The brain-gut axis is bidirectional, therefore treating depression will improve the bowel disease" reads as a natural inference and is a different claim from the one the evidence makes. Treat the psychiatric disorder because it is a disorder and it causes suffering. Do not sell it to the patient or to the gastroenterology team as disease-modifying therapy.

17.5 Working both arrows at the bedside

Bidirectionality becomes concrete as soon as it is turned into a sequence of consultation moves. Because **the effects run in both directions**, the first task is to work out where in the cycle the person currently sits. The psychiatric history on its own will leave that question open.

Begin with disease activity. Before attributing fatigue, poor concentration, disturbed sleep and reduced appetite to a mood disorder, establish with the treating team whether the bowel disease is currently active, when it was last assessed, and what the plan is. The activity measures used by the gastroenterology service are theirs to interpret and are not named or scored here; what the psychiatrist needs is the team's answer, in writing, to the question of whether this is active disease. A psychiatric formulation written without that answer is a guess about which arrow is operating.

Next exclude the treatment as the explanation. Corticosteroid-induced psychiatric disturbance is taught in full by the section of this chapter that owns it, and is named here only so that it is excluded before anything is attributed to the axis. Establish what the person is taking, what was started or stopped in the weeks before the change in mental state, and whether the timing fits. A mental state change that tracks a treatment change is a treatment problem until proven otherwise, and no amount of gut-brain reasoning displaces that.

Then characterise the illness experience rather than assuming it. Urgency, incontinence, nocturnal symptoms and the resulting narrowing of where a person is willing to go are facts that patients rarely volunteer, because they are humiliating. Asking about them directly is the part of

the interview that most often turns a generic depressive episode into a specific and modifiable set of avoidances.

RULE **Establish disease activity and treatment timing before you formulate.** In a person with inflammatory bowel disease, low mood, fatigue and poor concentration have at least four candidate origins: active disease, the treatment, the restriction the illness imposes on daily life, and an independent psychiatric disorder. These are not mutually exclusive and they demand different responses. Writing to the gastroenterology team with a specific question, and waiting for the answer, is faster than treating the wrong one.

17.6 Mechanism, and where a careful answer stops

This is the part of the topic where overreach is routine, so the boundary is worth stating plainly. The mechanistic literature on gut-brain communication is large and is written with more confidence than its evidence carries. Several families of explanation are commonly offered: immune and inflammatory signalling, the gut microbial community and its products, nutritional and absorptive consequences of the bowel disease, the effects of treatment, shared genetic or developmental liability acting on both systems, and the ordinary psychological load of a chronic, unpredictable and stigmatising illness. These are named here as categories only.

No evidence row available to this section grounds any specific mechanism in either disease, and none is asserted here. That is a declared gap, not an oversight: the two findings this section owns are an association in coeliac disease and the presence of bidirectional effects in inflammatory bowel disease, and neither identifies a pathway. A candidate asked to explain the axis mechanistically should name what is proposed, mark it as proposed rather than established, and then give what the evidence does support, which is the two claims above.

Four alternatives should be recited whenever an association in this field is offered as though it were a mechanism. The association may run in the reverse direction from the one assumed. A third factor may produce both. Detection may be differential, so that people already in one care system are more thoroughly investigated in the other. And the association may be entirely real yet wholly mediated by the burden of chronic illness, which is a psychological explanation and needs no biology at all. An answer that lists these four has demonstrated the exact competence being examined.

TRAP **Reaching for the microbiome because it is available.** A fluent mechanistic paragraph is easy to produce in this topic and is the commonest way of converting a good answer into a suspect one. Fluency is not evidence. Say what is proposed, mark it as proposed, and spend the remaining time on the two findings you can actually defend and on what they change in the consultation.

17.7 Where these two sit among the systemic presentations

It is worth placing coeliac disease and inflammatory bowel disease alongside the other systemic conditions that reach psychiatry, because they belong to a different column. The autoimmune conditions taught elsewhere in this chapter present as direct neuropsychiatric manifestations, in which the illness process itself produces the psychiatric picture and the diagnostic task is to recognise it. The two bowel diseases here are not taught that way. Their psychiatric relevance is

an elevated burden of common psychiatric disorders in coeliac disease and a bidirectional relationship with disease course in inflammatory bowel disease, which is a question of comorbidity and prognosis rather than of a direct neuropsychiatric syndrome.

The systemic autoimmune comparator plate sets each systemic presentation in this chapter beside its discriminating feature, so the conditions can be told apart in the moment rather than merely listed. Read it as a routing aid: the discriminating feature is what should redirect the assessment when it is present. The two entries relevant here are the ones whose discriminating feature is not a neuropsychiatric sign at all, and noticing that asymmetry is the point of putting them on the same plate.

That plate is printed with the neuropsychiatric lupus section, where it places these two conditions beside the other four, and it is the fastest way to revise the discriminating features together.

17.8 What a complete answer contains

A structured answer on the gut-brain axis contains five things in this order: the definition with the three claims separated; the coeliac finding stated with its comparator, which is the part most answers drop; the inflammatory bowel disease finding stated with both arrows and the qualifier intact; the design limitations, meaning direction, shared liability and differential detection; and the consultation consequences, meaning a lifespan history in coeliac disease, the required-versus-symptomatic restriction question, and disease activity and treatment timing established before any psychiatric attribution in inflammatory bowel disease.

QUESTION	COELIAC DISEASE	INFLAMMATORY BOWEL DISEASE
Type of claim the evidence supports	Co-occurrence against a comparison group	Covariation over time, in both directions
What is stated	**Increased risk of autism spectrum disorder, attention deficit hyperactivity disorder, depression, anxiety and eating disorders against healthy controls**	**Bidirectional brain-gut effects are present and may influence disease course and psychological health**
What is not stated	Direction of causation, disease specificity against another chronic illness, any mechanism	Any magnitude of effect, and any claim that psychiatric treatment alters the natural history
First move in the consultation	Full lifespan psychiatric history, developmental included, and the required-versus-symptomatic restriction question	Establish current disease activity and treatment timing with the treating team, in writing
Commonest error	Reading the association list as a causal list	Promising disease modification from psychiatric treatment

IN INDIA

No Indian prevalence figure, service audit or cost estimate for either disease appears in this section's evidence rows, so none is printed; the shortfall is declared rather than filled. What can be said is organisational. The gastroenterology service is usually in a different building from psychiatry and often in a different institution, so the liaison here is a written one, and it should carry a specific question rather than a request for an opinion: is the disease active, what changed in the treatment and when, and what is the plan for the coming months. The dietary restriction that treats coeliac disease is negotiated inside a shared kitchen, with food prepared for the household at once, so an adherence discussion aimed only at the patient misses where the decisions are actually made. And where a person travels a long distance to a tertiary clinic, align the psychiatric and gastroenterology reviews to the same visit wherever the services can manage it, because a review that needs a second journey is a review that will not happen.

GOOD TO REMEMBER

In coeliac disease, widen the history: the associated categories reach into development and into eating behaviour, so a history that covers only the last few months of mood is the wrong shape. In inflammatory bowel disease, narrow the question: find out whether the disease is active and what the treatment has been doing before you attribute anything to the axis. In both, treat the psychiatric disorder because it causes suffering and is treatable, and resist the pull to sell it to the patient or to the referring team as a way of changing the bowel disease.

MNEMONIC

Widen, then narrow

Widen for coeliac disease, because the associated conditions cross the lifespan and the eating-behaviour boundary. Narrow for inflammatory bowel disease, because the useful question is which arrow is operating right now, and that is answered by disease activity and treatment timing rather than by mechanism.

Three, not one	Comorbidity, not cause	Possible, not measured	Proposed, not established
CLAIMS INSIDE THE ONE PHRASE	WHAT THE COELIAC REVIEW SUPPORTS	WHAT THE QUALIFIER LEAVES OPEN	HOW MECHANISM MUST BE MARKED

Coeliac disease gives you a comorbidity fact and no direction; inflammatory bowel disease gives you a direction in both senses and no magnitude. Everything beyond those two sentences that sounds mechanistic is a proposal, and saying so out loud is what separates a careful answer from a fluent one.

18 · Burn injury and its psychiatric course

Burn injury is the one medical event in this chapter where the psychiatric question runs forwards and backwards: what the injury has done to the patient, and what the patient may have been doing when it happened. Everything examinable here follows from holding those

apart. This section installs a timeline, because each phase of burn care asks a different question, then a question that sits outside the timeline because it is asked at presentation and concerns the moment before the flame. It also states what this text can source and what it cannot, since burns psychiatry is taught nowhere else in these notes.

18.1 The acute phase: the ward you are called to

The referral comes from a surgical or burns team, and psychiatry walks into an environment organised around fluid balance, wound and airway. The mental state you are asked about is produced by several processes at once, and the acute-phase skill is separating them rather than settling on a label. Distress belonging to the event, distress belonging to the pain, a disturbance of consciousness and the effects of what is given for the pain are all live in the same bed at the same hour, and each responds to something different.

What was sought here, and not obtained in verifiable form, was a quotable statement from a burns or trauma source able to carry it that psychological shock, **dissociation** and **acute stress disorder** may occur in the acute phase after burn injury. State the reason exactly, because it changes what the gap means: of the burns records assembled for this section, several hosts refused automated retrieval, one address no longer resolved, and one quotation could not be found in the document actually served. Each of those is a fact about retrieval, none about burn patients. The claim, if made, would rest on the burns and trauma literature, where acute-phase presentations after burn injury are described from real cohorts, and which psychiatry reads rather than owns.

Without the figure, you describe. Acute distress after a burn injury is observable at the bedside and needs no prevalence attached. Record the phenomenology in the patient's own words, date it against the injury and against each operation, and note whether it fluctuates. That record lets a later clinician settle the question you could not, and it beats a confident figure from nowhere.

One process must be named and handed straight over. Disturbed consciousness, disorientation and fluctuating attention occur in burn patients, and the acute burns bed is one place a psychiatrist meets them. This chapter states that they occur and stops there. Assessment, motoric subtypes and management belong to the Stroke, TBI, delirium and focal brain syndromes notes. The routing is deliberate: a second delirium pathway written inside a burns section is how sibling chapters come to disagree, and a disagreement about an acutely unwell patient is a safety defect rather than an editorial one.

RULE **In the acute phase, ask which process, not which label.** Acute distress, pain, disturbed consciousness and drug effect co-occur in a burns bed and respond to different things. The examinable act is separating them at the bedside and routing each to its owner: the disturbance of consciousness out of this chapter, analgesia to the treating team.

18.2 Pain, and the part of it that is yours

Pain is the largest psychiatric problem of the acute phase and the one most easily handed back whole. Burn pain is unusual in being renewed deliberately: dressing changes, debridement and physiotherapy each produce a further episode of severe pain at a time the patient can predict, so

anticipation becomes part of the pain. That anticipatory limb is psychological and sits inside your remit whether or not the analgesic chart does.

The sourced statement available here is modest and useful. In a systematic integrative review of psychotherapeutic interventions for burns patients, **relaxation breathing techniques are an intervention to be considered for pain and anxiety relief in the care of burns patients**. The pairing is the teaching: the intervention is offered for pain relief and for anxiety relief together, which matches what the ward presents, a patient whose pain and whose fear of it have become one complaint by the third dressing change.

Its practical virtues belong in an answer: it needs no equipment, costs nothing, can be delivered by nursing staff once taught, and can be rehearsed with the relative at the bedside. It is an adjunct, and an adjunct sits alongside analgesia rather than in place of it. Analgesic prescribing stays with the treating team and this chapter prints no drug and no dose. Psychotropic selection and any organ-related adjustment belong to the Psychopharmacology II: emergencies, resistance, monitoring and interactions notes, which this chapter adds no further version of.

TRAP **Handing pain back whole.** Candidates write that analgesia is the surgical team's business, which is true of the prescription and false of the problem. Anticipatory anxiety before a predictable painful procedure is a psychological mechanism with a psychological adjunct, and an answer that omits it surrenders the part of burn pain psychiatry was consulted about.

18.3 Sleep, and where its causes sit

Sleep fails early after burn injury, and it fails for reasons that come from more than one place. What was sought here, and not obtained in verifiable form for the retrieval reasons already given, was a quotable statement that poor sleep in burn patients reflects psychological factors and the hospital environment together. That claim would rest on the burns and trauma literature, and on the ward-based sleep work within it.

The gap costs little at the bedside, because the instruction underneath it survives intact. Take the sleep history so that the sources separate: on one side what the ward is doing, meaning light through the night, noise, observations, position and procedures timed for the day list; on the other what the mind is doing, meaning intrusive re-experiencing, nightmares, worry about appearance and money, and the anticipated dressing change. Ask about each explicitly, because a patient asked only whether they are sleeping badly will say yes and tell you nothing actionable. Then correct the environmental limb first, since a hypnotic prescribed into a bright and noisy bay treats a cause that was never in the patient.

18.4 The subacute phase: appearance and disfigurement

As the patient stabilises, the question changes from survival to what the body now looks like and what that will mean for the life attached to it. Keep these apart. **Disfigurement** is a visible difference in the body, assessable by anyone looking at it. **Appearance concern** is what the person makes of that difference, assessable only by asking them. An assessment that measures the burn and infers the distress has measured the wrong variable, and it will be wrong in either direction.

The sourced finding comes from a multi-centre prospective cohort of adults hospitalised after burn injuries. **Increased psychological flexibility during hospital admission after a burn injury predicts lower appearance concerns over time, although not over the effect of baseline appearance concerns.** Each part carries an examinable point. The exposure was measured during the admission, so the acute admission is a measurement window and not only a treatment window, and the outcome came later, so an acutely measured variable travels forward into a later-phase result. That is why this section is a timeline rather than a list of complications. And the qualification is what an examiner will press: the prediction does not hold over and above baseline appearance concerns, so what the person already thinks about their appearance carries the prognostic weight.

The clinical consequence is direct. Ask about appearance concern during the admission, because it carries the prognostic weight and costs one question, and record it so that later change can be read against something. Be careful, though, describing any intervention aimed at flexibility, because the study supporting the association is the study that qualifies it.

TRAP **Reading a predictor as a treatment target.** A variable that predicts an outcome, then loses its prediction once a baseline is controlled for, is telling you where to look rather than what to change. Candidates keep the first clause of that sentence and drop the second, and the dropped clause is why the finding was reported as it was.

Social re-entry also begins in the ward rather than at the front door, and the work is concrete: rehearsing the first meeting with people who have not yet seen the scars, deciding what the patient will say when a stranger asks, and preparing the family, whose answers to the same question set the tone the patient has to live with.

PHASE	THE QUESTION IT ASKS	WHERE IT IS ANSWERED
Acute	Which process is producing this mental state, and what does each need?	This section, for acute distress and for the psychological limb of pain and sleep.
Acute	Is this a disturbance of consciousness, and how is it assessed and managed?	The Stroke, TBI, delirium and focal brain syndromes notes. Named here, never taught here.
Subacute	What does this person make of the disfigurement, and how closely are they followed?	This section, with its prevalence gaps declared.
Any phase	Which psychotropic, and how is it adjusted for organ impairment?	The Psychopharmacology notes. This chapter adds no further version.
Any phase	Does this patient have capacity to refuse the dressing change?	The Mental health legislation notes. Capacity is decision-specific and time-specific; the test is taught there.
At presentation	How did this burn injury happen, and was it an act?	This section, as an antecedent question.

18.5 Depression and post-traumatic stress: what is missing, and what holds

Here the declared gaps bite hardest. What was sought first was a citable prevalence of post-traumatic stress disorder after burn injury, as a proportion of a defined cohort at stated follow-up points inside the first year. What was sought second was a pooled estimate linking burn extent, as a proportion of **total body surface area** above a stated threshold, to an increased risk of depression expressed as a risk multiple. Neither was obtained in verifiable form, so this text supplies neither the proportions, nor the threshold, nor the multiplier. Each would rest on the burns and trauma literature, on primary follow-up cohorts for the first and a quantitative synthesis of such cohorts for the second.

Now the part that carries marks. A missing figure is not a negative finding, and converting one into the other is a larger error than the one it replaces. To say that post-traumatic stress after burn injury is uncommon, or that burn extent is unrelated to later depression, asserts far more than a failed retrieval can support. The correct sentence is short: the figure exists in the burns literature, I cannot state it from a source, and it does not change what I do with the patient in front of me. It does not, because prevalence tells you how hard to look, never whether this patient has the syndrome. That is settled by assessment, applied during admission, at the transition out of acute care, and across the long rehabilitation tail when the operations have stopped and the attention has thinned.

What holds, sourced and directive, is what to do with a patient who screens badly. European practice guidance for burn care states that **patients with an abnormal psychological profile, including suicidal ideation, should be given special attention, adequately monitored and regularly followed by appropriate mental health professionals**. Notice its shape. It is written around a profile rather than a diagnosis, so it is actionable on the day of the assessment and before any diagnostic conclusion is reached. It names obligations of distinct kinds, attention and monitoring and follow-up, which are commonly collapsed into one vague plan. And it names suicidal ideation inside the profile, which is the hinge into the last part of this section.

TRAP **Turning a missing number into a negative finding.** The candidate who cannot recall a prevalence says the association is weak or the disorder is rare. That is a categorical claim built on a failure of memory, unsafe in exactly the domain where being wrong costs a life. Name the gap, name whose literature holds the figure, and state what you do anyway.

18.6 Rehabilitation, and the return to work

Rehabilitation after a major burn injury is measured in years. Scars mature slowly, contractures develop and are released, and each new operation re-opens the acute and subacute questions in a patient who had begun to leave them behind. The consequence is unglamorous and examinable: psychiatric follow-up must outlast surgical follow-up, and the plan should say so in writing, because attention thins once the wounds are closed and it is then that appearance concern and social re-entry become the whole of the patient's day.

A further gap is declared here. What was sought was a comparison of work-reintegration outcomes between burn survivors whose injury happened at work and survivors injured

elsewhere, with the direction of the difference stated. It was not obtained in verifiable form, and it would rest on the burns rehabilitation and occupational health literature, where such cohorts are followed and outcomes defined well enough to compare.

The instruction underneath it survives the gap: ask where the burn injury happened, because the answer reshapes the rehabilitation problem. When the injury occurred at work, the site of the injury and the site of return are the same place, and that single fact brings in fear of the machine or the flame, the employer's response, blame, compensation and colleagues who witnessed it. A domestic injury raises its own version, since the kitchen is also a place the patient must return to. In Indian practice much work is informal, so returning to work may mean returning to a stove, a field or a roadside stall, with no graded return to arrange and financial pressure that overrides advice framed as a preference.

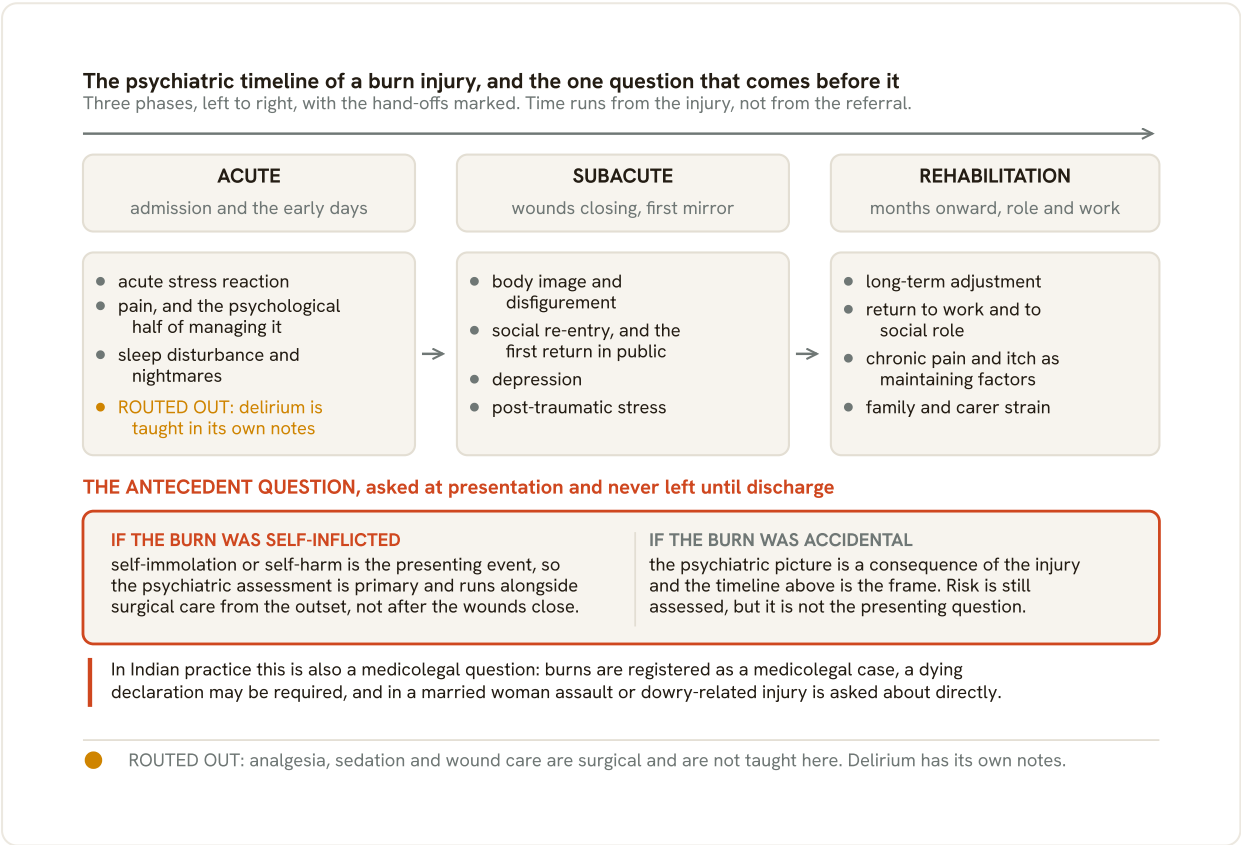

Fig 40.10 The psychiatric course of a burn injury across three phases, with the antecedent question set apart from the timeline because it is not part of it. This is the only plate in the series that teaches burns, so it is built to carry the whole construct rather than illustrate one corner of it. The phases are not merely descriptive: each has a characteristic failure, which is treating acute distress as a disorder before the wounds have closed, missing the subacute period in which body image and the first return in public do most of the psychological damage, and discharging at wound healing as though the rehabilitation phase were somebody else's problem. The block below the timeline is the discrimination that changes management, because a self-inflicted burn makes the psychiatric assessment the primary one from the outset rather than a consequence to be picked up later, and in Indian practice the same question carries a medicolegal weight that an accidental injury does not. From memory you should be able to name the phase-specific problems in order, say where the delirium pathway hands off, and state why self-harm is asked about as an antecedent at presentation rather than as an outcome at discharge.

18.7 The antecedent question, asked at presentation

Everything above treats psychiatric problems as consequences of burn injury. There is a question that runs the other way, asked at presentation rather than at discharge: was the injury itself an

act, and was psychiatric disorder present before the flame rather than after it. That discrimination changes management, and it is the one most often lost when a burns referral is treated as routine liaison work.

It changes management because consequence-work and antecedent-work run on different clocks. Consequence-work is rehabilitative and can be paced. Antecedent-work is risk-work and cannot be: if the burn injury was self-inflicted, the patient is already inside a high-risk period, the method remains available on discharge, the collateral history has to be taken while relatives are still in the hospital, and the discharge destination becomes a psychiatric question. A service that asks how the burn happened only when the wounds are healing has asked its most important question several weeks late.

The Indian relevance is direct, because self-immolation presents to burns units here rather than to psychiatric services, and because the Indian psychiatric literature has examined it. **An Indian report investigated four cases of attempted self immolation, with the psychiatric evaluation done according to DSM-III-R criteria.** Be exact about what that establishes. It is a small clinical series with formal diagnostic assessment applied to it, so it establishes the construct as one Indian psychiatry has studied with criteria rather than impression. Its denominator is small, and using it as though it described a national picture would misuse it.

The same literature shows that self-immolation is heterogeneous rather than a single clinical entity. In an Indian psychosocial study, **22 young people, mostly students, had indulged in this act to protest against the decision of the Government of India**. A public and collective act of protest is a different phenomenon from a private act of self-harm during a domestic crisis, and a formulation built for one will misdescribe the other. So the clinical question is simple to ask and easy to skip: what was the act for. The same physical burn injury can follow any of these.

- A suicidal act, after which the patient is already inside a high-risk period and the method remains available on discharge.
- A public and collective act of protest, which is the phenomenon the Indian psychosocial study above describes.
- An impulsive act inside a family quarrel, a private act during a domestic crisis rather than a public one.
- An accident, where the injury was not an act, though the question of psychiatric disorder before the flame still stands.
- An assault by another person, which this section names as an antecedent and does not follow further.

Those demand different assessments and different collateral sources, which is why the question belongs at presentation rather than in the discharge summary.

Where the assessment finds a self-inflicted injury, ongoing suicidal ideation, or a disturbed psychological picture of any kind, the sourced instruction above applies directly and is worth quoting rather than softening: **special attention, adequate monitoring and regular follow-up**

by appropriate mental health professionals. In a burns unit those obligations have concrete forms. Attention means your assessment happens at presentation, in the surgical bed, written where surgical staff will read it. Monitoring means the nursing observations reflect a psychiatric risk as well as a wound. Follow-up means a named appointment attached to a named person, since a patient who leaves with a dressing clinic date and a vague psychiatric intention will attend the first and lose the second. Where such a patient then refuses dressing changes, capacity becomes the question, and capacity is decision-specific and time-specific; the statutory test is taught in the Mental health legislation and forensic psychiatry notes.

IN INDIA

The burns unit is usually where this psychiatry happens, because the patient occupies a surgical bed and the psychiatric team travels to them. Your assessment competes with a dressing round, your notes are read by surgeons, and the family outside is your collateral source and the carer who will do the dressings at home. Distance and cost shape everything after discharge, so a plan written for a family travelling a long way looks different from one written for a city outpatient. Note what this text could and could not verify. The acute-phase, prevalence and work-reintegration claims were not obtained in verifiable form here, which is a limit of this text rather than a statement about the Indian record. What was verified is Indian, the self-immolation work, and that tells you where Indian psychiatry has looked hardest at burns.

GOOD TO REMEMBER

Ask how the burn injury happened before you ask how the patient is coping with it, because the first question sets the urgency of everything else. In the acute bed, separate the processes and route the disturbance of consciousness to the Stroke, TBI, delirium and focal brain syndromes notes rather than managing it here. Treat anticipatory pain as your work and offer the psychological adjunct alongside the analgesia the team prescribes. Ask about appearance concern during the admission, because it is the early variable that carries the later weight. Where a figure is missing, name the gap and the literature that owns it, then say what you will do anyway.

Antecedent first	**Which process, not which label**	**Asked in the admission**	**A named gap, not a negative**
ASKED AT PRESENTATION, NOT AT DISCHARGE	WHAT THE ACUTE BURNS BED ASKS OF YOU	WHEN APPEARANCE CONCERN CARRIES THE LATER WEIGHT	WHAT A PREVALENCE YOU CANNOT SOURCE BECOMES

Burns psychiatry runs in two directions: ask at presentation whether the injury was an act, then follow the timeline of what the injury has done, separating process from label in the acute bed, treating anticipatory pain as your work, asking about appearance concern during the admission, and naming a missing figure rather than converting it into a negative finding.

Consolidate and apply

19 · Worked vignettes

Every referral in this chapter asks one question in a different accent: is this the medical illness, is this the treatment for it, or is this a psychiatric disorder that would have arrived anyway. The sections before this one supply the content for that triage. What they cannot supply is the experience of running it against a referral somebody else has already answered, where all three possibilities are live at once and the answer is sometimes that the question belongs to another chapter.

Each vignette opens with the referral as it would arrive, works the reasoning in the open, and closes with what an examiner is testing. Where a vignette reaches a specific taught elsewhere, it names the owning section and stops. Two end without a treatment, because the answer is a hand-over. One ends without a fact, because the fact was sought and not established.

19.1 A decompensated heart and a request for an antidepressant

The referral. From a cardiology ward. A man in his sixties, readmitted within months for decompensated heart failure. Low mood, poor appetite, sleeping badly, no motivation, will not participate with physiotherapy. Please see and start an antidepressant.

The reasoning. The failing circulation can generate every item on that list. Fatigue, appetite change, broken sleep, slowed movement and withdrawal from effort follow equally from the haemodynamic state, from the treatment burden, or from a mood disorder, so the count will be high whichever is true and says nothing about which of the three is operating.

What separates them is **order in time**. Put the cardiac events, the regimen changes and the mood changes on one timeline. If low mood arrived with the decompensation and lifted as it settled, that is a person responding to a frightening event. If the breathlessness and the swelling improved while interest, outlook and self-reproach stayed where they were, the mood state has separated from the haemodynamic state and behaves as an illness in its own right. The second lever is pleasure in things costing no physical effort, because a man too breathless to reach the gate can still say whether a visit gives him anything.

Keep the treatment limb open: the regimen is itself a psychological load, and admission interrupts whatever he took at home. Then look again at what was asked. The note has gone straight to a prescription, and agent choice in established cardiac disease is not this chapter's to give: it belongs to the psychopharmacology notes, and prognosis with safe antidepressant choice after myocardial infarction to the merged organ-interface routing section.

TRAP **Accepting the triage the referral has already performed.** The note has decided that this is a psychiatric disorder and that the intervention is a tablet. A consultation answering only the question asked leaves the attribution unmade, and reads later as agreement.

What the examiner is testing. Whether you attribute symptoms rather than count them, and whether you can be useful to a cardiology team without writing a prescription.

19.2 Breathless at night, and already told it is anxiety

The referral. A woman in her forties with obstructive airways disease is referred to the psychiatric outpatient clinic with episodes of breathlessness, palpitations and terror that wake her from sleep. The letter states that her airflow is stable in clinic, that the attacks are anxiety, and asks for treatment of panic.

The reasoning. The whole difficulty sits in the letter's middle clause. Breathlessness and panic recruit the same body and the loop closes both ways: airflow limitation produces fear, fear produces hyperventilation, hyperventilation produces breathlessness. The features shifting the probability, the temporal shape of the episode, its relation to exertion or rest, and the content of the thought at the peak, are taught by this chapter's section on obstructive airways disease, asthma and chronic respiratory failure. This vignette is about what a clinician does when they shift the probability without settling it, which is most of the time.

Two things follow. The commonest correct answer here is both rather than either, and each condition worsens the other, so treating one and closing the case leaves the disability where it was. And the errors are not symmetrical: calling a panic attack an exacerbation costs an unnecessary course of treatment, while calling an exacerbation a panic attack can cost a life. Note too what the letter's premise establishes. Stable airflow in a daytime clinic is a statement about the clinic, not about three in the morning, and nocturnal episodes have nocturnal explanations a daytime measurement cannot exclude.

One contribution is concrete, not diagnostic. Coexistent anxiety and depressive symptoms are routinely used to filter patients out of the rehabilitation that treats the deconditioning, and the guideline position blocking that is stated, in its exact wording, by the owning section.

RULE **When the triage cannot be completed in the room, complete the safe half and record why.** Treat the airway first, interrogate the psychiatry once the episode has settled, and write down which half you answered today. A note committing to a label it cannot defend is more dangerous than one stating what it could not decide.

What the examiner is testing. Whether you accept a triage handed to you in a letter, which direction of error is dangerous, and whether you can offer both with an order of work.

19.3 Confusion after transplantation, and what the psychiatrist does not own

The referral. A call from a transplant unit, late evening. A man in his thirties, some weeks after receiving a kidney from a living relative, has become confused, does not recognise the ward and has had a witnessed seizure. He is on maintenance immunosuppression and has had pulsed treatment for suspected rejection in recent days.

The reasoning. Several sufficient causes are present at once, so the examinable skill is **sequencing rather than selection**. He may be septic while barely febrile, metabolically deranged from graft dysfunction, hyponatraemic or hypoxic, on more than one agent with recognised

neuropsychiatric toxicity, and carrying the load of a graft he believes he could lose. An opinion that names the drug and stops has chosen the interesting cause rather than the first one.

The sequence that survives scrutiny puts reversible and dangerous causes first, keeps the immunosuppressants permanently on the list rather than at the end of it, and treats the psychological formulation as concurrent rather than as a diagnosis of exclusion. One technique is worth taking away whole: the drug history here is a sequence, not a list. What was given, when relative to the event, and what was given alongside it carry the information, because the labelled neurotoxicity signals in this class attach to changes of regimen and to combinations. A chart transcribed as current medicines has discarded the structure that made them reportable.

The boundary, which is the point of this case. Three of the four things the team wants are not yours here. Detection, rating and management of the acute confusional state, including any drug used for it, are taught once, with the stroke, traumatic brain injury, delirium and focal brain syndromes notes. Which co-prescribed agent alters exposure to which immunosuppressant belongs to the psychopharmacology notes. The named neurotoxic syndromes of the individual agents belong to this chapter's transplant and immunosuppressant section. You hand over a dated mental state, a timeline against the drug chart, a statement that the immunosuppressant stays on the differential, and the pathway for each remaining question.

RULE **A referral you cannot answer completely is answered by naming who answers each part.** Routing is a clinical act, not an evasion. It moves a question to somebody who can settle it, and it beats a partial version from memory that commits the receiving team to something you never verified.

What the examiner is testing. Whether you sequence rather than select, and whether you can be useful while declining most of what was asked.

19.4 Two questions from a surgical ward, and three different owners

The referral. The surgical team telephones the day after major abdominal surgery on a man in his seventies. He is agitated at night, pulling at his lines, settled by day. They ask two things in one breath: does he have capacity to refuse the drain, and is this postoperative cognitive dysfunction.

The reasoning. Separate the questions before answering either, because one undifferentiated account of postoperative confusion loses marks in both directions at once. Capacity first. One property does most of its work here: capacity is decision-specific and time-specific. The question is never whether this man has capacity as a standing attribute, but whether he can make this decision at this hour, and the perioperative window supplies an unusual density of moments in which the answer moves: pain, disturbed sleep, premedication and the hours after anaesthesia all sit inside it. An opinion formed on the morning round does not transfer to a conversation that evening. Everything else is elsewhere: the statutory test and the procedure following a finding of incapacity are taught with the mental health legislation notes and are neither restated nor cited by provision. You describe functional ability for the named decision at the named time; the decision belongs to the treating team.

The second question turns on an observation nobody on the ward tonight can make. A cognitive change is a relation between two observations, so the first thing to establish is not what is wrong with him tonight but whether anybody measured him before the operation. If not, the trajectory question cannot be settled on this ward at all, and the honest note says so, manages the acute presentation through the chapter owning it, and arranges the review after discharge.

TRAP **Recording a global capacity verdict.** A note stating that the patient lacks capacity, with no decision named and no time attached, is unusable by the team receiving it and indefensible if later examined. Worse, it travels: written once, it is quoted for months across decisions it was never about.

What the examiner is testing. Whether you separate two questions that arrived as one, and whether your first move is to ask about the measurement taken beforehand.

19.5 A cognitive complaint after treatment ended, and a question the evidence does not answer

The referral. A woman in her fifties, referred by her family doctor some months after finishing chemotherapy. Back at work on reduced hours, she cannot hold several things in mind, loses words she knows well, and works far more slowly than before. She asks whether this will get better, and when.

The reasoning. Take the complaint seriously and decline its title. The word patients use for this names a cause and, in naming it, stops the clinician looking. Run the triage instead.

- The illness limb: fatigue, disturbed sleep, pain and the endocrine consequences of treatment all fail exactly these effortful functions.
- The treatment limb: the cytotoxic agents are one contributor inside a bundle that also holds the surgery and the anaesthesia.
- The independent-disorder limb: an untreated depressive episode degrades attention, retrieval and speed, and is the most treatable thing on the list.
- A fourth possibility peculiar to this population: something still evolving underneath, so whether the picture is static or moving is asked deliberately.

The declared gap, which is her actual question. She has asked for a trajectory. What can be said is that a change of this kind has been reported as still detectable at the end of the interval examined, and that an interval describes how far the looking reached, not where the problem ended. A statement of the course beyond that point would rest on longer follow-up in the oncology and neuropsychology literature, and none was obtained for these notes in a quotable form. The absence describes what these notes opened, is not evidence that the course is unknown to the field, and must not be converted into reassurance or into catastrophe.

What you do without it is concrete. Treat the mood, sleep and pain degrading her cognition today. Characterise the deficit well enough for her workplace to be adjusted around it, whether or not it reverses. And set a review point, because the moment the oncology course closes is the moment nobody is reviewing cognition.

RULE **A declared gap is a complete answer and it has three parts.** State what was sought, on whose authority the missing claim would rest, and what you do without it. An answer carrying only the first two is a shrug; one supplying a remembered figure is worse, because the person receiving it cannot correct it.

What the examiner is testing. Whether you convert an observation window into a prognosis, and whether you can still leave the room with a plan after saying that something is not established.

19.6 Psychosis in an established autoimmune disease, where the differential is the whole answer

The referral. A woman in her twenties with a long-standing systemic autoimmune disease is admitted under medicine with a few days of persecutory beliefs, hallucinations and badly disturbed sleep. Her disease has recently been treated more intensively. The team has sent a serology panel and asks whether this is the disease affecting her brain.

The reasoning. The referral asks for an attribution and offers a laboratory result as the route to it, and neither is available in the form requested. Serology establishes that she has the disease. It does not establish that the syndrome in front of you was produced by it, and a patient with unambiguous systemic disease can equally have an infection, a drug effect or an unrelated psychiatric illness. Attribution here is a reasoned judgement rather than a measurement, and it is the substance of the case rather than its preliminary.

So the answer is an ordered list of what must be displaced before the disease is credited. Infection first, and staying first, in a person immunosuppressed by both the illness and its treatment. Metabolic derangement and blood pressure next, particularly where there is renal involvement. Then the drug chart, read with the dates set against the onset, because the treatment of the disease and the cause of the psychiatric picture can be the same agent; that construct is owned by the routing section of this chapter and by the endocrine and metabolic notes, and is named here only as a direction of travel. Then a primary psychiatric illness with a history predating the systemic diagnosis, and the ordinary response of a young person to a relapsing, visible illness with an unpleasant treatment.

The order matters because of where the answers lead: one path escalates immunosuppression and the other reduces it, so an attribution made the wrong way round is a harm rather than an inelegance. The manifestations and the treatment recommendation with its restrictions are taught in full by this chapter's section on the condition. Give the attribution as a judgement, with the observations it rests on and what would change it. A judgement can be revised without anybody losing face; a finding is very hard to withdraw.

TRAP **Treating a positive result as the answer to the referral question.** The panel speaks to the disease, never to the syndrome, and answering with it skips the contested part of the case. It is also how a commoner and more reversible cause is missed while treatment is escalated in the wrong direction.

What the examiner is testing. Whether you recognise that the difficulty is attribution and not treatment, and whether you write a judgement rather than a verdict.

19.7 A burns unit referral, where the first question is how the injury happened

The referral. A burns unit asks for review of a man in his twenties, several weeks into an admission after a flame injury. He is described as low, withdrawn, sleeping badly and increasingly reluctant to cooperate with dressing changes. The unit would like something started.

The reasoning. The triage runs as it does everywhere in the chapter, but the order is unusual, because one question sits underneath all three limbs and gets harder to ask with every day it is left. Ask first how the injury happened. A burn may be an accident, an assault or a deliberate self-inflicted act, and the risk formulation, the conversation with the family, the safeguarding position and the discharge plan differ completely across those possibilities. Ask early, ask directly, ask the patient and whoever brought him, and record the accounts separately, because they harden with retelling and a unit that has settled on an accident will not re-open it.

Then work the ordinary causes, which this setting stacks. Pain, and specifically the anticipatory dread of a procedure repeated on a schedule, which is a distinct and treatable phenomenon rather than a general lowness. Sleep, degraded by the injury, by the analgesia and by a unit lit and busy through the night. Acute confusional states, which occur here and route out entirely to the notes owning delirium, including their bedside assessment and every drug used for them. And an independent depressive episode, which this setting makes easy to explain away, since comprehensibility is not a diagnostic exclusion.

The word uncooperative is a **referral word**, and it repays unpicking, because it names a behaviour and hides its reason. Reluctance to face dressings after a course of them is a learned response to a procedure that has reliably hurt, and it answers to analgesia, prediction, a share of control and specific procedural anxiety work, none of which is persuasion and none a tablet. Beyond the admission sit appearance, the reactions of others and return to work, all of which belong to this chapter's burns section.

TRAP **Reading a refusal of dressings as either a character problem or a depressive symptom.** Both readings skip the mechanism and both produce the wrong intervention, one punitive and one pharmacological. The behaviour is usually specific to the procedure, which is exactly what makes it treatable.

What the examiner is testing. Whether you ask how the injury happened before anything else, and whether you can decompose an unhelpful referral word into treatable parts.

The cases share a shape: the referral names a symptom and requests a treatment, while the real question is about order in time, the rest of the chart, or ownership.

THE REFERRAL AS WRITTEN	THE QUESTION UNDERNEATH IT	WHO OWNS THE ANSWER
Low mood in heart failure, start an antidepressant	Did mood move with the circulation, or separately	Attribution here; agent choice, psychopharmacology
Her attacks are anxiety, treat panic	What drives tonight's episode, and which error is dangerous	The obstructive airways and respiratory failure section
Confused and fitting after transplantation	What was given, when, and alongside what	Sequence here; the state itself, delirium; interactions, psychopharmacology
Capacity to refuse, and is this cognitive dysfunction	Which decision, at what hour, and was he measured beforehand	Decision-specific and time-specific here; the test, legislation
Will my concentration come back	What degrades it today, and over how long a window was it observed	Function here; the findings, the chemotherapy and interferon section
Is this the disease affecting her brain	What must be displaced before the disease is credited	Attribution here; manifestations, the owning section
He is not cooperating, start something	How did the injury happen, and what is he avoiding	Circumstances here; the sourced material, the burns section

Four moves sit under these cases, and not one of them is a fact to recall.

Re-opened, not accepted	**Attributed, not counted**	**Named, not attempted**	**Sought, not remembered**
THE TRIAGE THE REFERRAL ARRIVES WITH	WHAT MAKES A SYMPTOM LIST MEAN ANYTHING	THE PART OF THE REFERRAL THAT IS NOT YOURS	A FACT THESE NOTES COULD NOT ESTABLISH

The first move is the one the other three depend on, because a triage accepted at the door decides the answer before any of them is run.

IN INDIA

Several features of Indian practice change how these cases run, and none is a figure, because this section holds none. Referrals arrive late and pre-decided, so the first act is usually to re-open a triage somebody else closed. A relative is almost always present, which makes collateral history easy to obtain and the funding question answerable at the bedside. Follow-up happens by travel rather than by schedule, so a plan whose active ingredient is a review appointment fails quietly. And how a burn happened carries legal consequences from the day of admission.

GOOD TO REMEMBER

Before answering any referral in this chapter, ask three questions in order. What has changed, in what order, against what baseline. What else on the chart or in the admission could produce the same picture. And which part of this is not mine to answer here. The first settles the attribution, the second protects the patient, the third makes the note usable.

Run the triage rather than accepting the one in the referral letter, attribute by order in time rather than by symptom count, name the owner of every question that is not yours, and where a fact was not established, say what was sought, whose claim it would be, and what you do anyway.

20 · Consolidation and quick review

In the last week before the examination the useful question is not what this chapter contained but what it installed, and it installed one triage, one habit of naming owners, and one way of saying what is not established. Every section is a worked instance of those three. This consolidation restates them in the smallest form that survives questioning: the triage and the evidence deciding each limb, a grid of the features separating the conditions the chapter teaches, the boundaries stated as a competence rather than an apology, the shapes an answer should take, and what to read if there is an hour left. Read it as a set of moves rather than a summary, because content cannot be compressed without becoming the thin second copy the chapter argued against, whereas reasoning can.

20.1 The three-way question, and what each answer is made of

The chapter opens with a triage and never leaves it. A psychiatric presentation in a medically unwell patient is being produced by the illness acting on the brain, by the treatment for that illness acting on the brain, or by a psychiatric disorder that is the patient's own and has arrived in a body that happens to be unwell. Those are the three limbs, and the chapter is training in choosing between them and in saying why.

Two properties matter more than the categories. The limbs are not exclusive, and more than one is usually running at once, so the working question is never which limb is true but which is doing the most damage now and which, if missed, is dangerous. Each is settled by a different kind of evidence, which is why an answer naming a syndrome without placing it against a limb has skipped the examined step.

LIMB	WHAT SETTLES IT	WHAT IT OBLIGES	CHARACTERISTIC FAILURE
The illness acting on the brain	Disease course and physiology, read against the timing of the psychiatric change	Establish it and hand back for treatment of the disease, since no psychiatric intervention holds while the process continues	Waiting for a confirmatory test in conditions that have none
The treatment acting on the brain	Exposure and interval, from the drug chart and the procedure record rather than the mental state	Raise the exposure with the treating team, and keep the agent permanently on the differential	Pairing an agent with a syndrome and omitting the interval
A psychiatric disorder in a medically ill person	The patient's own history, baseline and account of themselves, with collateral	Treat it in full as a psychiatric disorder, since this limb is the largest and the least delegable	Accepting that anyone would reasonably feel that way, and stopping there

RULE **Name the limb, then name the evidence that placed you in it.** The follow-up at this interface is one question in different words: what else could be producing this, and what would separate them. An answer that has already given the limb and its evidence has answered it in advance, and bought time to be interesting about the rest.

20.2 The manoeuvres that decide it, in the order they are done

The triage is settled by history far more often than by investigation, and by a small set of manoeuvres that cost nothing and are frequently skipped. They are worth more than any single association here, because they transfer to every section and beyond the chapter.

- **Get a baseline from someone who is not the patient.** A medically unwell patient is observed by staff who never met the well version, so the comparison that would make a change visible does not exist on the ward until a psychiatrist goes and gets it.
- **Read the tempo, and read it for mismatch.** A presentation moving faster than the condition it resembles, continuing to move while adequate treatment is given, or following a slope rather than an episode, is telling you something.
- **Lay the psychiatric change against two timelines.** The medical course with its events dated, and the drug chart read for start dates rather than for the current list. This is the single act that separates the first limb from the second.
- **Ask what was stopped as well as what was started.** An admission removes alcohol, nicotine and whatever else was used at home, and often interrupts the patient's own long-term treatment. That syndrome, on a medical ward, is read as a complication of the illness.
- **Take consciousness and attention before anything else in the mental state.** A fluctuating disturbance of attention and awareness changes the entire answer and moves the problem into territory this chapter names and does not teach. Recognising the shape and handing it on is the examinable act.

TRAP **Settling for understandable.** The commonest error at this interface is not a wrong diagnosis but an abandoned one: the low mood is judged a reasonable response to a serious illness and the assessment stops. Comprehensibility is not a diagnostic exclusion and would not be accepted for any other comorbidity. It costs more here, because the psychiatric state is often what removes the patient from the treatment that would have changed the medical trajectory.

20.3 Telling the systemic conditions apart, which is how they are examined

The autoimmune and inflammatory band is not examined by asking what each condition is. It is examined by asking how you would tell them apart with a patient in front of you, which is why the six conditions sit together on one comparator plate. Two axes organise them: where the discriminating information sits, and what kind of claim you hold when you speak.

CONDITION	WHERE THE DISCRIMINATION SITS	THE SEPARATING SENTENCE	WHAT YOU MAY NOT SAY
Neuropsychiatric lupus	In the reasoning, not in any test	Diagnosis is **attribution**, built from timing against disease activity, absence of a competing explanation, and the character of the syndrome	That any investigation confirms it, or that one manifestation is the commonest
Neurosarcoidosis	Inside the mental state you are already examining	A picture crossing the confusional, psychotic and catatonic layers together, and it can present before the systemic diagnosis exists	That the presentation is common or typical, since a presenting feature is not a frequent one
Primary vasculitis of the central nervous system	In a specialty literature this text could not quote	A declared gap: no self-contained quotation explicitly linking it to a psychiatric manifestation was located	Any named psychiatric syndrome, and equally that it has none, since a failed search is not a negative finding
Antiphospholipid syndrome	Outside the mental state, in the record and the serology	The reported psychiatric range reads like a roster of general adult psychiatry, so the mental state is where the discrimination is not	That the antibody caused the syndrome, since the source reports co-occurrence and no proportion
Coeliac disease	Not in a neuropsychiatric sign at all	A co-occurrence claim against healthy controls, spanning neurodevelopmental, affective, anxiety and eating-disorder categories	That it is disease-specific or causal, since the comparison against another chronic illness was never made
Inflammatory bowel disease	Not in a sign either, but in the course over time	A covariation claim with two arrows and a qualifier: effects run both ways and may influence disease course and psychological health	That psychiatric treatment alters the natural history of the bowel disease

Read the third and fourth columns before the first. Two of the six carry no neuropsychiatric sign of their own, and that asymmetry is the point of putting all six on one plate, because the row not behaving like its neighbours is the row an examiner will use. One condition sits adjacent to the family without belonging to it: the paraneoplastic syndromes are immune-mediated, but their defining feature is a sequence rather than a sign or a claim type, since the syndrome arrives before the malignancy is detected, which is why suspicion, and not the workup, is the psychiatrist's part.

RULE **Name the kind of claim before you name its content.** Reported in is not caused by, an association is not a mechanism, a co-occurrence is not a covariation, and a presenting feature is not a frequent one. This distinction carries more marks than any single disease fact, because almost every systemic association here is reported at the level of co-occurrence. An answer keeping the claim and the clinical move apart reads as trained; one fusing them reads as memorised.

20.4 The treatment limb, compressed to exposure and interval

The second limb has one shape wherever it appears. The decisive evidence is in the drug chart and the procedure record, the question is what was given and when relative to the change, and the detail of what to do belongs elsewhere. What you carry is an agent family paired with a syndrome and with an **interval**, meaning the time between that exposure and the psychiatric change.

EXPOSURE	THE QUESTION IT FORCES	WHERE THE DETAIL IS TAUGHT
Calcineurin inhibitors after transplantation	What else was given, in what order, and when relative to the event, since one labelled signal is conditional on a combination	Label level in the transplant section; prescribing and interactions in the psychopharmacology notes
Corticosteroids	Which agent, over what course, and what was the earlier psychiatric history	Routed out of the chapter to the endocrine and metabolic notes, so there is exactly one place to look
Cytotoxic treatment	Did the difficulty predate the first cycle, does it fluctuate within a day, is it evolving, and has it an objective correlate	The cancer-drug section, which teaches the construct rather than the patient's word for it
Interferon-alpha	Prevention before a defined course or treatment after the syndrome declares itself, and in which population	The cancer-drug section; interferon-beta belongs to the neurology and psychiatry interface notes and is never pooled with it
Anaesthesia and surgery	Was anything measured before the operation, since a change is a relation between two observations	The perioperative section for the construct; the delirium notes for the acute confusional presentation
What the admission removed	What was stopped, at what hour, and whether the timing fits	Here, in the triage, since no other chapter owns a removal as an exposure

TRAP **Naming the agent and the syndrome and stopping.** That pairing is the least discriminating half of the topic and every candidate has it. The interval tells a clinician when to look and which explanations compete at that moment, and the population tells them whether the finding applies to this patient. A finding stated without its population is not a shorter answer, it is a weaker and different one.

20.5 The boundaries, which are a competence and not an apology

Liaison work is routing, so a chapter that practises routing is teaching the clinical skill rather than excusing an omission. A referral arrives from another team, written by someone unsure what to ask, and the first act is deciding whose question it is: the treating team's, the psychiatrist's, or a third specialty's. A resident who has practised deciding where a construct belongs has been practising the job; one who memorised a thin paragraph about each has not, and the paragraph fails the follow-up. Stating the boundary aloud also makes an answer checkable: whether a chapter mentioned a topic is a test it can pass while leaving its reader unable to answer anything, whereas whether the reader can name the owner has a right answer.

THE QUESTION IN FRONT OF YOU	WHO OWNS IT
Which agent, at what dose, adjusted how for renal, hepatic, cardiac or transplant disease	The psychopharmacology notes. This chapter teaches everything preceding a prescription and adds no second version of it.
Is this an acute confusional state, and how is it assessed and managed	The stroke, traumatic brain injury, delirium and focal brain syndromes notes, including every bedside instrument, rating scale and drug choice.
Does this patient have capacity, and what is the statutory test	The mental health legislation notes. This chapter says only that capacity is decision-specific and time-specific.
The general immune-to-brain model, and the workup of an autoimmune encephalitis	The neurology and psychiatry interface notes, which also own interferon-beta. This chapter owns the disease-specific presentation and the decision to suspect.
Depression and anxiety after infarction, critical-illness sequelae, dialysis, depression and demoralisation in cancer, palliative care psychiatry	The consultation-liaison, geriatric and transcultural psychiatry notes. These are defined by a setting and a referral pathway, not by an organ.
Psychiatric disturbance following a corticosteroid	The endocrine and metabolic psychiatry notes. This row follows a drug rather than a setting, and follows it out of the chapter.
A possible assault, and the pathway that follows it	The forensic and medicolegal material. Raised in the burns section as an antecedent question and handed on at once.

RULE **Route in the answer, out loud, before you are asked to.** A cross-reference is an address and not an abstract, so it will not survive being revised from, and the failure mode is a candidate who knows a construct matters but cannot say what it does. Say what you are handing on, who holds it, and what you keep. That costs seconds and demonstrates the judgement this interface examines.

20.6 The declared gap, and the sentence that carries it

This chapter declares more gaps than most, deliberately, and the declarations are examinable content rather than housekeeping. A candidate who can say what is not established, and on whose authority a statement would rest, answers better than one who fills the space, because a filled space is unverifiable and frequently wrong. A **declared gap** has three parts, each load-bearing.

State what was sought, with its boundaries: a quotable statement of a particular kind, linking a named condition to a psychiatric manifestation, in a source of stated standing, rather than a vague admission of uncertainty. Name whose literature would hold it, since the specialty following these patients owns the phenotype and deferring to it by name is a different act from not knowing. Then say what you do anyway, because a missing figure never changes the clinical move: prevalence tells you how hard to look, never whether this patient has the syndrome.

The declared gaps are worth revising as a set, since a stem often lands on one. The psychiatric phenotype of primary vasculitis of the central nervous system was not obtained, nor was a specialty statement binding psychiatric management to chronic respiratory failure. No prognostic figure is attached to anxiety after infarction, and no usable recommendation was opened on the desire for hastened death. The epidemiological specifics ordinarily quoted about the stress-precipitated cardiomyopathy are absent, and that section teaches what such a figure would have to measure. In lupus the antibody associations and every frequency statement are absent, because without a diagnostic gold standard each study defines its own numerator. In burns the prevalence figures and the work-reintegration comparison were not obtained, while the Indian work on self-immolation was. And no mechanism is asserted anywhere in the gut-brain material, because neither finding it holds identifies a pathway.

TRAP **Turning a missing number into a negative finding.** The candidate who cannot recall a figure says the association is weak or the condition is rare. That is a categorical claim built on a failure of memory, and it is unsafe where being wrong costs a life. Absence of a located quotation is a fact about a text's sources, never about the disease.

20.7 Answer structures, and the order the reasoning goes in

Almost every question at this interface is one of four stems, and each has an opening move that buys the rest of the answer. Learn the openings, because the first two sentences are where an examiner decides whether you are reasoning or reciting.

- **Discuss the psychiatric aspects of a named medical condition.** Open with the triage applied to that condition, naming which limb it mostly trains and why. Do not open with a list of syndromes that could have been written about any organ.
- **When would you suspect an occult or systemic cause.** Open with the readings that raise suspicion: tempo, the company the syndrome keeps, and whether a general history was taken at all. Then say what you would do, and route the investigation to its owner.
- **How would you tell these conditions apart.** Open by naming them separately and refusing the single undifferentiated paragraph about inflammation reaching the brain. Give each its discriminating feature, and mark which parts rest on a source and which on clinical reasoning.
- **A patient with a known systemic diagnosis presents with a psychiatric syndrome.** Open with the exclusions, in the order infection, metabolic disturbance, the treatment itself, and primary psychiatric illness, because those are commoner and more reversible than the manifestation being reached for.

The body then runs in the same order whichever stem opened it. Characterise the syndrome in the patient's own words. Place it against the three limbs and say what put it there. Give the discriminating feature separating it from its nearest neighbour. State each finding with its population and observation window attached. Name every construct you hand on, with its owner. Declare the gap where the chapter has one, in its three parts. Then say what you would do on the ward tomorrow, which is what most answers run out of time for and what a marker is waiting on.

Two sentences are worth rehearsing aloud, because candidates who have never said them tend to bluff. The gap sentence: that figure is held in the specialty's literature, I cannot state it from a source, and it does not change what I do with this patient. The attribution sentence: this is my judgement rather than a finding, and here is what would change it.

Both sentences are built from the same four fields, and so is every finding this page asks you to state. The comparator grid asked what kind of claim each row holds, the exposure table asked when and in whom, and the gap declaration asked what is not established and whose literature would hold it. Four words carry all of it.

MNEMONIC

Claim, Population, Window, Gap

Claim: say what grade of statement you are holding before you say what it contains, since the grades separated in the comparator rule above are not interchangeable and the weakest of them is the one most often reported here. **Population**: say in whom it was observed, because leaving that out does not shorten the answer, it changes what the answer means. **Window**: give the period over which it was seen, and on the treatment limb the gap between the exposure and the change, which is the half of that pairing most candidates omit. **Gap**: where nothing can be stated, declare it in the three parts set out above. Asked in that order the four survive a condition this chapter never taught, which is why they outlast any single row in the tables.

20.8 If there is an hour left

Revise in this order and stop when the hour is gone rather than when the chapter is finished. The order puts first what an unfamiliar stem is most likely to need.

- **The triage and its evidence table.** It is the answer structure for every question here, it works on constructs you have never met, and it is the shortest thing on this page.
- **The manoeuvres.** Baseline, tempo, the two timelines, what was stopped, and consciousness first.
- **The comparator grid for the six systemic conditions.** Work across each row, ask what makes that condition itself rather than the one above it, and check what kind of claim the row is.
- **The owner list.** Prescribing, delirium, capacity, the immune-brain model with the encephalitis workup, the setting-defined liaison constructs, and the corticosteroid.
- **The gap sentence in its three parts,** and the specific gaps this chapter declares, since a stem landing on one is a stem you answer well while others invent.

- **The exposure and interval table,** read for the second column, because agent to syndrome is the half everybody has and the interval is the half that separates.

What can safely be left is every list this chapter did not build an answer around, and every construct owned elsewhere. Reading a routed topic here in the last hour costs the material only this chapter carries: systemic and inflammatory disease presenting psychiatrically before anybody knows it is present.

If only one card leaves the hour with you, make it this one: four questions to ask of any finding before you say it aloud.

Claim	Population	Window	Gap
WHAT KIND, BEFORE WHAT CONTENT	IN WHOM IT WAS OBSERVED	OVER WHAT PERIOD, AND HOW LONG AFTER	NOT ESTABLISHED, AND WHOSE LITERATURE HOLDS IT

IN INDIA

No India-specific figure is held for this consolidation and none has been invented. The Indian point is about information rather than epidemiology. In most Indian general hospitals the psychiatrist reaches the medical bedside on request, usually late, to a referral question written by a team under pressure, and often without the previous notes, the collateral history or the drug chart's start dates. Every manoeuvre above depends on information the referring team holds and the letter rarely contains, so the skill is asking for it explicitly and early rather than working from the mental state alone. Distance and cost then decide whether the plan is followed at all.

GOOD TO REMEMBER

Three questions at the bedside, one afterwards, and one sentence held in reserve. Is the disease doing this? Is the treatment doing this? Is this a psychiatric disorder in a person who is unwell? Then, before writing: whose chapter answers the part I am handing on? And in reserve, for the moment a figure is wanted and cannot be sourced: that number is held in the specialty's literature, I cannot state it, and here is what I would do regardless.

The chapter installs a triage, a habit of naming owners, and a way of declaring what is not established. Everything else in it is worked examples, and a candidate who holds those three can answer on a condition this chapter never mentioned.

About the authors

Dr. Wilfred D'souza

MD Psychiatry (Resident) · Certified Gestalt Therapist · Weave, Centre for Integrative Psychiatry

Works in integrative psychiatry with Schema Therapy as the primary lens, alongside CBT, DBT, motivational interviewing and emotion-focused therapy, and is a certified Gestalt therapist. His clinical interests run through neurodivergence, ADHD, bipolar disorder, personality disorders, addiction and developmental psychiatry: work grounded in lived experience of attention difficulties long labelled as laziness, which made psychiatry personal before it became professional. He has been developing the Toroidal Model of Psychosis and Affect (TMoP), his computational model of mind, and TMoP thinking shaped the Claude Code AI system he builds with: clinical software, teaching tools and much of this series' production pipeline among its work, bringing psychiatry into the AI era in his own way. Lead author of the Weave Sprint series.

Dr. Niharika Reddy

Consultant Psychiatrist · Weave, Centre for Integrative Psychiatry

Consultant Psychiatrist at Weave, Mumbai, seeing people online through weave.clinic. Her work centres on relationships and family dynamics, family therapy and women's mental health, with a particular focus on neurodivergence in women and on adolescent mental health. Practises integrative, person-centred psychiatry. Co-author of this volume.

THE WEAVE LIBRARY

You revised from one. The whole shelf is open.

Field guides and references written in practice, for the people who do the work and the people living through it. Most are free to read and download.

field guides · references · for clinicians and families · free to read

STUDY TOGETHER

You do not have to revise alone.

These notes started as messages in a room full of residents helping each other through. That room is still open. Bring your doubts, your corrections, and the questions the textbooks do not answer.

Join the study group

https://chat.whatsapp.com/H7TsLGK2wFl4bSe2r0Zfzn?mode=gi_t

PRINTING AND DISTRIBUTION

Notes Next Door (NND), Delhi is the official printing and distribution partner for Weave Sprint. The soft-copy PDFs and the complete print-ready set are always available at weave.clinic/sprint, should you prefer to print the notes yourself. Weave Sprint is open source and free, and as part of Weave's commitment to residents it will stay that way, forever. We do, however, strongly recommend a printed set from Notes Next Door: in our experience, they have been the most reliable printing partner we have worked with.

WEAVE SPRINT · PAPER IV

The fourth paper of the MD psychiatry written examination, gathered into one book: the neurological interface from epilepsy and the dementias through stroke, injury and delirium; the endocrine, metabolic and systemic diseases that present to psychiatry before they present anywhere else; psychopharmacology in full, from why a drug is chosen to what to do when it fails; the recent advances and the studies behind them; and psychiatry at the scale of a population. Eleven complete sets of notes, written to be understood the first time and recalled every time after, with a colour memory code, a clickable contents and a full index.

Built to understand. Kept to revise.

All the very best for your exam.
